THE PHOTOGRAPHIC NEWS.

VOL. XXVIII. No. 1322.—*January 4, 1884.*

CONTENTS.

THE OLD YEAR AND THE NEW.

No progress has been made during the past year in several branches of photography, and especially in those processes which make the printing machine, whether typographic or lithographic, a means of rapidly multiplying photographs. The ink photographs of Sprague are in reality photographs, and are rapidly printed by the usual steam lithographic machine. The first picture by Sprague's process which was issued with a photographic journal appeared as a supplement to the PHOTOGRAPHIC NEWS on December 8th, 1882, and the numerous photo-ink supplements which we have issued during the past year serve to prove the wide applicability of the method in question. Sprague's method of photography has also been employed pretty extensively for the purpose of book illustration, and we have already noticed Fay's "Royal Road," and Neil's "Melissa's Victory," as examples indicating its value in this respect. Still we must not forget that photo-lithographs from nature are by no means new, as in 1866 we issued with the PHOTOGRAPHIC NEWS (No. 398) a photo-lithograph by Messrs. Bullock Brothers, of Leamington, and this appears to us fully equal, if not superior, to the work done at the present time by Messrs. Sprague (see Bullock Brothers' patent, No. 2954, 1865, and PHOTOGRAPHIC NEWS 1866, page 232). Why did not the process come into general use? May be asked. It is not difficult to give the answer. Eighteen years ago lithographic printing, especially by the steam machine, was somewhat neglected in England, and a photographer who had succeeded in producing a transfer with the required grain or stipple would have had a difficulty in finding a lithographer capable of putting it on stone or printing it satisfactorily; but now the case is different. There are several lithographic machine printers in London who can do justice to the highest class of work, and considering the comparative ease with which satisfactory transfers in stipple may be obtained, it is reasonable to expect a considerable advance in litho-photographic work during the coming year. From litho-photographic to typo-photographic printing is but a step, as any lithographic impression can be transferred to zinc and converted into a type block by etching away the uncovered parts with nitric acid. The notable progress made in this work during 1883 is so fully detailed in the PHOTOGRAPHIC NEWS and also the "Annals" of the YEAR-BOOK, that we need do no more than mention the names of Ives, Meisenbach, Woodbury, Zuccato, and Waterhouse, as having worked successfully in this direction.

The rapid production of photographic pictures by exposing successive portions of a band of sensitive material under a negative was referred to in our first number of the past year as a method likely to become important, and we found some admirable machine-exposed pictures of this kind in the Brussels Exhibition; while two "novel" exposing frames have been patented during the past year.

Major Waterhouse's important and thorough investigations on asphaltum in its relation to photo-mechanical methods can hardly fail to bring forth useful fruit; and indeed, we may refer to his series of articles on photo-lithography as being far more comprehensive and detailed than anything before published.

The need of accuracy in the use of terms, and uniformity as regards certain photographic dimensions, has long been felt, and something has been accomplished in the work of unification. The Photographic Society has established standards for screws and flanges, and it is to be hoped that more will be done by the Congress of photographers which is to assemble at Brussels.

The gelatino-bromide process has now become all but universal for ordinary negative work in England; and its application to the production of positive prints on paper—notably enlargements, but also small prints—is rapidly extending. Vigorous pictures are much more easily secured if the paper is enamelled with a composition of barium sulphate and gelatine, before the sensitive emulsion is applied.

The potash developer, as advocated by Stolze and Eder, appears to possess advantages, and many practitioners have adopted it. Full particulars as to its use have appeared in the PHOTOGRAPHIC NEWS; it will also be found in the YEAR-BOOK.

The view which judges now take regarding the law of copyright must be borne in mind by those who employ assistants to take negatives for them. If a master is present when a negative is taken, and assists by his directions or advice, he is the author of the photograph. Supposing, on the other hand, that the assistant is sent to take a negative of some distant scene, he is the author of the photograph, and the registration must be taken out in his name, the copyright being then transferred to the master. Such an assistant produces a picture for the master in the same sense as a literary man produces a book for a publisher.

Applications of photography to science have been made, and we may mention the successful work done by Messrs. C. Ray Woods and Lawrance in connection with the solar eclipse; and also the extensive use made of photographic records at the Saltpetriere Hospital in Paris by M. Charcot.

The New Patent Law (see page 725 of our last vol.) is now in operation, and it is to be hoped that much benefit will result from the increased facilities now offered to inventors. Some six or seven new societies have been formed, and the number of photographic amateurs has considerably increased, and we have not to record very

severe losses through death. Among those who are no more we may mentiou:—Mr. Pearsall, who was associated with Brande and Faraday; Mr. John Beattie; Mr. J. Lessels, the late president of the Edinburgh Society; Mr. Colin Sinclair; and Mr. A. G. Pettit, of Keswick, whose death was recorded in our last number.

LIGHTNING PHOTOGRAPHED.

WE have already spoken of Herr Robert Haensel's successful series of lightning photographs; today we are able to place before our readers one of his pictures. Herr Haensel, so our contemporary *La Nature* tells us, is a skilful photographer residing at Reichemberg in Bohemia, and his lightning pictures were taken on the 6th July last, between ten o'clock in the evening and midnight.

Wheatstone, who has measured the duration of a flash of lightning, says that it occupies but the millionth part of a second, and although to the human eye the effect appears far longer, this is due simply to persistence of vision. The gelatino-bromide plate, however, only receives an exposure of this brief duration, and it says much for the sensitiveness of modern films, to find that these are able to produce a picture in so short a time. The print we publish is a photo-etching from a photo-gravure made from the original plate by M. Gillot of Paris, so that the result is in all respects a pure photograph, and has not been touched by hand.

Herr Haensel, to secure his photographs, simply set up his camera in the dark night, with slide drawn and shutter open. Ten exposures were made, and four very good negatives secured. As far as he could judge by setting up his apparatus next morning, and observing the same objects as were included in his views of the previous night, Herr Haensel considered the flashes to be some 1,700 metres distant—about a mile, therefore—at the time he photographed them.

As our readers are well aware, photographs of lightning flashes have been obtained in this country, but the series of Herr Haensel is, we think, the most perfect yet secured.

ON THE QUANTITY OF AMMONIA USED IN THE AMMONIA EMULSION METHOD.

DR. EDER was the first, or one of the first, to give definite quantities for the manufacture of gelatine emulsion, ammonia being used to gain sensitiveness. He gave from time to time much information on the subject, and amongst other statements of his there is one to the effect that the quantity of ammonia required to cause sensitiveness is not proportionate to the silver salt held in suspension by the gelatine, but is proportionate to the quantity of water which is used; that, in other words, there is not required, when a certain amount of nitrate of silver is employed, a certain corresponding quantity of ammonia, but that it is necessary to have a certain percentage of ammonia in the emulsion which is being rendered sensitive, so that, the quantity of silver salt remaining the same, we have to increase the quantity of ammonia if we use more dilute solutions.

Our experience confirms this, or even somewhat more than confirms it, inasmuch as we find that, if sensitiveness is to be gained in the same length of time, we require rather a larger percentage of ammonia with weak solutions than with strong. To take a definite example: when using 100 grains of silver nitrate to form an emulsion, we may use any quantity of water from about two to four ounces. In the latter case, we will have to add somewhat more than double as much ammonia as in the first.

It is curious that there has been little or no discussion as to what is the maximum amount of ammonia which may be added to an emulsion without producing fog.

The original formula of Dr. Eder gave the quantity to be added as from three to five per cent., the strength of the ammonia being such that the specific gravity is ·88. He also gave, as the temperature at which stewing was to be performed, from 90° to 100° Fahr.

It has been our experience, and we think will have been that of most other experimenters, that with such a quantity of ammonia, and employing such a temperature, no reasonable time of stewing would give a very sensitive emulsion.

We found that, stewing for half-an-hour, which was what Dr. Eder recommended, we got a sensitiveness of perhaps a fifth or a sixth that of an average commercial plate; that is to say, a sensitiveness which would be represented by 10° or 12° of Warnerke's sensitometer. By longer stewing we got greater sensitiveness, even up to that of a good commercial plate, or about 17° or 18° sensitometer, but we found ourselves in difficulties with the gelatine, which lost its powers of setting after being kept ten or twelve hours at the temperatures mentioned in the presence of three to five per cent. of ammonia. This difficulty could of course be got over by using only a part of the gelatine at first, and adding the remainder just before putting the emulsion on one side to set for washing. We prefer, however, to employ means whereby we can gain rapidity without the long-continued stewing which we have mentioned.

Some time ago we described certain experiments in which we had used much higher temperatures than those usually recommended when ammonia enters into the composition of the unwashed emulsion. We at that time adhered to the percentage of ammonia recommended by Dr. Eder, but increased the temperature. At 160° Fah. we got emulsion as rapid as anything which we had ever handled, and plates which gave fine dense negatives.

We have since tried the effect of keeping the temperature down, and of adding larger quantities of ammonia. We have been somewhat surprised to find how a large quantity can be added without producing fog. We find no tendency to fog even with ten per cent. of ammonia, and somewhat concentrated solutions, the temperature of stewing being 100° Fah., and the length of time thirty minutes.

To make our statement more definite, we give the exact quantities experimented with :—

No. 1.

Silver nitrate	200 grains
Water	2 ounces

No. 2.

Bromide of potassium	160 grains
Iodide of potassium	10 ,,
Nelson's No. 2 gelatine	50 ,,
Water	2 ounces

No. 3.

Hard gelatine (soaked in water) 100 grains

No. 4.

Ammonia ·88 ... ... 1 ounce

No. 5.

Hard gelatine (soaked in water) 100 grains

The emulsification is performed at a high temperature th Nos. 1 and 2. No. 3 is then added, and the tempera- re either raised or lowered as is necessary to bring it to 0° Fahr. No. 3 is then added, and the temperature is ain raised to 100° Fahr. It is kept so for half-an-hour, e solution being constantly stirred. At the end of that ne No. 5 is added. There will probably be just enough at left in the emulsion to melt it ; if not, a little warmth ist be applied, but in any case as little as possible ; and soon as the gelatine is melted, the emulsion must be oled as rapidly as possible.

The reason why the whole of the gelatine is not recom- nded to be added at first is that if it were, the action the ammonia would so far reduce its setting powers at there would be no getting it into a condition fit for shing. Indeed, there is liability, even when the half the gelatine is added only at the last, to want of stiff- ss, the large quantity of ammonia used robbing the gela- e of much of its setting property. Here the use of bromate of potash will be found to give a good result. We would recommend the use of bichromate with any ulsion, as it undoubtedly reduces the chances of fog, l does not in our experience reduce the sensitiveness of emulsion. Two grains may be added to each ounce of ulsion immediately after the sensitizing process, either boiling or by the use of ammonia, is gone through. It l be found that a somewhat stiffer jelly results in its sence than without it. It is, of course, necessary to sh the emulsion somewhat longer than if no bichro- te be used, but not for the excessive lengths of time ich we have heard stated. We find an emulsion in ich there is bichromate to have reached its maximum sensitiveness after half an hour's washing, if it be finely ided.

The formula which we have given will be found to give ery sensitive emulsion, and plates which give great sity.

UTILIZING SCRAP GOLD.

HERE are not a few photographers who are sufficiently erprising to prepare their own chloride of gold, though manner which the powers that be do not approve of, rely, by dissolving up a gold coin. This is an offence the eyes of the law ; but an ingenious gentleman has gested to us that the little difficulty may be surmounted procuring the coin of some other realm, say of France America, from a money-changer, who will only demand rifling premium for the accommodation. We merely eat the hint, and leave the reader to take it for what it y be worth ; but for the present only wish to throw out ggestion as to how small and comparatively valueless s and ends containing gold may be put to some use by photographer. There are, probably, few families where e piece of broken jewellery is not occasionally laid aside as not being worth the expense of being repaired, and such trifles are often allowed to accumulate in some convenient toilet receptacle, as, in spite of the gold they contain, the sum that would be offered for them by a goldsmith would be almost nominal. In a family boasting a disciple of photography, these scraps may, with but little trouble or knowledge of chemical manipulations, be put to some use by extracting the precious metal and converting it into chloride.

The gold used for ornamental purposes ordinarily contains from twenty-five to seventy-five per cent. of the precious metal, the other metals alloyed with it being silver and copper, or, more frequently, both of them ; but very many articles which are regarded by their owners as gold, consist of a mere shell or casing of the precious metal, the interior being filled in or weighted with lead. Even when the proportion of copper in the alloy is high, we have not found that its presence interferes in any way with the efficiency of the gold chloride as a toning agent for silver prints ; still, cases may arise in which it is desirable to obtain the chloride of gold free from copper, and we will briefly indicate such means as are most suitable for the photographer.

On a commercial scale, gold of very low quality is often boiled with strong sulphuric acid as a means of removing a considerable proportion of the copper and silver, but this method is by no means to be recommended to the photographer, as boiling sulphuric acid is a dangerous agent for an amateur chemist to meddle with, and an attempt to part low gold by the sulphuric acid method might lead to a serious accident if a test-tube or small glass flask were used. A suitable platinum pan is not often to be found in the photographer's chemical corner.

In accordance with the more usual *aqua regia* method, a mixture of three parts of strong hydrochloric acid to one part of strong nitric acid is taken, and the flask containing the alloy and the acid is gently warmed till the metal is completely dissolved, great care being taken that the liquid does not boil, as otherwise the free chlorine, which is the active agent in dissolving the gold, would be driven off. If great care be exercised in regulating the heat, it will suffice to use as much of the mixed acids or *aqua regia* as is equal to four or five times the weight of the metal to be dissolved ; but we recommend eight or nine times the weight in ordinary cases. The silver is of course converted into chloride, but as this is soluble in strong hydrochloric acid to a very considerable extent, the solution is diluted with water, and the chloride of silver filtered out, but the chloride of copper remains in solution. The solution is then evaporated down in a porcelain dish till nearly all the free acid has been separated. A little water is then added, and evaporation continued. The mixed chlorides are then dissolved in about twenty times their weight of water, and as much powdered oxalic acid as the liquor will dissolve is stirred in, a small excess of the oxalic acid doing no harm. After this, the solution is allowed to stand for forty-eight hours, by which time all the gold will be precipitated, and may now be collected on a filter and washed with boiling water to remove soluble materials.

Nothing remains to be done now but to convert the gold into chloride. This is best accomplished by placing it in a glass flask, and dissolving it in eight or nine times its weight of *aqua regia* (that is to say, a mixture of one part of nitric acid and three parts of hydrochloric), but, as in the previous case, care must be taken not to boil the mixed acids. When all the gold is dissolved, the solution is poured into a porcelain capsule, and evaporated on the water bath until acid fumes are no longer evolved. Water is now added to the extent of one drachm for each half grain of (pure) gold dissolved ; and this solution will be found about equal in strength to that made by dissolving commercial chloride of gold in water in the proportion of one grain to the dram.

Though these little operations take some time to describe, they give really very little trouble in the performance, and only require the ordinary amount of care which the photographer has to give to most of his work. Too much trouble is perhaps involved to render the working up of scrap gold a method to be generally employed in the preparation of the chloride, but it will be found useful, and certainly economical, to thus utilize any odds and ends that may be lying about. The amateur, especially, who likes to make things for himself, may derive much satisfaction from making his own chloride.

PHOTOGRAPHIC ENGRAVING.

IN our previous article on the subject of Photographic Engraving, some of the parent processes were passed in review, notably that of Fox Talbot, who was the first to produce a photo-engraved plate fit for publication. Although Talbot's process was confined to the production of copper and steel plates, yet it proved available for the purposes of periodical illustration, prints having appeared in the pages of the PHOTOGRAPHIC NEWS in 1858 and 1859. For all that, the claims of Paul Pretsch as an original and successful investigator in this branch of photography must not be overlooked, as it is to his labours that we are, in a great measure, indebted for the production of commercial printing blocks that can be employed with letterpress in book illustrations.

Pretsch discovered—by taking advantage of the twofold properties of a bichromated film of gelatine, viz., its becoming insoluble under the action of light, and of the portions unaffected by light retaining an affinity for water—that a cast in high relief could be obtained.

M. Poitevin, an engineer, even at an earlier date than Talbot or Pretsch, laboured in the same field. He was engaged in 1842 in attempting to produce photo-engravings on the basis of Daguerreotype plates. After the picture had been developed with the fumes of mercury, and before it was fixed, the plate was connected with the negative pole of an electric battery, and placed in an electric bath. Copper was only deposited on the parts not protected by the coating of silver iodide, and the plate was subsequently fixed, and the silver laid bare where it had been protected by its coating of silver iodide. The copper was then oxidised by heat, and treated with mercury, which attacked the silver. It was next coated with gold leaf, the gold amalgamating with the mercury, the plate being afterwards etched with nitric acid, the acid attacking the plate wherever it was unprotected by the amalgam.

This process, however, came to no practical issue, and the illustrious pioneer was constrained to turn his attention to photo-lithography, in which his experiments were crowned by a greater measure of success. He coated a lithographic stone with bichromated albumen, and after allowing the mixture to dry spontaneously, by the action of light the albumen became insoluble and resisted water. A stone so coated and exposed under a negative united readily with fatty ink, while the parts unaltered by light had an affinity for water. Potevin's process was brought to wonderful perfection in the hands of M. Lemercier.

M. Baldus appears, as an independent worker, in 1854, to have produced some notable examples of photographic engraving on copper plate by the use of chromic salt and gelatine, thus following in the footsteps of Talbot; while M. Garnier, in 1855, proceeding in the line of research instituted by Poitevin, exposed a brass plate to the vapours of iodine, printed it under a negative, and after exposure treated it with mercury, which amalgamated with the part unaltered by light. The subsequent steps are marked by originality in so far as he unfolds a new property in the repellent action of the mercury when treated with printing ink. When an inked roller was passed over the plate, the ink adhered only to the parts unaffected by mercury.

DR. GORE'S RESEARCHES ON THE REDUCTION OF METALLIC COMPOUNDS BY VARIOUS GASES AND VAPOURS.

THE most important photographic methods are founded upon the easy reducibility of metallic compounds: their reductions being ordinarily effected by the joint action of light, and a reducing agent, the presence of light serving to determine the reaction. Although the reduction of silver compounds is the main feature of very many photographic reactions, it is not necessary to seek far for instances in which other metals undergo either complete or partial reduction. Ferric salts are reduced to the ferrous condition in Pellet's cyanotype method, and also in the platinotype process, while the partial reduction of chromates in the presence of organic matter is the fundamental principle of carbon printing and most photo-mechanical methods.

Dr. George Gore, of Birmingham, has recently published details of experiments which show how energetic are the reducing properties of certain gases or vapours which are frequently present in a vitiated atmosphere. His experiments with coal gas, and with the products of its combustion, are especially interesting, as they elucidate the well-known fact that such gaseous products frequently cause insolubility of carbon tissue, or other forms of bichromated gelatine; and that they cause many of the irregular surface reductions met with on sensitive surfaces containing silver salts is extremely probable. Mr. Gore says:—

1. A mixture of dry and pure carbonic oxide and carbonic anhydride gases, passed in a stream slowly through various liquids, had the following effects:—A solution of bichloride of palladium was rapidly decolourised, and all its metal precipitated as a black powder. One of tetrachloride of platinum was slowly decomposed, and yielded a small amount of yellow precipitate in two or three days.

3. By passing carbonic oxide during two days through a solution of potassic cyanide, with a rod of bright magnesium half immersed in it, the liquid became brown, and the metal was coated with a blackish film in the liquid. Magnesium alone in a similar solution did not turn the liquid brown in three days.

4. A dilute solution of bichloride of palladium exposed to a mixture of hydrogen and carbonic anhydride (or to pure hydrogen alone) had the whole of its palladium precipitated in the metallic state in a period of twenty-four hours.

5. An atmosphere of coal-gas was maintained in contact with the following dilute liquids, each of which had a vertical platinum wire partly immersed in it. The liquids were in open bottles in a dark place. Dilute solution of palladic chloride:—Rapid reduction to the state of metal as a film upon the surface of the liquid in four hours; the solution became colourless in a few days; some of the metal was also precipitated as a black powder, and some as an adhering bulky lump on the end of the wire. With dilute terchloride of gold, in the course of a few days, beautiful films of metal, bright, and of exceeding thinness, were produced upon the surface of the solution. Much gold was also deposited on the bottom end of the wire. The films formed successively and sank. The liquid was not wholly decomposed in three weeks. Solid crystals of auric-chloride were gradually reduced to metal. Solution of platinic chloride was only slightly decomposed in ten weeks. With a solution of argentic nitrate:—Signs of decomposition occurred in a few hours. In fourteen days a deposit of metal had formed on the sides of the glass bottle; but the whole of the silver was not deposited in seven weeks.

6. The gaseous products (containing acetylene) of a blown down and smoky flame of a Bunsen burner were collected over water and passed through various liquids. They rapidly decomposed a solution of palladic chloride, and less quickly one of terchloride of gold; a solution of platinic chloride was slightly affected, and one of chloride of iridium and potassium remained unaltered.

The films of gold and palladium formed upon the surface of a liquid by contact of a gas, or between two liquids at their dividing line by a non-miscible solution, might prove of service in some physical experiments.

It is worthy of consideration whether the reduction of metals to the native state in the interior of the earth may not in some cases have been effected by contact of their solutions with liquid or gaseous hydrocarbons derived from coal and other mineral substances of organic origin.

THE NEW PATENT LAW.

A FEW days before the expiration of the old year, the Board of Trade gave notice that all fresh applications would be dated for January 1st, and be treated under the new law; but whether they really intended to act up to this, or only wished to prevent applications being made during the last few days, it is impossible to say. At any rate, things went on as usual at the Patent Office till the end of the year, except that during the last day or so there was a slight increase in the number of applications for provisional protection, doubtless from persons who were afraid of being forestalled in the rush of specifications expected on New Year's day.

In visiting the Patent Office on Wednesday, we were surprised to find a record of only 262 applications on the first day of the year, but among these there were three of direct interest to the photographer — Hart, cameras; Van der Weyde, vignetting photographs; and Morgan, picture mounts. The first patent of the whole series (No. 1) is that of Mr. Johnstone, for an apparatus to divide dough into loaves, while Mr. Hart's patent is numbered 8, and Mr. W. E. Debenham comes in as No. 10, with an improvement in electric-lamps emitting light in a vacuum.

By-the-Bye.

GOOD SITTERS.

PERHAPS we ought rather to have written "Good Customers" at the head of our article, for as it stands the title scarcely expresses our meaning. In fact, the more we look at the heading, the less we like it; readers outside the photographic world may take it we are about to speak of the incubating virtues of certain domestic fowl, while those who continually hover about the posing chair will naturally believe it is the docility and amiability of sitters who do as they are told, we are going to admire and enlarge upon. So that our heading is really a very bad one, and if it were not too late for the printer to make an alteration, we should ask him to do it.

Still, with all its faults, the title may serve as well as any other to the few random words we have to say about photographers and their good sitters and customers. Defined by many, the client who falls under this denomination is he who does not ask for a re-sitting, who makes no fuss, and gives orders for several dozen of his carte, with one or two painted enlargements to follow. This, we take it, is what photographers are apt to term a good sitter, and what they generally look for. It is the good sitter, of all others, most studios desire to secure; whether the means taken to attract and to ensure the sitter being a good one are successful, the photographer alone can tell.

For it is no use shutting one's eyes to this fact; that there are among the photographic community many who have done their best to spoil good sitters. No calling or profession exists that has not its black sheep, and we shall have the sympathy of every righteous brother, when we say that half the troubles photographers suffer from are due to the unscrupulous dealings of those who hang on to the skirts of the profession. Fortunately, with every day that passes, photography is taking a higher standing, and the public are beginning to find out that it is not everybody who blackens his fingers with chemicals that can make a picture, even if he can take a photograph. Still the public have generally a very absurd notion of the price of first-class photographs—due in a great measure to former experiences—and the consequence is they are often disinclined to pay reasonable prices, simply because they believe these are uncalled for, and, therefore, extortionate.

In proof of this, ask any gentleman or lady outside the ken of photography what he or she presumes to be the salary of a first-class artist in the studio? Take any one of the first half-dozen establishments in town, where the principal himself does not occupy himself with posing, and enquire what pay these gentlemen demand and receive. The answer will most certainly be very much below the actual fact. Your friend would stare indeed if you mentioned such sums as three, four, or five hundred a year as the salary of a capable artist-photographer, and yet these salaries are given not only in the best establishments in town, but in the provinces, too. Or, again, putting the highest class of assistant on one side for a moment, ask what income the principal who acts for himself, not as a business man, but as an artist-photographer, would consider an equivalent for the services which have gained for him a high reputation. We make bold to say that no due consideration is ever given by outsiders to this point, who would perhaps be surprised to hear that such authorities as the late Adam-Salomon, Fritz Luckardt, H. P. Robinson, &c., to name a few of the élite, expect as comfortable an income as the thriving painter, barrister, doctor, or other professional man.

It is thoughtlessness on this head, combined, as we have said, with a mistaken notion that anyone with black fingers can dabble in the black art, that robs the photographer of many a good sitter. But it is only one of the reasons, and we merely touch upon it first as it is the great natural difficulty the photographer has to get over. But he must not lay the flattering unction to his soul that therefore the matter is out of his hands; that if he gets a good sitter, he may praise Allah, and that if he does not, the fates are against him. Where prejudice on the part of the public robs him of one good sitter, his own shortcomings rob him of half-a-dozen. In fact, so far as our experience as one of the public goes—and it is not insignificant—we would say it is, generally speaking, the photographer himself who makes a sitter good or the reverse. Even when a customer enters with mistaken notions as to the capacity of photography and photographers, it is often in the power of a good photographer to make a good sitter of the visitor. But this is no doubt a delicate and difficult task; what is neither difficult nor delicate is to keep a good sitter when you have got him, and this many photographers fail to do most singularly.

We are ready with chapter and verse to prove our case, so we trust the reader will hear us to the end. Here is instance No. 1. Not a twelvemonth ago, a lady was introduced to us, and one of her first questions was as to a studio we could recommend for a portrait. The lady was not fair, but dark; she was handsome, with good bearing, and a fine figure. You cannot go wrong in the matter of advice, if you never give any, is a good maxim to act upon in these circumstances; but as the lady found we would give no positive opinion, she asked for a negative one. Did we think Mr. Tripod's a good studio? she asked, for she had seen some charming pictures of Miss Esther Vane in the shop windows; she had indeed almost made up her mind, but she would so like somebody else's idea on the subject.

Our opinion was briefly that it was a very good studio, and the lady in consequence visited it under a double recommendation. That is to say, there was every reason why she should be pleased; she paid a fee of a guinea and a-half without murmur or dissent, and there was, in a word, the making of a good sitter out of her. And what was the result? The proof submitted was that of a plate underexposed in every corner, and taken altogether in the most slovenly fashion. It is true a few lines came with it, stating that if the picture were considered unsatisfactory, the firm would readily give a re-sitting; but that meant the sitter's former trouble was all thrown away, and that

the careful dressing up in finery and the apportionment of another morning were all to be done over again. Could not some one have taken the trouble to inspect that negative; or was the customer estimated at low value, since she paid her money promptly, and did not give a West End address? From a brief account we received of her visit, the most scant attention seemed to have been bestowed upon her.

This was a London experience Here is one from the provinces, from a studio established in one of our fashionable resorts. A gentleman, a military man, brought us a little brown vignette of his better half. "Here, look at this; I know you will give me a true opinion—what do you think of it?" We did not say what we thought of it then, but we will now; the paper was yellow, and the features and hair were unsharp everywhere. You could almost make out a double eye-brow on the left side of the face, and there were double hairs all over the forehead. Yet that picture had been paid for handsomely, and my acquaintance told me he had looked forward to visiting Summertown, in order to visit this well-known studio. Out of curiosity, we made it our business to enquire afterwards about these two particular pictures, and we may add that in both cases an assistant had done the work; still, this fact, obviously, does not take the responsibility off the shoulders of the principal.

But these, will say some of our readers, are isolated and unfortunate cases that may happen occasionally in the most carefully-conducted studio. We cannot agree with them; on the contrary, the head and front of the offending is the discipline of the studio. When it is first opened, and when the actions of all come up to those good intentions, which they say are to be found elsewhere than in the studio, everything goes well and satisfactorily. But if followed by a relaxation of discipline, whether this has to do with the appointments of the studio or its personnel, then, from that moment, you begin to turn good sitters into bad ones. Directly you commence to judge this sitter or that, to show this one a certain amount of attention, and that one less—in short, as soon as you begin to make a distinction between them in treatment—you run the risk of losing many a good sitter. You set yourself up to judge, and as often as not you judge wrong. To treat all studiously alike with the same strict precision and consideration is the only wise plan, and the only way of ensuring good sitters.

If any further proof were wanting, we have but to point to the "Half-a-dozen Portraits" of which we spoke last year. In these cases, it will be remembered, we maintained the secret of our visit so closely that in not one studio were we recognized. And what were the results of our experience. That although we passed as a good sitter, as one who was easily satisfied, and who paid without murmur what was asked, in three instances, at any rate, out of six, we were dissatisfied. Thinking and acting as one of the public, we should never repay a second visit to three of the studios, for the simple reason that we did not receive due attention; we should try our fortune elsewhere. From this, it would almost seem that half of our studios do not deserve to have good sitters. In any case, this is clear to our mind—that good sitters may often be made by the photographer himself, and if they fail him, the fault lies more with the studio than with the sitter.

Next week, our "By-the-Bye" will be on "Bad Sitters."

PERMANENCE OF PHOTOGRAPHIC PRINTS.

BY JOHN G. HORSEY.

On the 28th of November, twenty years ago, I was employing my leisure exactly as I am to-day, producing photographic prints, but not prints from negatives obtained by the easy dry plate process of to-day, nor under quite such convenient circumstances as we are accustomed to here in London. Then (November 28th, 1863) I resided a short distance from the city of Sydney in Australia, surrounded by sandhills which, in this particular month of the year, are always extremely hot and unpleasant, and render it necessary, when working near them, to hasten the collodion plate through the process of exposure to development. Except from rain, we were entirely dependent for our supply of water on a well about two hundred yards from our cottage. What I required I had to draw and carry, and as this was hard and warm work, especially in summer, I did not waste much over washing prints.

A great deal has been written about the impossibility of producing permanent prints on albumenized paper. My object in contributing these few lines is to prove the contrary, if twenty years is sufficient lapse of time to do so, and I think it is. At the time I speak of I produced prints from whole-plate negatives on paper prepared by myself. After toning, I carried them direct to the fixing bath, there to remain for twenty minutes, then gave five changes of water, allowing half-an-hour between each, finishing off with hot water for a few minutes only, and then dried them.

One of the prints then so treated (I put the date on it at the time), after lying in a drawer for about ten years, has since for a similar period been hanging framed in my bedroom, and is as clear and perfect as on the day I produced it. Others of same batch have been kept between the leaves of books, and are equally perfect and unchanged. May we not from these facts congratulate ourselves that our beautiful prints are not so evanescent as many of my fellow scribblers would have us believe? I think so.

A Dictionary of Photography.

ALBUMENIZED PAPER (Printing on).—*Continued.*

Fixing.—This operation consists in dissolving away the redundant silver chloride, and bringing the print into such a condition that it may be freely exposed to a strong light without being injured. The most suitable agent we are acquainted with for dissolving the silver chloride, and the one universally employed for the purpose, is sodium thiosulphate ($Na_2S_2O_3$), known among photographers as "hypo." This salt, though a most valuable photographic agent, may do serious injury to the photographer should it be allowed to mingle with other materials used. To be forewarned is to be forearmed; therefore the student will be most careful not to spill any about the floor, to be afterwards kicked up in the form of dust; neither must he drop a portion into any other solution, nor wipe his hands on the towel while fixing, without having previously washed them. Innumerable failures may be traced to a little laxity in the above respects.

The quantity of solution to be made up must be determined by the amount of work in hand. Small batches consisting of only a couple of dozen prints of small size can be fixed in a pint of solution; but for quantities of ten or fifteen sheets, a bath containing at least three gallons should be used. We recommend the fixing solution to be prepared some time previously, and it will be well to perform this and the operation of fixing the prints in a separate apartment. The proportion of crystal to water should be about 1 to 5. When small quantities are employed, it is usual to make it fresh every day, and slightly alkaline by means of ammonia, thus preventing the liberation of sulphurous acid, the presence of which would inevitably cause the prints to fade. After the bath has been used once for prints, it need not be thrown away because it is inexpensive; it will answer quite as well for fixing gelatino-bromide films as if freshly-prepared, and should be eventually treated with liver of sulphur to recover the silver.

Opinions differ regarding the use of a fixing solution more than once—and, as we have pointed out, for small quantities, once only should be the rule. When large quantities of, say, four or five gallons are used to fix as many hundred prints, the solution may be employed at least three successive days, provided it be strengthened each day, and kept slightly alkaline.

To make a small quantity, dissolve sodium thiosulphate 4 ounces, in warm water 20 ounces. When cold add ammonic

hydrate, 5 minims. A wide-mouthed bottle will he a useful vessel to keep for this quantity of bath.

Pour the fixing solution into a deep flat dish, having the toned and washed prints in a vessel of water near at hand; transfer the prints, one by one, from the vessel of water to the fixing bath in the following manner. With the right hand withdraw a print from the water, dropping it into the fixing solution. With the left hand press it face downwards, continuing the operation until all the prints are added. Let the vessel used for washing be put in its place before the right hand be allowed to touch the fixing solution. By a strict observance of this rule, another cause of failure is removed. If many prints are to be treated it is better for one person to drop the prints into the solution, while another separates them.

It is quite as important to agitate the prints during fixation as when toning, otherwise stains, and eventually yellow patches, will result. To prevent such an occurrence, keep turning the prints one by one face upwards; next turn them all face downwards, and continue turning them for the space of fifteen minutes from the time the last print was added from the washing water.

The prints, if treated as we have described, will be thoroughly fixed, and, if examined by transmitted light, will appear clear in the white portions. Collect the prints in bulk, drain off the superfluous liquid as much as possible, and separate them in a vessel of clean water. At least four changes of water should now be given, separating the prints each time. They should be next placed separately on a sheet of plate glass, or a flat porcelain dish, and pressed with a sponge to remove as much of the water from them as possible, after which they may be put in the washing apparatus.

Washing Appliances.—Photographers are more divided in opinion as to which is really the best mode of washing their prints after fixing, than might be expected; each one avers his method to be correct both in principle and practice. Doubtless this arises in some measure through individual circumstances, among them being water supply, quantity of work, and inventive capacity. To mention the scores of contrivances we have seen would be more likely to confuse than to teach; therefore we will mention two only to illustrate rapid and slow washing respectively. The first of these is Mr. Marshall Wane's rapid cylindrical washer, described in "Studios of Europe," pp. 189-190, and shown in fig. 1. The outside cylinder, A, is simply a casing of tin to keep in the water; the inside cylinder, B,

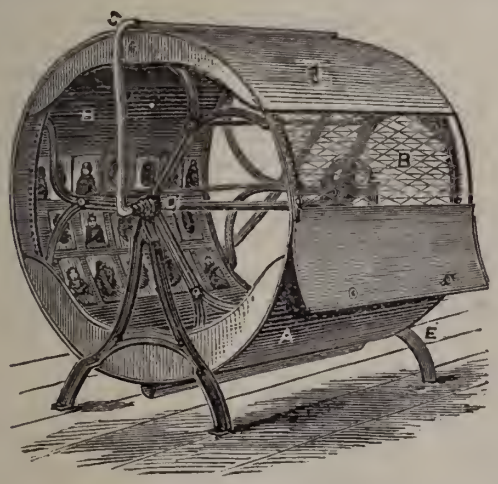

Fig. 1.

that revolves, is a few inches smaller than the exterior one, and it is simply a frame-work covered with twine netting. The prints are laid on this netting in the act of washing, the water being supplied by small holes pierced in tubes passing through the drum. Prints washed by means of this arrangement for twenty minutes, after the previous treatment of four changes of water and pressing with the sponge, are not found to contain any trace of the fixing salt.

The other apparatus is a simple and effective arrangement intended for slower washing and larger quantities. We believe it is manufactured by Doulton and Co., Lambeth, from the design of Mr. W. Pitcher (fig. 2). A, water supply. B, zinc cover to fit over C, perforated with fine holes, to allow the water to stream all over the surface of the prints. C, deep glazed earthenware vessel for the reception of the prints, a number of fine holes being made in the bottom for the water to pass through. D, outer vessel, of the same material, fitted with syphon (S), to permit the wash-water being removed from the bottom at regular intervals, dependant upon the rate of supply. Three or four hours' washing with such an arrangement will be found ample for the removal of the last traces of the salts retained in the pores of the paper after fixation. That is more than can be said of the custom of soaking prints a dozen or more hours in water, with one

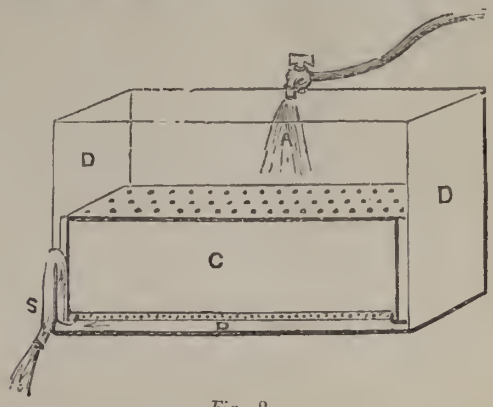

Fig. 2.

or two changes at the commencement, and as many at the finish of the soaking.

FRENCH CORRESPONDENCE.

PHOTO-TYPOGRAPHY—PHOTOGRAPHIC COPYRIGHT QUESTION—CALICO DISHES AND FUNNELS—CELLULOID VARNISH FOR GELATINE NEGATIVES.

Photo-typography.—The question relating to the transformation of a negative or positive print, having soft gradations of shadow, into a typographic negative with hatched or stippled shading, is becoming more important every day; yet it is surprising to see how little used are the processes producing this transformation. For example, we have been in the habit lately of receiving with the NEWS very fine impressions by the "Ink-photo" process of Messrs. Sprague and Co. To reproduce these lithographic impressions as typographic negatives requires only that one of these prints be reduced, using the negative thus obtained for an impression on bitumenized zinc. The result, when bitten with acid, would be a remarkable typographic negative. Finding that none has availed himself of the application of this process, I have undertaken—as a demonstration only—to reproduce one of these prints, of which the typograph will be published in my treatise on photo-typography, now in the press. By a careful examination under a magnifying glass, it will be seen that these prints realise all the requisite conditions for giving typographic images. A network of fine black lines, clearly separated by white spaces without any continuous half-tint, will be observed. The custom of interposing striated or granulated pellicles between the negative and sensitive film causes a hazy half-tint over the white spaces, and a far more complete result is obtainable from images similar to those by the "ink-photo" or Woodbury films previously inked. The interposing of an artificial network should therefore be abandoned unless in exceptional cases. If a regular grain over the high lights is desired in certain parts of a typographic negative, the bitumen image having been printed from the negative and developed, the engraving plate is re-coated with bitumen, and exposed under a network, and again developed. It is easier, perhaps, after the first exposure, to trace with fatty ink the desired network on the plate, and afterwards let it bite with acid as usual.

Photographic Copyright.—The question of copyright of

photographic works is following its course at the Senate A commission has been appointed to study M. Bardoux's bill. The point is whether our legislative body, after considering photographic copyright equal with that of works of art in general in most international commercial treaties, will contradict this course by depriving photographic works in France of protection. The Photographic Society of France and the Syndicate are both taking active measures to avoid such an undesirable state of affairs.

Calico Dishes and Funnels.—I have lately been studying the possibility of diminishing as much as possible the tourist's photographic baggage, by making calico dishes and funnels. Strong, well-made stuff is cut into pieces of the desired shapes, and coated with normal collodion; afterwards varnished with celluloid in a warm place, the stuff being about 30° or 35° Cent. Dishes, &c., may thus be carried in the pocket, and used for developing, fixing, and washing of plates or pellicles. Pellicles without paper or collodion as support are much more easy of manipulation.

Celluloid Varnish.—Celluloid varnish is excellent for gelatine negatives, but difficult to spread evenly. This substance is proof against water and other agents, with the exception of alcohol, ether, and acetic acid. Still, the protection of the negative is rendered more complete than with any other varnish. LEON VIDAL.

Notes.

The International Exhibition at the Crystal Palace is announced to open on April 23rd. There has been some doubt expressed whether photography will find a place under its roof, but as the exhibition is advertised as "Universal," and is to contain sections for art, science, and industry, photographs and photographic appliances must perforce be admitted.

We are very diffident about the wisdom of printing Herr Haensel's photograph of lightning, which appears in our columns this week; it is so unlike any picture, painter or draughtsman has ever produced. The orthodox zigzag is entirely wanting, and there is not a single sharp angle throughout. In fact, the photograph, with its gentle curves, is the very reverse of what our artists always put before us.

The Meisenbach process—the method by which our portrait of Sarah Bernhardt was produced—is surely, if slowly, making way. The best of the German comic papers, *Fliegende Blätter*, last week contained a very good specimen, the original being a pencil or crayon sketch, and not a pen-and-ink drawing, like those usually chosen for reproduction by "process."

Captain Abney, in the *Bulletin Belge*, says that the Platinotype Company's intensifying solution contains chloride of potassium and mercuric chloride dissolved in water.

The first number of *Le Progrès Photographique*, edited by M. Leon Wulff, has just appeared.

It is said that the "Sunshine Recorder" at Kew had a holiday during Christmas week. Seemingly, this "Recorder" has been doing nothing ever since.

Dr. Liesegang claims to have issued no less than eleven editions of his handy little book on carbon printing; the last issue of *Kohle Druck*, which reaches us with the date of 1884 printed on its title page, will no doubt be received with the same favour as its predecessors.

By the way, we see that, according to Dr. Liesegang, the first photographic business established was that of Professors J. W. Draper and Morse, in America, who began work in 1839, the same year as Daguerre announced his discovery.

It is more than a dozen years since Mr. Spiller called the attention of the Photographic Society to a white ivory-like material called Xylonite, manufactured from gun-cotton, camphor, castor oil, and a suitable pigment. We ourselves, at the time, made experiment with the material in the form of thin plates, for developing carbon prints, its white and pliable nature giving hopes of successful employment for this purpose. But we found the surface was not sufficiently like enamel, being waxy and liable to scratch. For knife-handles, pianoforte keys, and billiard balls, the material has, however, found a wide application.

In Paris they evidently use billiard balls of this description, for at a café on the Boulevard Poissonière, says the *Globe*, "as two persons were playing the other evening, two of the balls, after coming into contact rather sharply, ignited and not only destroyed themselves, but also set fire to the cloth of the table." The proprietor, naturally indignant, threatens to bring an action against the manufacturer of the balls, and with this view has sent sundry fragments of them to be analysed. If the balls are made of soluble guncotton, this will be easily discovered by the chemist, and the fact that such balls are liable to ignite by cannoning will be a bar to the further use of this material in connection with billiards.

We seem to have made a serious mistake the other day in describing M. Chapiro of St. Petersburgh as "Court Photographer." It should have been "By special appointment to the Academy of Fine Arts." Daily papers, please copy.

The nomination of candidates to fill vacancies in the Council of the Photographic Society must be made during the present month. There is an impression abroad that he who receives most nominations is usually elected, and that a candidate well "requisitioned" is almost certain of success. No doubt popular candidates have an advantage, but we should be sorry to see the day that electioneering traits are introduced among the members of the Pall Mall Society.

A correspondent announces in the *Times* the discovery of two inscriptions of King Nebuchadnezzar on Lebanon. The inscriptions are engraved on rock, right and left of a pathway, and although their translation has already been made by M. Pognon, a clever Assyriologist, the *Times* cor-

respondent says: "It is very desirable that at least photographs of them should be executed, and mouldings taken before the originals, already so seriously injured and exposed to the vandalism of the natives, have suffered new and irretrievable harm." Pleasure-seekers are, it appears, one of the scourges of Syria, and as these Arabs will do anything to get money, such a discovery as this is never safe. To photograph it is a kind of assurance against loss, and, therefore, its reproduction in this wise should be undertaken without delay. The inscriptions, it seems, which are headed by the titles of Nebuchadnezzar, relate to the felling of cedar trees in the neighbourhood of Lebanon.

"The old curiosity shop" of Charles Dickens, where lived in fancy, if not in fact, little Nell and her grandfather, is doomed. To many people, a memento of the quaint old pile that inspired Dickens to write his touching story would be very welcome, and the best memento would undoubtedly be a good photograph. The house is No. 14, Portsmouth Street, Lincoln's Inn Fields, and is said to be the last house in the parish of St. Giles-in-the-Fields. For some time, the old premises—they are now used as a store for waste paper—have been in a shaky condition, and on Boxing Day steps were taken to have the building shored up.

It is gratifying to learn that the fourteen observing parties stationed around the North Pole, of whom we have several times spoken in these columns, have been able to fulfil their duties successfully, and return home without mishap. The stations were chosen by Professor Wild, the President of the International Polar Committee, and most of the European nations, as well as the United States, sent representatives. The time allotted for the observations was a twelvemonth, and they were carried on simultaneously at all the stations, viz., from August 1882, to August 1883. Besides meteological and magnetical instruments, most of the parties were provided with photographic apparatus, of which very good use seems to have been made.

Truth employs a new phrase in criticism; instead of repeating Hamlet's oft-quoted dictum about out-heroding Herod, our contemporary speaks of a bigger and intenser nature, as a photographic enlargement of the character.

An object of considerable interest to photographers is announced for sale next Thursday, among the effects of the late Mr. J. J. Bennett, F.R.S, at Sandrock, Maresfield. This is no other than "the original invention of Heliographie by Mons. Nicephore Niépce, with his autograph memoir." This manuscript would be of considerable value in any historical collection, and we sincerely hope it will find a sympathetic purchaser. The auctioneers entrusted with the sale are Messrs. Austen and Son, of Marling Place, Wadhurst.

There has always been an objection to awarding medals to portraits pure and simple. How can any judge decide upon the work of a portrait, unless he knows the original? while its contributor, on the other hand, if he sends a fancy portrait or figure study, may run the risk of being put out of the portrait class, and relegated to the "genre" collection, which, strange to say, usually commands but an inferior award. A model for the best type of beauty would at once clear away doubts of this kind, and any costume, however fanciful, and pose, however romantic, would be admissible. Indeed, the competition would be an incentive to strive after something outside the conventional.

No doubt much would depend upon the model chosen, but this is a matter as important almost to the painter as it would be to the photographer. The obtaining of a charming model is of itself a display of taste, for it is not every damsel, however comely, who satisfies artistic exigencies. Again, while this lady's oval face and olive complexion would serve well as a "Maid of Athens" if she were draped, say, as "Ophelia," the result, despite the model's beauty, would be probably a failure; and in the same way, obviously, a "Hetty Sorrel" or "Dolly Varden" could not pose as Cleopatra. Here at once is plenty of artistic scope for the photographer. Next come pose and expression; and last, but not least, the lighting, all of which would give competitors plenty to do. In the end, possibly, it might be that the judges inclined to one type of beauty rather than another, but this must remain one of the elements of chance, to be found in every competition.

Though Mr. Pancoat's remarks at the Photographic Society on photographers who exhibit pictures from negatives which they have neither prepared nor developed excited a murmur of response from the meeting, it by no means follows that there is nothing to be said on the other side of the question. That which governs excellence in photographs now-a-days is, to use a somewhat hackneyed phrase, their artistic merit. Superb manipulative photography is quite out of count if the subject be ill-chosen or ill-arranged. Time was when photographic excellence alone was sufficient, but that was before we had become masters of our materials. In many first-class studios the photographer—or, as he should be called, the artist—does not trouble himself about the development, but concentrates his whole attention on the posing and lighting of the figure, to the manifest advantage of the picture. Where it is a matter of out-door photography, development, however, is in many respects like the laying on of colours in painting; judgment, skill, and tact are all necessary.

The great point to insist upon is that the picture shall really be the result of care and study, and not a mere "fluke." It is quite possible for a man quite ignorant of the rudiments of artistic composition to obtain by chance a most charming picture; but for every one so obtained he will show with equal pride twenty abortions. Mr. Pancoast probably alluded to such, and if so, everyone will agree with him, that photographic societies ought not to be overrun with new members whose only photographic

qualification is that of being able to uncap the lens. A recent test to secure only good men would be, previous to election, the submission of (say) a dozen pictures, which, if uniformly good artistically, would show that they had not been secured by stray shots.

Apropos, it may be no breach of confidence to point out that at a competition held not long since, an award was decided on this very ground. Between two series of photographs very nearly equal in merit, the choice fell on the series which showed the most uniform compliance with the canons of art. The unsuccessful photographer, though he had produced some beautiful pictures, had made mistakes in others, which clearly indicated that his results were not altogether dissociated from accident.

Patent Intelligence.

Applications for Provisional Protection.

5896. ALEXANDER BORLAND, of Wilmslow, in the county of Chester, for an invention of "Improvements in and apparatus for the production of photographic negatives to be used in the processes of photo-lithography, photo-zincography, photo-engraving, photo-etching, or photo-type productions.—Dated 28th December, 1883.

New Patent Law, 1884.

8. HART, "Photographic cameras," known as portable folding or tourists' cameras.

114. VAN DE WEYDE, "Producing vignetted photographs."

175. W. MORGAN, "Production of picture and other like mounts."

Grant of Provisional Protection.

5681. WILLIAM ROBERT LAKE, of the firm of Haseltine, Lake, and Co., Patent Agents, Southampton Buildings, London, for an invention of "Improvements in and relating to colour-printing, also partly applicable for producing coloured photographs and for similar purposes."—A communication to him from abroad by Auguste Bisson, of Paris, France, Heliographic Engraver.—Dated 8th December, 1883.

Patent Sealed.

4732. JOHN EDWIN ATKINSON, of Greenwich, in the county of Kent, for an invention of "Improvements in apparatus for use in transporting and exposing sensitized photographic plates or films."—Dated 4th October, 1883.

Specifications Published during the Week.

2316. BENJAMIN JOSEPH BARNARD MILLS, of the firm of Harris and Mills, of 23, Southampton Buildings, in the County of Middlesex, Patent Agent, for "A new mode of and apparatus for packing and preserving sensitive plates."—A communication to him from abroad by Antoine Lumière, of Rue St. Victor, Monplaisir, Lyons, in the Republic of France.—Dated the 7th of May, 1883.—(*This Invention received Provisional Protection only.*)

The invention consists of a metallic box intended to contain previously prepared dry plates for photographic purposes, and to preserve them from all exterior action of light, of humidity, or of any other agent which could injure them. The height of the box is a little less than that of the plates which it is to contain, these latter are held therein in parallel grooves formed of a corrugated sheet soldered to the lateral walls, which are thus strengthened. The four vertical faces are also strengthened by projecting ribs of various forms. The cover is provided with a shoulder parallel to its edges, which limits its application to the box in such a manner as to cover without touching the upper edges of the plates which project above the box. The plates are thus held perfectly without contact, and can be easily placed and withdrawn by their upper edge. All sides composing the cover of the box are carefully soldered by the overlapping of one of them over each edge in such manner as to render the whole perfectly tight. The closing is effected by a sealing with cement, with sealing-wax, or any other material preventing the entry of light, covered, if required, with a band of cloth or paper.

2323. JOSIAH ADAMS the younger, of Liverpool, in the county of Lancaster, for "Improvements in the manufacture of coloured photographic pictures."—(*This Invention received Provisional Protection only*).

My plan of operation is to place the photographic image on the back of the plate, then paint its outer surface either after varnishing or otherwise. When the paint is dry, coat the entire back with a mixture of oxide of zinc, gum, and balsam, or oxide of zinc and a drying oil. In place of oxide of zinc, the sulphide of zinc may be used, if the colours used do not chemically decompose it, or other suitable chemically neutral pigment could be used with either of these menstrua. While the gum, which can be gum copal, gum elemi, or other like transparent gum, is still wet, a sheet of pure white cellulose paper is laid on in such a manner as to avoid the enclosing of air-bubbles, and gently pressed against the photograph, so that the menstruum in which the oxide of zinc or other pigment is suspended shall penetrate the pores of the paper, and he thus, by capillary attraction, withdrawn from the surface of the photograph. The paper is allowed to dry on the plate, and as evapouration goes on on the outer surface of the paper, still more of the menstruum is withdrawn from the surface of the plate. The result is, when the whole has set, a clear, closely-adhering coat envelops the surface of the plate, and an effect almost if not quite equal to opal glass is obtained. Instead of pure cellulose paper, other bibulous material could be substituted, but it must be absorbent, not brittle, and absolutely neutral chemically. The bibulous matter in some instances can be done away with altogether. Thus, if a varnish menstruum be used, it can be laid on thick, and before setting, the outer surface repeatedly but gently washed with ether. The ether, having a strong attraction for the menstruum, rapidly draws it from the surface of the plate, leaving the pigment against the latter. The result, however, is not as good, as it is liable to scratch or rub off, and is but a poor and expensive substitute for the process already described.

Patent Granted in France.

154,972. SCHLOTTERHOSS, for "An automatic apparatus for exposing flexible and elastic bodies to the action of solar rays and other agents."—Dated 19th April, 1883.—Class 12.

155,104. TOMMASI, of Paris, for "A photo-electric selenium-regulator."—Dated 25th April, 1883.—Class 12.

Patents Granted in America.

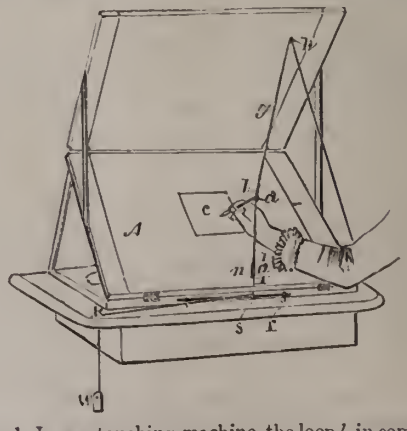
Issued December 11th.

289,951. W. IRVING ADAMS, Mont Clair, New York, "Photographic developing pan or tray." Filed Aug. 1883. No model.

A glass bath with a well at one end, like the well-known "Burton bath."

Issued December 18th.

290,217. JAY DENSMORE, Niles, Mich., "Machine for retouching photographic negatives."—Filed August 29, 1883. (No model).



Claim.—1. In a retouching-machine, the loop *l*, in combination with the pencil *d* and the cord or string *g*, substantially as described.

2. In a retouching machine, the elastic section *a* in the cord or string *g*, in combination with a retouching-pencil, substantially as described.

3. In a retouching-machine, the combination and arrangement, with the cord or string *g*, of the bar *b*, the eye *h*, the loop *l*, the eye *n*, the ring *s*, the rod *r*, and the weight *w*, substantially as described.

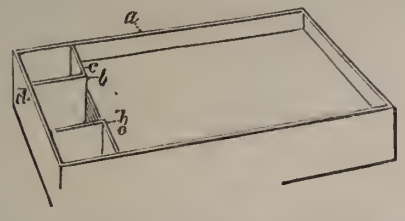
290,655. Charles L. Wright, New York, N.Y., "Process of colouring photographs."—Filed April 18, 1883. (No specimens.)

Claim.—1. The process of making coloured photographs, substantially as herein described, which consists in applying to photographic paper in a raw state an even coating of a mixture of egg-albumen, neutral sulphate of barium, chloride of ammonium, salicylic acid, and glycerine, then sensitizing, printing, toning, and fixing in the ordinary manner, and then softening the albumen coagulated in the preparation of the paper with concentrated ammonia, then applying the colours in a mixture of albumen, salicylic acid, glycerine, aqua-ammonia, and water, and then setting the colour in the prints by passing them through a bath of alcohol, water, and nitric acid, in or about the proportions as set forth.

2. The process of preparing photographic paper to receive the impression from the negative, substantially as herein described, which consists in applying to the paper an even coating of a mixture of egg-albumen, neutral sulphate of barium, chloride of ammonium, salicylic acid, and glycerine, in or about the proportions as set forth.

3. The process of colouring photographic prints, which consists in applying the colours in a mixture of albumen, salicylic acid, glycerine, aqua-ammonia, and water, and then passing the coloured prints through a setting-bath of alcohol, water, and nitric acid, in or about the proportions as set forth.

290,587. Edward Klauber, Louisville, Ky., 'Box for Photographic Dry-Plates."—Filed June 11th, 1883. (No model).



Claim.—A dry-plate box having near one end the rectangular abutments *b*, with their edges *c* truly vertical and in line with each other, and between the abutments the interspace or recess *d*, which is a little larger than the thumb, and sits out sufficiently from the adjacent end wall of the box to allow the introduction of the thumb for removing the dry-plates, substantially as specified.

CHAPTERS ON LANDSCAPE.

No. 1.—In the Field.

BY H. P. ROBINSON.

I am afraid that in these chapters a great deal more will be found concerning my own personality and productions than a modest writer would willingly admit; but I cannot see my way out of the difficulty, and for fear the reader should find the individuality offensively prominent, I apologise beforehand and hope to be forgiven.

The nature of the information I wish to convey, and the lessons I desire to inculcate, seem almost to demand that I should teach the results of my own experience, and to suggest that the pictures which have been the outcome of that experience would be the most suitable illustrations. It ought to be evident that pictures which have been actually produced by photography will better show the peculiarities and limitations of the art than any other method of illustration. At the same time, the lessons to be learnt from the great masters of painting and the allied arts are not to be neglected: indeed, without some knowledge of the laws which govern the arrangement of a picture so that the greatest amount of pictorial effect shall be got out of any given material, the student is scarcely ready to take the field. For our present purpose, however, we will suppose the pupil has some slight inkling of this knowledge, and is, to some extent, acquainted with the laws of Composition and Chiaroscuro.

Before you go out with the camera in your hand, it would be well to decide what you intend to do. A camera, if of any size, is but an encumbrance the first time you inspect an unknown district in search of subjects. A note-book and pencil are much more appropriate implements, and a view-meter may be useful, but the camera is best left at home. Of course, I know that when you are hurried, as on a tour, you have no time to make these preliminary arrangements; but, under such circumstances, you are not so much looking after pictures, as endeavouring to secure reminiscences of your travels, in the nature, as it were, of sketches. Our present object is to make pictures. Equipped, then, with note-book and pencil, you may go forth prospecting.

When you meet with a scene that strikes you as giving unusually fine opportunities for obtaining a good picture, don't throw it away by making a careless use of it, such as taking it at the wrong time of day, or without the necessary figures and accessories to make all out of it that can be made. Don't leave the arrangement of it until you want to expose the plate. Think it all out thoroughly before the time of action comes, so that you may have nothing else to do than to execute when the moment arrives—when the weather is propitious and all things are conducive to a successful result. Waste your time and plates as much as you like, but don't throw away a fine subject. Besides being the nearest road to success, it is a saving of time to "think before you leap."

As an illustration of how time may be saved by preliminary inspection, I may state that in addition to walking several miles, I once exposed thirty 15 by 12 plates in nine hours. These were all landscapes with figures—each, more or less, telling a story. A few of the plates were used for duplicate exposures, so as to make more sure of difficult or favourite subjects; but twenty-two of the resulting pictures have since appeared in exhibitions, and some have taken medals, so their quality must have been up to a certain mark. This rapidity is easily accounted for. We were staying at a country house, and had been troubled with unsuitable weather for eight or ten days, and had little else to do but look out subjects and make a complete study of them. So the work was all cut and dried when the fitting day arrived. And what a day it was! It was worth waiting for. The light seemed to alter to suit every effect I desired. A slight sketch was made for each picture, and the subject and title decided, the models selected, and the exact place and pose assigned to each figure. There was nothing left to be done, speaking metaphorically, but to turn the handle and grind out the tune.

When a view is selected, you should consider it as a painter would if he were going to make an important work of it. You have not so much power of modification as he possesses, therefore your skill and ingenuity must make up for the loss. In most cases there is more to be done than some photographers are aware. The chiaroscuro is very considerably in the photographer's hands. It is proverbial that everything will come to him who knows how to wait; and if he is not hurried—and I am not writing for the American tourist—he can select from twenty different effects of light,—from the long shadows of early morning, through the almost shadowless noon, to the softened lights and deepened shades of coming evening.

The composition, also, is capable of great modification Variations of a foot or two in the point of view will often very materially alter the arrangement of the lines and masses. The removal of the limb of a tree or less obtrusive twigs and branches, will sometimes disclose a picture which scarcely existed before. The opening of a gate may serve to give variety of line and opportunity for figures that did not previously exist. I have even seen the floodgates of a weir opened, so that a photographer might obtain the effect he required. When all has been done that can be done, take yet another look round to see that nothing has been forgotten. Above all, don't trust to your memory

for anything. Make sketches and notes, so that nothing may be left to chance; you will then be free in your mind to proceed with the selection of your next subject.

As there are no two things alike in nature, no two blades of grass, nor even two accurately corresponding sides of the same face, it is difficult for me to be very particular and minute about the arrangement of any special view or views, and what I have to say will consist a good deal in negative advice. I can, however, refer slightly to some subjects that have not yet been much hackneyed or made the common property of every photographer, like the ruins of our castles and abbeys, our churches and waterfalls. This, by-the-bye, reminds me that I did not notice any representation of Conway Castle in the last exhibition of the Photographic Society. We miss our old friend. The venerable ruin has never been absent any previous year. Kenilworth and Warwick, however, were still to the fore.

Enough use has not been made of the sky. We sometimes see a photograph of a good sky with a bit of sea—witness Mayland's splendid "Sea and Cloud," and the use of a second negative in ordinary landscapes has fortunately become common, notwithstanding the opposition the method met with for several years—but we seldom see what might be called a sky picture; that is, a picture the principal subject of which is the sky, the land and figures taking a secondary position. Here is a slight sketch of the kind of effect I mean.

The peculiar charm of aerial phenomena is too much neglected. The clear, bright day, when all objects are sharply defined, is still the sort of weather in which the photographer delights. There are lovely pictures to be got in the mist, but the opportunities for these effects are rare. Some years ago I rose very early each day for a week in the attempt to get a group or two of mushroom gatherers in the morning mist. But "The breezy call of incense-breathing morn" was wasted, and I was not rewarded for my constancy. Who has not seen and admired the beautiful, dreamy, indefinite effect of mist among the nearly leafless trees of autumn, when the sun, trying to pierce through the vapour-laden atmosphere, has reproduced a scene from fairy-land?

Such a scene as this I saw a day or two ago. I was out with a shooting party, and was one of what is called the "forward guns." I was waiting at the end of a beautiful cover. A fine mist partly obscured everything, but so slightly that the strong sunlight penetrated and illuminated the foreground, which consisted chiefly of a light, broken clay bank that gave great breadth, and threw back the mist-enveloped trees. A keeper in dark brown velveteen, with a black retriever at heel, listening to the beaters working their way from the far side of the wood, added life to the scene, and gave point to the composition. It was a quite possible subject. I was forgetting all about the shooting when a dead pheasant plunged at my feet and awoke me from my dream.

In the selection of a view, great attention should be paid to the foreground. The foreground is of so much importance that I do not hesitate to say that if a view is not well-fitted in this respect, it can never be an effective picture. An uninteresting plain of smooth meadow, for instance, is sufficient to ruin a view, however beautiful the middle distance and distance may be. A landscape photograph seems to require a good foreground more than any other kind of picture. Other parts of the scene must compose well, and be in harmony, but it is not necessary that they shall be of importance, while if the foreground be weak or ill-composed, no strength or importance in other parts will save the picture.

It is fortunate, however, that the foreground is just that part of the scene over which the artist has most control. It would be useless to go into any detail as to the arrangements of foregrounds; the disposition of each can only be settled as each case arises, but I here give an illustration of how one of the most uninteresting foreground has been ameliorated by the introduction of figures.

In this case there was a pretty, varied belt of trees in the middle distance, and a wooded height in the distance; the foreground was a plain piece of park-land, with useful clumps of gorse and braken scattered about, but a photograph of this would have no claim to be a picture. The simple introduction of a couple of figures with some little action in them breaks up the plainness of the field, gives interest, and accentuates the composition.

The student having now made up his mind what he is going to do, may go and do it. He should see that his mechanical arrangements are so complete and easily accessible that he will scarcely have any necessity to think of them; but for fear he should have to do so, let him put his hands in his pockets and get an assistant to look after the luggage, for it is not easy to arrive on the ground capable of good work if you have been doing duty as a heavy porter on the way. All preliminaries should be so complete that no doubt or hesitation should be possible. The battle should be fought and the victory won before the cap is taken off the lens, or the trigger of the shutter is pulled.

(To be continued.)

CASEIN EMULSION.

BY JOHN BARTLETT.

THE following experiment, though resulting in nothing of practical importance, may have its value in the suggestion it offers.

From the relation which casein bears to gelatine, albumen, and the other members of that group of bodies known to the chemist as the protein compounds, I was induced to try it as a vehicle for the sensitive salts of silver; more by way of curiosity than with any expectation of receiving good results. Never

theless, the comparativo success which attended my experiments, although conducted in rather a hap hazard manner, has induced me to make known the facts.

Casein as it occurs in its ordinary state of solution in milk, has certain properties which are entirely different from those possessed by cascin obtained perfectly free from alkali.

To obtain it in the latter condition, ordinary skim milk is taken and freed as much as possible from every trace of cream, and then coagulated by a few drops of acetic acid. The coagulum or cheese thus formed is pressed in a flannel cloth to free it from the whey; it is then dissolved in a dilute solution of carbonate of soda (sal soda), from which it is again precipitated by hydrochloric acid, the precipitate collected and thoroughly and repeatedly washed in a flannel bag with water containing two per cent. of hydrochloric acid; the object of the washing is to free the cascin from fat. It is then mixed with pure water, in which it swells and gradually dissolves, especially if the temperature be slightly raised.

The casein in a pure condition may be thrown down by careful neutralization with an alkali, and the precipitate washed.

So formed, casein dissolves only slightly in cold water, rather better in hot water, but not at all in alcohol. It forms solutions with carbonate and phosphate of soda which no longer exhibit an alkaline reaction. It dissolves very readily in chloride of ammonium, nitrate of potassa, and other neutral alkaline salts, forming on evaporation a film of horny cascin. It dissolves in dilute mineral acids, but is precipitated on addition of excess of acid. The solution in hydrochloric acid, as we have said, dissolves readily in water, but before doing so swells up like gelatine. It was this property which confirmed my notion of its probable use as a substitute for gelatine.

I accordingly made use only of this combination of casein with hydrochloric acid without experimenting with the pure casein, the properties of which I have merely quoted to direct the attention of those who may desire to experiment further.

I tried several combinations, using the bromides of zinc, cadmium, and ammonium; making the emulsions by the cold and by the hot method.

I found that a precipitation of the cascin invariably occurred on adding the nitrate of silver; but by the cautious addition of pure ammonia and subsequent gentle boiling, a complete solution was effected, and a rather fine-grained emulsion produced, which, when poured warm upon the plate, flowed tolerably well, and hardened in about twelve hours. The plates produced were sensitive to the light, giving impressions in fifteen seconds.

But I do not consider the rapidity of the plates of any value in my experiments, knowing that by proper use of the chemicals any degree of sensitiveness may be obtained—my object being merely to show the possibility of the employment of casein as a vehicle for sensitisation. As far as my knowledge extends, I have not heard any mention made of its use, and, therefore, hope that these few and imperfect essays may have their value in stimulating some one possessed of more knowledge and experience.—*Philadelphia Photographer.*

Correspondence.

PHOTOGRAPHIC BLOCK METHODS.

DEAR SIR,—Now that so much is being said about priority in successful photo-typography, I must insist upon the recognition of a fact which appears not to be generally known outside of this country. It is this: the "Ives' Process" is the first patented or published process which was introduced into truly successful commercial operation. I see that this claim is now made for the process of Meisenbach. Meisenbach's original specification dates nearly four years later than my own, and nearly one year later than my U. S. patent on that form of the process which is now in use. Moreover, my process was in successful commercial operation here some months before the patent was issued, and has turned out hundreds of plates every year since.

A southern trade journal (published semi-monthly) commenced the publication of a series of Ives' process portraits in January, 1883, which appeared regularly for more than six months, and still continue to appear at irregular intervals. This is undoubtedly the first series of photo-typographic portraits which ever appeared in a regular periodical publication, printed in a page of type matter.

A great many other Ives' process plates have been used in illustrating newspapers and magazines in various parts of the country, and we have letters which prove that they have usually given unqualified satisfaction.—Respectfully yours,

Philadelphia, December 8th, 1883. FRED. E. IVES.

GREENISH-YELLOW LIGHT IN THE DARK-ROOM.

DEAR SIR,—It may interest your readers to know that I am still using the green light, and would be very sorry to be obliged to use any other; but why photographers go on with the ruby light I cannot understand, as I found it most injurious to my eyesight.

I am glad to see Mr. Debenham's experiments confirm my views as expressed on page 764 of your volume for 1882; but does he use it in his dark-room? I think if the dry plate makers used it they would find a great advantage in being able to see better.—Believe me, yours truly,

W. S. BRADSHAW.

[Mr. Bradshaw recommends (*loc. cit.*) one thickness of ground glass, one of green, and one of deep orange.—ED. P. N.]

THE HYDROKINONE DEVELOPER.

SIR,—I should be glad to have the experience of some of your practical contributors as to development with hydrokinone. I have used it according to Mr. Pocklington's formula, and I have succeeded well when a full exposure has been given; but with instantaneous work, the image almost disappears in the hypo bath (full strength). Though I shall try all I see in the NEWS on the subject, I think the experiences of the photographic fraternity will be acceptable to many of your readers, myself included.—Yours truly, G. ST. JOHN BIGGS.

BRISTOL INTERNATIONAL EXHIBITION.—AWARD IN CLASS IX.

DEAR SIR,—Permit me to send you the following resolution passed by the Council of the Association, with regard to the above award. For the clearer information of those interested, I may say that the regulation for Class IX. reads thus:—"A silver medal for the best enlargement of any subject, and by any process, *provided it be the work of the exhibitor.*"

Mr. W. F. Donkin inadvertently omitted to state that the enlargement exhibited by him was not his work, when sending his exhibits, the result being that a difficulty now arises, and with much regret the Council feel that the least unsatisfactory course is the one they have adopted.—Yours faithfully, H. A. HOOD DANIEL, *Hon. Sec.*

Resolution.—"That in consequence of Mr. W. F. Donkin having disclaimed the medal awarded to him in Class IX., *the enlargement in question not being his own work, but that of the Autotype Company*, and the conditions of exhibition in this class thereby not having been complied with, the Council, with reluctance, feel compelled to retain the medal."

INSTANTANEOUS PHOTOGRAPHY IN NEW YORK.

SIR,—On receipt of your much esteemed journal of November 30th, it stated that instantaneous photographs in America appear to be somewhat a novelty. The *Illustrated World* of New York, thinking it worthy of remark that a photographer should be successful in obtaining photographs of views of interest in and about the city, and that at the opening of the Brooklyn Bridge, photographs were taken with absolute fidelity, the exposure of the plates being so brief that the vibration caused by the machinery of the steam tug in which the camera stood

had no perceptible effect on the pictures. "Such photographs, the PHOTOGRAPHIC NEWS says, in England are of everyday occurrence."

Allow me to say, that instantaneous photographs have been taken in and about New York years before the bridge was completed. Enclosed I send you three instantaneous pictures which speak for themselves. One was taken by the writer in the fall of 1880, from the West Street steam ferry boat, and you can see the road-way of the bridge was just commenced. The others were taken down the bay in the Spring of 1881, from a small cat boat, and if there is any kind of craft that has more motion, in a sea way, than that description of boat, I don't know it.

Three-fourths of our instantaneous negatives are made by amateurs, and the bromo-gelatine plates were used by them at least two years before the professional photographers introduced them into their galleries. Now, in 1883, when they occasionally make instantaneous views, they think that they are doing something very wonderful for the profession.

The fact is that, with us, portraiture is the only branch that pays, and neither pains nor expense are spared by the professional to make it a success.

Landscape photography, and all out-of-door work, is almost unknown to them, if we are to judge by the few pictures for sale in the stores.

The amateur photographers on this side of the water would be very reluctant to let the amateurs of England suppose that they have never derived any benefit from the many valuable articles which have been contributed to the photographic journa's by the English amateurs, and found their way over here, much to our enlightenment. It is true we are few in number, but we hope to see the day when we will be many. We have difficulties to encounter of which you have no conception; even the standing of an amateur is not with us as with you; the very acceptation of the word with the press means a beginner or novice, and a man that will work for the love of the work, and nothing more, is only fit for a lunatic asylum.

There are numbers of doctors who never get a call, of brokers that never make a sale, of lawyers who never have a case in court, men of ample means, but who have to make a pretence of business because it is respectable to do so, and who no doubt would find photography a more pleasing occupation if they could brave public opinion.

Please accept my excuse for offering this explanation, which has overflowed its limits, and believe me to be, yours truly, LEWIS ATKINSON.

[Mr. Atkinson's note is accompanied by some delightful little sea sketches taken by photography.—ED. P.N.]

PHOTOGRAPHIC SOCIETY OF IRELAND.

SIR,—In the report of the Society's meeting, and of the paper read at that meeting on the 14th December, 1883, by an error, the name of Mr. McGhie was substituted for Mr. J. H. Halvey. Will you kindly, in justice to Mr. J. H. Halvey, make this correction?—Yours faithfully,

CHARLES W. WATSON, *Assistant Hon. Secretary.*

[A notification to the same effect appeared in our columns last week.—ED. P.N.]

PHOTOGRAPHIC ILLUSTRATIONS OF DICKENS' WORKS.

DEAR SIR,—Reading your YEAR-BOOK for 1884, what you say on page 141 in reference to a society or an association to take negatives of places referred to by Dickens struck me as being a very good idea, and I should think could be managed by a few amateurs who liked to take it up. It only wants some one to start it, I am sure, to be a success, and so I write to you to ask you to kindly publish this in your paper, so that any amateurs who may like to take it up can write to me, and then we can see if we are able to get up an association for that purpose. If you would publish what you say in the YEAR-BOOK with this letter, it would give your readers an idea of what is wanted. Letters can be addressed to me at the subjoined address, or at my house, "Oak Villa," Beulah Hill, Upper Norwood, S.E.—Yours truly, A. R. DRESSER.

2, *Park Terrace, Bognor.*

[We shall be happy to give any assistance in our power towards the furtherance of the scheme. Our readers can themselves refer to the YEAR-BOOK, page 141.—ED. P.N.]

Proceedings of Societies.

GLASGOW PHOTOGRAPHIC ASSOCIATION.

A CONVERSAZIONE under the auspices of the Association was held in the Victoria Hall, Glasgow, on the evening of Tuesday, the 18th inst. Councillor ROBERTSON, president of the Association, occupied the chair, and in a few opening remarks expressed his pleasure at seeing so many members and friends gathered together, and hoped they would spend a happy evening.

The chief feature of the conversazione was the exhibition of photographic and philosophical apparatus, tastefully arranged on tables in the centre of the hall, which was beautifully illuminated by the incandescent lamps of the Edison and Swan electric light Co.'s. The lights, which were encased in delicately coloured globes, and arranged in festoons, had a very fine appearance, reflecting great credit on Mr. Grant, manager of the company.

Mr. SMELLIE, of the National Telephone Co., had fitted up sets of telephones and telegraphs. These instruments were very much appreciated, and messages were flashed from one end of the hall to the other the whole evening, one wire doing duty for both instruments. An electric pen and several other articles were exhibited by the same gentleman.

Mr. WHITE, optician, sent an attractive contribution, including graphoscopes, revolving stereoscopes, a fine set of Geisler's tubes, a galvanic battery, &c.

Messrs. MARION, of London, amongst other things, showed an Enjalbert camera, Cowan's changing box, and an Academy camera, which received a great deal of attention.

The local dealers were represented by Messrs. Mason and Co., McGhie and Bolton, and Kelso and Co., who had all well-filled tables, showing the finest apparatus and the latest novelties of the season.

Mr. MACTEAR lent a grimo-kistoscope, an instrument invented for the use of caricaturists. It is somewhat in the form of a stereoscope; its lenses are, however, made to revolve by clockwork, and a portrait inserted into it undergoes many mirth provoking transformations.

A few specimens of work were also exhibited. Walter Macfarlane, Esq., showed some of Mr. Vernon Heath's large Autotypes, which were very fine; Messrs. Goodall and Stevens exhibited some very good specimens of their bromo-argentic enlargements on opal and canvas; and Messrs. Annan had a large photo-engraving of Sir Noel Paton's "Fairy Raid"; while Messrs. Maclure and Macdonald showed some magnificent specimens of Lichtdruck printing. Passing on from these signs of profession, we come to some exhibits which may be regarded as almost antiquarian.

The PRESIDENT exhibited a complete list of Daguerreotype apparatus.

Mr. ABBOTT, of Dundee, sent some specimens illustrating the early stages of photography, including a lens made by himself about forty years ago.

Mr. CHURCH showed the first pneumatic plate-holder, made about 1852.

A volume of Calotypes in the possession of Mr. Thos. Annan, taken and printed about the year 1844 by the late D. O. Hill, R.S.A., showed very little signs of fading. Having been taken in direct sunlight, they have a pictorial breadth sadly wanting in the smoothly touched-up portraits of the present day.

The meeting was enlivened by a considerable display of amateur talent in music, song, and recitation, and altogether a very pleasant evening was spent. The meeting terminated with votes of thanks to the exhibitors, committee, and chairman.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

A MEETING of this Society was held on Thursday, the 27th ult., Mr. A. COWAN in the chair.

Mr. W. M. Ashman, with a view of testing whether mercuric iodide solution acted as an accelerator when added to a sodic developer, exposed three plates in a very dull light on the previous day, and developed as follows:—

No. 1. Exposure five seconds:—

Pyro	2 grains
KBr	2 „
Ammonia ·880	2 drops
Water	1 ounce

No. 2. Exposure, five seconds:—

Pyro	2 grains
KBr	2 „
Saturated solution of washing soda ...	1 ounce
Mercuric iodide solution	3 drops

No. 3. Exposure, twenty-five seconds:—

Pyro	2 grains
KBr	2 „
Saturated solution washing soda ...	1 ounce

It had been claimed that exposures can be reduced four-fifths by this means. He (Mr. Ashman) could not corroborate this. No. 2 would be seen to possess more detail than No. 1, each having received one-fifth the exposure of No. 3.

Mr. W. Cole said a saturated solution of soda would be a stronger alkali than the ammonia and water used in No. 1.

Mr. W. E. Debenham thought if the ammonia plate had been developed longer, or received one half the quantity of soluble bromide, it would have produced the same result; or if the plate had been developed with as much ammonia as it would bear, it would have been quicker.

The Chairman enquired whether the mercuric iodide was dissolved in excess of iodide or excess of mercuric chloride; he considered the difference in the manner of mixiug material to the result.

Mr. Ashman said he used a slight excess of potassium iodide.

Mr. A. L. Henderson considered the gain was due to the intensifying action of the mercury; he did not think it was generally known that no restrainer was required with sodic developers. Glycerine and colloid substances generally were all restrainers; he had obtained the best results with 5 mimims of a 30-grain solution of caustic potash.

Mr. F. W. Hart suggested the use of pure carbonate of soda; he saw no advantage in using common soda, which contained sulphate and other impurities.

Mr. Debenham enquired how long the plates were in the developing solutions.

Mr. Ashman replied that No. 1, being sufficiently dense, was removed from the developer at the end of three and a-half minutes; Nos. 2 and 3 required seven minutes to obtain sufficient density.

After some further discussiou on the properties of mercury with iodide, in which the Chairman, Messrs. Henderson, Hart, Tunny, Debenham, Ashman, and others took part,

The Chairman suggested that Mr. Ashman should expose equally two more plates, developing one with sal. soda, and the other with sal. soda and an additiou of mercuric iodide.

Mr. Henderson said on the last occasion Mr. Starnes lent his lamp to him to try a few experiments; he exposed a fairly-rapid dry plate in four divisions close to the lamp for 30, 60, 90, and 120 seconds, and a wet plate in three divisions 5, 10, and 15 minutes respectively. In each case there was a deposit; but after intensifying and clearing the wet plate, the five minutes' exposed portion disappeared, leaving a very good indication in the other two. He had since tested one of Mr. Starnes' plates in the sensitometer, and obtained 9. If Mr. Warnerke considers 10 on his sensitometer a good speed for a wet plate, the slowness of Mr. Starnes' plate would account for the discrepancy in their experiments. Mr. Starnes, acting on the suggestions offered at the last meeting, has altered his lamp. The back is matt, and the front glazed with cathedral green; a plate exposed to this light at a distance of 15 inches for 1, 2, and 3 minutes respectively, turned round, and exposed 10 and 20 seconds, was not acted upon, there being light enough to coat plates three yards from the lamp.

Mr. Starnes exposed four plates up to 15 minutes at a distance of 27 inches; no effect was visible.

Mr. Debenham enquired if Mr. Henderson did not find the combination of green and yellow gave more light than ruby.

Mr. Henderson had not made many experiments, but he preferred canary medium to anything he had met with up to the present, this being a greenish yellow.

Mr. Cole asked for informatiou on the best means of restoring a faded silver print.

Mr. Henderson said there was several ways: one would be to wash out all the starch, soak it in iodine followed with platinum, thus converting the image into the latter metal, and washing thoroughly afterwards; another plan would be to bleach the image with bichloride of mercury followed with lime water, not ammonia or hypo, which would probably dissolve it entirely. Some time ago he brought an old print up by means of acid pyro; in any case a good wet plate negative should first be taken.

Mr. J. G. Tunny promised to send some examples of paper negatives for examination recently shown before the members of the Edinburgh Photographic Society.

It was announced that the proceedings will commence punctually at eight o'clock on lecture nights, when all who may be interested in the subject are invited to attend. The next lecturette will be given on January 10th, on "Printing."

Talk in the Studio.

Large Woodburytype Moulds by the Stannotype Process.—We understaud that some especially large moulds have recently been made in a perfectly satisfactory manner, in the laboratories of Messrs. Woodbury, Treadaway, and Co., at South Norwood, the subjects being beyond the power of the hydraulic presses available in this country. Our readers are aware that moulds have been made by the roller press, but we have never seen one in which that truth of surface which is necessary for the production of a really good print was secured; and in the case we refer to, we understand that the Stannotye process was only adopted after repeated attempts had been made to obtain good results by the roller method (see Photographic News 1883, p. 660).

A Method of Photometry.—We read in a Continental journal of Dr. H. Hammerl and his very ingenious method of reducing the intensity of a light for photo-metrical comparison, by cutting off one-half, three-fourths, or even nineteen-twentieths of the light, so that what remains is easily measured. It consists in placing in the path of the rays that fall upou the screen a revolving metallic disc from which are cut sectors that allow a portion of the light to pass through, but cut off and absorb the remainder. If the sum of the angles of all the sectors taken together equal 180°, one-half of the light will be intercepted, while the other half passes through. Experiments show that three sectors will suffice to give an uniform illumination with a moderate speed of revolutiou. The size of these sectors will, of course, depeud upon the amount of light to be cut off. When it is desired to reduce the light to one-third, each sector must have an angle of 40°. If each sector has au angle of 12°, the light will be reduced to one-tenth, and so on. When two discs are employed, each having three sectors of 60° each, they can be so arranged on the axis as to give any desired result. If a single disc is employed, the openings should not be true sectors, having a definite angle at the centre, but cut so that the angle increases from the centre towards the circumference in a definite ratio. This may be so chosen that the weakening shall regularly increase from centre to circumfereuce just as the distance from the centre increases. When this form of disc is employed, the usual greased spot on the screen must be elongated instead of round, and as long as this opening. One end of this spot will be dark, the other light, and it must be noticed where this change occurs, and the amount of weakening read by a scale on the disc itself.

Endowment of Research.—We have frequently expressed our conviction as to futility of paying money to aid research. No discovery of any importance has ever been made through a promise of filthy lucre, and the world at large has never been kept out of an invention because encouragement was lacking to unearth it. But the great objection to paying away money in this way is, that it does not go into the pockets of the starving student or needy chemist, but simply to those who have the most interest. The poor inventor is as poor as ever, for the money falls to the clamouring ones in the front row, who look to these windfalls as a regular addition to their income. Let anyone look over the yearly list of recipients, and he will not find one in ten who has deserved reward more than any other of his brethren. In these circumstances, it is very satisfactory to find the gentle author of "Alice in Wonderland," and of that wonderful ballad "The Walrus and the Carpenter," hurling a

shaft at the monstrous sham, in the clever lines headed "Fame's Penny Trumpet-"

Blow, blow your trumpets till they crack,
Ye little men of little souls!
And bid them huddle at your back—
Gold-sucking leeches, shoals on shoals

Fill all the air with hungry wails—
"Reward us, ere we think or write!
Without your Gold mere Knowledge fails
To sate the swinish appetite!"

And, where great Plato paced serene,
Or Newton paused with wistful eye,
Rush to the chace with hoofs unclean
And Babel-clamour of the sty.

Be yours the pay, be theirs the praise;
We will not rob them of their due,
Nor vex the ghosts of other days
By naming them along with you.

* * * *

Go, throng each other's drawing-rooms,
Ye idols of a pretty clique:
Strut your brief hour in borrowed plumes,
And make your penny-trumpets squeak:

Deck your dull talk with pilfered shreds
Of learning from a nobler time,
And oil each other's little heads
With mutual Flattery's golden slime.

And when the topmost height ye gain,
And stand in Glory's ether clear,
And grasp the prize of all your pain—
So many hundred pounds a year—

Then let Fame's banner be unfurled!
Sing Paeans for a victory won!
Ye tapers, that would light the world,
And cast a shadow on the Sun.

Lewis Carroll.

DECOMPOSITION OF IODOFORM AND CALOMEL BY LIGHT.—Mr. S. J. Bendiner, of New York, points out that a mixture of iodoform and calomel—such as is not unfrequently prescribed by physicians as a dusting-powder for sores—is more or less affected by light, even when the chemical rays are excluded, and at ordinary temperatures. When heat is applied to the mixture, in a test tube, the decomposition takes place more rapidly, with evolution of the vapour of chloroform and hydrochloric acid gas, which latter strongly reddens litmus paper introduced in the upper part of the test tube. As an explanation of the reaction, the author cites the behaviour of mercuric chloride towards iodoform mentioned in Flückiger's Pharmac. Chemie. When these substances are brought together, iodo-chloroform, a substitution product of chloroform, is produced, which is almost identical in odour with the latter:

Iodo-form.		Mercuric chloride.		Mercuric iodide.		Iodo-chloro-form.
CHI_3	+	$HgCl_2$	=	HgI_2	+	$CHCl_2I$

A similar reaction probably occurs with mercurous chloride. —*Pharm. Rundschau* (Hoffmann's), 1883, 245.

PHOTOGRAPHIC CLUB.—At the next meeting, on Wednesday, January 9, the subject for discussion will be "Reducing Over-dense Negatives."

To Correspondents.

*** We cannot undertake to return rejected communications.

G. ST. JOHN BIGGS.—It is not ordinarily kept by stationers, but you can obtain it through any photographic stock dealer.

MAJOR-GENERAL P.—1. We will post you a sample, but you may gather some idea as to the depth of shade required by noting that two thicknesses will about equal one thickness of the "signal green" used on railways. The ordinary "signal green" will thus serve as a rough standard for depth of colouring, but not for the tint, as the cathedral green has a yellowish cast. 2. It certainly looks rather puzzling at first, but as the commercial preparation referred to is decidedly acid to test paper, the first assumption falls to the ground, and we have verified the statement that thirty minims are approximately neutralised by three-quarters of a minim of ammonia. 3. Commercial pearlash is quite pure enough for the purpose referred to.

MR. C. J. CHESTERMAN.—Thank you for note just to hand. Hope you have received YEAR-BOOK.

LITHO.—Nothing which has yet been published gives such a full and practical account of the various photo-lithographic methods as the articles by Major Waterhouse, which commenced on page 483 of our volume for 1882. The articles will be re-printed in book form.

J. C.—We do not know of one.

ARTHUR HOLLIS.—If you will send us particulars as to its composition, we shall have great pleasure in preparing some, and trying a few experiments regarding its merits as a reducer. It would interest our readers but little to read of trials made with a mixture of unknown composition.

ASPIRANT.—No two persons will give you exactly the same advice with regard to enlarging, but, circumstanced as you are, we should recommend you to set about it as follows:—Lay your original negative in a printing frame, and after having placed a gelatino-bromide plate behind it, expose to gas-light for a sufficient time to impress the latter. We should suggest half a minute at a distance of four feet from an ordinary burner, as a first trial of exposure. Develop the plate just as you would for a negative, and you will obtain the required transparency. This transparency is placed in the carrier of the enlarging camera, the film being directed towards the lens; and either of the lenses you mention will answer your purpose, provided that your enlarging camera is sufficiently long to enable you to obtain the required degree of amplification; but it may prove necessary to use the short focus objective with which the pictures were originally taken. The wet collodion process is perhaps more suitable than the gelatino-bromide method for making the enlarged negative; but before giving yourself the trouble of providing all the requisites for the wet method, you had better try how you can succeed with the dry.

A. B. C.—Either prepare them on glasses of the exact size required, or on plates which will cut to the required size. Varnish with the usual negative varnish, and mount in the frames with ordinary putty. Naturally, either the varnished side should be inside, or an extra glass should be placed in the frame first. You can mount silver prints on glass by the method described in the YEAR-BOOK (see article on "Colouring photographs against glass").

J. BERRYMAN.—We are sorry you have not the results of your experiments to hand, and we will communicate the contents of your letter to some who are working with the process. If you had used a dabber in a good condition, we do not think you would have experienced the clogging up you refer to. The fibres should be thoroughly imbued with ink, and yet the actual quantity present must be very small. This condition is realised by forcing a large quantity of ink with the dabber, and then removing the bulk of it by working the dabber against a piece of clean rag or canvas. Try again.

A. H. C.—The picture is very pleasing and decidedly effective.

CONSTANT READER.—For general work we should prefer either the first or the second. There is nothing to choose between them.

BISMUTH.—Next week.

S. W. S.—See Mr. Berkeley's article in the last number of the PHOTOGRAPHIC NEWS.

PAPYRUS.—The facts are as you suppose; but it does not by any means follow that your conclusions are correct.

The Photographic News Registry.

Employment Wanted.

Manager of Marion's Works.—C. Francis, Marion's Works, Southgate, N.
Retoucher & Assist. Operator.—A. B., 6, Oswald-rd., Milverton, Leamington
Printer & Toner, Berlin Medals.—G. Dendle, 27, Portland-st., Ilfracoombe.
Young Lady for Reception Room.—S. F., 69, Grosvenor-rd., S.W.
Enlarger or Dry-plate Maker.—B., 7, Northumberland-ter., Regent's-pk.
Operator, dry plate manufacturer.—J. R. H., 11, Lewisham High-rd., S.E.
Operator, retoucher, all round.—Mr. Ems, 12, Bartholomew-ter., Exeter.
Reception Room, book-keeper, &c.—M. R., 34, High-st., Sittingbourne.
Lady, to mount, spot, &c.—A.S., 3, Silchester-rd., St. Leonards-on-Sea.
Retoucher, can operate.—H. A. G., 35, Brooker-st., Hove, Brighton.
Retoucher, operator, or manager.—J. Jones, 79, Euston-st., Euston-rd.
Operator, gen. assist., good all-round.—T. W. 59, Tredegar-rd., E.
Retoucher and assist. operator.—A. R., 27, Cross-st., Ryde, I. W.

Employment Offered.

Printer, Toner, & Vig. (first-class).—J. H. Goldie, 7, Temple-st., Swansea.
Spotter, good.—W. and A. H. Fry, 68, East-st., Brighton.
Portrait Painter, experienced.—W. H. Ledgard, Lumb-la., Bradford.
Young Man (wet-plate) for Copying.—Hill & Co., 45, Essex-st, Strand.
Port. Painter (lady or gent.)—J. M. D. Worsnop, 154, Leeds-rd., Bradford
Artist for carbon enlargements, &c.—C. F. Treble & Co., 371a, Brixton-rd.
Silver Printer, quick & experienced.—C. F. Treble & Co., 371a, Brixton-rd
Lady, exp., for mounting & spotting.—Mr. Gandy, 5, Bishopsgate-without.
Printer, artistic vignetter.—E. D Lavender, Tweedy-bldgs., Bromley, Kent.
Artist for monochrome, carbon enlargements, &c.—Lex, *Photo. News* Office.
Miniature Painter, first-class.—Lex, *Photo. News* Office.
Fitters, artificial light apparatus.—Luxograph Co., North-end, Croydon.
Learner, for retouch.—N. M., c/o. Shew & Co., Wardour-st., Oxford-st., W.
Operator, first-class, & to retouch.—Hodson, 8, Market-pl., Retford.
Enlarger for general work.—D. S., *Photo. News* Office.
Dry-plate man, first-class.—Dry plate, 37, Thornton-st., Brixton.
Operator and retoucher.—F. Baum, c/o Disderi & Co., 4, Brook-st., W.
Female Assistant Printer.—F. Baum, c/o Disderi & Co., 4, Brook-st., W.

CONTENTS.

DIFFUSED LIGHT FOR THE DARK-ROOM.

SOME experiments we have recently undertaken in connection with the illumination of dark-rooms bear so much upon a matter of every-day importance to the photographer, that we do not delay to publish them. The tests, we may mention at the outset, were made with a view to selecting a material for the developing room rather than for emulsion making, for it stands to reason that illumination which may well serve the former purpose, may not answer the latter.

Our experiments were very simple. A steady-burning fish-tail gas-burner was employed as a standard light, and as this was not more than an hour in actual use, we could rely upon its constancy. In employing a light for developing, there must always be a sort of "give and take" arrangement, or, in other words, the photographer must weigh the disadvantages of admitting a little injurious light in order to get the advantage of seeing what he is doing; and the best medium for a dark-room window is naturally that which admits sufficient light to work by, and which quantity of light does least injury to the sensitive film.

We made our tests as follows:—

1. To estimate the actinic value of the light admitted.
2. To ascertain the visual value of the light admitted.
3. To note the pleasant character or otherwise of the light.

Naturally, the test for actinic light came first, for unless this was satisfactory, there was no need to go further. The well-known Warnerke transparent screen with numbered squares 1 to 25 was employed as negative, and put in a printing frame with a gelatine plate behind it. This plate in each instance was exposed to the gas-burner for the space of two minutes exactly, at a yard distance, precisely, from the flame. The development (pyrogallol) was in all instances the same.

In front of the Warnerke screen, pressing against it, was tried:—

1. One green and one orange glass combined: Result, the No. 13 very legible.
2. Two green glasses and one orange glass: Result, the No. 9 very legible.
3. One orange glass and one ruby glass: Result, No. 1 slightly visible, and a trace of No. 2.
4. A stout yellow paper, supplied by Harvey Reynolds: Result, no trace of the scale visible.
5. Four sheets of yellowish tissue paper, known as "stout buff," and used for copying letters: Result, no trace of the scale visible.
6. Three sheets of "lumberhand" paper—a light yellow packing paper universally employed: Result, no trace of the scale visible.

In the face of these results, it was unnecessary to proceed any further with experiments Nos. 1 and 2.

The visual tests were next taken. For this purpose—for want of a better apparatus—a Sciopticon lantern was lit, burning a double paraffine wick. The lantern has in rear, as most of our readers know, when the reflector is turned back, a clear opening whence the flame is distinctly seen. This opening was closed successively by:—

1. One orange glass and one ruby glass: Result, the double flame of the lamp was to be seen distinctly through the ruby glare, and small type was legible within six inches of the coloured glass.
2. Four sheets of "stout buff": Result, the double flame of the lamp was not to be seen at all, but the visual effect was such that small type could be read at more than twelve inches distance.
3. Three sheets of lumberhand: Result, scarcely to be distinguished from No. 2.
4. Stout yellow paper (one sheet) of Harvey Reynolds: Result, same as Nos. 2 and 3.

Finally came the question as to which was the pleasantest light? The red glare of the glass screen was at once pronounced against, in favour of the papers, all of which gave a most agreeable illumination. The Harvey Reynolds gave the palest light, then came the "stout buff"; while the lumberhand was slightly more orange than either of the others.

Indeed, the difference was so slight between the three papers, that there was scarcely any choice, and our readers who wish to employ paper screens may elect as they will. On the side of the "stout buff," it may be advanced that being thin, you may use it in one, two, three, or four folds; while the lumberhand is slightly thicker, and the Harvey Reynolds thicker still. Against the buff may, perhaps, be urged that it is unsized; while the Harvey Reynolds and lumberhand are sized. The "stout buff," examined chemically, is shown to contain both salts of iron and chromium, the latter, no doubt, introduced in the form of bichromate of potash. A very dilute acid discharges the yellowish colour from the paper at once. There is, in fact, no doubt in our mind that a very suitable yellow paper might be prepared by the photographer himself, using a solution of bichromate of potash. This, combining with the size of the paper, forms, of course, a pigment that darkens slightly in light, but the amount of gelatine and chromate salt employed could be reduced to a minimum.

We may add that we examined our combination of orange and ruby glass by means of the spectroscope in comparison with the "stout buff" paper. The glasses extinguished from the orange region the whole of the more refrangible portion of the spectrum; while even four thicknesses of "stout buff" failed to extinguish the

green. In short, the paper let pass red, orange, yellow, and green, while the glasses only permitted the red and orange to get through.

How is the superiority of the paper to be accounted for in these apparently contradictory circumstances? For on the one hand the photographic and visual tests prove the paper to be more valuable, while on the other, the spectroscope gives judgment in favour of the glasses. We think the reason is not far to seek, and it is one that has before led us to advise not too blindly to follow the dictates of the spectroscope. It is a mere question of diffusion of light.

In support of this theory, there is the fact that in making the visual test with the ruby and orange glass, the eye saw plainly the double flame of the lamp, and yet *less* visual light was emitted than when a paper screen was used, which effectually prevented any view of the flames. To put it another way, if we desired to look at the sun, we should not employ the paper screen, but should have perforce to use glass—the ruby and green would do very well—for the rays in the latter case are not so much interfered with. If it were simply the opacity of the paper pulp itself stopping the light—it does stop some, of course—then there would be an absence of visual light: but as we have shown in all three samples of paper tried, much more light of this kind got through than traversed the glass screen. Still, diffused white light will not do, for white paper, even when thick, lets through a vast amount of injurious illumination: this must be of a yellow or ruddy character to be comparatively harmless.

We next went a step further. We took in hand once more the ruby and orange glass, and went back to make another actinic experiment. We have said that the Warnerke screen, when these two glasses were upon it, printed off a faint No. 1 and No. 2 of the scale. We exposed precisely as before, but we lifted off the ruby glass, and substituted in its place a sheet of ground glass. We were, therefore, exposing a bromide film under a single orange glass and ground glass. What was the result? Why, fully equal to that previously obtained; there was no trace of any No. of the Warnerke scale.

The ground glass and orange glass were now taken to the sciopticon lamp, in order to make the visual test. As in the case of the papers (but unlike the ruby and orange glasses), the formation of the flames could not be made out, and when an essay was made at reading, the small type was found to be legible at more than *three feet distance*.

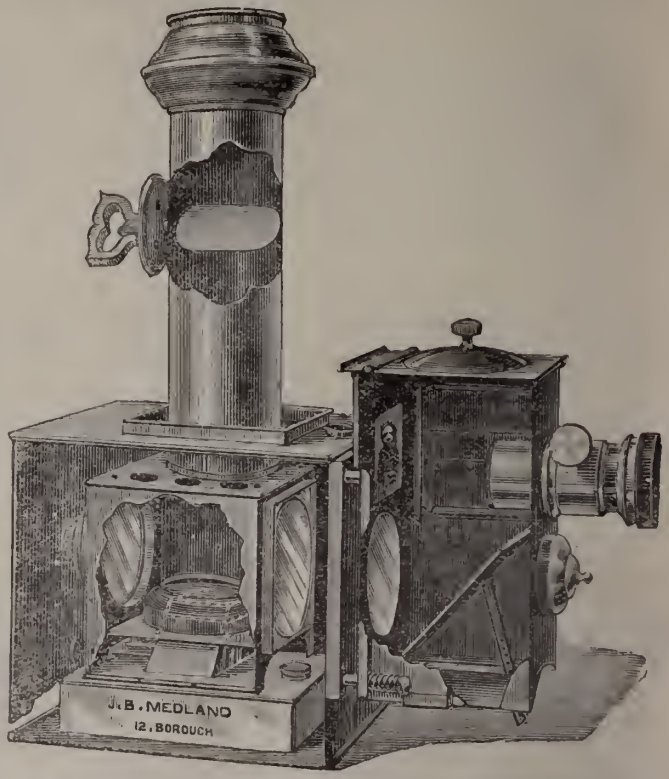
The experiment speaks for itself, and it is so simple that any of our readers may repeat it in a few minutes. To employ ground glass for dark-room windows is, as we are aware, no novelty, but the extent to which yellow diffused light may be used with impunity has never been so clearly shown; nor do we think, has a single sheet of orange glass combined with ground glass ever been proposed for dark-room illumination.

We are far from saying that yellow or orange diffused light is the most advantageous—giving least actinic and most visual light—for dark-rooms; that is a matter for after experiment. Meanwhile we trust our readers will give orange and ground glass a trial in their developing rooms.

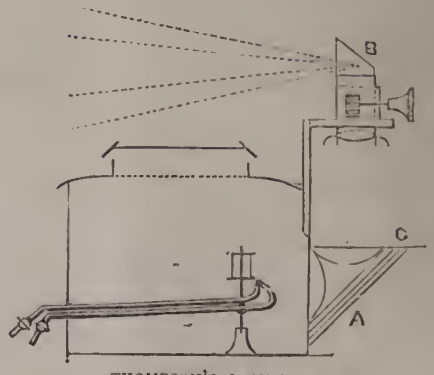
A NEW ARRANGEMENT OF THE OPTICAL LANTERN.

FEW scientific instruments are now so popular as the lantern, and, as a consequence of this, improvements are frequent, and we now place before our readers a sketch of one of the latest models.

The "Pentaphane," as Mr. Medland calls his new lantern, is provided with a paraffin lamp, or rather a battery of lamps, for there are no less than five wicks; while the intensity of the illumination is such as is calculated to rather surprise those who have been used to the old form of lantern. The especially novel feature of the "pentaphane" is the arrangement of the front, this being provided with an ingenious arrangement for showing opaque objects. If the mirror, which is shown mounted at an angle of 40°, is lowered by means of the casement bar, and the objective is screwed into the lower flange, all is ready for exhibiting the ordinary transparent slides; but to raise the mirror and screw the lens into the upper opening is not the work of ten seconds. Of course it will be obvious to our readers how the light is reflected upwards upon an opaque object which is to be exhibited (as, for example, the portrait shown in the diagram).



We would suggest one slight alteration which would make the lantern even more serviceable as an instrument for scientific demonstration, and that is, the addition of a horizontal stage between the two flanges, and a third flange



THOMPSON'S LANTERN.

at the top of the front compartment. A mirror (silvered on the face) or a prism must now be added to the objective, and we have an arrangement having all the characteristics of the convenient instrument which Professor Sylvanus Thompson recently used at the the Society of Arts.

If the proposed addition were made to Medland's lantern, we should have an instrument well adapted for all the purposes of the science lecturer. Ordinary chemical decompositions could either be shown in a vertical cell, or an open trough on the horizontal stage; the former arrangement being generally more convenient for precipitations and colour tests, the precipitant being allowed to flow slowly from the point of a pipette; while the horizontal arrangement is better for such an experiment as the formation of the so-called ammonium amalgam on the growth of crystal. Electrical and magnetic experiments are especially easy on the glass stage, as Professor Thompson so ably demonstrated on the occasion we referred to. It is also extremely easy to develop a collodion negative before a large audience if a pale yellow glass is placed on the stage. Indeed, there are very few branches of experimental science which would not profit by the extensive use of the lantern. Another circumstance which gives the horizontal stage arrangement value for the purposes of demonstration, is the ease with which the lecturer can point out the characteristics of his diagram, or even write on the slide, the prism or mirror serving to correct the reversal caused by the lens.

A SUN STEAM ENGINE.

The construction of a motor or engine set in action by sunlight is not new. More than a year ago there was a motor of this nature exhibited in Paris, in the Tuileries Gardens, the steam generated on a clear morning in May being sufficient to set in action a printing machine by which a small newspaper was printed. This French sun-motor was shaped like a huge umbrella, open, but inverted; the concavity of the umbrella reflected the sun's rays upon the stick, which was simply a blackened tube containing water. The heat concentrated upon the tubular boiler was sufficient to get up steam in half an hour, and to regularly work, as we have said, a small engine as long as sunlight lasted.

Captain Ericsson's sun steam-engine, or sun-motor, as he prefers to call it, is not unlike the French apparatus of which we have just spoken. There is a thin tubular boiler, if it may be so called, but this contains either steam or air. This cylinder is shown at *a* in fig. 1. This boiler

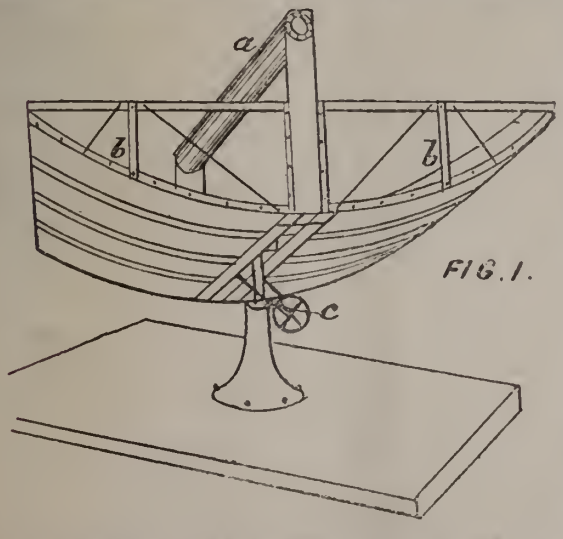


FIG. 1.

is also blackened to absorb the sun's rays, which are reflected upon it from the troughs *b*, *b*. A contrivance at *c*, where the trough is pivoted, keeps the trough turned towards the sun in the best position to receive the rays.

Fig. 2 will explain the apparatus yet more clearly. The heater or boiler is shown again at *a*, and the reflecting

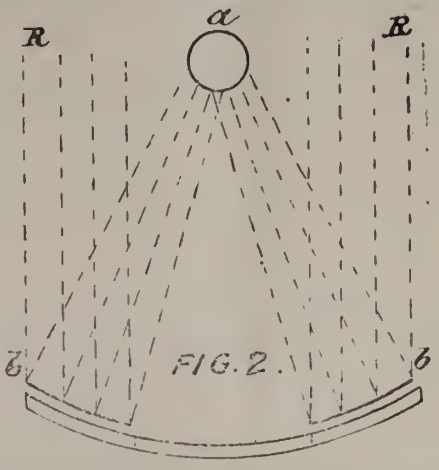

FIG. 2.

surfaces of the trough at *b b*, while the dotted lines *R R* indicate the manner in which the rays fall upon the trough and are reflected again upon the boiler *a*.

Captain Ericsson says of the trough, in *Nature*:—"The bottom consists of straight wooden staves supported by iron ribs of parabolic curvature, secured to the sides of the trough. On these staves the reflecting plates, consisting of flat window glass silvered on the under side, are fastened.

"It will be readily understood that the method thus adopted for concentrating the radiant heat does not call for a structure of great accuracy, provided the wooden staves are secured to the iron ribs in such a position that the silvered plates attached to the same reflect the solar rays towards the heater. Fig. 2 represents a transverse section of the latter, part of the bottom of the trough, and sections of the reflecting plates; the direct and reflected solar rays being indicated by vertical and diagonal lines.

"Referring to the illustration, it may be said that the trough, 11 feet long, and 16 feet broad, including a parallel opening in the bottom, 12 inches wide, is sustained by a light truss attached to each end; the heater being supported by vertical plates secured to the truss. The heater is 6¼ inches in diameter, 11 feet long, exposing 130 × 9·8 = 1274 superficial inches to the action of the reflected solar rays. The reflecting plates, each 3 inches wide and 26 inches long, intercept a sunbeam of 130 × 180 = 23,4000 square inches section. The trough is supported by a central pivot, round which it revolves. The change of inclination is effected by means of a horizontal axle—concealed by the trough—the entire mass being so accurately balanced that a pull of five pounds applied at the extremity enables a person to change the inclination or cause the whole to revolve. A single revolution of the motive engine develops more power than needed to turn the trough, and regulate its inclination so as to face the sun, during a day's operation.

"The energy developed in the heater works a steam-engine, the working cylinder being 6 inches in diameter, with 8 inches stroke. The piston rod, passing through the bottom of the cylinder, operates a force-pump of 5 inches diameter. By means of an ordinary cross-head secured to the piston-rod below the steam cylinder, and by ordinary connecting rods, motion is imparted to a crank shaft and fly-wheel, applied at the top of the engine frame; the object of this arrangement being that of showing the capability of the engine to work either pumps or mills. It should be noticed that the flexible steam-pipe employed to convey the steam to the engine, as well as the

steam chamber attached to the upper end of the heater, have been excluded in the illustrations. The average speed of the engine during the trials last summer was 120 turns per minute, the absolute pressure on the working piston being 35 lbs. per square inch. The steam was worked expansively in the ratio of 1 to 3, with a nearly perfect vacuum kept up in the condenser inclosed in the pedestal which supports the engine frame.

"In view of the foregoing, experts need not be told that the sun-motor can be carried out on a sufficient scale to benefit very materially the sun-burnt regions of our planet."

GELATINO-BROMIDE PAPER FOR POSITIVE PICTURES.

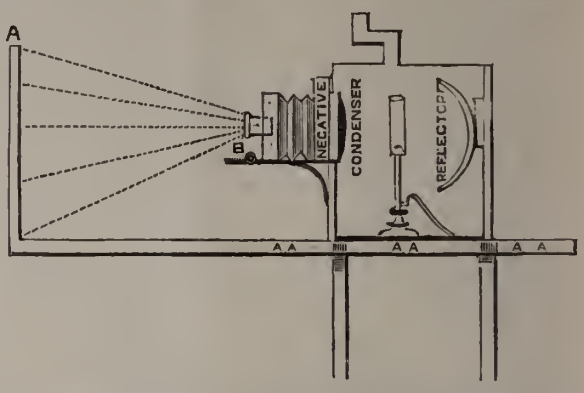
FOURTH ARTICLE.

IN the previous article we described a means of obtaining enlargements by converting the dark-room into an enlarging camera; we also touched on the salient points regarding vignetting, and a suitable illumination for an enlarging camera or lantern by means of artificial light. We shall continue the consideration of the latter subject a little further in the present article, by giving a few practical details of the method of fitting and using such an apparatus.

It will be readily understood by those of our readers who are possessed of an ordinary optical lantern, or a sciopticon; their requirements are exactly fulfilled, the sciopticon being well suited for producing the smaller sizes. The luxury of a lantern is not found in every household, but the means of constructing a suitable arrangement is within the reach of every one possessed of a lens. Probably nothing better for the purpose can be desired than the tin biscuit box suggested by Morgan and Kidd, and used by those gentlemen when demonstrating before the South London Photographic Society and other subsequent gatherings. This arrangement, it will be remembered, served the purpose of emitting the rays which traversed from a paraffin lamp, through condenser, negative, and lens, to the focal plane on which was arranged the sensitive paper. One of the sides was fitted with ruby glass, which permitted development being carried on in safety, there being no other source of light in the room after the lens had been capped.

Mons. Hutinet, when illustrating his mode of enlarging recently in this country, employed a very similar arrangement, excepting, however, a long focus lens was used, and no condenser employed. The use of long focus lenses do not obviate the necessity of using a condenser; they are employed simply on account of their greater covering power, the duty of the condenser being to provide an equal illumination to all parts of the small negatives. To overcome the difficulties met with when no condenser is available, it is customary to employ a screen of ground glass, which, while permitting a more equal illumination by diffusion, necessitates the use of a much longer box, in order that rays of light emitted from an Argand gas or paraffin lamp may be evenly diffused over the ground glass screen, no light being allowed to escape beyond the rays emitted through the lens during focussing and exposure.

The requirements are, then, a metal or other case which shall be light-tight (except when the lens is uncovered) fitted with a metal chimney to carry off the heat from the lamp, a lens, and small camera attached to a hole in the front, a frame for securely holding the negative in the position usually occupied by the dark-slide in the camera (film side of negative towards the lens); immediately behind this is fixed a four or six-inch condenser, according to the size plate used. Failing this, a sheet of ground glass, and behind this, at a suitable distance, a gas or paraffin lamp with a suitable reflector. The accompanying sketch will indicate very clearly the positions occupied by the various parts of the apparatus when in use. The upright board, A, upon which the sensitive material is placed to receive the enlarged image, should be capable of sliding nearer to or farther from the camera, as shown at A A. The distance



between the lens and negative should also be adjustable, as shown by the rack-and-pinion at B; the reason having been pointed out on page 786 of the last volume.

Contact Printing.—The great ease combined with the rapidity and certainty with which positives can be printed in contact with negatives and afterwards developed, renders bromide and chloride of silver of the greatest service to the commercial world. With regard to the quality of surface being suitable for the smaller sizes, we may say there is not the least difficulty in obtaining a surface as smooth and transparent as a highly-glazed albumen print if such a result be considered desirable, for very little consideration will reveal the fact that it is by no means more difficult to squeegee the freshly-prepared gelatine positive down on a collodionized glass plate than it is a carbon print, as in the Lambertype process or the ordinary enamelling of silver prints.

In the production of certain subjects, exceptions may be taken to the neutral character of the colour. To such exceptions we would say that the objection can be met by employing citro-chloride of silver emulsified in gelatine. Such an emulsion spread on a suitably surfaced paper can be printed out in less time than is required for printing on ordinary sensitized albumenized paper; the after operations of toning, fixing, and washing being the same, and the results are quite equal in every respect; but on this subject we shall have more to say at a future time.

There is not the least difficulty in printing at least twenty impressions an hour on bromide paper from one negative, and we think that circumstances alone should largely influence photographers to favour its use wherever possible; besides, a very agreeable tone is obtained by development with ferrous oxalate, which may be modified by the after process of toning if this be considered necessary.

Briefly, then, negatives are charged in the ordinary way by placing the gelatine surface in contact with the varnished side of the negative in a printing-frame, and erected at right angles to the source of light. If one second's exposure, one foot from a gas jet, gives a good result, then any number of such exposures may be made without any variation.

The mode of obtaining given degrees of magnitude, and the probable or approximate duration of exposure, have each received a due share of attention previously, and on the subject of developing we need say very little, beyond mentioning that ferrous oxalate or alkaline pyrogallol may be successfully employed with the addition of a small quantity of citric acid or an alkaline citrate, such as the salt, citrate of potash. By the addition of a small quantity of a citrate, development is somewhat retarded; but there is a decided gain in the character of the image obtained. In

using ferrous oxalate developer, it is found that the employment of saturated solution of ferrous sulphate and potassium oxalate give much better results than when less concentrated solutions are used. Each solution should be filtered before mixing, and one part of the iron solution should be added to four parts of potassium oxalate solution (not the oxalate to the iron); the addition of one-fifth of a grain of bromide of potassium per ounce of developer will be found a very good working proportion. Should the positive be too much exposed, which may be known by the image developing up very quickly, and wanting in contrast, it may be saved by pouring off the developer, diluting it with an equal volume of old ferrous oxalate developer, and returning it again to the developing tray with the addition of a few drops of a twenty-grain solution of potassium bromide. As a rule, when the exposure has been too little, no amount of coaxing will produce a good positive, the result of such being a black and white print, totally deficient in harmony of tone. Instead of doctoring up such a result, it is by far wiser to make a second exposure, just doubling the time given to the first. On no account should the positive remain in the developer until the tones are well out and the shadows very strongly marked, because a deepening action always takes place in the fixing bath. The strength of the fixing bath is the same as for silver prints, one to five; but the time of immersion need not be quite so long, ten minutes being ample for all purposes. After a prolonged washing, to rid the paper of the last traces of the sodium salt, they are passed through acidified water (two per cent. solution of sulphuric acid), again washed, dried, and finished; should there be any tendency to peeling, the acid bath may be saturated with common alum.

There is no need to quote formulæ here; anything the reader is not familiar with, will be found under the heading of "Standard Formulæ," in the present Year-Book.

CHEMICAL EXPERIMENTS IN THE LANTERN.

There is always a charm about a pretty and striking experiment that an audience, whatever its nature, seldom fails to appreciate. Let an experiment be ever so simple, or let it be only partially calculated to illustrate the subject of a lecture, it is not only young people who delight in it, but "children of a larger growth" will evince an interest in and applaud it. On a good experiment the success of a lecture will often depend, providing it is done on a sufficiently large scale. Even famous men of science look to successful demonstrations to gain the attention of their audiences. And not only in the lecture room, but at home, also, may such experiments be turned to account, and instruction follow what, in spite of all that is frequently said to the contrary, is done quite as much for the sake of amusement.

Photographers are not slow to take advantage of this popularity of experimenters, and often we see this exemplified in the proceedings of societies, where the practical demonstration of a process draws the attention of those who would otherwise scarcely give it a passing thought, but who go away to repeat the experiment, or try the process in their own laboratories or dark rooms. It would be difficult to estimate how much gelatino-bromide paper, to take a notable example, is indebted for its popularity, among amateurs, at least, to the way its development has so frequently been shown in public; though, at the same time, it cannot but be admitted that its own good qualities, its practical usefulness, and readiness of manipulation, furnish the main reasons why it is in demand. There is one class of experiments, however, which has hardly received all the attention it deserves—namely, chemical experiments performed in the lantern, an image being thrown on to the screen. Not only are such experiments attractive in themselves, but they may be put to real service in showing on a large scale many of the principles on which the science of photography (to bring the matter home to our readers) depends. The apparatus required is simple and easily constructed, the small amount of trouble involved being amply repaid.

The first desidirata (next to the lantern) are a few suitable cells. We mention two ways in which these may be constructed. The first method is to obtain two pieces of clear glass, preferably thin patent plate, of a suitable size. Then cut some narrow strips of thick plate glass, and smooth the edges by rubbing them down on a piece of flat stone; the polished surfaces of these strips should also be rubbed down to give them a ground surface, which will afford them a stronger hold. The cell may then be put together by warming the glass and applying marine glue, with the aid of a heated piece of iron, an old file—for instance—or, in the absence of anything better, that useful domestic implement, the kitchen poker. One disadvantage of marine glue, however, is that the heat from the lantern, if it is in for a long time, may cause it to leak. Another good way of joining the glass, and one which requires less skill, is to cement it with bichromated gelatine, and expose to light; if this plan be adopted, it is advisable to paint the cemented edges, inside and outside, with sealing-wax varnish or gold size applied with a camel-hair pencil. Gold size may itself be used to cement the glass; but, except for microscope cells, we do not care for this. A very good form of cell may be made by enclosing two pieces of glass in a wooden frame the size of an ordinary carrier but thicker, these two pieces of glass being separated by a piece of rubber tubing, or, better still, a strip of solid rubber such as is used for catapults, bent round to form the bottom and sides; the glass plates are placed sufficiently near together to squeeze the rubber and make a watertight joint. One great advantage of this form of cell is, that it can readily be taken to pieces and cleaned when necessary.

Few of the lanterns now manufactured require any alteration to render them available for this class of work. In most of them the fitting which receives the slide carrier—in this case the cell—is open at the top as well as at the sides; if the lantern does not already possess this convenience, an opening must be cut. A few minor pieces of apparatus required are—a small funnel, one or two pipettes, and a thin glass stirring rod.

We give a few examples of the kind of experiments which may thus be shown to a large audience—precipitations, for instance, as by dropping solution of nitrate of silver into a solution of a chloride, or *vice versa*, and subsequently dissolving the precipitate in hypo; or the precipitation of mercuric iodide by adding potassic iodide to mercuric chloride. On the screen the particles will appear to move upwards instead of falling down; but this only enhances the effect. A very pretty experiment is to add a drop of solution of red prussiate of potash to a weak solution of ferrous sulphate, by way of illustrating iron processes; another pretty effect is, add a solution of a sulpho-cyanate to a weak solution of ferric chloride; the absorption of iodine by hyposulphite of soda; the bleaching action of such compounds as sodic hypochlorite on a solution of some dye, such as turmeric or indigo; the effects of acids and alkalis on solutions of blue and red litmus, &c., &c. So many experiments will naturally occur to the mind of the reader, that it is needless for us to enumerate more. One of the best things we have seen demonstrated in this way, though it is hardly within the province of the photographer, was the electrolysis of a substance, a solution of chloride of copper being used to which a small quantity of a solution of indigo in sulphuric acid was added. As the chlorine gas was evolved in little bubbles at the positive pole, the indigo was rapidly bleached, the experiment being rendered very striking by dividing the cell into two parts with a little roll of blotting-paper, a terminal being placed in each of the two divisions of the cell.

JOHN HENRY DALLMEYER.

"ON the 30th ult., off the coast of New Zealand, John Henry Dallmeyer, Esq., of Sunnyfield, Hampstead, and 19, Bloomsbury Street, London, in his 53rd year," is the announcement of sad news indeed, that comes to us from beyond the seas. The gentle spirit of a great and good man has fled, his unwearying brain has ceased to throb, and the world is the poorer of one who was as kindly as he was gifted, as modest as he was rich in talents. A generous master, a sympathetic friend, with the soft heart of a woman, and the warm impulse of a true benefactor, the late Mr. Dallmeyer is remembered by those who knew him with a yearning regret that, sad to say, is but rarely felt in this work-a-day world of ours.

> "His life was gentle; and the elements
> So mixed in him, that Nature might stand up
> And say to the world, 'This was a man!'"

Only 53! And yet his name has been for a generation, almost, prominently before the world of astronomy, micrography, and photography. That no man is a prophet in his own country is a proverb well exemplified in the late Mr. Dallymeyer. For his work as a scientific optician, honours came to him spontaneously from abroad, but at home he was known simply as a Fellow of the Royal Astronomical Society. America bore high testimony to his works, he earned the thanks of high officers in Austria and Germany, Russia constituted him a Chevalier, and France nominated him Officer of the Legion of Honour.

These honours were rendered for special optical work outside the domain of photography; but it is by his eminent services in the construction of improved lenses for the camera, that the late Mr. Dallmeyer was best known to our readers. His instruments are universally prized. Their high cost is no bar to their general employment, and in the studios of every civilised nation the Dallmeyer lens is to be found. Nor was this success undeserved; for rumour says that every instrument that passed out of the Dallmeyer establishment, passed first through the master's hands.

Sad to relate, the strain of work was too much for a brain so delicately poised. For nearly three years past, the late Mr. Dallmeyer had been compelled to abandon work; indeed, it was for the sake of health that he undertook this voyage to Tasmania and New Zealand. Fortunately his eldest son, Mr. Thomas R. Dallmeyer, had been fitted by parental and University training to undertake the father's duties, so that, despite the latter's absence, the establishment in Bloomsbury Street has gone on in the same methodical and straightforward manner; and we have no doubt that, under the same able direction, it will still continue to prosper.

By-the-Bye.

BAD SITTERS.

WE spoke recently of good sitters, and we said that if these were strangers to the studio, it was as much the fault of the photographer himself, as anybody else. In other words, we gave it as our opinion that in the case of many visitors to the studio, it was in the photographer's hands to make them into good sitters. We are bound to say, however, that this is not so with bad sitters. These latter, or at any rate the greater number of them, are beyond the control of the best-tempered principal or most painstaking assistant. They are bad paymasters and bad models; they are "uppish" and discontented when they make their first appearance in the studio, and they display the same unamiable qualities when you bow them out for the last time.

And who are the bad sitters? Well, one class of them is easily named—that which knows something about photography. Indeed, it may almost be taken as an axiom that there is no worse sitter than the *soi-disant* photographer, and the less he is acquainted with the art, the more unsatisfactory he is. He knows "the whole box of tricks," he tells you, and you may infer also that if he pays you money, he is well aware it is being thrown away more as a charity than anything else. He knows all about it, bless you! It is no use your trying to take him in with your posing, your lighting, your retouching; you may pretend to spend half-an-hour arranging drapery, in managing the illumination, in attempting to secure this position or that expression; but, thank Goodness! you can't hoodwink him.

Of course, we exclude from this category all who are capable of taking good pictures, for these know full well what is involved in securing high-class negatives one after another, which shall be soft and brilliant, and shall not offend against good taste nor well-known art canons. We are far from saying that the honest artist-photographer, whether he is an accomplished amateur or skilled professional, takes a pleasure in plaguing his brethren; we repeat, he knows better, for he is well aware how much skill, judgment, tact, and patience are necessary to the fulfilment fo good work. But it is not so with those who have but a smattering of the art of photography, who know that you must put your head under the cloth to focus, and must pull out the dark slide before you can expose. They are acquainted with the cost per dozen of the dry plates you are using, and they know, too, the price of the albumenized paper upon which you will presently print their effigies. Even the work of retouching has no mysteries for them; they are thoroughly aware it is done with a finely pointed pencil—you can't have the point too fine, you know—and they volunteer the information that silver prints are given to fading, unless you take great care in the washing of them.

This sitter it is who tells you he has a brother, a most accomplished painter, who, if not actually a Royal Academician, lives next door to one. His cousin, too, is a most famous man of science, and with him he is going to take up photography, not as a mere picture-taker, but, seriously, to find out all kinds of things—colours, you know, and instantaneous plates, and that sort. He never gives you a moment's peace the whole time he is in your studio; he exhausts you, himself, and every subject that happens to turn up. There is nothing he does not know, and he regards it as an insult if you ask him to comply with this or that demand. The first moment he enters, he demonstrates his superior wisdom, and you will do well if you can keep your temper in listening to his platitudes.

Next in the list of bad sitters to him who knows something of photographic manipulation, is the man or woman who has been an art-student at some time or other. The latter acts upon this simple and delightful notion: that he is an artist, and the photographer is not. Their singularly fresh and unaffected bearing in the studio not unfrequently baffles the photographer altogether, so much so, indeed, that he is sometimes constrained to seek sanctuary in the dark-room, there to recall once more his proper position. Is he "boss of the concern," he asks himself, after the manner of a defiant Yankee, or is he not? If he possesses courage and self-control, he will go back and have his own way; still, he is the wiser man who kills his fish with plenty of line, for to lose one's patience and temper is often to lose the quarry at the same time.

Sometimes a sitter is bad only because he has brought as companion "an artist to pose him." In some studios such posing is not permitted; in others, the photographer takes care to secure his fee, stipulates that his work is undertaken without responsibility, and then follows Dogberry's advice to let him go, and thank goodness you are rid of him. One day, at a public dinner, a neighbour asked us whether the Mr. Medallist at the other end of the table was the well-known photographer who had se-

cured so many awards. Our reply was in the affirmative. "Ah, I knew him well when he was at Seabourne; I often looked into his studio, and he used to ask me to pose his sitters for him." Naturally, this was very interesting, but when we made known to our neighbour that Mr. Medallist was a personal friend, and that we would introduce him after dinner, the art gentleman declined the honour, and thought Mr. Medallist would scarcely remember him after so many years. If we had not offered the introduction, our new friend would doubtless have dilated upon the valuable aid he had given, and possibly laid claim to the medals bestowed on the photographer.

If the art student has studied sculpture, he may be able to give the photographer a few valuable hints; but if he is a painter who has no knowledge of photography, then he will most assuredly be a hindrance rather than a help. If proof of this were wanting, look at some of the photographs of great painters that have been produced—of Millais, of Holl, of Marcus Stone, where these gentlemen have posed themselves. Millais, with his pipe in his mouth and his arms tightly folded across his breast—his favourite pose, apparently, before the camera—is the acme of wretchedness and angularity. No doubt the clever painter thought he was placing himself in a most free-and-easy, here-you-are sort of position, and probably he himself felt free-and-easy enough at the moment he was photographed; but in the result no pose could be more constrained. The exception that proves the rule to all this is Rejlander's picture of Gustav Doré, which has all the grace and repose that an artist photographer can bestow.

If, then, the great painter often fails when he enters the domain of photography, what can be expected from the gentleman who formerly studied in an architect's office, or the lady who attended an art school once in her life? This model always knows better than the photographer; would rather sit when asked to stand; and prefers to show his full face, although the line of his nose is not straight, his lips thin, and his eyes unequal. We envy no photographer who is brought face to face with a bad sitter of this kind, and well knows that, do what he will, he cannot give satisfaction. If he lets such a model have it all his own way, the result will be, in nine cases out of ten, a woeful failure. An attempt on the part of the sitter to be naive, bright, and unconstrained, generally ends in the pourtrayal of insufferable conceit; while on the other hand, a simpering pose will result in that dying-duck expression which is, perhaps, the most ludicrous of all. Posing oneself, as we have before pointed out, is not unlike acting. An amateur actor may deport himself as a gentleman well and gracefully in the drawing-room, but let him try to emulate Charles Matthews on the stage, and he will find he has over-matched his capacity. He may please himself vastly, and be altogether at his ease, when he throws himself into an arm-chair, or when he puts his hands into his pockets and his feet upon a couch; but to the audience his whole appearance is awkward and vulgar. And so it is in the posing-chair: it is not one pose in ten that subsequently pleases the person who has chosen and assumed it.

The true artist, let it be said to his credit, seldom interferes with the work of the photographer; he is not a bad sitter, and, therefore, to him our words do not apply. So many of our good painters, too, have taken up with photography of late, and have found how difficult it is to secure a succession of even tolerable pictures, that every day that passes secures more of their sympathy.

Bad sitters are, for the most part, then, those who, having a smattering of photography or a smattering of art, use their slight knowledge to plague the photographer. There are other bad sitters, no doubt—sitters who do not pay, sitters who are mean, and sitters who are given to re-sitting out of all conscience. But these cannot be grouped into classes, and, since they do not belong to any community, are not worth special consideration.

The next "By-the-Bye" will be "Who is a photographer?"

FRENCH CORRESPONDENCE.

M. MAUDIT'S SHUTTER—STARCH IN EMULSION—DRYING PLATE APPARATUS—MEDICAL PHOTOGRAPHS—DIRECT LIFE-SIZE PRINT—DIACHYLON PLAISTER FOR FIXING PELLICLES—DEVELOPMENT AND FIXING OF A PELLICLE—NEW PHOTO-TYPOGRAPHS.

M. Maudit's Shutter applied to Binocular Lenses.—At the interesting meeting of the Photographic Society of France, held on the 4th inst., the most striking feature was the adaptation of M. Maudit's shutter, with piston, to stereoscopic lenses. The piston, placed between the two objectives, is worked by two little jointed levers, which both sink at the same moment, causing the piston to allow the slides of the drop shutter to fall at the same moment.

Effect of Starch in Emulsion.—M. Audra, seeking to increase the sensitiveness of gelatino-bromide emulsion, has tried the effect of introducing starch. He has not attained the desired result, but proofs printed on the emulsion with the addition of starchy matter have all the character of prints on ground glass. No doubt M. Audra will be able to make some practical use of this effect produced.

Drying Box for Plates.—M. Roger, director of photographic works to the Minister of War, has invented a drying-box for gelatine plates. It is an arrangement of grooved rails sliding over one another, the points of contact with the plates being entirely of glass. A suitable ventilation from the bottom to the top allows of the plates drying in seven or eight hours. Plates of various sizes may be dried in the same drying-box by the ingenious arrangement of sliding into grooves.

Medical Photographs.—Dr. Richer and M. A. Londe have produced some remarkable medical photographs by the photo-electric apparatus previously described—the same subject having been reproduced successively at regular intervals, more or less frequent, at the will of the operator.

M. Chalot's Direct Life-size Print.—M. Chalot, the able successor to M. Franck, has shown a life-size portrait of a man taken direct with a Darlot lens three inches in diameter. The photograph is 45 by 60 centimetres in dimension. The exposure was forty seconds on a gelatine plate at a focal distance of 112 centimetres, taken by a light of medium intensity. The picture is mounted on a very firm black mount, with gilt bevelled edges, and the effect of the whole is admirable.

Use of Diachylon Plaister.—During the meeting I showed an improvement in the use of diachylon plaister for supporting pellicles. The sticky side of the plaister is applied to the wooden, celluloid, or metal slide, and firmly pressed down so as to exclude all air-bubbles The tissue is then wetted, and with care separated from the waxed surface, which, adhering to the slide, is ready to receive the pellicle, applied by pressing it down, a piece of clean paper intervening between it and the hand. After exposure, the pellicle is easily detached without loosening the sticky surface, which may be used several times with care. I next developed and fixed one of M. Stebbing's pellicles in a full light. I commenced operations by introducing the pellicle into the ferrous oxalate bath, with exposure to light. The exposed pellicle was contained between two slips of blackened celluloid, tinfoil being glued round the edges of one and folded over the other. The whole thing is plunged into the developer, and the tinfoil unfolded. The operations of developing, fixing, and washing took place in pocket-dishes made of calico coated with celluloid varnish, the liquids being afterwards returned to their respective bottles by means of pocket-funnels of the same materials. The pellicle, increased in size by one quarter, was taken from the water, placed between blotting-paper, fixed on a glass plate, dried, and finally coated with a film of normal

collodion, and, when the one side was dry, cut off the plate, and the film spread over the under side.

Herr Meisenbach's Photo-typographs.—Some beautiful photo-typographs, by Herr Meisenbach, of Munich, were greatly admired by all present. They show great progress on the part of the inventor; some portraits, especially one of Sarah Bernhardt, of which a remarkable example has appeared recently in the NEWS, show a delightful softness in the half-tints. These pictures do credit to Herr Meisenbach, and it does not concern us here to discuss who claims the priority of this application; therefore we hail with joy the most perfect specimens of the process which have come to our knowledge. LEON VIDAL.

Notes.

A New Year's wish: That our readers will try a combination of orange glass and ground glass in their developing rooms, and that it will serve to lighten their labours.

We are happy to announce that our colleague, Dr. J. M. Eder, of Vienna, has been awarded the silver medal of progress by the Photographic Society.

It may interest some of our readers to know that the illustration which forms the frontispiece of the last volume of the *Graphic*, and which is issued with the last number, is drawn from an instantaneous photograph by Mr. J. J. Acworth. The picture represents the pigeons of the Piazzi of St. Mark being fed by three fair and graceful young ladies.

The Photographic Congress, to be held this year at Brussels, under the protection of the King of the Belgians, is receiving a good deal of attention by Russian photographers. A committee has been appointed to consider what subjects should be put before the Congress, and so much importance does the St. Petersburg Society attach to it, that for president of this committee has been chosen a general officer who but a few years ago held the portfolio of Minister of the Interior.

The chief aim of the Congress, as our readers know, is to bring about unity in the matter of photographic sizes, forms, and formulæ expressions, as also in the matter of names and terms, so that one process—like collotype, for example—shall not be called by a dozen different titles. One thing our Russian friends seem to favour is the adoption of the English whole-plate and half-plate sizes, in place of the French, as the former lend themselves more economically to studio work. The invitation to English photographers to take part in the Congress will reach this country through the Foreign Office.

Some time ago the *Graphic* instituted a Gallery of Beauties, which was contributed to by such men as Millais, Leslie, and other Royal Academicians. These artists were each asked to paint a picture which should represent their idea of feminine beauty, and in this way various types were brought together, with which the public have from time to time been made familiar. Something of the same kind might be done in photography, and an excellent plan would be for some of our societies who get up exhibitions to offer medals for the best beauty types exhibited on their walls.

It is not at all improbable that Herr Haensel's photographs of lightning may serve to explain certain phenomena which have been placed on record in regard to persons who have been struck by what the newspaper reporter is fond of calling the "electric fluid." There are many well-authenticated instances of the tree-like impressions having been developed on the body after the latter had been struck by a lightning-flash. The narrators have in each case called the impression a representation of some tree near which the person struck had been standing, and naturally so, because the zigzag path of a lightning-flash as we see it in no way resembles a tree. But photography has a knack of upsetting conventional notions, and so it has in this case. Herr Haensel's photograph, given in our last issue, has distinctly a tree-like appearance.

To artists whose talent lies in freedom of style and rapidity of execution, photography must prove a welcome boon. Miss Thackeray, writing of her father as an artist, says: "The hours which he spent upon his drawing-blocks and sketch-books brought no fatigue or weariness; they were of endless interest and amusement to him, and rested him when he was tired. It was only when he came to etch upon steel, or to draw for the engraver upon wood, that he complained of effort and want of ease; and we used often to wish that his drawings could be given as they were first made without the various transmigrations of wood and steel and engraver's toil and printer's ink." This facsimile reproduction is now a thing of every-day occurrence, though much more common in the American illustrated periodicals than in English. Unfettered by the conventionalities of treatment which drawing on wood imposes, the artist can indulge his fancy, and attempt effects quite impossible in the old days.

The experiment of a daily illustrated paper has failed in New York. The affairs of the *New York Daily Graphic* are now being wound up, its liabilities being 779,500 dols., and assets only 140,000 dols. The *Graphic* made use of photography in the production of its pictures, and had a photographic editor on the staff. Practically, however, the outcome was not startling, the major part of the illustrations being taken from electros of blocks in the European illustrated papers. A process which will readily transfer from the negative, and will stand the wear and tear of a newspaper printing machine, not particularly good paper, and the carelessness of machine operations, has yet to be devised.

The late M. Gambetta was a photograph hunter. It is said that when he went to Rome, he made a collection of the photographs of all the cardinals, and picked out the photograph of Cardinal Pecci, saying, "That is the man who will be Pope"—a tribute to the truthfulness of photography, as all students of physiognomy will allow.

The *Globe* complains of the shabbiness of the Gambetta demonstration, and, by way of justifying the assertion, remarks: "M. Spuller made a speech, and a photographer read a poem." Why the presence of a photographer—the *Globe* did not think it necessary to give his name, although the *Times* did—should add shabbiness to a demonstration, our contemporary did not explain.

M. Ferrand, of Lyons, an expert in hand-writing, has continued his experiments touching the scrutiny, by means of photography, of ink marks, whether in the form of caligraphy or blots. His first success was in a criminal case in which a certain No. was illegible because of a big blot upon it; it was a question of tracing a bill of 50,000 francs, and this blot had been designedly dropped over the verifying No. M. Ferrand, by having recourse to photography, proved the No. underneath to be 1,200, which had been converted into 1,203 and then blotted. The No. was read more plainly in the negative than in the print; but still it could not be mistaken.

From the United States comes also a story of detection by photography. A New York merchant was accused of having falsified certain documents in recovering a fire assurance. Nothing definite could be proved against him until a blotting-pad was examined. This had no suspicious ink marks, but one sheet bore impressions as if it had been underneath a paper upon which somebody had scribbled with pencil. An expert conceived the idea of photographing the sheet with the indented marks. The electric light was employed, and a gelatino-bromide plate, with a result truly surprising. The whole of the calculations and all the fraudulent figures were reproduced as if they had been in the clearest handwriting.

M. Henri Becquerel has made a most quaint experiment. It is well known to many photographers that the phosphorescent paint, with which we are all familiar, after being excited by light, may have its glow extinguished by red rays, whether these red rays come through red glass, or are represented by the red end of the spectrum Further, it has been found that not only the red region of the spectrum, but the region beyond that, which is dark, acts in the same way, and is also capable of extinguishing the phosphorescence. The red region of the spectrum, and the so-called infra-red region, have already been investigated by photography, and now M. Becquerel has made a thorough research into the darkness beyond the red, by observing its behaviour upon a phospheresceut body.

M. Becquerel's singular result is this. He has found that in the perfectly dark part of the spectrum there are intense lines, just as in the ordinary visible spectrum there are vivid lines. These lines—in a perfectly black region, remember—he is able to record upon his phosphorescent tablet, incandescent sodium vapour, for example, producing two well-marked dark bands upon his plate. Of these, the photo-observer, no less than the ordiuary optical observer, had hitherto no knowledge.

As the infra-red rays of the spectrum have but a very weak action upon a bromide film, a modification of Becquerel's process might possibly be applied to photographically record the lines in this region. That is to say, after the phosphorescent tablet has been impressed in the above manner, by the intense lines extinguishing the phosphorescence, the tablet, brought face to face with a bromide film, would print off the intense bands on the latter, and thus the fleeting results on the phosphorescent tablet would be permanently fixed by photography.

Mr. Chesterman has been good enough to send us a Sunshine Record of St. Petersburg, issued, we believe, from the State Paper Department, where M. George Scamoni exercises control. In the Russian capital, as with us, November is a gloomy month; for only nineteen hours during a possible of 225 in that month did the sun favour our Russian friends with a visit. In June, however, they are very privileged, for there were 318 hours' sunshine out of a possible 555, which means that during every hour the sun was above the horizon, it shone for 34 minutes. Next to June is April, the sunniest month in St. Petersburg; while the average all the year round of sunshine is 21 minutes out of every possible hour.

Perhaps the best testimony to the value of the late Mr. Dallmeyer's services to science, was that borne by Professor Stokes, after lecturing before the Photographic Society in February, 1873. Mr. Dallmeyer, said the secretary of the Royal Society, had done more to reconcile theoretical and practical optical science than any man of his generation.

Captain Abney is good enough to call our attention to the circumstance that we printed "potassium" instead of "platinum" last week. He stated that the intensifying solution of the Platinotype Company contains chloride of platinum and mercuric chloride—not chloride of potassium.

We have already pointed out that bichromated gelatine, among other of its valuable attributes, is a capital cement for repairing broken articles of glass or china; indeed, one of these days it would be well to enumerate the many useful services it will serve. Not long ago a patent was taken out for waterproofing walls with a solution of bichromate and glue; while, mixed with a little glycerine, the mixture is sometimes employed as a substitute for marine glue.

By the way, although everybody is aware that bichromated gelatine was largely used in place of sausage skins during the Franco-German war for enveloping the well-known pea-sausages, it is not so generally known that the idea brought its suggestor, Dr. Jacobsen, of Berlin, a handsome fortune.

Patent Intelligence.

Applications for Provisional Protection.

319. SAMUEL DUNSEITH MCKELLEN, of 18, Brown Street, Manchester, Watch Manufacturer and Jeweller, for "Improvements in photographic cameras."—Dated 2nd January, 1884.

416. GEORGE DUNCAN MACDOUGALD, Chemist, of Dundee, in the county of Forfar, North Britain, for an invention for "Improvements in apparatus for storing, conveying, and applying developing and other chemicals required or suitable for the production of photographic pictures."—(Complete Specification). Dated 2nd January, 1884.

712. FREDERICK HAZELDINE, of Lant Street, Borough, in the county of Surrey, Contractor, for an invention for "Improved apparatus for use in washing photographic prints and other articles or materials."—(Complete Specification).—Dated 4th January, 1884.

CHAPTERS ON LANDSCAPE.

BY H. P. ROBINSON.

No. 2.—What to Photograph.

"WHAT is beautiful must be decided by each man for himself, and at his peril," says an able writer. "There are some who maintain that all nature is beautiful. Fortunately, we can now disprove this monstrous position by our daily experience of photographs. Even if they were quite true in effect, form, or expression, they would often be more or less ugly. They are usually planned and made by men of some chemical knowledge, but tasteless, and entirely unacquainted with fine art. Consequently, the photographers unconsciously offer us the mean and ugly mixed up with some beauty."

The writer of course refers to unselected nature, or nature selected without intelligence. The photographer can have no claim to the proud title of "artist" if he is content to take things as they are. Art has been said to exist in all nature, and we have only to learn the art of seeing it pictorially, to reproduce it in our paintings and photographs. This is true enough as far as it goes, but it does not go far enough. *A work of art is a work of order*, and if the artist is to put the stamp of his own mind on his work, he must arrange, modify, and dispose of his materials so that they may appear in a more agreeable and beautiful manner than they would have assumed without his interference. In the field the artist may select the time of year, the time of day, the direction of light, the conditions of the weather—for which he has sometimes to exercise one of the greatest qualities of a photographer, patience—the point of sight, and to a great extent the arrangement of the masses. Figures may be introduced to join two masses of either light or dark together, and to give life and motion to the scene, scale to the parts, balance to the composition, and—it is only carrying the thing a little further—a house may be pulled down or a tree up-rooted. That this is not a fanciful statement, I may say here that I once employed two men a day in clearing a wood to afford access to a particular scene I wanted to photograph. In the studio, effects are still more under the control of the operator. The arrangement of light, the pose, backgrounds, accessories, and, if he is a master, he can also, within limits, control the expression of his sitter. In this chapter on "What to Photograph," however, we will forget the studio, and keep out in the fresh air.

In taking local views, art must, to some extent, be sacrificed to utility. It is not essential that a local view should be pictorial. If some picturesqueness can be secured, so much the better, but the object is to give a portrait of the place. If a castle is the object, it must be made to appear bold and prominent, and, above all things, clear. Atmospheric effect, so beautiful in other pictures, must not be allowed to interfere with the clearness of a local view. If a distant mountain comes in the scene, it must be made to look as large and prominent as possible. If a church is the subject, it is more to the purpose to show every porch and window than to get a good effect of light and shade. But my object in these chapters is to help the student to make a picture which may have a just claim to be called a work of art, and local views in their intention are more nearly allied to maps and plans. Nevertheless, a careful study of the rules of art will enable the photographer to improve these useful productions, and the very fact of representing them may add interest to a scene. As Browning says:—

> "For, don't you mark, we're made so that we love
> First when we see them painted, things we have passed
> Perhaps a hundred times, nor cared to see."

A local object need not be taken at its worst. The ugliest thing with which man has disfigured nature—a square block of stuccoed house—may have to be photographed; it may be the first hotel in the town, for instance, and an important local view. I have seen such an object taken squarely in a full light, when it would have been easy to get it in perspective by moving the camera a few feet. I purposely give a plain and bald example, that the effect may be more easily seen. The principle may be applied to most subjects.

Many photographers find it difficult, even in the most beautiful country, to find anything to photograph, whilst others cannot turn in any direction without seeing subjects for their art. The only difference is, that the first mentioned have learnt to see, and the others have not. Subjects, or the materials for subjects, abound everywhere; but the art of seeing them is a cultivated sense, and does not come by nature.

It is a great fallacy to suppose that all art, even very good art, is the work of what is vaguely called genius, except that genius which has been admirably defined as the capacity for taking infinite pains. I willingly admit that the greatest art is the product of inborn genius—added to labour—but there is very little work in any art that touches the highest point, and, therefore, little that is not the product of acquired talent.

The constituents of a picture are plentiful, but they have to be found and arranged. A picture may contain a vast amount of landscape material, without being in the strict sense of the word a picture. It may contain a sufficient number of facts to make up half-a-dozen pictures, without being one in itself. There must be something more than imitation. Imitation, merely, is not sufficient for art, though it is a great requisite, and, in photography especially, is a factor which must not be left out of the reckoning. It must never be lost sight of, although Ruskin says that the pleasure resulting from imitation is the most contemptible that can be derived from art. It is at once weak, indolent, and spurious art which breaks down the natural for the sake of the artificial; it is easily detected, and the trick exposed. At the same time, imitation is no more to art than grammar is to language. But imitation may be subordinated, even in our imitative art. Literal fact may give way to higher truth.

It has been the practice for photographers, especially the least experienced, to select fine scenes in nature for the purposes of their art; while simpler subjects, if properly treated, are much more likely to yield picturesque effects.

A collection of views of cities, or other famous places, will pass from the mind and be only remembered as a set of very fine photographs; while a few simple photographs of bits of country with a figure or two, well-posed and lighted, will dwell on the mind for years. Why is this? It may be explained in two words—"human interest." There is the interest in the figures themselves apart from the artist, then there is the interest in how the artist has done his work. Then, perhaps, the title will help, as it should do.

There is no scope for a title in a view, you can only call it by the name of the place it represents; but in pictures of incident, although the subject shown describes itself, the title is not unimportant. Some of the finest effects are those which consist of broad masses of light and shadow. Breadth of effect is one of the most pleasing qualities in art; it harmonizes everything, and will give beauty to the ugliest objects. A great deal may be done by selecting the time of day. A subject that may be flat and weak with the sun shining full on it in the morning, may have every element of the picturesque in the afternoon, with the sun shining from the side or behind the view. To select a view with the sun shining in the front of the lens was once thought to be most unorthodox. It used to be a direction to the young photographer to have the sun at the side of the view, perhaps a little in front. It is curious how we all run in grooves. It is only during the last few years that photographers have shown any disposition to throw off their trammels, and take their pictures where they found them so lighted as to be most conducive to pictorial effect. It is but recently that photographers have dared to try to be original, and then only after a good deal of "showing how."

In connection with the effect of lighting I have referred to, I think I may venture to allude to a picture of mine as an illustration without giving a sketch, as copies are in the hands of many of my readers, the picture having been distributed as a presentation print by the Photographic Society of Great Britain, and the same scene with some variations in the figures was selected for a like purpose by the Edinburgh Photographic Society. I refer to "Wayside Gossip." I had often considered this particular view as to its capabilities of affording a picture, and given it up as not containing sufficient interest. It was nearly south, and I had either seen it in the morning or the evening, when the light fell flatly upon it. But one day I passed the place at noon, and found it changed as if by magic—"the daily miracle of the sun"—into a most picturesque scene. The trees, formerly an uninteresting collection of stems and leaves, were transformed into broad masses of shadow, delicately tipped and outlined with silvery light. The foreground was a fine breadth of light. There was little thought required to decide where the figures ought to go. The spot on the lake-dam, where the two figures are seated, seemed to insist that some figures should be placed there. After one plate had been exposed it struck the photographer that a third figure would add variety and interest, and, perhaps, a title, so another model was added to the group—the standing figure resting on a stick—and a second plate exposed without moving the camera. If my reader has an opportunity of seeing a print of this picture, he will notice the almost stereoscopic effect of figures lighted in this manner. The standing figure in particular seems to come quite solid from the background. This is due, in a great measure, to the edging of light round the figure which this kind of lighting gives, and the gradation in that part of the landscape which forms the immediate background.

Gelatine plates practically open up a new world to the photographer. He can get at subjects that hitherto he could not approach, and he can depend upon securing them, whether nature is playing with thunderstorms or sunbeams, with considerable certainty. He is also in a much readier state to take a picture when called upon suddenly than the old process would allow. This should induce him to take advantage of what may be called the accidents of nature. Many of these accidental effects have never been well represented in photographs; such as a rain cloud, for example, or the weird effect of cloud shadows passing over hill and valley. Transient atmospheric effects are always worth securing; so also are animal studies. It would be impossible for a photographer to decide beforehand that he would do a picture of cows in a stream; but he should be ready to avail himself of such a chance if it should occur.

As another instance of accidental effects, I may mention that I have several times exposed a second plate on a view containing water, because, after the first had been exposed with the water still, a puff of wind had ruffled the lake in places, and added surface to the mirrored depths. Quick plates enable the photographer to see the beauty of these accidents of nature. In the olden time—say four or five years ago—a puff of wind would have been considered a nuisance.

HANDY METHOD FOR LONG AND SHORT FOCUS WITH FINE ADJUSTMENT.

BY THOMAS FOTHERGILL.

HAVING recently made a large camera for enlarging, to which I wanted a quick and ready method for long and short focus combining a fine adjustment, the result of considerable planning and scheming led me to hit upon the following plan. Doubtless many of your readers will at once recognize the article that suggested the idea—viz, the nut of the leading screw of the screw cutting lathe. Finding that now I have it in practice it meets all my requirements, and is everything I would desire, the thought struck me a rough sketch and description in the NEWS may be of service to others.

Diagram 1 is the supposed folding tail-board of

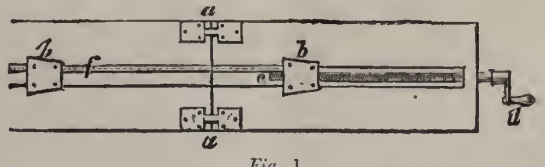


Fig. 1.

camera; *a a*, flush hinges for folding; *b b*, sloping brass plates fitting in receptacles in bottom of camera; *c*, fine double thread focussing screw. Diagram 2, a square nut

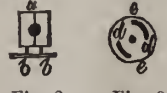

Fig. 2. *Fig.* 3.

cut in two, as marked at *a*, afterwards soft soldered, then tapped to screw (*c*, diagram 1), and separated by again heating. At the bottom of each half is a pin, *b b*, and these pins work in radial slots of a cam plate, as shown in diagram 3, *d d* and *e e*. It will be noticed that the points *d d* are much nearer the centre of plate than those of *e e*. To this cam (which with nut is enclosed) is fastened a handle, *f* (diagram 4), so that by turning this

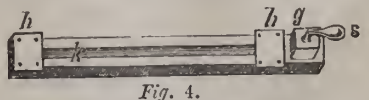

Fig. 4.

handle the points *b b* on nut (diagram 2) are forced from each other, and the pins, occupying the position of *d d* (diagram 3), are moved to *e e*, or *vice versa*, and the nut opened or shut; consequently the screw *c* (diagram 1) is liberated, allowing the camera to be freely moved either backward or forward. Diagram 4 is the under side of the piece of wood carrying the nut (which, with cam, is enclosed in a brass

box, *g*), and on the top of which are fastened the two plates, *b b* (diagram 1), for securing camera, which can be placed on either the one or the other. *h h*, plates of brass, slightly projecting to fit in groove, shown by dotted line, *f* (diagram 1); *k*, groove for focussing screw to work in.

Should any of your readers be tempted to adopt the idea, and fail to fully comprehend the detail, if he will write to me through the Editor, I should be glad to render him any assistance I can. A glance at a self-acting lathe will help to make my meaning clear.

A REALLY GOOD METHOD OF PRINTING IN CLOUDS.

BY W. CLEMENT WILLIAMS.

THE following method of printing in clouds will be found to be most reliable and simple in practice. For printing the landscape, take a piece of sensitized paper, rather broader than the negative to be printed from; this will enable us to afterwards balance the proportion of sky and foreground when cutting down the print, for it often happens there is too little sky, or too much foreground, or "more of a sort," than is advisable to retain. Place the negative and paper in a large size printing frame, so as to prevent the paper being crumpled where it projects beyond the limits of the negative. All the portions desired to remain white, for afterwards receiving the sky, must be carefully masked by throwing over the frame a velvet or other dark cloth, and folding so as to cause it to follow the outline of the horizon line of the negative underneath; small lead weights being placed at frequent intervals to keep all in proper shape. Up to this point, the only wrinkle introduced is the use of larger paper for modifying sky and foreground, the finished picture still remaining the same size as the original.

My "new idea" consists in dispensing altogether with black paper outline masks, and the frequent failures incidental thereto owing to abrupt joinings, while at the same time a perfect registration line is provided in its place to work to. With this parenthesis, we will return to the above picture in course of printing. Now take a piece of French chalk, and after sharpening to a point, sketch a horizon line, and follow the outline of the one before us, but a little lower down on the picture. This will be found to adhere to the glass firmly; it may be rubbed off with a dry cloth, and again become visible on breathing on it, and so a transparent guide mark is produced that will not in any way interfere with the printing by casting a shadow under it. This horizon line is not so essential in printing the landscape, but is absolutely necessary when the sky comes to be printed. In the present case, after the velvet shaded outline has printed a short time (in the shade, not sunlight) it is pushed a little towards the chalked line, and in a little while longer on the outline, then in the same way gradually back to the true horizon. When the landscape is sufficiently printed, it will be seen that the horizon is, if anything, very slightly vignetted, but this will be corrected when the sky is printed in.

Now take the sky negative in your hands, and bring the face of the print in contact with it, and hold up to the light to enable you to see how the horizon of the print cuts into the cloud forms; after sliding the print with the thumbs along the surface of the negative until the composition of cloud and landscape make the best picture, clip the same together with spring clips, and then with the French chalk pencil trace the horizon line of the print on the glass side of negative. To do this, you must again hold up to the light. Now place once more in a large printing frame, remove clips, and fasten up without in any way disturbing the relative positions of print and negative. On turning over the frame, the transparent chalk outline will denote where the velvet cloth should be placed for effectually masking the landscape, and a line sketched parallel to it with chalk as before will show how far to move the cloth during printing. This chalk line effectually takes the place of a correct mask and counter mask line; the velvet cloth and lead weight are a perfect mask, all edges being softened, which is not the case in any other method I have tried; it is an idea of my own, and I hope it may prove as successful in the hands of all who try it, as it has in mine.

SHEFFIELD PHOTOGRAPHIC SOCIETY'S EXHIBITION.

THE annual exhibition of photographs and apparatus in connection with this Society was opened this morning (January 7th) at the Cutlers' Hall, by the Mayor, Alderman Brittain. The pictures are over four hundred in number, and comprise specimens of all known processes, from different parts of the country. The photographs are carefully arranged, and include not only many fine foreign scenes, but charming views of local interest, and portraits of many prominent men. Perhaps the most finely treated work in the exhibition is one sent by Messrs Valentine and Sons, of Dundee—five snow scenes in the country, exquisitely done, showing, as they do, the trees delicately clothed in white, the frozen stream, and the lane down which there is just a suspicion of footsteps. The two pictures, "A May morning on the Wear," and "Nature's Mirror," exhibited by Messrs. M'Liesh, of Darlington, are fine examples of the gelatine dry process, and this firm send other two photographs of merit. "Miller's Dale," and "Bradgate Park, Leicestershire," are the titles of two silver prints of great softness, an effect produced by rendering them transparent and giving them a white background. These pictures are contributed by Mr. F. W. Broadhead, of Leicester, but the one of Miller's Dale is scarcely representative, for it reveals no limestone rocks, no gigantic Chee Tor. Messrs. Adam and Scanlan, of Southampton, send five portraits, different positions, of Sir W. Siemens, admirably done, and above these is an exceedingly clever photograph of the Bishop of Sodor and Man—an enlargement, an excellent likeness, by the Autotype Company, from one taken by Mr. G. Patterson, of Ramsey.

A number of studies of great ability are contributed by Mr. H. P. Robinson, of Tunbridge; one of them, "A Merry Tale," in which several country women have stopped in a field, and are laughing over some story, is very adroit in composition. A Chesterfield photographer—Mr. A. Seaman—exhibits a very large number of artistic pictures, some of which have historic interest. There is an attractive little photograph of the Revolution House at Whittington, where in 1688 the Earl of Devonshire and others plotted the revolution which ended in King James's overthrow. There are also views, exquisite for their detail and contrast, of Bolsover Castle, where Charles I. was feasted. But not the least valuable is the one showing Chesterfield Market Place on the day of the fair—the cattle, the farmers, and somewhat unsightly Market Hall, Glumangate Corner, High Street, are all got into the picture, which is very faithful and distinct. The Rufford Meet at Sutton Hall; Hardwick Inn, at the foot of the slope of the Marquis of Hartington's Derbyshire mansion; the pond and wooded bank at Tapton Grove, the bit of Westbar, and the church with the crooked steeple, are also capitally done by this artist. Mr. G. V. Yates, of Sheffield, sends several fine specimens of portraiture obtained by the gelatine process, and also a number of bromide enlargements, one particularly commendable—that of Dr. Atkins.

Mr. T. S. Hicks sends some nice enlargements; and Mr. Ainley contributes a case of portraits and some novelties—gaslight pictures on Morgan's paper. An admirable portrait of the ex-Mayor (Mr. Michael Hunter) taken by Messrs. Maule and Fox, is one of the exhibits; and not far from it are three careful enlargements on bromide paper by Mr. S. Foxon. Close by Mr. Taylor, the secretary of the Society, has on view two splendid views, showing the real character of Miller's Dale, with its pretty stream, varied foliage, and giant rocks. Just beyond, Mr. W. B. Hatfield, the treasurer of the Society, contributes several frames. In one of them is a delightful little picture of the village street at Bolsover, with the old-fashioned inn the Angel; and in others, amongst composition pictures, are three fascinating photographs of children bird-nesting and fishing. The scenes at Blackpool, too, giving a vivid idea of rough seas that are always dashing on the shore, are a credit to this exhibitor. A

frame of work sent by Mr. E. Peakowe, of Glossop Road, is distinguished for its detail and finish, the portraiture groups and interiors being alike good. The ex-president (Dr. T. H. Morton) sends a number of interesting views, mostly taken in India, and also a series of micrographs. The autotype enlargements representing cottage life, and sent by Mr. T. B. Blow, are also very attractive; and the same may be said of the splendid photographs sent by Messrs. G. West and Sons, which have taken no less than three gold medals. Mr. H. J. Palmer sends a valuable collection of views of Devonshire, Derbyshire, and Swiss Scenery; and Mr. W. Davies contributes a frame of Derbyshire scenes beautiful in manipulation. Messrs. Alfred Davy, M. Auty, T. S. Yeomans, E. Malcham, A. Chadburn, T. Firth, Dakin, J. H. Dickinson, W. England, also add materially to the beauty and completeness of the exhibition by their contributions. In the corridor of the hall is a large and important collection of apparatus.—*Sheffield Evening Star.*

PHOTO-LITHOGRAPHY AND PHOTO-ZINCOGRAPHY.

BY MAJOR J. WATERHOUSE, B.S.C.,
Assistant Surveyor-General of India.

CHAPTER XV.—ASPHALT PROCESS.—(*concluded*).

In some cases it is unnecessary to coat the plate with printing ink, but only to expose the plate covered with asphaltum to the light, then develop in turpentine, which, though it will not dissolve the asphaltum, will soften it and render it easily removed from a great part of the ground with a soft brush; the remainder can then be removed with the charcoal.

It may also be noted that M. de la Noë uses glass plates coated with asphaltum at about 12 per cent. for making negatives by contact printing from tracing.

Captain Biny, of the French Engineers, also attached to the Topographical Brigade at the Invalides, has described in the *Moniteur de la Photographie* for 1881 another method of engraving the zinc plates as follows:—

The bitumen image on the zinc plate being inked and gummed, the plate is passed rapidly into dilute nitric acid, and brushed with a soft brush to clean the surface. It is then well washed with water, and plunged, still wet, into a coppering bath, where it remains five or ten minutes. The zinc thus becomes coated with an *adherent* film of copper in all the parts unprotected by the bitumen. The heavy parts of the image become lighter and clear up under the action of the coppering bath. When the zinc is well covered with copper it is taken out of the bath, washed and dried, and then placed in a bath containing benzine, which removes the bitumen forming the image, leaving the clear zinc showing on the copper ground.

When the image has been thoroughly removed, the plate is washed with a strong jet of water to remove all the benzine, and is then rubbed with a cloth or a sponge in a tub of water. That done, and without wiping, the plate is placed in the same bath of weak nitric acid as was used for the cleaning, and it will be perceived that this only bites the zinc forming the image, leaving the copper untouched. In about fifty or sixty seconds a fine topogravure plate is produced, which is inked and worked just in the same way as described by M. de la Noë. In this process an ordinary reversed negative must be used instead of an original drawing or positive transpareucy.

For giving a very light coating of copper, Captain Biny uses the following coppering bath:—

Sat. sol. bichloride of copper ...	100 parts
Liquor ammonia	150 ,,
Water	3000 ,,

If a strong coating is required, he adds to the foregoing, which is of a beautiful blue colour, saturated solution of cyanide of potassium till the blue tint has nearly disappeared. The coppering is then slower, but nearly as firm as with the battery.

M. Mongel, the chief of the Photographic Ateliers of the Ministry of Public Works in Paris, has simplified M. de la Noë's process of topogravure, so as to avoid the second exposure to the light.

The zinc plate is first of all washed over with the preparation of gallic acid used for etching, or protecting the surface from printing ink. It is then thoroughly washed, dried, and coated with asphaltum. It is exposed to light under a drawing or a transparency, and developed in the usual way with turpentine.

After washing, the plate is treated with acetic acid diluted with four parts of water, which restores to the lines forming the image their faculty of receiving greasy ink. The plate is then washed and dried, and inked all over with the roller; the bitumen forming the reserves is washed away with benzole, and the plate is inked in again and is ready for printing.

The plate may, if desired, be bitten in with nitric acid at three per cent. as described by M. de la Noë. It is washed, treated with acetic acid, and the other operations follow as above described.

In trying this process with the usual zincographic etching fluid containing gum, the writer found it difficult to ensure the adherence of the bitumen over the gummy coating of the zinc, however well the latter might be washed. The simple decoction of nutgalls would probably be better.

Bitumen may also be used for photo-lithographic transfers, but, so far as the writer is aware, no process of the kind has come into general use.

A transfer process by Mr. Lewis, of Dublin, has already been noticed.

In 1863, Mr. Pouncy, of Dorchester, patented a tissue for this purpose, made by coating tracing paper with a mixture of printing ink, asphaltum, benzole, and fatty matter with or without bichromate of potash. The paper is exposed to light with the plain side under the negative, developed in turpentine, dried, and transferred to a damp cold stone.

M. Despaquis, of Paris, has proposed tissues made by coating sheets of gelatine with bitumen, a film of gum being interposed between the bitumen and its support, in order to facilitate the removal of the latter after transfer of the bitumen to stone or zinc. The print, having been exposed and developed, is laid, while still wet with turpentine, upon the stone, or, if it has been dried after development, it is moistened again with turpentine before being laid on the stone. A sheet of thick moist blotting-paper somewhat overlapping the print is placed upon it, and pressed down to drive off air-bubbles. One or two dry sheets of blotting-paper are placed over the wet one, and the whole is covered with a few sheets of glass. After the lapse of a few hours the dried sheets are removed. Water is applied with a sponge to the last sheet, and the gelatine being softened, the gum is dissolved and the film comes away, leaving the bitumen image on the stone. The gelatine has the advantage of transparency, and, being quite unaffected by the turpentine used in developing, does not extend, cockle, or warp. The method has the further advantage that the scale of the image is not altered in any way, either during the development of the image, or in transferring to stone or zinc. As several transfers can be joined up, the process is suitable for large work.

From the above and the previous chapter, it will be seen that the manipulations of the asphaltum processes are of the simplest nature, and when once the conditions of success are attained, exceedingly beautiful results can be secured with very little trouble. But the uncertain quality and properties of the material, even when purified by ether; the comparatively long exposure; the invisibility of the image; and the nicety required in developing to just the proper point, are difficulties which militate against the extended adoption of asphaltum in photo-lithographic work. Nevertheless, it is peculiarly suitable for the reproduction of very delicate line work, and will give very

much finer results than can be obtained by the ordinary collochromate processes, or even collotype.

The whole subject of the photographic working of asphaltum requires a much more thorough investigation than it has hitherto received; but it is to be hoped that as the interest in these processes is reviving, more attention will be given to the subject, and our knowledge of it be increased.

Correspondence.

THE CHARLES DICKENS ALBUM.

DEAR SIR,—Mr. A. R. Dresser, in last week's issue, makes an appeal to amateurs and others to assist in forming a collection of photographs illustrating the works of the late Mr. Charles Dickens—a good idea that should be carried out before the negatives that may already have been taken, fade, crack, or injure, in their several owners' plate-boxes.

I shall be happy to contribute four 12 by 10 clear and vigorous negatives of "Tom Tiddler's Ground" ("Mr. Mopes the Hermit"), and the "Maypole," "Chigwell Row," mentioned in "Barnaby Rudge."

If characters are to be included, they must of course be "properly made up." I would willingly undertake a share, or certain number of these, free from any expense.—I am, sir, yours truly,

RUBY D'OR.

HYDROKINONE DEVELOPER.

SIR,—Mr. St. John Biggs' failure with hydrokinone in the case of instantaneous exposures is probably due to insufficient development. Hydrokinone is a very slow developer, and from twenty to thirty minutes will probably be none too much time to give an "instantaneous." I have a couple of negatives taken on Nelson's extra rapid (20°), with an exposure of $\frac{1}{20}$ of a second, before me as I write. They were developed with the formula referred to by Mr. Biggs, and are so dense as to be practically unprintable these dark days. I may add that minute details of embroidery on a child's dress, the grain of the bricks in a red brick wall, and dark wood door behind the child, are given in these negatives with perfectly unnecessary sharpness. The lens was a cheap so-called aplanatic one of French manufacture, 6-inch focus, full aperture, autumnal light, about three o'clock in the afternoon of a fairly good character.—Your truly,

HENRY POCKLINGTON.

GREENISH-YELLOW LIGHT IN THE DARK-ROOM.

SIR,—In reply to Mr. Bradshaw's question as to whether I use the green-yellow light in my dark-room, I can only repeat what I stated at the meetings of the societies when I spoke upon the subject, that I had for some time past had my dark-room window fitted with green glass and deep yellow paper, and that it answered so well with me that several other dark-rooms had in consequence been similarly fitted, and that in every case the greatest satisfaction had been expressed.

Amongst other combinations, I tried one similar to that mentioned by Mr. Bradshaw, but did not find orange glass so safe as yellow paper in conjunction with green glass. It is, however, no doubt, as Mr. Bradshaw says, better than a ruby light, which would give the same amount of luminosity to the eye, and the value of his testimony in the matter will be appreciated by those who know how he insists upon technical excellence in his work.

I have been sometimes surprised by being asked whether I venture to use the kind of light that I advocate for preparing plates, or whether for that purpose I do not still use ruby light. As I have shown that for an equal amount of luminosity to the eye there is less chemical action on the plate with the green-yellow than with ruby light, I use the former as a matter of course in the preparation of plates, and I certainly think that my plates are clearer than they were when using the accustomed ruby.

It must be understood that I do not claim that the light I use is without chemical action, but if it and the ruby light are used of such intensity as each to afford a certain amount of light to work by, there is less action on the plate with the green-yellow than with the ruby.

To any photographer desirous of getting rid of the trying red light, and wishing to see the particular colours of glass and paper that have succeeded with me, I shall be happy to post patterns.—I am, yours obediently,

W. E. DEBENHAM.

Massingham House, Haverstock Hill, N.W.

Proceedings of Societies.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

AT the ordinary meeting of this Society, held in the Gallery, 5A, Pall Mall East, on Tuesday, the 8th inst., Mr. J. GLAISHER F.R.S., President in the chair,

The minutes of the previous meeting having been read and confirmed, Messrs. A. G. Dew Smith, M.A., and A. Tagliaferro, were admitted members of the Society.

The PRESIDENT said it became his painful duty to announce to the meeting the news of the death of Mr. J. H. Dallmeyer, which is reported to have occurred on board a vessel within sight of the shores of New Zealand. Members and council, looking up with respect to Mr. Dallmeyer's opinions, all sympathized with his family in their great loss, which would not only be felt by them, but the Society, the optical world, and England.

Mr. G. L. ADDENBROOKE showed a folding lantern made of cardboard and bookbinders' cloth, and sufficiently high to burn an ordinary candle in; the colour emitted being red. The many advantages it possessed when travelling being his excuse for bringing it before the notice of the Society.

Mr. W. E. DEBENHAM: Has Mr. Addenbrooke tried any other medium than red? This colour having been found injurious to the eyesight, whereas a mixture of yellow and green would not be so. The mixture of yellow and green gives a better illumination, and is a much more pleasant light to work in.

Mr. ADDENBROOKE said the quantity of work he did not being large, he had not found the light injurious; he had not tried the mixed colours alluded to by Mr. Debenham.

The PRESIDENT observed that the lantern appeared to be of a practical nature, and they were always glad to have practical ideas placed before the Society. Mr. Spurge being present, the adjourned discussion on his paper would be resumed, and if anything new had cropped up since the paper was read, he should be glad if Mr. Spurge would let them know.

Mr. J. B. SPURGE replied that he had nothing to add to the paper. He passed round the several examples, showing the effect produced by 16 and 25-candle gas respectively, using Mr. Warnerke's sensitometer side by side with his own, the duration of exposure being varied from two seconds to 256 seconds. The standard light, being four of Mons. Giroud's standard gas burners, one mm. in diameter, arranged in a line parallel to the plane of the white screen, at a distance of 25 cm., the length of the flames being equal—that is, 67·5 mm., and regulated by two cross lines. Between the opening formed by the two jets near the centre the sensitometer is placed, and an exposure of sixty seconds was mentioned as a suitable exposure. The advantage claimed for this plan was that, being made from measurement, it could be made by anyone who possessed a foot rule.

Mr. DEBENHAM said elaborate mathematical calculations are very useful, and should be very exact. In this case there was uncertainty, a radical fault attached to all sensitometers. Plates exposed to extraneous light, or from other causes, may render the sensitometer reading sixteen times greater, without the plate being any faster in reality. The new point was the employment of the gas unit, and the question is, whether or not any advantage is gained over magnesium? Gas may vary from many causes; barometric pressure will change its power.

The PRESIDENT reminded the speaker that a governor being used, variation would not be likely to occur.

Mr. DEBENHAM, continuing, said it was a question whether gas burning continually at the aperture would not of itself make the

instrument uncertain; altogether, he considered it less certain than the Warnerke sensitometer.

Mr. T. Sebastian Davis had very little to add to the remarks of the previous speaker. In the present instance, they were considering the reliability of gas as a constant source of light, and in Mr. Warnerke's they had a given quantity of magnesium ribbon consumed. It being established that some batches of plates are more sensitive to the yellow and red rays than others, left room for inaccurary. Does the same ratio hold good between gas, magnesium, and daylight? He (Mr. Davis) could understand exposing plates of one make to the same source of light, the unit would then be reliable: but when we take into consideration the difference between it and camera exposures, there are so many chances of failing, that it could scarcely be considered a perfect standard.

Mr. Spurge, in replying, remarked that, supposing the plates to be fogged in preparation, or exposed to any extraneous light, the ratio of degrees would not be affected any more with gas than by the phosphorescent unit. The standard size of the gas jet was that of M. Giroud, of Paris, and a variation of 0·05 in the size of the hole would not affect the intensity more than 0·015; while the quality of the gas employed may vary thirty per cent. It would be seen, in the example marked I., two plates were exposed, side by side, to the gas flame and in the camera respectively, the ratio being 1 to 48. The objection regarding plates of varying composition holds good with the phosphorescent unit; but in the case of bromide and bromo-iodide, the variation may be overcome by having a constant for each class of plate. In his sensitometer there is no medium between the plate and source of light. All his experiments were conducted side by side with the phosphorescent unit. Gas poor in quality answered equally well, provided the line of measure be taken from the principal luminuous point, not the length of the flame.

The President announced that nominations must be sent in not later than Monday, January 21st.

The gentlemen appointed to act as auditors were:—Mr. G. L. Addenbrooke and Mr. C. Ray Woods. Scrutineers:—Messrs. W. K. Burton, W. Cobb, A. Cowan, and F. Hollyer.

The retiring officers are Captain Abney, F.R.S., vice-president; Mr. W. S. Bird, treasurer; Messrs. Bedford, Bolton, England, Dallmeyer, Mawdsley, and Captain Darwin.

South London Photographic Society.

The annual lantern meeting of this Society took place on Thursday evening, the 3rd inst., in the Hall of the Society of Arts, a large number of members and their friends being preseut. The chair was occupied by Mr. F. Howard, vice-president.

The Chairman, after remarking on the continued popularity of the annual gatherings of members and friends, inaugurated, like the Technical Meeting, by the South London Society, said there were not quite so many slides sent in this year as on some former occasions. He had no doubt some of the members had slides with them. Among those sent in he was pleased to announce contributions from Messrs. F. Beasley, Junr., F. A. Bridge, J. J. Briginshaw, W. Brooks, W. Cobb, J. Gale, H. Godbold, Hepworth, R. Trueman Wood, F. York, and others. Mr. Bridge had very kindly offered to give a brief description of the subjects, and Mr. Brooks had undertaken the duties at the lantern. Some music was also promised, and he thought an enjoyable evening would be spent.

Mr. F. A. Bridge said there were not so many slides as they usually had; he supposed several of the members had formed the same opinion—*i.e.*, every one else is sure to send slides. If all the members had entertained the same opiuion, the Society would have come poorly off. In case of a searcity, he had provided for such by bringing the series used to illustrate his lecture on Holland.

The first slides projected on the screen (a disc about twenty-five feet in diameter) were by Mr. Beasley, Junr., on gelatine plates toned with mercury. These were followed by Mr. H. Trueman Wood's series on gelatino-chloride plates of his own make.

Mr. Brooks then showed a very fine slide of the president, and another of Mr. Jabez Hughes, whereupon Mr. Bridge sang Mr. Hughes' version of the "Spider and the Fly," which caused much amusement.

A series of microscopic subjects by Mr. York; microscopic and landscape by Mr. J. J. Briginshaw on gelatino-chloride plates; views in Holland, taken by Mr. Bridge, and prepared on collodion emulsion (contact printing) by Mr. Brooks; also a series taken in Wales, and produced in the same manner by those gentlemen; Mr. Gale's series on wet collodion, Mr. Smith's by the Woodbury process, Mr. Hepworth's on gelatine bromide, Mr. Cobb's street views by the same process, Mr. W. Ayres' comic sketches on wet collodion, Mr. Wheeler's and Messrs. Bridge and Brooks' Holland collection, were all passed through the lantern. During a brief interval between each exhibitor's slides being shown, vocal music was admirably rendered by Miss Harrison, Mr. Page, and Mr. F. A. Bridge, the latter gentleman, as usual, presiding at the piano.

A vote of thanks to those ladies and gentleman who contributed to the evening's entertainment brought the proceedings to a close.

London and Provincial Photographic Association.

The usual meeting of this Society was held on Thursday, the 3rd inst., Mr. W. E. Debenham in the chair.

Mr. W. T. Wilkinson asked if any members had had experience in using an old pyro developer.

Mr. A. Mackie said that some time since he received about two ounces of an old pyro developer that had been kept twelve months, Mr. Cowan having previously developed eight plates with same. He (Mr. Mackie) developed half an exposed plate with this developer the plate being in the developer one hour and a quarter: the plate was not stained. The other half of plate he developed with a fresh solution in four minutes. He was of opinion that the old developer gave the best negative.

Mr. A. L. Henderson said about three years ago he had, as a matter of experiment, prepared a solution of pyro, ammonia, bromide, and free bromine. After keepiug it twelve months he had found it slow; he had still some left, with which he promised to make experiments, and report at a subsequent meeting.

Mr. Mackie, referring to a notice he had seen of Mr. Henderson's method of cleaning a gelatine plate by placing it over a solution of cyanide of potassium, said he had put a negative on the top of a bottle containing cyanide for some days without effect.

Mr. Henderson said he had noticed an account of Mr. Spiller's experiments in this direction in the News Almanac. He accounted for the slowness alluded to, that sufficient free air had probably not been allowed between the cyanide and plate. In Mr. Mackie's case he observed that the plate should have been soaked first in water.

Mr. Wilkinson, in reference to a remark as to the best means of removing silver stains from a negative caused by damp silver paper, said he had found a solution of two ounces nitric acid and five ounces of saturated solution of alum quite clear a plate of any stain from this cause.

In reference to this subject of stained negatives, Mr. Henderson remarked that the bleaching action of hydrochloric acid and alum on a gelatine plate taken direct from the fixing bath without washing, was much greater than if washed first. He attributed this to the sulphurous acid liberated acting in conjunction with the hydrochloric.

Mr. F. Parsons showed a finder for a large camera, constructed to view the object from the side; it was a box about two inches square, with a small lens in front to focus with, a mirror fixed obliquely inside throwing the reflection on to a glass screen, forming a small camera-obscura, a japanned tin projector shading the screen.

Photographers' Benevolent Association.

The Board of Management held its monthly meeting on 3nd inst., at 181, Aldersgate Street.

The minutes of the previous meeting were read and confirmed.

Messrs. Carroll, Dugdale, Cotrell, Dubbin, Logan, and Wilkinson were elected members of the Association.

It was then decided that the annual general meeting should be held on Wednesday, January 30th, at 181, Aldersgate Street, at 8 p.m. All members who can attend are requested to do so, and members of the profession are earnestly invited.

Talk in the Studio.

Spectrum Research—M. Henri Becquerel has been pursuing his researches upon the infra-red rays of the spectrum. For the investigation of this region there are four methods, the first of them involving the use of a line-thermopile and a rock-salt prism;

the second, Abney's photographic method ; the third, Langley's method, with bolometer and a reflecting diffraction gratiug; the fourth, that of Becquerel, depending upon the discovery that the infra-rays have the effect of extinguishing the glow of a phosphorescent body exposed previously to ultra-violet rays. M. Becquerel finds that water, for example, gives in the region to which this method is applicable three well marked absorption-bands, having wave-lengths respectively of 930, 1,080, and 1,230. The newest result of Becquerel's researches is worth more than passing mention. He fiuds that there exist in this wholly invisible region of the spectrum bright-line spectra—equally invisible, of course—just as in the visible parts of the spectrum, observable in the radiations of hot vapours. Thus, incandescent sodium vapour prints upon the previously "insolated" phosphorescent substance two well-marked lines (wave-leugths 819 and 1093), corresponding to two bright lines hitherto unknown. The extent of the region which is capable of being explored by this novel process is from wave-length 760 to 1,300, or exceeding in extent that of the whole of the visible and ultra-violet rays.

ESTIMATION OF CHLORINE, BROMINE, AND IODINE IN PRESENCE OF ONE ANOTHER.—Mr. F. Maxwell-Lyte, referring to the recent paper of Paul Julius on the "Decomposition of Silver Chloride by Bromine, and of Silver Bromine by Iodine."—Doubtless these experiments were made by him with a view to the separation of chlorine, bromine, and iodine from one another. In this connection the following will be found a convenient method :—The haloids having been precipitated together with silver, the precipitate is to be collected, dried, aud weighed. It is now dissolved in about thirty or forty times its weight of water by the addition of the least possible quantity of cyanide of potassium. A quantity of pure bromide of potassinm is now added, which need not be above the weight of the precipitate. The cyanide is now decomposed by the addition of au excess of dilute sulphuric acid. The precipitate, in which any silver chloride has become by this means converted into silver bromide, is now collected on a filter, dried, and weighed. It is once more dissolved by the least possible quantity of potassium cyanide, aud the same quantity of water, and to this is now added one and a-quarter times the origiual weight of the precipitate of potassium iodide. The cyanide is now again decomposed by dilnte sulphuric acid, and the precipitate once more collected on a filter, dried, and weighed. In this last precipitate all the silver is converted into iodide, excepting such as was iodide already. In the second experiment all became bromide, exceptiug such as was bromide or iodide already. From the weights then obtained from the first, second, and third weighings, the chlorine, bromine, and iodine may easily be calculated. I use this plan, dissolving in cyanide, as I find sometimes that the soluble iodide or bromide may not suffice to decompose completely the bromide or iodide respectively. The cyanide used may be the ordinary commercial cyanide, *providing always*, as is usually the case, it be free from iodide.

PHOTOGRAPHIC CLUB.—At the next meeting, on Wednesday, January 16, the subject for discussion will be "On Gelatine Plates for Lantern Slides Camera for Exposures."

To Correspondents.

*** We cannot undertake to return rejected communications.

C. R. B. D.—It is intended that a glazed tile should be used, and the softening of this glaze is sufficient. If, however, an unglazed tile is employed, the following will serve your purpose ; it must be poured on over the picture before it is fired.

Cornish stone	40 parts
Borax	5 ,,
Soda carbonate	5 ,,
White lead	75 ,,
Flint glass	10 ,,
Flint	23 ,,

Fuse these together, and grind with water until a creamy liquid is obtained.

F. W. VOLKMAR.—Both are excellent instruments, and, indeed, so similar, that it is not possible to recommend either as superior to the other.

A. B.—Try Mr. Plener's plan of immersing the plates in a very dilute hydrofluoric acid—a few drops to each ounce of water. When the film is off the glass, squeegee it on a waxed glass plate to dry ; it will separate easily from this.

PHOTO.—If proper steps have been taken to protect the designs you refer to, you will certainly incur considerable risk in reproducing them as you propose ; if, however, you have no wish to make a profit out of the copies, it is not unlikely that the proprietors would give you permission to reproduce. 2. It is protected, and it makes no difference whether your copy is larger or smaller than the original. You do not seem to clearly perceive that you have no more right to appropriate the whole or any part of a work of art belonging to another, than you have to take the whole or a part of the cash stored in your neighbour's strong box.

S. PORTER.—If your paper is kept in a moderately damp place, so that it shall not be too dry when floated on the sensitizing bath, it is very likely that you will not experience the difficulty again.

ARTHUR STANLEY.—As regards the Stannotype, you should write to Messrs. Woodbury, Treadaway, & Co., of Manor Road, Lower Norwood.

J. H. LEWIS.—We have, as you requested, sent you the address on a post-card.

EDWIN GRANT.—1. Under such circumstances one would call 160 high. 2. We do not quite understand your question.

J. BERRYMAN.—There is a descrepancy, and we will make enquiries.

GEORGE PERRY.—A trifle over thirty grains.

A SUBSCRIBER.—Hang them on small screw eyes, fastened into the sash-bars.

R. P. GEGSON.—We are not aware that it is made commercially ; but our description is sufficiently detailed to enable a workman to construct the apparatus.

G——— & Co.—We have given you all the information in our power by post, but should advise you to construct it for yourselves.

BISMUTH.—The following melts at the temperature you mention :—

Cadmium	1 part
Tin	2 parts
Lead	4 ,,
Bismuth	7 ,,

D. G. A.—1. The reproductions can be made by the ordinary zinc transfer process. 2. Intaglio plates for printing suitable grains, can be purchased from Messrs. Hughes and Kimber, of West Harding Street, Fetter Lane, London.

DR. SCHLEUSSNER.—We have posted you a number of the PHOTOGRAPHIC NEWS containing the description, and imagine you will have no difficulty in constructing the machine.

A. S. HOPKINS.—We have never experienced any difficulty in obtaining it at a leather-seller's.

The Photographic News Registry.

Employment Wanted.

Operator, dry plate manufacturer.—J. R. H., 11, Lewisham High-rd., S.E.
Operator, retoucher, all round.—Mr. Ems, 12, Bartholomew-ter., Exeter.
Reception Room, book-keeper, &c.—M. R., 34, High-st., Sittinghourne.
Lady, to mount, spot, &c.—A.S., 3, Silchester-rd., St. Leonards-on-Sea.
Retoucher, can operate.—H. A. G., 35, Brooker st., Hove, Brighton.
Retoucher, operator, or manager.—J. Jones, 79, Euston-st., Euston-rd.
Operator, gen. assist., good all-round.—T. W. 59, Tredegar-rd., E.
Retoucher and assist. operator.—A. R., 27, Cross-st., Ryde, I. W.
Salesman to photo. & frame makers.—L. W., 18, Plantation-rd, Oxford.
Operator, colourist, &c.—S. George, Sherwood-villa, Brunswick-pk., N.
Neg. Retoucher, lady.—M. F., Gaskell's, 15, Sussex-rd., S. Kensington.
Reception-Room or Shop.—C. M., 2, Dover-ter., Dover-st., Sittingbourne.
Retoucher, Lady, first-class.—E. M., *Photo. News* Office.
Spotter & Mounter.—Miss Stewart, 2, Albany-ter., Bournemouth.
Retoucher & Spotter.—L. F., 30, Swanmore-rd., Isle-of-Wight.
Silver Printer, first-class.—F. G., *Photo. News* Office.
Reception-Room, Lady.—F. W., 16, Chryssell-rd., Brixton.
Retoucher (Lond. only), c/o. J. S. Cockerton, 2, Hanover-pl., Regent's-pk.
Retoucher & Assistant Operator.—Artist, 19, Waterloo-st., Southsea, Hants

Employment Offered.

Artist for carbon enlargements, &c.—C. F. Treble & Co., 371a, Brixton-rd.
Silver Printer, quick & experienced.—C. F. Treble & Co., 371a, Brixton-rd
Lady, exp., for mounting & spotting.—Mr. Gandy, 5, Bishopsgate-without.
Printer, artistic vignetter.—E. D. Lavender, Tweedy-bldgs., Bromley, Kent.
Artist for monochrome, carbon enlargements, &c.—Lex, *Photo. News* Office.
Miniature Painter, first-class.—Lex, *Photo. News* Office.
Fitters, artificial light apparatus.—Luxograph Co., North-end, Croydon.
Learner, for retouch.—N. M., c/o. Shew & Co., Wardour-st., Oxford-st., W.
Operator, first-class, & to retouch.—Hodson, 8, Market-pl, Retford.
Enlarger for general work.—D. S., *Photo. News* Office.
Dry-plate man, first-class.—Dry plate, 37, Thornton-st., Brixton.
Operator and retoucher.—F. Baum, c/o Disderi & Co, 4, Brook-st., W.
Female Assistant Printer.—F. Baum, c/o Disderi & Co., 4, Brook-st., W.
Painter in Oils, Club work.—K., *Photo. News* Office.
Printer & Toner, good Vignetter.—Mr. Vanderweyde, 182, Regent-st., W.
Photo-litho. Oper. (transfers, collotypes,).—Stewart, *Photo. News* Office.
Lady, Youth, and Apprentices.—2, The Pavement, Clapham Common.

THE PHOTOGRAPHIC NEWS.

VOL. XXVIII. No. 1324.—*January* 18, 1884.

CONTENTS.

THE ELECTRIC SPARK CONSIDERED AS A STANDARD LIGHT.

To the modern photographer some system of photometry or actinometry has become almost an imperative necessity, and already several rival methods have made their appearance, the merits of which entitle them, more or less, to scientific consideration and respect.

It must be conceded that any system to be reliable (and therefore practically perfect) must embody a *constant*, and undoubtedly that constant should be the acting property —the *light*. It is no part of our object to detract from the merits of any system which has so far obtained publicity; our aim is to improve thereon; and whilst we give every credit to the manifest skill and ingenuity of their proposers, we take the liberty of contrasting or comparing their systems with the one we are now about to advance; our apology will be in our earnest desire to advance science, and especially photometry.

We have often considered whether out of electrical laws there could not be formulated a *light* standard which should be capable of being copied or set up in any part of the world, and which could be spoken of in terms of figures signifying unity, just as in electrical science there are units or constants. No one who has experimented with electrical machines, such as the old type of frictional cylinder or plate machines, can fail to have been struck with the intense luminosity of the sparks drawn therefrom; but frictional machines are too complicated for our present purpose, and are, indeed, superseded by the more modern machines, called induction machines, such as that of Holtz, or the more recent invention of Voss. We will not now stop to study the principle and functions of these machines, but will at once point out that the discharge or spark between the terminals of the Voss machine conveyed to our minds the belief that a constant could be calculated therefrom, and we proceeded to reduce it to practice.

It must be understood that no claim is laid to novelty in the use of electric sparks in connection with photography—that has been done years and years ago—the claim we shall now advance is in utilizing the sparks from the Voss induction electric machines as a *standard* unit of light, and we will proceed to show how this is done. A second article will treat of the machine, its construction, principles of action, its convenience of use, the laws which apply to bear out the theory of a constant or unit, and the methods of using the machine for the purposes of our subject, together with suggestions for simplifying the arrangements of the machine, so as to express in figures the conditions for a definite standard.

If we take a Voss machine, and revolve the plate in a darkened room, and as soon as a manifestation of electrical disturbance is visible, we approach the knobs of the discharger to about an inch apart, we shall notice bright straight sparks leaping across, accompanied by a snapping sound. One cannot fail to notice the apparent similarity of the sparks as they fly in quick succession from knob to knob; in the darkened room their illuminating effect upon the walls and surroundings has the appearance of even greater regularity than when we look at the spark itself, for the eye is liable to error by becoming fatigued or habituated to a dazzling light. If we turn the handle of the machine so as to get *one hundred* sparks with the balls or knobs of the discharger set at one inch apart, we get a quantity of light of an actinic character, which our photometric experiments lead us to believe is a reliable *standard*—a standard light.

There are conditions that *may* interfere with the accuracy of such a standard; we say *may* interfere just in the same sense as there are conditions that may interfere with the correct performance of the most perfectly made chronometer, or any other piece of machanism; but the disturbing conditions are such as are not fatal to the system, nor are they so serious as those which appertain to the employment of gas or other combustible illuminants, or the use of the excited tablet of phosphorescent sulphide of calcium —*alias*, luminous paint. We shall compare these things by-and-bye.

The whole of the following experiments were conducted in the dark room, and may be repeated without leaving that apartment. The "screen" employed was the nearest thing that happened to be at hand, viz., the screen of a Warnerke's sensitometer, and for the present purpose serves well enough to illustrate our remarks, because it enables us to express by *its figures* the results obtained by the system we are now discussing. But after we have established the fact of the standard light, we shall proceed to draw further attention to the standard sulphur light screen, which was first suggested in these columns. If our readers will refer to page 38 of the volume for 1881 they will find details as to the only standard light screen or sensitometer scale yet proposed, the gradations being obtained by varying thicknesses of the element sulphur.

A standard light and a standard screen would not be perfect unless we used a standard or normal developer. Accordingly we performed all our experiments with a developing solution compounded as follows:—

Pyrogallic acid	1 grain
Bromide of potassium	1 „
Ammonia (·880)	2 minims
Water	1 ounce

We preferred to use the ammonia and bromide dissolved in the water by taking 60 minims of ammonia and 30 grains of bromide and dissolving in 30 ounces of water; this sufficed for thirty experiments.

Taking from a box of plates of our own make (and whose sensitiveness was such as to entitle them to the term "rapid") one plate 6½ by 4¼ was cut into two quarter-plates; we next cut them in twain, and had thus four pieces from the same plate to experiment upon. Placing the "screen" of Warnerke's sensitometer in the usual quarter-plate printing frame, we put thereon one piece of the cut plate, closed the frame as usual, and, first covering the glass side with a piece of black cardboard, we took it to the Voss machine, which stood on the bench not very far from our developing table, and which is also near to the stove which warms the laboratory. Placing the frame glass side up, and still covered by the black card, on the base board of the machine between the two little jars which support the discharger, it is exactly six inches from the face of the screen to the axis of the spark between the knobs. Then we turn the handle of the machine; it soon "takes," in electrical parlance, and sparks fly between the inch-separated knobs; we now withdraw the black card and count a hundred sparks, and then stop. It will thus be borne in mind that we expose the sensitive plate beneath the screen to a hundred sparks one inch long at a distance of six inches.

We now proceed to develop with the standard developer just named. The impression quickly appears, and we see the first two columns of figures, from No. 1 to No. 10, quite distinctly within one minute, and then we observe the other numbers coming up in the third column and indications of those in the fourth, until developing action seems to stick at the ghost of 17 or 18. These results correspond pretty closely with the figures revealed by the careful use of Warnerke's system with luminous tablet; hence we prefer for the present to adhere to the hundred sparks one inch long at six inches distance, and for other reasons which we will indicate further on.

Our next experiment was with the piece of the same plate from the opposite diagonal corner, and, therefore, somewhat unequal in thickness of the coating of gelatino-bromide of silver. We proceeded with this exactly as before described, and on developing we obtained indentically the same figures and general characteristics as in the first experiment, the only slight difference being attributable to the thick ridge of the film at the pouring-off corner of the plate. To settle any question as to the doubt of the constancy of our light, we had the remaining two pieces of the plate to fall back upon, and to eliminate any possible error due to variations in the energy of separate developers we exposed the remaining two pieces of the plate one after the other, and developed them in one dish together, with one ounce of the normal developer. The two developed exactly alike, they started together, and the figures became visible with such identically similar density that the conviction is forced upon us that, within reasonable bounds and under ordinary conditions, this light is a constant, an unit, and a standard of most reliable nature.

Yet, to make assurance doubly sure, we determined upon further experiments. We preferred to employ *known* plates—known in the sense that their make, history, and sensitiveness are familiar to us, not that we would like to flatter ourselves into the belief that because such and such a plate was quick and another was slow, so the electrical standard light should prove it, but rather that we should take the evidence furnished by the system *first*, and then, knowing the speed of the plates, to sum up and return the verdict "proven." We therefore took down a totally different make of plate, and proceeded in the manner indicated in the foregoing, and every time with the like result. The second set of experiments were with plates which were slow, and whose behaviour under the developer after camera exposures was very different from that of the first lot of plates; their behaviour under our standard light system in every respect convinced us of the superiority of the electrical discharge light, as compared with the phosphorescent tablet. The experiments were repeated over and over again with unvarying results—results which we might have led ourselves to *expect* when we reduce a system to simplicity, to eliminate grand errors, and minimise small ones.

Before we proceed further we had better explain why we advocate pyro. as a normal developer, and why we give the proportion of bromide so high. Ferrous developers are very useful, but their energy depends too much upon temperature, the degree of saturation of the components, and the purity of the oxalate used. Photometric experiments are worthless if not clear, exact, and precise. Fog on a gelatine plate can so help the photometric image as to make it really misleading; therefore the formula for the normal developer embodies an amount of bromide sufficient to keep most plates clean under development, so that the figures or ghosts of figures may be clearly made out.

Given, a standard light, a standard screen, and a normal developer, development by time might appear to be the only other condition necessary to assess the sensitiveness of a given plate; but this is not so. It is notorious that some plates will flash out under the developer and are done; others are slow to start and sluggish in arriving at the end, and yet their sensitiveness and quality may be equal to those of the first named. Therefore we fear we cannot at present advocate developing by time, but rather leave it to be pursued as is usual when plates are under treatment for obtaining as much detail as the exposure will give, stopping the action of development when fog threatens to set in. This is very easy in photometric development, for there is generally a space of clean bromide along one edge of the plate, whose integrity is a guide to the duration of development.

Now of all the standards of light proposed, probably daylight would be the worst, gas-light next, the standard candle next; the phosphorescent tablet has its merits, but is far from being entitled to be called a standard, because not one inch nor one foot of magnesium wire can saturate a tablet with light as compared with sun-light; then, again, its rapid decline during the first minute is a serious disturbing element, to say nothing of the effect of varying temperatures, which are known to alter the light given off an excited surface of phosphorescent sulphide of calcium. The material, too, is, as we well know, too variable in its very make to entitle it to be reckoned as a constant article.

In the electrical discharge system, as typified in the Voss machine, the disturbing elements are, the condition of the air through which the spark passes, and the storage capacity of the condensers (two small Leyden jars), and the material of which the knobs of the discharger are made. These will be treated of in our next article; meanwhile, any Voss machine may, under ordinary conditions, be considered as a standard in relation to itself, if not to others of similar make.

SILVER PRINTING.

THE DISCUSSION ON MR. ASHMAN'S LECTURE.

THE lecture lately given by Mr. Ashman at the London and Provincial Photographic Association was in itself very instructive, and was rendered even more so by the discussion which followed. Fortunately, there were present several of the older photographic workers, who have practised silver printing for more than a quarter of a century, and to whom we naturally look for information as to the permanency of prints got by different methods. It would appear that theoretical reasoning on the subject of the permanency of silver prints is little to be relied upon; not, probably, because the theories are wrong, but because we have not taken into account all the factors which govern the matter. When, many years ago, the alkaline toning bath was introduced, and the habit of toning and fixing in one solution was given up, we were told that perma-

nency would result. Has it? Most certainly not; but we imagine that there is a general impression among photographers that at any rate a nearer approach to permanency has resulted from the change. From the information given at the meeting which we refer to, it would appear more than doubtful whether even this much may be said with truth.

The lecturer had confined his remarks for the most part to the albumenizing and sensitizing, but the discussion drifted in the direction of toning. Mr. Ayres handed round several large-sized prints, which had, he said, been produced twenty years ago, and which had since been kept "anyhow." These were as perfect prints as we have ever seen. There was not a trace of either fading in tone, or of yellowing of the whites. The first question which was asked of the exhibitor was in what bath they had been toned, and no little surprise was evinced when Mr. Ayres replied that they had been treated by the sel d'or or mixed gold and hyposulphite of soda bath. The surprise was still greater when Mr. Ayres went on to say that the prints which had been toned by him in this bath had, without exception, shown greater permanency than those toned in the alkaline toning solutions, which is, at the present day, all but universally used. This statement was, however, fully borne out by Mr. York, than whom no one ought to be able to give better evidence on such subjects. Reference was made by a member to a certain series of stereoscopic slides which had been produced about twenty-five years ago, and which, he said, were now as bright and unfaded as when new, whilst others of more recent date, which had been kept along with them, were faded.

It happened that the author of this series was in the room, and, in reply to a question, he said that they had been toned by the sel d'or bath. There did not appear to be a single one among the elder workers who did not indorse the statement that the most permanent silver prints that had been produced were those which had been toned by the hyposulphite of soda and gold toning baths. It was not stated that all prints so toned were permanent; merely that amongst those so toned were to be found the most permanent. The pertinent question was asked: Why, if the sel d'or bath could give the most permanent prints, had it also given prints which had faded as rapidly as did the sulphur-toned prints, which were in vogue before gold was used at all? The answer was clear enough. The sel d'or bath is totally different in its action from the alkaline gold bath. The latter bath ceases to tone whenever the gold which is in it has all been deposited. The former does not, because by the time that the gold has been exhausted from it there are present all the constituents for a sulphur toning bath; that is to say, there is hyposulphite of soda with dissolved in it sulphite of silver got from the decomposition of the chloride of silver of the prints which were first toned in it. As a consequence, the bath continued to tone after the gold was exhausted, and photographers wishing to make a small saving continued to use it, imagining that they were toning their prints with gold, whilst in reality they were using the old sulphur toning bath.

The most experienced printers of the meeting were of opinion that if the sel d'or bath were properly used, a certain proportion of gold chloride being used for each sheet of paper toned, and the baths being afterwards poured away, a great increase in the permanency of prints would be the result.

We cannot enter here into the possible reasons for the greater permanency of prints toned and fixed in a mixed bath than those toned in separate baths, but may mention one likely cause which was pointed out by Mr. Henderson.

When toning is done first, and fixing afterwards, the toning is performed in the presence of the whole of the chloride of silver in the paper. When toning and fixing are done together, the toning is not commenced till at any rate the greater part of the chloride has been removed by the hyposulphite of soda.

It is an undoubted fact that the presence of salts of silver in the paper during toning have a very marked effect on the permanency of the print. It is well known that if but little of the free nitrate of silver be washed out of the paper before toning, the operations will take place with great rapidity. The prints are, however, much less permanent than than those which have been thoroughly washed before toning commences.

The importance of the subject discussed cannot be overestimated. We hope that those of our readers who have had long enough experience in the matter to form an opinion, will let us know what that opinion is.

Another subject which was treated of both by the lecturer and those members who joined in the discussion was, that of "ready-sensitized paper." The opinions given by those who had experimented in the matter was, that none of the published formulæ gave papers the same as those to be purchased commercially. It would appear that the means of making a sensitized paper which will keep well, tone easily without fuming, and give a good quality of print, is one that has, as yet, been kept a trade secret.

MR. H. J. NEWTON'S ACCELERATOR.

IT will be noticed in our reports of societies that the suggestion emanating from Mr. H. J. Newton (New York) to add a few drops of a solution of iodide of mercury to the washing soda developer, to act as an accelerator, is receiving some attention on this side of the Atlantic. The subject has been under discussion on two occasions recently before the London and Provincial Photographic Association, the gentlemen who made the subject one of experiment averring that the addition was beneficial, although they did not find the enormous gain claimed for it by the introducer.

Mr. Newton makes two solutions as follows:—

A.—Bichloride of mercury	...	30 grains
Water	...	4 ounces
B.—Iodide of potassium ...	...	90 grains
Water	...	1 ounce

When these are dissolved, B is slowly added to A. The result should be a clear solution, the excess of potassium iodide dissolving the red precipitate formed on the first addition.

The developer is composed of:—

Carbonate of soda (dry)	...	25 grains
Sulphite of soda... ...	...	4 ,,
Pyrogallol...	...	2 ,,
Water	...	1 ounce

Our own trial consisted in exposing three plates, five, fifteen, and twenty-five seconds respectively. The conditions as regards lens, diaphragm, and strength of light being the same in each case. The plate which received the largest exposure, viz., twenty-five seconds, was developed for six minutes in a developing solution compounded as above, and is beyond all doubt the best negative of the three. The plate which received fifteen seconds' exposure was developed four minutes in a similar solution to the first plate; the details being nearly all out when two drops of the iodide of mercury solution were added, and the development continued another four minutes. Finally the plate exposed five seconds was treated similarly to the first as regards length of time in the first developing solution; then three drops of the so-called accelerator were added; the development continued three minutes longer, then another three drops of accelerator, the development being prolonged another three minutes. Six drops more were added, making twelve in all, and time of developing increased to eighteen minutes in all. The result was a little disappointing. The negative was purposely

very much under-exposed, it is true; but we had some hope at the outset that we should be able to get a printable negative. Such, however, did not prove to be the case. Whatever we might be able to do with ammonia, or soda alone, in the way of forcing, we could not do with iodide of mercury added. There appears to be a certain amount of intensity gained by a slight addition of the mercuric solution. The same may also be said of iodide of potassium, tincture of iodine, and several other substances; and with certain batches of plates we think the addition recommended is likely to prove beneficial. In our hands iodide of mercury does not supply those sterling qualities attainable by a full exposure.

Modifying the conditions, by omitting the sulphite of soda, making the soda solution stronger, and also adding fifty per cent. more iodide of potassium to the mercury solution (five drops of this mixture being added to the developer before starting), we obtained a better result, the plates being exposed under similar conditions to those described above.

NOTES BEARING ON THE GELATINE EMULSION PROCESS.

BY DR. J. M. EDER.

Hemp Fibre for Filtering Emulsions.—To prevent air-bubbles in the filtration of emulsion, it is usual to employ cotton-wool as filtering medium. This, however, frequently gets pressed together, and then the filtering takes a long time. Much more quickly acts sheep's wool or unspun hemp. I now employ the latter exclusively, and can filter a pint of emulsion in a minute. A funnel having a little bulb at the top of the neck, as shown in the annexed sketch, is advantageous, I find.

To Introduce Nitrate of Uranium in Gelatine Emulsion is a process not attended with success so far as I have tried. All the kinds of gelatine I have been able to procure coagulate with this salt more or less. Two per cent. was sufficient to form a sinewy mass, and I found no advantage was to be gained by the addition.

Oxalate of Uranium and Potash, employed as a developer for gelatino-bromide plates, did not come up to the expectations raised in my mind by its powerful reducing qualities. The uranium salt* was dissolved in an aqueous solution of oxalate of potash. A dark brown solution is formed which has a strong reducing action upon gold, silver, and platinum salts. Used as a developer upon a gelatino-bromide film, it gives, however, but a very weak image. Not only was the sensitiveness very small, but the picture very thin. The gelatine became tanned like leather, and perhaps herein was the explanation of the above phenomenon.

Red Prussiate of Potash, which destroys every description of light fog in gelatine plates, renders most kinds of gelatine insoluble, a fact that was unknown to me some years ago, when I suggested this substance as an antidote to fog. A solution of hard gelatine, treated with red prussiate of potash, remains clear, but yields on cooling a caked mass, which, on warming, melts with difficulty, if it melts at all. Once dried, its insolubility is increased. The admixture of this salt may therefore be employed as a hardening material.

A mixture of Gelatine and Red Prussiate of Potash is Sensitive to Light.—As I have just said, a dried mixture of the above is almost insoluble in warm water, and swells up but little, if at all, in cold water. By exposure to direct sunlight, yellow prussiate of potash is formed, and the solarized parts become blue. These parts then swell up more easily, and are more soluble in water (exactly the reverse of what takes place when a mixture of gelatine and bichromate is exposed to light). Here, therefore, is the principle of a new photographic process.

Density of an Aqueous Solution of Oxalate of Potash.—It is easy to test the amount of salt in a solution of crystallized oxalate of potash by means of the hydrometer. An ordinary hydrometer of Baumé, which is to be found in every laboratory, will answer the purpose, if only recourse is had to the following table, which I have prepared for the purpose:—

The Solution contains					Density at 15° C.		Degrees Baumé.
1 part oxalate of potash in							
		3	parts	water	1·159	...	20½° B.
,,	,,	4	,,	,,	1·126	...	16° B.
,,	,,	5	,,	,,	1·103	...	13½° B.
,,	,,	7	,,	,,	1·076	...	10° B.
,,	,,	10	,,	,,	1·055	...	7½° B.

The Pre-exposure of Gelatino-bromide Plates.—It is well known that the pre-exposure of all kinds of plates, whether wet or dry, has a favourable influence upon their sensitiveness. The following experiment shows how the sensitiveness may be increased two to threefold. An emulsion prepared with carbonate of silver and ammonia, with half-an-hour's heating to 40° C., was found to give No. 15 on the Warnerke scale. A plate, however, stood close to a red lamp (candle) for two minutes, previous to exposure, gave No. 19 on the Warnerke sensitometer. By standing a plate close to the red lamp for six minutes, Nos. 19 and 20 were legible. Pushing the experiment further, the plate fogged.

The Action of Warmth upon the Sensitiveness of Gelatine Plates.—A well-dried and vigorously working plate has its behaviour at once changed if it is heated at the back from 60 to 120° C. My friend Mr. Plener, a well-known correspondent of the NEWS, communicated to me this fact. The plates become much thinner by the action of warmth, and certain parts of a film may be so attacked that they have no density at all. Experiments conducted on my own part bore out this discovery of Mr. Plener.

* This I prepared by exposing to light for months, mixed solutions of oxalic acid and nitrate of uranium.

By-the-Bye.

WHO IS A PHOTOGRAPHER?

A GRUMBLE, long if not loud, has recently been heard on the subject of authorship in a photograph, but it was reserved to Mr. Pancoast, the secretary of the Philadelphia Photographic Society, to put this grumble into words. We think a good deal of credit is due to Mr. Pancoast for formulating the grievance—or, rather, supposed grievance—for it is only in this way that the matter gets fairly discussed. The introduction of modern dry plates, said Mr. Pancoast, is responsible for the creation of a new class of amateur photographers. "These men buy their plates, expose them, and take them to a photographer to be developed; then they come to the Society and say, 'I made this picture.' The question is, how much did they make? All they did was the uncapping of the lens, and once in a way they got a picture, but very often they did not."

These are Mr. Pancoast's words as printed in the Journal of the Society, and we say we owe a debt of gratitude to that gentleman for speaking out on the subject. For it is now possible to discuss the state of things put before us, and estimate it at its real value. We have heard the same complaint, put forward in almost the same words, many a time during the past few years, and the question naturally arises: Is there anything in it? To be frank in our reply, we think not. We believe that

there is no instance on record of any man obtaining credit as a skilled photographer, whether in the shape of a medal or of fame, for prints secured under the circumstances mentioned by Mr. Pancoast. No doubt instances could be produced, among professional photographers, in which principals have obtained *kudos* for work done by assistants, but this is not the case in point. The complaint is, that one who knows nothing of photography brings forward work with the words, "I made this picture," when he has done no more than expose the plate in the camera. Our view of the matter is this: that in nine cases out of ten, the picture exhibited by a novice of this kind will show no more merit than was to be anticipated from its mode of production; and when your brand new amateur says, "I made this picture," you will fully believe what he says.

But supposing an ignoramus shows you even a dozen prints from plates which he has simply exposed, what then? The pictures will call for no comment. They will never raise the ire of a Russell Manners Gordon, a Seymour Conway, or a Whaite, to name three well-known artist-photographers who make their own plates and make their pictures as well. Were our novice at photography even a fine landscape painter, possessing, therefore, the keenest eye to composition, he would be equally impotent to bring forth pictures comparable in any way with the photographs that take awards at our exhibitions. The novice, we grant, obtains material assistance in getting his plate developed for him, although, here, he is not likely to secure the aid of men in the foremost rank—men who have won medals, and know how hard they are to win. But he has the exposure to make himself, and a man profoundly ignorant of photography and its capacity could only secure a good picture by the most fortunate fluke in the world. To obtain then a series would be virtually an impossibility, we hold; at any rate, nobody, we venture to say, has ever heard of a man taking out a camera half-a-dozen times only, and exhibiting as the result a frame of those soft, delicately-pencilled views, with transparent shadows and hazy atmospheric effects, such as good photographers find no difficulty in producing year after year, and showing in our exhibitions.

To choose the proper direction, to judge of the lighting, to adapt photography to chiaroscuro, to maintain proper contrast photographically as well as artistically; in short, to bend your tools to furnish a successful picture, to say nothing of the dozen technical details connected with focussing and exposing—to do all this is necessary to the getting of a successful photographic picture. The ignoramus may, by a fortuitous concourse of circumstance, hit upon success in all these matters, and then, if the plate is not spoilt in development, he may bring forth a photograph to rival one of Russell Manners Gordon. But we must say we have never seen any such marvel, nor heard of one. What we have seen many a time and oft, are little brown prints representing scenes of travels, which fulfil their object well enough as mementoes for the traveller, and which, to the traveller himself, are of value; but these—the result of a few hours' practice with the camera—no more enter into serious competition as pictures with the productions of a Robinson, a Bedford, a Payne Jennings, or, to instance three clever amateurs, a Brightman, a Gale, or a Manfield—than would the sketches of a boarding-school Miss vie with the water-colour drawings of Leitch, Varley, or David Cox. There is surely no harm in gentlemen making use of photography even to the most limited extent, if it so pleaseth them, and until they usurp the honours of an exhibition, we may well afford to smile when they say, "I made this picture."

No doubt, of two gentlemen who exhibit pictures equally fine, the one who has made his own plates and his own emulsion deserves, as a photographer, more honour. Unfortunately, or perhaps fortunately, it is seldom that the series of exhibits are exactly alike, and jurors are not frequently called upon to adjust the beam so nicely. But we must mind not to be carried too far with this argument. If a man produces his own plates as well as his own pictures, it is not likely that his lens and his camera are home-made; nor is the paper on which the pictures are printed prepared by him, if, indeed, it has been sensitized with his own hands. In the good old days, the photographer rarely made his own collodion and iodizing mixture, albeit, he generally made his own bath; so that he has a very good precedent for considering that he is not called upon at the present time to produce the sensitive film upon which the picture is taken.

Again, it must be remembered that he who can prepare his own emulsion, and prepare it well, enjoys this undoubted advantage: that he knows more about the plates he is using, and hence has the more chances of final success. And as it is by final success that he and his brother will be judged, this making of his own emulsion handicaps his rival.

Development in many cases is a work of infinite skill, especially in the case of the out-door photographer, and this is why we say that if a man gives over his plates to another to develop, the results, if good, are never likely to be of first quality. Any photographer will convert the exposed plates into clear bright negatives for him, but let the former be ever so skilful, you cannot expect the same result as a Russell Manners Gordon naturally gets by slowly and gently developing a subject he is familiar with. We say slowly, because it is only in this way that the beauty of the picture is thoroughly under control. Mr. Gordon once said that to develop two plates in a day was quite enough for any amateur, and although he remarked this in respect to the old gum-gallic process, it holds good, with slight modification, at the present day. Now Ignoramus is scarcely likely to get a Gordon to develop his plates, and therefore we repeat that his photographs, inadequately exposed, are likely to be inadequately developed as well.

We are speaking here of out-door photography only, because the new class of amateur that some of us are afraid of does not practise in a well-ordered establishment. The development of plates taken in the usual conduct of a studio is another matter altogether, and may be undertaken almost mechanically. The sensitiveness of the plates used is so well-known, the lighting so much under control, that in several first-class studios the development is now done by time and in a rocking trough, several plates being treated simultaneously. Here the whole of the artistic photographic work is done at the time of exposing. The late M. Adam-Salomon, certainly our premier portraitist, did not, as a rule, develop his plates, but contented himself with the lighting and posing of the model; during the last years of his life, indeed, he scarcely entered his own dark-room, but engaged the most skilful photographer he could find to aid him in the photographic work. Mr. Valentine Blanchard—to give another authority—on the other hand, never permits the development of a portrait to be undertaken by anyone but himself, and it may be remembered that when he worked the collodion process he frequently made use of daylight, half way through the development, to intensify the picture.

The development of out-door plates, even when the emulsion has much latitude of exposure, is then very different to treating films lighted uniformly in the studio. We come, therefore, back to the conclusion that the new class of amateur is quite welcome to all the honour and glory he is likely to get from his method of co-operative photography, and that though he may be well content with such prints as he obtains, these are never likely to deprive the careful and painstaking photographer of his rightful due.

The "By-the-Bye" next week will be "Something Practical About Lenses."

CAMERA LUCIDA—PALETTA OBSCURA. A STUDY IN LIGHT AND SHADOW.

BY HUME NISBET.*

MY subject—the union of painting and photography—is not so short as you or I might wish it to be, yet I have tried to make it as terse, as a subject so crammed with incident, and so exhaustless in manner, could he made. Yet, if you will try to endure it to the end, I trust you will not be disappointed.

Photographers, as far as I have seen of them, are a jealous-minded race. They don't think enough of their art, or of themselves. They are too apt to think that the painters despise them, while in reality the painters of to-day hang on to them as a drunken husband is apt to hang on to his good-templar wife during this festive New Year season; or, to be more poetic in simile, as a half-drowned sailor will clutch on, teeth and nails, to the hard rock which may have broken up his rotten old boat, but now keeps him alive in the middle of the surf. The painters of to-day have become realists, and photography is realism, or nothing.

A photographer, to be able to produce a good picture, must be a true painter in the highest sense of the word; so a painter ought to know the right qualities about a good photograph, whether he knows the mixing of the chemicals or length of exposure, or process of focussing, &c., or not, although to he able to compete, the tricks of the trade have to be learned. Witness Napoleon, Sarouy, Mora,† and such men, with their fancy dodges and splendid effects, and Seavey, with his unapproachable backgrounds.

Thus my title is almost superfluous, for painting and photography, requiring the same direction of talent, are already united; only it may be of a little service to hear a painter avow the marriage publicly, which is so constantly being consummated on the quiet.

It is in your work, as in ours, the doom to be annoyed constantly with talented triflers who dip a finger into all the sciences, and are for ever ready to dispute the poiut with the originators—buyers of brains—who imagiuethat their cash gives them full liberty to find all sorts of faults, or suggest improvements upon the worker's designs; who will not huy unless their idiotic improvements are executed to the last letter, and who afterwards lay the whole blame of the spoiling of the pie upon the haker, when the guests condemn.

Having a direct object in view, I need not trouble you about chemicals, or lenses, Aurora lights, or secrets that you all now know much better than I, but will come direct to what is of vital interest to us both in our wedded state—viz., the seeking how we may put as much of the soul of nature, with her innate force of feeling and motion, into our pictures as possible; the men, modern and ancient, who may best aid us hy the examples and teachings they have left as a legacy to us; a quiet consideration of what they really have done for us; a right straight look at the men themselves, unbiassed by veneration or prejudice, with a consideration as to how much we have taken advantage of the legacies left to us.

The first aim of our investigation is, therefore, the *Exact Imitation of Nature—i.e.*, the outward form and appearances of nature, the body, in fact, of that mystic Deity whom all men worship, no matter what is the dogma, whether they have a creed or whether they be creedless.

Secondly,—The *Feeling, Sentiment, or Sensations of Nature*—how her appearance touches us, as we look upon her in the wealth and loveliness of her colouring, also how we may keep that sentiment alive in our light and shade.

Here the painter, with his colours, gets a better hand and a long start ahead of the photographer, engraver, and etcher; and it is here that if those workers in light and shade can keep the sentiment as well as the painter in colours, they gain a double and richer triumph—the triumph of a racer who has been heavily and unfairly handicapped at the beginning of the race.

Thirdly,—*The Motions, Actions, Passages, Expressions, and Impressions of Nature.* There, both in photographer and painter the man himself is brought out, whether he is a trained mechanic or a horn genius.

Lastly,—*The Perfect Image*, the whole innate force, which ist he spirit and soul of that matchless creation towards which we must all constantly turn (as the sun-flower turns or the daisy opens to the glance of day) for the light and life of our artistic beings.

Let us drop the weak word artist out of consideration altogether. Personally I abhor it, as denoting nigger minstrel, sword-swallower, or that undefinable member of society who plays with single foils and sable hairs inside a studio, enriched with Turkey ruggery, old armour, and marble busts. Let us, who are workers, be plain painters and photographers, never heeding the comforts of our surroundings, having only to do with objects as accessories to our work, thinking only upon the *utility* of every nick-nack we may have, aiming only at the result without considering the trouble or the inconvenience to the animal who is bringing it all about, every conception or experiment being an undiscovered country which we mean to find all out and make our own—Stanleys or Thompsons with our Africas; Pizzaros conquering and annexing our Mexicos; plain, hard-working, earnest painters and photographers; brothers in one grand service—Art.

I think, at the present day, painters recognize this fraternal staud even more than photographers give them credit for doing; they know how much they are indebted to the camera for making matters lucid which were before obscure. Witness the galloping horses done by instantaneous process, the shape of waves in full action, the rushing of waterfalls, and the contortions of muscles in moments of great excitement. How many of the old masters knew what a horse at full speed was like? and what eye-openers to battle-painters those photographs have been. None of the sea-painters were able to draw a wave in all its subtiltics and froth accessories as painters now-a-days may do if they study the imprint of a flying second; we may also have clouds in their strata, as they actually are, with shadows perfect, in those artistic studies coming, like the institution of Christmas cards, more and more into vogue every year that we live. And painters do use them constantly, whether they admit the fact or, induced hy a false pride, pretend that they do not. I see in every exhibition glaring evidences of hay-carts and field horses, yachts and ships of all degrees, blankly copied, with hardly any disguise, from the photographic studies suspended in the shop windows. Clear photographic studies, faithfully drawn out, and in the painting knocked about a little, sometimes not so true as the original to Nature, blurred and mystified into that obscurity which does for feeling with the crowd, the most original bit of painting being the man's signature who sells it, that strictly being his own, and not the copyright of either the photographer or the horse.

And why not? Clouds will not wait on our pencils and palettes being set; horses will not stand until we draw out a faithful enough study of their forms, nor ships pause until we get in all the rigging. The winds are against it, and the waves. The hours flying along and tearing down the sun-shadows before we have fixed one line of them on our paper or canvas join in the protest, jeering at our deliberation, and mocking us as slow coaches in these steam-engine days, we trying to crawl on six miles an hour, and dreaming that we can enter into competition with the mile-a-minute express.

The pride which keeps the artist silent, or makes him deny the charge of photo-borrowing, is an utterly false pride, and the sooner it is knocked out of sight the better for all parties. Why should we not correct our sketches—done for the sake of the colour and feeling, and not for the form—from faithful photographs? It does not hinder us from being original in the after-treatment, although it may save us much time in the elaboration of sketch-details. Why not save our precious time for something so much more worthy of it—the picture?*

Hitherto I have wanted so much to be original that out of conscientious scruples I would not use the photographic studies which some of my friends have sent me. I looked upon them longingly, and put them out of sight reluctantly, and so went down to sea-boards and meadows, catching rheumatics and toothache, and wasting hours upon hours, and many valuable sheets of Whatmau's hand-made paper, trying to draw out all the rigging of ships, and the shapes of cows, losing the effect often in my endeavours to get the manipulation, and in reality not getting a hundredth part of what I might have got with half-an-hour's rapid dashing on of colour effects, and a moment's focussing.

At present I know little or nothing about the art of photo-

* Read before the Edinburgh Photographic Society.

† Three of the photographs shown at the meeting were by Sarony and Mora, kindly lent by J. L. Cox, Esq., representative of the firm of Mason and Co.

* Only not to the encouragement of lazy habits, at times (for the sake of practice), a painter ought to draw the most minute point detail with the pencil, as a singer practises his scales, otherwise for the object the photo. is most to be relied upon for truth in all, *except perspective.*

graphy, but I intend to make it my duty to learn a little more, —enough to be able to sight a picture correctly, take and develop a dry plate, and afterwards fix a print; for I can see plainly that time is coming on with rapid strides to the point when, along with his present utensils of colour-boxes and sketching block, the painter will require to carry his camera and stand, box of dry plates, and head covering. And how proper is it that it should be so, a little experience will prove to every one. An old castle or abbey, or the view of a town, or even the markings upon the trees, it would take us days to outline; the buildings of the town, the fret-work about the abbey and castle, or knots and gnarling of the woodland—and even then it would be incomplete. To illustrate my meaning, look at even the most careful outline pencil drawings of Turner, one of the most delicate of outline draughtsmen, *when he liked*, or the scrupulous and untiring delicacy of his admirer, Professor John Ruskin, with his pencil, and compare those efforts with the lines about even the most common-place photograph of a building or tree-trunk, and I need say no more on that point. The painter has lost the half, and distorted the rest; and although the drawing may appear more attractive at first sight, the photograph will be the best, for it embodies the first grand principle of a painter's training—faithful imitation of the object which he desires to represent. Photographers are apt to labour under the mistaken notion that we do not recognise this plain fact of artistic necessity; but we do, and if we do not have the manliness to own it, that is our cowardice and not our blindness. Be content, therefore, when you go into exhibitions and see the misty result of your photographic-studies in the realism of to-day hanging all round: that is recognition enough of the obligations palette owes to camera.

To consider the first of our united art aims—viz., "*The Exact Imitation of Nature*,"—as she appears to us, and as she appears to others. The eye is the organ to which we all appeal, and I do not know a more fickle umpire—except, perhaps, the ear. I had a friend once in Auckland, New Zealand, who had weak eyes, and used blue spectacles for the glaring. He never was satisfied with my colouring, the yellows always had such a green appearance. "Why won't you stick to pure chrome?" he used to ask, seriously transfixing me with two blank window panes of deep indigo. Many people are colour-blind, yet not entirely so, and more is the pity; but just on one point, *like the sun-stroke of Sir Roger Tichborne*; and the worst is, they are not aware of that particular point, and feel quite put out if it is explained to them. They will think the man an ass who tries to prove them wrong, for if they are strong upon any point, it is upon that particular point. I have proved it dozens of times in cases of partial sun-stroke and colour-blindness. I mean, just a slight wipe out of the mental slate, a blurring, or, as it were, a Dutch effect in the case of sun-stroke; or a delicacy of perception wanting in the colour-blindness, a gauze veil dropped over, not nearly so apparent as the blue glasses, or the lack of distinction between red and green, for daltonism, like this, ought to be palpable, both to the sufferer and his suffering friends. There is also a distortion of vision apart from nearness or longness of sight, which is a very troublesome agent to fight against for the producer of pictures, a little nerve gone agee through partial paralysis, or an accident before birth, and everything is different to him than to any one else, or it may be that it is spasmodic and occasional in its effects, and then woe to the picture that comes under his lash (if a critic) at the moment the twisted fit is on him.

Ten artists sit down to one landscape and make ten different pictures, and the camera drops in and makes the eleventh, like none of the ten, but wonderfully like the original, as those ten different pairs of eyes will testify, in spite of their varied distortions. Ten different critics look at a picture and find out different faults, each praising as virtues the faults of the nine others. Ten women will look upon one man, and ten chances to one, they will all find different uglinesses about him, with the exception of the tenth, *whom he may have chosen*, and yet they will all unite in agreeing that she wasn't worthy of him; which clearly proves, I think, that this form-distortion of vision is only partial.

Realism is the passion of the day, both in writers and painters; and this passion photography is only too well qualified to gratify. To note down a scene or describe an emotion by the aid of its most minute outer symbolism, as faithfully and as free from complexity as possible, seems to be the greatest virtue and the highest aim of the modern school. The names which I would select as samples of this style of work will be those names which, by engravings and etchings, are best known to us, and so likely to be of most use in our search after excellent examples. Amongst the old masters I would quote Albert Durer, Rembrandt, and David Teniers. I take those three great names as samples, because their manners are distinctly separate, because their systems and tricks for reaching effect are easily penetrated.

(To be continued.)

Notes.

An International Photographic Exhibition, to be held this year in Berlin, is spoken of. Unfortunately, the German Societies do not seem to be all of one mind, and at present there is little prospect of making the gathering representative of Germany, let alone civilised nations generally. The German Photographic Society, which has its head-quarters at Weimar, will hold their annual meeting in Berlin, and this circumstance apparently gave the idea of an exhibition. But the biggest of the Berlin societies has not, so far, ratified the scheme, and without this aid its prosperity is very doubtful.

The last weekly return of sunshine made by the Astronomer-Royal shows an improvement, for he tells us that while the sun was above the horizon fifty-six hours, it shone no less than three hours at Greenwich. The previous week the number of hours' sunshine was officially returned as 0.

The photographic album was scarcely likely to escape long the attention of moralists. Last Sunday, at one of the suburban churches, the preacher put very forcibly before his congregation the uncertainty of life. "Look at your family album of ten years ago, and see how many faces appear in its pages that are now mere memories of the past." The illustration is, indeed, apt, for it comes home to us all.

We have before urged upon our readers never to disturb an album of portraits that embraces friends and relatives. A book of notables or of beauties you may do with as you please, but spare your household gods. If a friend gives you a better portrait, take it, but let the old one be; and when your album is filled, put it away, and allow no one to meddle with its pictures. Gradually, as years go on, its value will increase apace, and in time to come you will possess a treasure which, to your inmost self, is beyond price. That book to you will contain more old stories, tender recollections, odd fancies, bygone memories, and touching reminiscences—half solemn, half sad—than are bound up in the weightiest volume of history or romance.

Not only to the old, but to the young, is the family album a cherished treasure, as a short story we can tell amply proves. A little girl of five, of parents who had emigrated to Australia, learnt all she knew of her cousins in far-away England through this volume, and so often had she studied the bright faces that a longing to be with them was for ever in her soft little heart. A friend once told her the

story of the Piper of Hamelin, and how, having been ungratefully treated by the burgomaster, the piper enticed away all the little children of the village, who followed him into a chasm in the mountains, and were never seen again. "Did they die?" said the child. "Oh no; there was music and lights and dancing, and they lived on merrily," was the reply. "Were there any cousins there?" asked the little exile, wistfully.

The ordinary gelatine negative may be stripped with a little care, if the glass to which the film is attached is well polished and free from any of those tiny points of roughness that common glass frequently displays; to strip from patent plate is, indeed, easiest. With a pen-knife you cut through the film one-eighth of an inch from the edge, and carefully raise it; warmth will sometimes assist the operation. As the film is scarcely thicker than gold-beater's skin, you must be careful not to breathe upon it, for moisture thus unevenly applied brings about partial cockling, that is afterwards difficult to remedy.

Mr. Plener's method of stripping is, however, applicable to any plate whatever. The negative is immersed in extremely dilute hydrofluoric acid—a few drops to each ounce of water—and as the acid penetrates the film and etches the glass, instant separation takes place, and the film floats off. It can be dried flat by squeegeeing it on a slightly waxed glass plate, from which it separates easily when dry. If a more rigid film is required, a sheet of plain gelatine should be soaked and squeegeed down over the film.

The regulation made by the Belgium Photographic Association, that its members would be admitted to the Exhibition on presenting a card with a portrait upon it, seems to have exercised a singularly rejuvenescent influence. Everybody became, on the spot, ten years younger—at least, in their portraits. Well-known members, whose beards had been streaked with silver for years past, presented pictures of black-bearded Adonises, and those whom Father Time had robbed of their ambrosial locks appeared once more with well-dressed coiffure. Fortunately, the secretary was present with the check-taker at the inauguration, or there might have been some difficulty in declaring the Exhibition open.

New aspects of the copyright question are continually cropping up. The latest is comprised in a somewhat novel point recently raised before the Paris Tribunal of Correctional Police. Some miniature portraits had been photographed with the consent of the artist, and afterwards coloured. The art of colouring photographs has in Paris been brought to great perfection, and in this case the copies were so faithfully rendered that they could not be distinguished from the original miniature. A suit for piracy was brought by the owner of the latter, and the Tribunal decided that copyright in a painting extended to every form of reproduction, and that the offering of photographs—though they may be taken with the artist's consent—coloured for sale was an infringement of copyright in the picture, and is prohibited.

Many enterprising photographers have found Board schools do them good service. Their plan is to get the permission of the master to photograph the various classes, and as in all probability each child's mother will want a copy, the photographer can afford to sell the latter at a low price, and yet get a good profit. The constant changes, too, which are going on in schools render a fresh series every year possible, and so a regular source of income may be depended upon.

But there is a danger lest the photographer should kill the goose which lays the golden eggs. Talking with the master of a large Board school the other day on the subject, he said that he had refused permission to have the school photographed on the ground of the trouble it cost him personally. "Just imagine," he remarked; "I have fourteen classes, and it would be necessary for me to stand for my portrait fourteen times, because the boys would have nothing to do with a picture which did not contain a portrait of the head master as well as the pupil teacher. Then there may be one or two failures, so that sixteen times, at the least, I may reckon I have to stand for my portrait. But this is not all. The photographs are sent to the school, they arrive in batches of two's and three's, I have to distribute them and hear the complaints of those who are kept waiting for their proofs; I have to collect the specimens; and virtually I am turned into a photographer's assistant."

We were compelled to own that there was justice in our friend's complaints, and ground for his refusal; but we may also remark that he let fall a hint which photographers who go in for this class of business might do well to note. "The photographer," he went on to say, "pressed me very much to have the school done, and wanted to know how he could make it up to me. Of course such a thing as a pecuniary equivalent was out of the question, and I flatly refused. But I don't know if he had offered to subscribe a guinea to our Teachers' Association that I should not have consented."

The comet Pons-Brooks has had the honour of being photographed. This has been accomplished at the Observatory of the Liverpool Astronomical Society, West Kirkby. The exposure was fifty-three minutes, and the appearance on the plate is that of a circular haze without any tail. A heavy dew was falling at the time of exposure.

Another view as to the best light for the dark room. Meeting Mr. Samuel Fry the other day, he greeted us thus:—"All through our factory we use one thickness of cherry fabric, and a sheet of white tissue paper, as a protection against artificial light. The tissue paper has a truly remarkable effect in diffusing the light, while the "cherry" tint is more agreeable to my eyes than either

the glaring colour of ruby glass, or the heavy gloom of orange. We use no daylight in our dark rooms, as its variations would quite upset our work."

Applications for Provisional Protection.

912. Robert Galland-Mason, of Hambleton House, Promenade, Douglas, Isle of Man, Schoolmaster, for an invention for "An instrument to be called the microphotoscope."—Dated 8th January, 1884.

934. William Henry Duncan, of Coalbrookdale, in the county of Shropshire, Engineer, for an invention for "Improvements in apparatus for changing dissolving views."—Dated 8th January, 1884.

1042. Samuel Dunseith McKellen, of 18, Brown Street, in the city of Manchester, Watch Manufacturer and Jeweller, for an invention for "A new photographic exposing apparatus."—Dated 9th January, 1884.

1113. Thomas Storey Davis, of Halifax, in the county of York, Photographer, for an invention for "An improved construction of apparatus for photographing without the aid of daylight."—Dated 10th January, 1884.

1206. Leon Warnerke, of Champion Hill, in the county of Surrey, Gentleman, for an invention for "Improvements in shutters for photographic purposes."—Dated 11th January, 1884.

1251. George Rydill, of 52, Chancery Lane, in the county of Middlesex, for an invention for "Improvements in treating and producing coloured photographic transparencies for decoration and production of various designs on sheet or plate glass, glass-ware, talc, gelatine, bladder, parchment, or paper, so as to represent stained, cut, embossed, or enamelled glass in one or any number of colours or designs."—Dated 11th January, 1884.

Patent Sealed.

3476. Richard Brown, Robert William Barnes, and Joseph Bell, all of Liverpool, in the county of Lancaster, for an invention of "Improvements in means for and methods of producing designs upon paper or other fibrous or soft material, or upon metallic surfaces."—Dated 14th July, 1883.

Specification Published during the Week.

2495. John Imray, of 28, Southampton Buildings, Chancery Lane, in the county of Middlesex, "Improvements in the manufacture and treatment of photographic paper."—communicated to him from C. Cros and A. Vergeraud, both of Paris in the Republic of France. (*This Invention received Provisional Protection only.*)

This invention relates to the manufacture and treatment of photographic paper for the purpose of reproducing by the action of light the dark lines of designs drawn on transparent surfaces such as tracing paper, glass, and the like, or the images of flat objects that can be applied to the prepared paper. The paper can be prepared either during its manufacture by mingling with the pulp the sensitive materials, or these can be applied to the paper at some stage of its manufacture, when it can be moistened, or after its manufacture, whether the paper be sized or not. Thus, there may be added to the pulp which is to be converted into paper, a sensitizing solution of about eleven parts bichromate of potassa and 120 parts of dry glucose in 1,000 parts water, the quantity of the solution being such that the sensitizing ingredients constitute an addition of about sixteen per cent. to the weight of the dry paper. For sized paper the proportion of sensitizing material may be considerably less. Or, again, manufactured paper may be gelatinized in the usual way, impregnating it with a solution of about ten parts bichromate of potassa, 100 parts dry glucose, and twenty-five parts gelatine in 1000 parts water. Paper thus prepared is particularly applicable for obtaining designs in organic colouring matters. For developing, a solution of about ten parts nitrate of silver, twenty parts acetic acid, and fifty parts alcohol in 1,000 parts water gives a ruddy colour, which after washing and drying in the light becomes dark brown. Hydrosulphuric acid gas, reducing salts of copper or iron such as oxalates or ammoniaco-sulphites, carbonates of soda, and potassa may be then applied. By the action of the latter substances, carbonate of silver is produced which becomes blackened by exposure to light. Another developing solution consists of about twenty parts acetate of lead, twenty parts acetic acid, and fifty parts alcohol in 1,000 parts water. This gives a yellow, which is blackened by hydrosulphuric acid gas. Development in dark violet colour may be effected by applying a mixture of about twenty parts extract of logwood, fifty parts alcohol, and five parts carbonate of potassa, with 1,000 parts water, and then washing with water acidulated with oxalic acid to remove the colour from the ground. In all these operations, alcoholic liquids are preferable to pure water, as they dissolve less the bichromate. For the glucose employed in the sensitizing mixture, dextrine, sugar, or gelatine may be substituted.

CHAPTERS ON LANDSCAPE AND OUTDOOR-PHOTOGRAPHY.

BY H. P. ROBINSON.

No. 3.—Models.

It is only of late years that photographers have given anything like adequate attention to the figures they introduce in their landscapes. Anything that happens to be at hand, from a Cockney tourist to the porter who carried the camera, was once thought quite good enough for every occasion. Now, I am glad to see, something better is thought necessary, and if this is not obtained, the photograph is a very ordinary photograph indeed; and is usually, if admitted at all, passed over in an exhibition as a commonplace production. The sins against fitness become fewer every year, while anything really vulgar in taste is extremely rare.

There are those who go for absolute purity of production, unmitigated nature, who will admit nothing in a picture but what is indigenous to that picture, so to speak; but Art, according to Lord Bacon, is man added to nature, and unmitigated nature is certainly not art. I do not fear to say that nature alone, as a picture, has far less interest than the same nature represented by a great artist. "What are you painting?" said I to one of my painter friends when we were out on a certain painting and photographing excursion; "your sketch does not seem, if I may be excused the criticism, to be exactly a coloured photograph of the scene you have before you." "I am not painting a local view," was the reply, "I am painting what nature suggests to me." Now, as regards models, I seldom find the "real thing" to quite answer my purpose. The aboriginal is seldom sufficiently intelligent to be of use, especially if you have "intention" in your work

I remember a case in Wales very much to the purpose. Some artists who were of our party came home from a walk one day, enthusiastic about the beauty of a girl they had seen in a field two miles away, planting potatoes. I must go next day and photograph her. I went, and found they had not exaggerated; she really was a beauty, and her clothes also were lovely, both in colour and in delapidation. Knowing how shy the Welsh peasant is, I got the gamekeeper who carried my camera to speak to her first, and I approached the subject warily by beginning an agricultural talk with her mother. After a time I got the girl to stand for a picture, but it was a dead failure—all the "go" was gone out of her, and she looked as frightened as a hunted hare. After another trial, she objected to be tortured any more, and ran away. I persuaded her mother to bring her to the house next day. She came, and I got the housekeeper to talk to her, and left her for an hour to get used to the place and people. I then tried a picture. I posed her by the side of a pool with picturesque surroundings. Naturally she had a most winning smile, but I could not succeed in calling up anything better than a scowl. I got a fine picture in every respect, except in the one essential—the expression. The picture has since been called, "The Welsh Ophelia contemplating suicide."

But if fine nature, in the way of natural models, is not

to be obtained, art supplies the remedy, as I am now going to show.

I am quite conscious that I am laying myself open to the charge of masquerading, but art is a state of compromises and sacrifices, and I cannot but think that what is lost in absolute unrelenting naturalness when substituting trained models for the newly-caught raw nature, is compensated for in many ways. Graceful figures, if not over done, give an ideal tinge to the picture that lifts it above the cleverest transcript of mere prosaic fact.

My models may be called to some extent artificial, but they are so near the real thing as to be taken for it by the real natives, just as the trout does not seem to know the difference between the natural and artificial fly. One day two of my models were walking across the park, and a gamekeeper, seeing them for the first time, made after them, shouting in the high tone that sounds like quarrelling to the stranger when he first hears it in Wales. As they would not stop he did not hesitate to give way to all he knew in both languages, and did not cease to vituperate till, getting near them, he found to his dismay they were "the daughters of the house."

This, I think, shows that our imitation is sufficiently like the original for artistic purposes.

My models are trained to strict obedience, and to make no suggestions. If the photographer has really got an idea in his head, he had better carry out that idea. Any interference, even from superior intelligence, is sure to go wrong. Some people are wonderfully patient under the application of information, but I confess that I am so peculiarly constituted that the most admirable advice, when I am in the middle of posing a group, quite upsets the ideas I had, and I don't find it possible to adopt those offered. Therefore, from my own experience, I would recommend that if a friend feels the twitchings of sufficient skill to offer advice, you had better allow your candour to exceed your courtesy, and order him off at once. Two heads knocking together produce anything but harmony.

In speaking of my models in what I have written above, I allude to those that have appeared in many of my pictures the last few years. They are not always the same persons; in fact, I get as much change in that respect as possible, to avoid monotony. It is almost as difficult to get variety in dresses as in persons. I always endeavour to secure a picturesque dress when I see it. It is not always easy to explain what you really mean when you meet a girl in a

lonely country lane, and you offer to buy her clothes, but a little perseverance and a good offer usually succeed. A country girl's dress is not often worth more than eighteen pence, and if you turn the pence into shillings, and look business-like all the time, you may make pretty sure of walking off with the property, or at all events getting it sent to you next day.

Some models require considerable education, others take to it at once. One young lady, who had no thought of sitting, and I no thought of asking her to do so, as she was then almost a stranger to me, made one of the best models I ever photographed. We had no intention of photographing, but the camera was in the house, and half-a-dozen plates, and we had nothing better to do. The first picture she posed for is represented in the sketch. We had no costumes with us; but a sun-bonnet, bought in Regent Street, and intended to be worn while playing tennis, was as picturesque as one made of calico in the country. A white apron borrowed from a servant, and a handkerchief tied round the neck, transformed the dainty young lady into a comely country maiden. She was posed against a tree by the pond, and told to look a thousand miles away, and think of the future, and the result has been considered a success. The same model, half-an-hour afterwards, with very little change of dress, made a very good representation of a Puritan maiden standing by a window in an old oak-panelled room; and the remaining four plates were used up to like advantage.

Young children make good models; but you must capture them wild. To ask their mothers if you may have them is fatal. They insist on dressing them in their Sunday-school clothes, to "have their pictures took." Now a dirty country child is often a delightful lump of picturesque humanity; but when it is "washed, and dressed all in its best," it is about the most priggish bit of nature I know. It loses all its freedom, and becomes stiff and awkward.

Old people are often very useful in landscapes. With them, as with children, you may take the real native. It is between the years ten and thirty that the genuine peasant is so difficult to manage.

Sometimes a model will suggest a picture. Everybody knows the story of Rejlander and the model for his wonderful "Head of John the Baptist in a Charger." Rejlander saw this head on the shoulders of a gentleman in the town in which he then resided. The curious thing is, that he did not so much see the modern gentleman as always the picture which the head suggested. It was some months before the artist ventured to ask the model to lend his head for his purpose, and years before he obtained his consent. The result, from an art point of view, was splendid, and, considered photographically, a mystery.

One of the best models I ever employed was an old man of 74. He was a crossing-sweeper. I should never have accomplished one of my best works if I had not seen him sitting at a table in my studio, waiting till I could talk to him. I not only saw the old man there, but, mentally, the old lady, and the interior of the cottage, although, as it happened, he was sitting before an Italian landscape background. The old man, by his attitude and expression, gave the germ of the idea; the old lady had to be found, and the cottage built, but they appeared to me then quite visibly and solidly. This was the picture called, "When the Day's Work is Done." I believe a great many pictures originate in the same way, of which more in the next chapter.

PRINTING.

BY W. M. ASHMAN.*

THE subject of this evening's lecturette or paper, whichever you prefer to call it, has been entitled, "Printing." The vastness of this subject is, however, far beyond my capabilities, since we find it dating back as an art to a very remote period; my remarks will therefore be confined to that kind of printing adopted by photographers, and known as silver printing on albumenized paper; or what might with truth be designated, "the fugitive photographic printing process."

I do not wish to occupy your time this evening with a lengthy description of all the various methods of printing, photographic or otherwise; neither shall I reiterate all the discoveries which

* Read before the London and Provincial Photographic Association.

led up to their elaboration, as I have little doubt but that our worthy curator, who was the instigator of this effort of mine, will not rest contented until he has made you acquainted with the secret workings of all and every process based on photographic research. Unfortunately for me, there are no secrets attached to this subject which are not known to you all, unless it be that the ordinary silver print is not the most imperishable souvenir of photographic art one can possess.

Example 1.—Here are some samples which speak for themselves. These were all printed on the 19th May last, and the faded ones have been exposed in a damp atmosphere—viz., a cellar; those prints which have not faded have been kept under the ordinary conditions of the atmosphere. You will notice the extraordinary influence of damp on these prints.

The subject, then, we have to deal with to-night is the means employed to obtain positive images on a suitably prepared surface of silver chloride, incorporated in albumen, by the direct action of light, and if you will allow me, I will deal with this matter in successive steps.

If we expose ordinary white paper to the sunlight, no change is seen to take place; neither should we notice much difference if we soaked a piece of pure Swedish filtering paper in a solution of pure nitrate of silver, dried it, and exposed it to light; but if we were to coat the Swedish paper with gelatine, arrowroot, or some similar organic substance previous to silvering it, we should find that the paper would readily darken in the light. From this we gather that an organic compound of silver is formed, which is more easily acted upon by light than a layer of the pure salt would be.

Example 2.—Here are some prints which have been produced on filtering paper soaked in gelatine, and silvered in the ordinary manner.

Chloride of silver behaves in a somewhat similar manner to nitrate when exposed to light in the presence of organic matter, excepting that chloride of silver is more sensitive; for this reason, as a sensitizing salt for making prints, it has long been the photographer's sheet anchor. If I may be allowed to speculate, I would say that chloride of silver will in all probability be the printing process of the future; not in combination with albumen, however, but a mixture of gelatine and collodion on a sulphate of barium surfaced paper. At no distant date I shall endeavour to show you some examples printed as I have indicated.

Example 3. —In this tube we have a solution of silver nitrate in water; you will notice it is quite transparent. I will add a few drops of hydrochloric acid, and immediately a copious flocculent precipitate of silver chloride is formed. If I wash some of this chloride of silver, and expose it to light, it readily darkens. The same also happens when a soluble chloride, such as common salt, is added. I will take one of these tubes, containing silver chloride, and expose it to burning magnesium ribbon. You will notice it has darkened considerably.

For the purposes of printing, we find it more convenient to form our silver chloride in a very much finer state of division on the surface we intend to act on as a base for the picture, and chemical decomposition is resorted to for the attainment of that end, but not quite in the same manner as I have just shown you. A given proportion of one or more of the soluble chloride salts is incorporated in the albumen coating given to the paper. When this salted albumenized paper is floated on a moderately strong solution of silver nitrate, the soluble salt becomes changed, and an extremely finely-divided layer of silver chloride results, the coating of albumen being rendered insoluble, or coagulated by the silver nitrate.

In this tube I have some white of egg (albumen); upon the addition of a small quantity of this silver nitrate solution, you will notice a white cloud formed; this is coagulated albumen.

Dilute silver solution does not coagulate albumen perfectly; for this reason stronger solutions are used than would otherwise be necessary. When weak solutions are used, portions of albumen will be dissolved, producing an effect called stripping, and may be recognized by a semi-opaque scum floating on the surface of the sensitizing bath; also dull patches and streaks on the paper itself.

Example 4.—Here are some examples of albumenized paper which have been floated for the space of three minutes each on silver solutions of six grains, nine grains, and twelve grains per ounce respectively, fuming thirty minutes. It will be noticed that the 9 and 12 grain examples are very good, but those on 6 grains have very little albumen left. Nearly all the paper used by silver printers throughout the universe is manufactured in the south-east of France, or in Saxony, and is designated, according to the mill from which it issues, either Saxe, Rives, or Renat "New Rives." These papers are sent out sized, ready for albumenizing, which latter operation is performed very extensively in this country and in Germany. Each albumenizer has his own pet formula, and some degree of secrecy is observed by them all. The formula here appended is a fair specimen, and yields excellent results. To every gallon of fresh albumen, free from yelk or germ, add the following:—

Ammonium chloride	... 1½ ounces
Barium chloride	... ¼ ounce
Glacial acetic acid ...	... ½ „
Soft water previously boiled ...	... 4 ounces

When dissolved, add gradually to the albumen, beating constantly until the whole is a froth; after twenty-four hours' subsidence, the mixture may be strained through fine cambric, and is ready for use, Coating is performed by floating the smoothest side of the paper on the albumen bath for the space of thirty or forty seconds according to the nature of the paper; the sheet is then dried on laths or rods at a temperature about 90° F. In Germany the sheets are pinned up by two corners to dry. The coarseness of texture sometimes noticed in silver prints is due to the paper being coated on the wrong side. Drying at too high a temperature gives a brilliant surface, but causes blistering in the after process. Drying at too low a temperature causes dullness. The quantity of albumen required to coat a ream of paper weighing 10 kilogrammes will be about 2 gallons. Various tints may be given to the paper by the addition of suitable liquid dyes mixed with the albumen. Albumenizing and sensitizing cannot at present be successfully performed at one operation; as far as experiments have been made, all attempts to preserve the paper have failed, and the results have not proved satisfactory. Sensitizing, therefore, becomes a distinct operation. I may fairly assume that many present indulge in the luxury of ready sensitized paper; still I have taken the liberty of introducing this subject as one of the stages necessary to obtain a result. Silver nitrate and sodium chloride, if permitted to attack each other in the presence of water, form, as everybody knows, silver chloride and sodium nitrate. In practice it is not necessary to deal with exact equivalent proportions, it being sufficient to ensure an excess of silver nitrate strong enough to prevent stripping, and not strong enough to produce bronzing of the shadows to any appreciable extent. It has been pointed out in "Text-Books," "Lessons," and other places, what happens when silver chloride is exposed to light, and no doubt you are all familiar with the reaction from a practical point of view. We will suppose we are using a paper salted as above mentioned, viz., a paper coated with 6 grains of soluble chloride per ounce of albumen. We should make up the sensitizing bath at least five or six times that strength, say 40 grains of silver nitrate per fluid ounce of water. Half a gallon of this solution would give us a bath on which half a quire of paper could be sensitized. It would then be necessary to replenish with more silver, as about 290 grains of silver nitrate would have been converted into chloride, or absorbed in the paper. Other nitrates with silver are used by some printers, the principal being the nitrates of soda and potash. They are said to effect a saving of silver, but they are seldom used by practical printers. I have appended a formula which has worked well in my hands:—Nitrate of potash 35 grains, nitrate of silver 30 grains, water 1 ounce.

The time required for floating on such a bath will be from six to eight minutes, and ammonia fuming will be found advantageous when good results are desired. There is really no distinct advantage gained by the addition of any other substance to the silver solution. In proof of this statement, I now show you untoned prints sensitized on the following:—

Nitrate of silver	... 10 grains
Nitrate of potash	... 10 „
Sugar-candy	... 10 „
Water	... 1 ounce
Also	
Nitrate of silver	... 5 grains
Nitrate of potash	... 5 „
Sugar-candy	... 5 „
Water	... 1 ounce

The results are very little, if any, better than the prints shown from a weak, plain silver bath.

(*To be continued*).

Correspondence.

HYDROKINONE DEVELOPER.

SIR,—From what Mr. Pocklington says, I imagine his experience of his developer is in portraiture. I have attempted landscape and marine subjects, the latter instantaneous (so-called), with the result I stated: that I lost a great deal more in fixing with hypo. of the full strength, than I did with pyro developer, and consequently had a thin negative requiring intensifying. As a very old photographer, I am not given to under-development, and in the cases referred to the development was carried so far as to give a deep brown tint to the transparent parts of the negative, which cannot be wholly removed by clearing solution. I thank Mr. Pocklington for his formula, which I think the best of several I have tried. I may add, that so far as I have gone with hydrokinone, I believe it to admit of shorter exposure than any other developer I have used, and am consequently desirous of continuing to use it.—I am, sir, yours truly, G. ST. J. B.

PHOTOGRAPHY IN THE ULTRA-RED REGION.

SIR,—In reference to your note on page 25 of last week's NEWS regarding the interesting work of M. Henri Becquerel, permit me to say that several of the lines in the infra-red region of the spectrum due to metallic vapours were first noted by me in a paper to the Royal Society in 1881, and that many more have since been mapped by me from photographs. The absorptions by liquids in the same region can also be found in the Phil. Trans. of 1882 in a paper by Colonel Festing and myself. M. Becquerel's method of observation is most ingenious, but photography leaves it far behind, both for detail, sharpness, and, I may add, accuracy. With photography, the use of the high dispersive power of a closely-ruled grating is easy, whilst with phosphorescence the dispersion employed is of necessity small.—Yours faithfully, W. DE W. ABNEY.

A MODIFIED FERROUS-OXALATE DEVELOPER.

SIR,—Amongst many modified ferrous-oxalate developers I have experimented with during a prolonged series of experiments with developers in general, the following promises so well that I venture to ask you to allow me to submit it to your readers.

To one ounce of the usual ferrous oxalate developer add one drop of a saturated solution of biehloride of mercury. Fully, but not over-expose, and develop as usual. Wash well, and fix. The colour of the negative or transparency is a rich full black with clear shadows. For lantern transparencies on slow plates, the developer has in my hands given most excellent results.

I defer any statement as to the results obtained with other chlorides to a later period. HENRY POCKLINGTON.

HOW ENLARGEMENTS ARE SUPPLIED TO CO-OPERATIVE STORES.

DEAR SIR,—I am informed that a large wholesale firm of dealers in photographic materials has entered into arrangements with a well-known Co-operative Stores to supply them with finished enlargements, which are retailed by the Stores at an advance of 4s. on the wholesale price charged to the members of the profession. Now I should like to ask the profession, if they think that a wholesale house is acting fairly by them in thus indisputably taking away their most profitable work?

If my information be correct, I should surmise that photographers will not care to deal with those who, not satisfied with doing a wholesale business, seek to undersell the whole profession in this, and I firmly believe in every other branch of our business.—I am, dear sir, yours obediently, X. Y. Z.

January 12th.

GELATINO-STARCH EMULSION.

SIR,—In M. Vidal's letter in your last issue, I note that M. Audra has been experimenting with a gelatino-starch emulsion. In some experiments made about a year ago, I found that while the replacement in a gelatino-bromide emulsion of half of the gelatine by a small proportion of starch did not affect the sensitiveness, the resulting films were capable of being fixed and washed as quickly as those of collodion. I think, however, that for ordinary purposes, starch cannot be employed, as the "ground glass" appearance referred to by M. Audra always occurs in the resulting negatives. This granularity is due, no doubt, to the fact that starch paste is not a solution, but a suspension in water of the swollen granules.—Yours, &c.,

ARNOLD SPILLER.

Proceedings of Societies.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

At a meeting of this Society held on Thursday, the 10th inst., Mr. W. K. BURTON in the chair,

The CHAIRMAN, in a few introductory remarks, called upon Mr. W. M. Ashman, to deliver his lecturette on "Printing," this being the fourth of the series announced to be given at regular intervals (see page 42.)

The discussion on the subject was opened by the Chairman. He did not think any one believed preserved paper gave better results than freshly prepared, or as good. In common with many amateurs, he tried the method spoken of by the lecturer, and most or all of the published methods, but could not equal freshly prepared. In testing commercial papers, he could not get a trace of acid, and must say the secret of manufacture was well kept.

Mr. W. E. DEBENHAM considered it strange the secret should be kept back so long. Did Mr. Ashman fume the paper preserved on the bath recommended? In his experience, fumed paper discolours in the frames more readily than unfumed. Had the Chairman tried the perchloric acid method? It does not require fuming, is not acid, and will keep a year, giving a passable print not quite equal to freshly prepared paper.

The CHAIRMAN had not tried perchloric acid; he thought any volatile acid might answer.

Mr. F. YORK found many advantages in having a stock of sensitive paper always at hand. His practice was to stop printing on Saturdays, and make a stock of paper on that day. The paper is floated three minutes on a 60-grain neutral silver bath, followed by floating one minute on a 30-grain bath containing 5 grains per ounce of citric acid. There is no loss of silver in the second bath, but there is a loss of acid; for this reason he added 1 grain acid solution when required. The paper keeps a month; there is no difficulty in toning; if the prints were immersed, before toning, in a soda solution, 1 ounce to each gallon of water, he did not find fuming necessary.

Mr. A. L. HENDERSON disagreed with the lecturer on some points. He did not think there would be any gain in the proposed adoption of gelatine and collodion instead of albumen. Dr. Vogel, Mr. Cowan, and he (Mr. Henderson) had experimented in that direction. If the lecturer had gone a little further with his experiments, and saturated the five-grain silver solution with nitrate of potash, and fumed the paper, he would get rich prints and perfect coagulation of the albumen. In answer to Mr. Debenham, he found perchloric acid wanting. What was really required was a paper which, when preserved, can be worked in quantity as well as it does in an experiment with a few prints. He had succeeded very well with oxalate of ammonia and honey. In his experience, fumed paper kept better than unfumed. Paper could be preserved with as little as $\frac{1}{300}$ of a grain of citric acid per ounce.

The CHAIRMAN had no difficulty in working preserved paper in quantity.

Mr. W. M. AYRES showed some prints in fine condition toned by him twenty-two years ago by the lime and gold toning bath, the lime being in the proportion of 2 to 1 of gold; the fixing bath being 1 of hypo to 20 of water.

Mr. J. T. TAYLOR said it was due to Mr. Ayres to mention that he gave him some prints about that time, which are, at the present moment, about the best he possesses. Perhaps Mr. Ayres will say how he produced them?

Mr. AYRES said that the prints mentioned were toned and fixed at one operation—*i.e.*, the old hypo and gold process.

In the course of a general discussion on the merits of alkaline toning *versus* hypo and gold,

Mr. YORK said the uncertainty of the old process was due to continuing the toning action after the gold was exhausted, thereby toning by sulphur. The proper way to mix the bath is to dissolve 1 part of hypo in four parts of water; then add gold terchloride gradually to it.

Mr. F. W. HART was of Mr. York's opinion. If photographers would stick to fresh hypo, there would be less fading. He made it a practice to use a pint of every solution per sheet of paper. After several changes of water, the prints were passed through the eliminating solution, washed again, and dried, the whole operation occupying less than four hours.

Mr. W. T. WILKINSON adopted citric acid for preserving paper in India; when the air was very dry, he resorted to fuming.

Mr. W. H. PRESTWICH said no difficulty existed in toning preserved paper, if the prints are soaked in washing soda, as mentioned by Mr. York.

Mr. HENDERSON, referring to the sel d'or bath, said he used to put his prints into salt and water without washing, then into the hypo, and tone them afterwards; the results were more permanent than the present system.

Mr. W. COLES thought the discussion had not been confined to the subject, which did not include toning and fixing. He should like to ask the lecturer how best to vignette an under-exposed negative, and the best way of softening intense shadows; he used a board suspended from a roasting jack to get good blending.

Mr. ASHMAN, replying to Mr. Debenham, said he fumed the preserved paper before printing. Under ordinary circumstances, fumed paper would keep longer than unfumed. Replying to Mr. Cole, he said the distance between the opening and the negative would determine vignettes being well graduated or not. Under-exposed negatives requiring greater distance than those properly exposed, any semi-opaque colour could be applied on the back of the negative to block the intense shadows; tissue paper answered, so also would black varnish applied with an old stencil brush.

Mr. HENDERSON showed three negatives to illustrate the gain in speed of Mr. H. J. Newton's sal. soda developer with the mercuric iodide added, as already published. No. 1 plate exposed 2 seconds; No. 2, exposed 4 seconds; No. 3, exposed 4 seconds. No. 1 was quite equal to Nos. 2 and 3. They were developed as follows:—No 1. Ordinary sal. soda developer. No restrainer. 3 drops of mercuric iodide added. No. 2. Ordinary sal. soda developer. No restrainer. Without addition. No. 3. Ordinary ammonia pyro and potassium bromide. He considered the gain at least two to one.

Mr. HADDON asked if iodide of potassium alone would not answer as well. In developing gelatino-chloride plates with Dr. Eder's formulæ, if iodide of potassium is substituted for common salt, the image develops in a few seconds, instead of ten or twelve minutes.

Mr. HENDERSON had used a good deal of carbonate of ammonia in making emulsions lately. When filtered through wash leather, nothing particular was noticed, but if not passed through leather, there was a very fine sandy deposit. In the example shown, half the plate showed green fog; the other portion had been removed with hydrochloric acid and alum; the deposit could be distinctly seen in both portions.

A vote of thanks having been passed to the lecturer, it was announced that the next lecturette will be given by Mr. F. W. Hart, F.C.S., on "Residues," February 14th; the following by Mr. T. Bolas, F.C.S., on "Phototype Printing," March 13th.

PHOTOGRAPHIC SOCIETY OF IRELAND.

THE usual monthly meeting of this Society was held in the Royal College of Science, Stephen's Green, E., Mr. GREENWOOD PIM in the chair.

The minutes of the previous meeting having been read and confirmed, Messrs. Joseph Dollard, William Rigby, J. C. King, and P. Crosthwaite were elected members.

Mr. COWAN gave a most interesting account of his late visit to the Photographic Society of Great Britain's recent exhibition. He also passed round a number of copies of photographs there exhibited, those of Professor Donkin's Alpine views being particularly beautiful.

In the discussion which followed, Dr. PEARSALL thought that amateurs, as well as professionals, might learn a great deal from colour artists, in the way of producing picturesque as well as really artistic pictures, for, as he remarked often, by shifting the camera a little to one side or the other, and by using a little judgment in the choosing of the subject, very much better pictures would more often be seen than what we are accustomed to.

Mr. WATSON exhibited Messrs. Atkinsons' new camera and instantaneous shutter, which was kindly lent for the occasion.

The next meeting is intended to be held on February 8th.

GLASGOW AND WEST OF SCOTLAND AMATEUR PHOTOGRAPHIC ASSOCIATION.

A MEETING was held in the Religious Institution Rooms on Tuesday, January 8th, Mr. HUGH REID, President, in the chair.

After the reading of the minutes, the following new members were admitted:—Messrs. Ross, Wingate, Horsefield Bannerman, Barr, Smillie, Percy, and McKenzie.

Mr. W. SNELL ANDERSON was called upon to give a demonstration of enlarging on argentic gelatino-bromide paper. He employed an optical lantern fitted with a double wick lamp, and made two successful enlargements from half-plate negatives. The demonstration was watched with interest by a large attendance of members.

Mr. PARKER was then called to explain his sky-shade, which he said he had pleasure in doing on this occasion in order to call attention to an improvement that had been made on it by Mr. Skinner. The improvement consisted in replacing the brass collar fitting the hood of the lens, by a strong rubber band, by which means the shade could be fixed to any size of lens.

In reply to the President,

Mr. PARKER said that the exposure when using the shade was about doubled.

The PHOTOGRAPHIC NEWS and *British Journal* annuals, presented by the respective Editors, were laid upon the table.

It was intimated that at the February meeting Mr. T. N. Armstrong would give a demonstration of transparency printing and mounting on glass.

Votes of thanks having been awarded to Messrs. Anderson, Parker, and the Editors of the annuals, the meeting adjourned.

EDINBURGH PHOTOGRAPHIC SOCIETY.

THE third meeting of the session was held on Monday, 7th January, Mr. WILLIAM NEILSON, President, in the chair. The room was inconveniently crowded, between eighty and ninety members being present.

The minutes of the last meeting having been passed, the following were unanimously elected ordinary members:—Messrs. W. Adams, H. B. Melville, William Peek, William H. Muir, J. Clinton Nott, William Meikle, James Lessels, W. Cuthbertson, Andrew Paterson, and Miss Ann C. S. Calder.

Mr. H. H. PILLANS proposed:—That the Council be empowered to extend a sum, not exceeding £5 every year, in purchasing books towards forming a library for the Society. That the Council may suspend this payment any year they may think that the funds of the Society do not warrant such expenditure. That the Council determine what books shall be purchased, where kept, and how made available to members.

Mr. FRASER suggested that the Secretary might communicate with other societies in Edinburgh to bring about united action for the securing of suitable rooms where various bodies might hold their stated meetings, with accommodation for books, apparatus, &c., and a permanent caretaker.

Ultimately it was agreed, on the motion of Mr. J. HENDERSON, that the question of the rooms, &c., be referred to the Council with full powers.

Mr. HUME NISBET then delivered a lecture entitled "Camera-Lucida—Paletta Obscura: The Union of Painting and Photography" (see page 38). Mr. Nisbet illustrated his remarks by a number of photographs from various sources and by rapid charcoal sketching. The lecture was listened to with marked attention, and the beautiful word painting elicited frequent applause.

At its conclusion, the PRESIDENT said the Society was much obliged to Mr. Nisbet for his interesting and practical address, which was both instructive and suggestive. In some respects, however, he differed from what had been advanced. He was afraid that the painter who relied on photography would find that it tended to interfere with the freedom of his brush, and conduce to a mere hard rendering of details. Photography had its own province in black and white; but coloured canvas involved a different principle—the principle of selection. The

details of nature were grand by their dimensions; but if these were crowded into a small canvas they became paltry, not conveying a feeling of nature. The business of the painter was not to give a paltry imitation of nature, but to translate nature into art, by missing out non-essential details so as to enhance the leading features of the scene on which its character depended.

Mr. J. G. TUNNY said the meeting could not separate without according to Mr. Nisbet a hearty vote of thanks for his most interesting and instructive lecture. There must be few, if any, in the audience who had not felt their souls stirred by the graphic word-pictures that had been presented. The perusal of the lecture, he hoped, would make every photographer proud of his art, and awake in each a stronger ambition to realize the ideal he had placed before him; and he hoped it would also have the effect of lessening the unconcealed prejudice that is sometimes evinced against the productions of the camera by those who use exclusively the palette and the brush.

Dr. THOMPSON seconded the motion, which was carried with applause.

Mr. J. M. TURNBULL exhibited an ether generator, and Dickson's improved burner for the lantern.

Mr. J. CRIGHTON exhibited a large collection of photographs by Mr. Foster, of Coldstream. These were hung round the walls of the room, and were examined with great interest, Mr. Nisbet making use of many to illustrate his lecture.

A number of photographs by Messrs. Crighton, Matheson, Murray, and Dr. Sidey were distributed by ballot.

The attention of members was directed to the first "Popular" meeting, to be held on Wednesday, 23rd inst., and members were requested to send in their transparencies to the curator or secretary as soon as possible. None would be exhibited received after the 19th inst.

After a hearty vote of thanks to Mr. Turnbull, Mr. Crighton, the contributors to the ballot, and the chair, the meeting adjourned, to meet again in 5, St. Andrew Square, on Wednesday, 7th February.

HALIFAX PHOTOGRAPHIC SOCIETY.

THE monthly meeting of this Society was held on the 8th inst., Mr. BIRTWHISTLE in the chair.

After a lengthy discussion, it was unanimously decided that the proposed exhibition should be held as early as arrangements could be made, and a committee of management was appointed to settle all details.

The question-box was found to contain the following query: "The opinion of the Society is solicited as to the relative merits of ferrous oxalate on the one hand, and alkaline pyrogallic on the other, as developers, more especially bearing on the latitude each afforded for meeting the extremes of over- and under-exposure?"

Mr. Illingworth, Mr. Davis, and Mr. Smith (of Sowerby Bridge), in offering their opinions as professionals, concurred in giving preference to the alkaline pyro. developer, their experience being that if the exposure was not finely hit upon there would be a great difficulty in producing a good negative, and the loss of time involved under such circumstances meant to the professional money as well as inconvenience. When a plate required forcing, the results would be harsh and hard. Mr. Illingworth, however, found a great improvement in results, and a considerable lessening of this evil, when forcing had to be adopted, by reducing the ferrous salt and increasing the oxalate of potash. He was also under the impression that, up to a certain point, an under-exposed plate developed quicker with ferrous oxalate than with pyro., but beyond this much slower, and, as far as latitude was concerned, pyro. held the palm when taken as an all-round developer.

Mr. J. E. JONES believed that when strong contrasts of light and shade were desirable—"à la Rembrandt" for instance—ferrous oxalate was the best, but pinned his faith to pyro. for general purposes.

Mr. GLEDHILL liked pyro. best because of the greater latitude it afforded by modification, but when good blacks were required, as in the case of transparencies for the lantern, then ferrous oxalate was to be recommended.

Mr. BULMER had heard a deal said about pyro. staining, but he could get as clean and bright negatives with pyro. as it was possible to do with ferrous oxalate. Most advocates of the iron developer referred to the staining question as being an evil inseparable from the use of pyro. Stains could be produced with any developer if not used intelligently. He was not prejudiced against ferrous oxalate, but preferred pyro. on account of the great power it afforded for regulating the character of negative.

Mr. Councillor SMITH well knew there would always be exponents of, or partizans of, both sides of the pyro. and iron question, and it was only natural that parties should uphold and praise the one that pleased them the most. He would point to the striking fact that on the Continent ferrous oxalate reigned supreme as a developer, being used daily by a large body of workers eminent in their profession, and there could be no question that France, Germany, and Italy could compete favourably with the very best results produced in England. He was sure the iron developer was but imperfectly understood on this side of the Channel. One of the chief causes of failure was owing to development being stopped too soon; he always allowed it to proceed until all trace of a picture had become lost to sight when viewed by reflected light; in fact, the plate should appear "dense to blackness." When fixed, such pictures would be found to possess all the qualities necessary for a good negative. Possibly many who tried the ferrous oxalate developer in its early days condemned it without sufficient trial, and he ventured to think that if it had received the same amount of study or attention conferred upon pyro., it would to-day have held the place of honour in the first rank of developers. As regards latitude, he claimed for it anything that could be conceeded for the alkaline method. Dr. Eder, and other eminent scientists, distinctly stated that any amount of latitude was obtainable, and if he (Mr. Smith) erred in this, his own views of the question, he did so in good company. Dr. Eder's formula for his concentrated iron developer gave as much latitude for forcing as ammonia did, and that without its drawbacks. He remembered the suggestion thrown out some time ago by Mr. Williams, that two plates should be selected of exactly the same description, and exposed under the same conditions—or, rather, under-exposed—and then developed with iron and pyro. respectively. He thought this would prove of practical value if followed; the result, he was sure, would remove much misconception. The proportion he generally adopted was 1 part of iron solution to 4 parts of oxalate of potash solution, varying it at times to 1 to 3. He began development by using very little iron, gradually adding more as the action proceeded, removing the plate as each addition was made. For bromo-argentic paper, he used ½-ounce of iron solution to 3½ ounces of the oxalate, the whole added to about 24 ounces of water. Referring to Mr. Gledhill's remarks, he thought the colour of a transparency depended as much on the character of the plate as on the developer. He had obtained beautiful warm browns with ferrous oxalate. He had tried Newton's washing-soda developer, but had not succeeded in getting negatives free from a general yellow cast of stain, which deepened if any forcing was resorted to.

Mr. BIRTWHISTLE agreed with all Mr. Smith had said in favour of the iron developer. It was a magnificent discovery, and, he believed, the developer of the future. He had never found it weak, although he used only one part of iron solution to eight of oxalate. He liked slow development, and often got the best results by first bringing out the details with an old and previously used developer, and finishing off with a new one. He believed the real meaning and bearing of a "saturated" solution was only imperfectly understood, and did not think the mere dissolving the oxalate or iron until crystals remained deposited, was a saturated solution giving the greatest concentrated developing energy possible. The addition of citric acid was a grand step forward, altering all this wonderfully. If both solutions were not properly saturated, a precipitate would be the result directly they came together, which would detract from its developing power.

Mr. W. C. WILLIAMS, while acknowledging he had not given Dr. Eder's latest formula a trial, and conceding a high place to the iron developer, still felt bound, by his past experiences, to give his verdict in favour of alkaline pyro. He agreed with the previous speakers who attributed a greater latitude to pyro., but although this was a great power to recommend a system, he was afraid undue prominence had been given to it. He believed that iron had a stronger proportionate affinity or energy for developing the higher lights, and rapidly bringing these out, than for parts acted upon more feebly by light, and consequently a want of roundness and softness follows its use. With pyro., the case being different, the high-lights and deep shadows are brought forward more regularly, and in harmony with one another—this irregularity of action or special affinity being marked in other chemical operations in connection with photography. He quite agreed with slow development, and this was his invariable rule, but always liked to complete development on the same day of the month it was commenced, which did not happen on one occasion when using ferrous oxalate. When using pyro., and under-exposure was suspected, a preliminary soaking of the plate in a 4-grain solution of pyro. having the least possible trace of

ammonia, but no bromide, previous to the development proper, would be found advantageous at other times. Soaking the plate in ammonia solution, and after washing in pyro. with a trace of bromide, is another good plan. For many years he had used glycerine and water to soak plates in for about ten minutes before developing, which prepared it for the even and rapid action of the developer, and so prevented any undue proportion of ammonia being used.

The thanks of the Society was then passed unanimously to the PHOTOGRAPHIC NEWS and YEAR-BOOK, also to the proprietors of the *British Journal* for the gift of Year-Book and Almanac, and a very interesting meeting was brought to a close.

NEWCASTLE-ON-TYNE AND NORTHERN COUNTIES' PHOTOGRAPHIC ASSOCIATION.

THE annual meeting of the above Association was held in the College of Physical Science, Newcastle-on-Tyne, on Tuesday, the 8th instant, Mr. JAMES DOWNEY in the chair.

The third annual report was read by the Secretary as follows :—

Your Council have pleasure in offering to you the third annual report. The past year has been a busy and prosperous one. Since the last report was issued, four members have resigned, and five names have been removed from the books. The Society now numbers 81 members. Eleven gentlemen have joined during the year. The ordinary monthly meetings have been well attended. Four out-door meetings were held, and were very successful; Mr. Maling's kind offer of a medal contributing largely to this result. Three practical demonstrations have been given, and two lantern demonstrations. These were highly appreciated. The success of the Society's exhibition, held in the Central Exchange Art Gallery, was well assured—the list of contributors containing, as it did, the names of numerous well-known prize-winners. The Exhibition was highly spoken of by the local press and by the photographic journals. The best thanks of the Association are due to the Council of the College of Physical Science for placing their rooms at our service; to the Rev. T. F. Hardwich, Messrs. Edgar Goold, Thomas M. Laws, J. B. Payne, J. Pike (two), Lyddel Sawyer (two), and A. A. Campbell Swinton for the contribution of papers; also to the President, Mr. R. Jobling, and Mr. George Spruce for acting as judges at the Exhibition. Your Council trust that a liberal supply of papers will be forthcoming at the ensuing meetings, and rely on your generous support and assistance.

The TREASURER (Mr. P. M. Laws), on presenting the financial statement, said it was satisfactory, considering the severe strain there had been upon the funds, to be able to show a balance on the right side at all. Not only had the expenses incidental to the Exhibition to be met, but the presentation prints for the preceding year had to be paid for. To defray the cost of the latter alone the balance of 1882 was reduced to less than five pounds. The entire cost of the Exhibition was £31 1s. 5d., and when the sum realised by advertisements in the catalogue was deducted, the actual disbursement for the Exhibition was £24 8s. 4d. As a set-off against these two items in the balance sheet, each member received, for 1882, a print nearly, if not quite, equal in value to his annual subscription; whilst for last year members received an exhibition ticket entitling them to a fortnight's free admission to the Art Gallery. The balance-sheet shows an advance of eight subscriptions over last year; and three more were received after the accounts were audited. There were still, however, six subscriptions in arrears. All things considered, the Association was financially in a very satisfactory position, there being a small balance on the right side.

The reports were favourably criticised and unanimously passed.

Mr. J. P. GIBSON proposed in eulogistic terms a vote of thanks to the Secretary and Treasurer.

After remarks by Mr. Sawyer and the Chairman the vote was carried with acclamation, as were also thanks to the President, the Auditor, and the Exhibition Sub-Committee.

The CHAIRMAN presented to the Association, on behalf of Colonel Sheppee, a handsome portfolio.

The SECRETARY was requested to convey the thanks of the Association to Col. Sheppee for his useful and much-wanted gift.

The scrutineers (Messrs. T. M. Laws, Ridley, and Gray) appointed to examine the voting papers reported the result of their investigation as appended :—

President—Col. Sheppee.

Vice-Presidents—Prof. A. S. Herschel and Prof. P. Bedson.

Hon. Treasurer—Mr. P. M. Laws.

Council—Messrs. Auty, Dodds, Downey, Gibson, Goold, Galloway, Payne, Maling, Ridley, and Sawyer.

Hon. Secretary—Mr. J. Pike, 11, Grey Street, Newcastle.

Auditor—Mr. E. Schnmann.

In accordance with notice given at the previous meeting, the HON. SECRETARY moved to alter rule 61 by making the subscription for ladies 5s. per annum, and said that his object was to increase the number of members, to assist the funds, and to make the Association more social in character. Of course such lady-members would receive presentation prints and be on the same footing as other members, except with regard to holding office. The motion was, after some little discussion, passed.

The adjourned discussion of Mr. A. C. Swinton's paper, entitled "The Past, Present, and Future of Photography in Natural Colours," read before the Association December 11th, 1883, was opened by the SECRETARY, and was sustained with much animation by Messrs. Gibson, Downey, Pae, Sawyer, Laws, Swinton, and other gentlemen. At the suggestion of Mr. J. P. Gibson the discussion was again adjourned, pending the result of some promised further discussion.

LEEDS PHOTOGRAPHIC SOCIETY.

THE usual monthly meeting was held on January 10th, at the Philosophical Hall.

Professor THORPE, F.R.S., occupied the chair, and in the course of his presidential address, said that the extraordinary development of photography in these latter-day dry-plate days, and the extent to which the art was intelligently practised by scores of people to whom it was the chief occupation of leisure hours, seemed to many sufficient reason for the establishment of a Photographic Society. Leeds was among the earliest of the towns in which the process of Daguerre gained a habitation. To the late Mr Huggon must be given the credit of being the first resident portrait photographer in the town. That gentleman taught and spread a knowledge of the process. More than thirty years ago a small band of enthusiastic workers, including Messrs. Wm. Fieldhouse, Wm. Gardham, Wm. Halliday, Thos. Briggs, Thos. Dixon, Thos. Hope, R. J. Fowler, Wm. Pumphrey (of York), and Henry Brady, F.R.S., centred round the vice-president (Mr. J. W. Ramsden), and, thanks to his liberality, the Yorkshire College possessed a number of the results of the efforts of the first Photographic Society of Leeds. This Society seemed to have been comparatively short-lived, and to have become merged in a general scientific society. The photographic section of this Society lost its independent existence on the creation of the Photographic Society of London. Under the leadership of Mr. Teasdale, the Leeds Society was resuscitated about two years ago as a section of the local Natural History Society, and from that had sprung the present body. Of the vitality of this organisation the newly-elected President had little doubt. Its members already numbered more than fifty, and included most of the best-known amateur and many leading professional photographers in the district. Having given this brief sketch of the rise and progress of photographic societies in Leeds, Professor Thorpe delivered an interesting address, whose object was to further the scientific and experimental side of the art, and to show how fruitful and promising is this department of chemical-physics. There was much in the early work of photography which, read in the light of to-day, merited intelligent examination. Many of the earlier methods were still worthy of attention; indeed, some of them were capable of affording results which, in point of artistic merit and technical excellence, were hardly surpassed by the productions of our modern processes. Any association that would make pretensions to be a photographic society in a real and complete sense should never lose sight of the fact that, of all the pictorial arts, photography had the most direct and immediate connection with physical science. Photography was essentially a branch of applied chemistry and physics. Everybody recognised this, yet little was done towards the solution of many of the problems which were essentially connected with the scientific or theoretic side of photography. For example, practically nothing was known beyond the fact of the phenomenon that a gelatino-bromide plate, after exposure, will, if kept in the dark, gradually lose the impress which is called the latent image. There was in fact, no lack of questions relating to the scientific, and especially the chemical side of photography, many of which might be answered by systematic experiment. There was the perennial question of canary *versus* ruby medium, the influence of thick and thin films of gelatine, and the causes which determine the deterioration of plates. After giving other instances wherein experiment and research might be rewarded, the President pointed out that the number of scientific workers in photography

was really very small. The field was still open, and rich in promise to the intelligent worker. In no branch of science could results be more easily got; the returns and the profits were equally quick and great. Some there were who looked upon photography as a mere pictorial art, and had scant sympathy with the scientific aspect of their work. To these gentlemen the Society was ready to give every appreciation, while welcoming among them all who were willing to contribute to the systematic and scientific development of the art.

BRISTOL AND WEST OF ENGLAND AMATEUR PHOTOGRAPHIC ASSOCIATION.

THE deferred annual meeting was held on Saturday, December 1st, at the Association's Studio, Portland Street, Kingsdown, Mr. T. DAVEY, vice-president, in the chair.

The previous meeting's minutes having been confirmed,

The TREASURER (Mr. C. Brightman) read the accounts and balance sheet, which showed the Association to be in a healthy financial condition.

The HON. SECRETARY (Mr. H. A. Hood Daniel) stated that the next business was the election of officers.

Col. PLAYFAIR suggested that it might save time to re-elect all the officers together; but as there seemed to be a feeling that it would be better to elect each officer separately, that plan was adopted, with the following result:—

President—Mr. T. Davey.

Vice-presidents—Rev. W. J. Whiting and Col. Playfair.

Treasurer—Mr. E. Brightman.

Hon. Secretary—Mr. H. A. Hood Daniel.

One of the existing vacancies on the council was filled by the election of Mr. J. Phillips.

The meeting then formed itself into committee, and discussed the extensive arrangements requisite to be made for the successful carrying out of the International Photographic Exhibition, with regard to which the report given by the Hon. Secretary was of a very satisfactory nature, especially with reference to the foreign exhibits, and the gentlemen who had kindly signified their willingness to act as jurors.

Talk in the Studio.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN. — The next mid-monthly meeting of this Society will take place on Tuesday next, January 22nd, at 8 p.m., at the Gallery, 5A, Pall Mall East.

A PHOTOGRAPHIC ACTION.—At the Metropolitan County Court of Bloomsbury, on the 15th inst., the case of Ashber *v.* Clark was heard before Mr. Judge Bacon, the plaintiff and defendant being both photographers. The action was brought by the plaintiff to recover the sum of £12 15s. under the following circumstances. From the plaintiff's evidence, it transpired that in May, 1882, he lent the defendant, who was anxious to take some large heads, a camera with lenses for that purpose, and although he had made repeated applications to the defendant for its return, he had failed to obtain it, and, in consequence, was obliged to bring the present action to recover its value. In reply to the learned judge, the plaintiff said that the camera originally cost him £12 10s., but he had expended more money on having extra fronts to receive other lenses for it. The plaintiff's solicitor produced letters written by the defendant promising to return the camera in June last, but he had never done so. The plaintiff said, in consequence of the inconvenience he had been put to, he had to purchase another instrument, which cost him £9 10s. He was of opinion that the defendant had pawned the camera, and he offered to redeem it if he would give him the duplicate, but he could not obtain even that. At this stage of the case, the learned judge said the plaintiff was clearly entitled to judgment for the full amount claimed, with costs on that amount. Judgment was entered accordingly.

THE ALLEGED DECOMPOSITION OF PHOSPHOROUS ANHYDRIDE BY SUNLIGHT. - Messrs. Cowper and Lewes have made a series of experiments which lead them to conclude that the results obtained by Irving are consequent upon the use of an impure phosphorous anhydride, it being apparently contaminated with minute crystals of phosphorous; and the darkening observed on its exposure to light doubtless arises from the conversion of this phosphorous into the amorphous variety.

PHOTOGRAPHIC CLUB.—At the next meeting of this Club, on Wednesday, January 23rd, the subject for discussion will be "On the Preparation of Cloud Negatives, and Using Them."

To Correspondents.

MAJOR-GENERAL P.—1. Gas or candle flame may very well be trusted for sensitizing. Thank you for suggestion, which we will certainly act upon.

CHAS. G. WILLIAMS.—A method based upon the principle you refer to is not likely to prove satisfactory, but you may gather all the information you desire from an article on page 402 of our last volume.

STAINS.—It seems to us that it is a consequence of an inequality in the albumen coating. Try another sample of paper.

T. LEWIS.—1. We should advise you not to allow less than an inch between them. 2. They arise from the use of an unsuitable gelatine. Try Nelson's X opaque.

J. H. W. B.—We should advise you to communicate with Captain Abney. A letter addressed to the Science and Art Department, South Kensington, will reach him.

A. G. LEVY.—It has been too long in the developer. You should have given double the exposure.

SOUTH DEVON.—The term is generally applied to gelatine containing a soluble bichromate, such as the bichromate of potassium or ammonium, and we may mention the following as examples of its use. A sheet of gelatine is soaked in a 5 per cent. solution of potassium bichromate until it is flaccid, after which it is carefully laid on a sheet of glass and rapidly dried. Such a film, if exposed under a negative, loses its property of swelling in water where acted upon by light, and if the exposed film is soaked in water, a picture is obtained in relief. Take another example. Six parts of gelatine and one of bichromate of ammonium are dissolved in thirty parts of water by the aid of heat, and a layer of the mixture is allowed to dry on a levelled glass plate. When exposed and soaked, the plate may form the matrix upon which copper is deposited by the electrotype process. Printing plates are often made by methods of this character.

EDWIN GRANT.—About two ounces of water will be taken up by the gelatine, and this will be found sufficient to reduce the emulsion to a convenient consistency for working.

ALFRED M. SHARP.—1. The difference probably arises from the fact that cold solutions soften the gelatine film much more slowly than warm liquids, and, under the circumstances, we should prefer to increase the ammonia rather than reduce the amount of bromide. It is not likely that anything was wrong with the sample of ruby glass, but you probably expected too much of it. You will see a note about the use of cherry fabric and white tissue paper in another part of the NEWS.

F. G. M.—Thank you; we shall be very pleased to see it.

E. WILLIAMS.—Decidedly make a claim upon the publishers. Mention that you have proof which you can supply them with; that the illustrations are taken from your work. You seem to have a very good case.

H. SPINK and W. K.—Mr. Oborne, of Red Lion Square, supplies earthenware washing troughs, grooved.

IRON.—Under the exceptional circumstances to which you refer, we should advise you to make a contact transparency on a gelatine plate, and to intensify this. From the intensified transparency you will obtain a reproduced negative.

R. W.—It is cheaper than the ordinary lantern, but we should certainly not regard it as better.

REV. H. B. HARE.—We have forwarded it.

The Photographic News Registry.

Employment Wanted.

Salesman to photo. & frame makers.—L. W., 18, Plantation-rd, Oxford.
Operator, colourist, &c.—S. George, Sherwood-villa, Brunswick-pk., N.
Neg. Retoucher, lady.—M. F., Gaskell's, 15, Sussex-rd., S. Kensington.
Reception-Room or Shop.—C. M., 2, Dover-ter., Dover-st., Sittingbourne.
Retoucher, Lady, first-class.—E. M., *Photo. News* Office.
Spotter & Mounter.—Miss Stewart, 2, Albany-ter., Bournemouth.
Retoucher & Spotter.—L. F., 30, Swanmore-rd., Isle-of-Wight.
Silver Printer, first-class.—F. G., *Photo. News* Office.
Reception-Room, Lady.—F. W., 16, Chryssell-rd., Brixton.
Retoucher (Lond. only), c/o. J. S. Cockerton, 2, Hanover-pl., Regent's-pk.
Retoucher & Assistant Operator.—Artist, 19, Waterloo-st., Southsea, Hants
Carbon Enlarger, Painter, &c.—G. Fischer, 54, Berners-st., W.
Recep. room and manage (Lady).—Rembrandt, 5, High-st., Ryde, I.W.
Retoucher, work-up black-and-white (Lady).—W. J., *Photo. News* Office.
Operator, manager.—A. E. Walker, 118, Abbeyfield-rd, Pittsmoor, Sheffield
Operator or manager.—W. D., 2, Nursery-vils, Bounds-grn, New Southgate

Employment Offered.

Fitters, artificial light apparatus.—Luxograph Co., North-end, Croydon.
Learner, for retouch.—N. M., c/o. Shew & Co., Wardour-st., Oxford-st., W.
Operator, first-class, & to retouch.—Hodson, 8, Market-pl., Retford.
Enlarger for general work.—D. S., *Photo. News* Office.
Dry-plate man, first-class.—Dry plate, 37, Thornton-st., Brixton.
Operator and retoucher.—F. Baum, c/o Disderi & Co., 4, Brook-st., W.

VOL. XXVIII. No. 1325.—*January* 25, 1884.

CONTENTS.

A NEW PLAN OF REDUCING THE INTENSITY OF GELATINE NEGATIVES.

MANY methods have been proposed for reducing the intensity of too powerfully developed negatives, which have thus become too dense. Some of these—as, for instance, perchloride of iron and iodine—attack the shadows rather too vigorously, and hence require to be used with much discretion; but still they have found advocates among practical men. Others use chloride of copper (or, what amounts to the same thing, a mixture of sulphate of copper and chloride of sodium). In this process, the copper chloride forms a thin film of chloride of silver, while subchloride of copper is precipitated. Subsequent treatment of the negative with hyposulphite of soda solution dissolves this chloride of silver, and leaves behind a thinner film of silver.

Herr L. Belitzki, of Nordhausen, has recently brought forward another weakening method, which is particularly suitable for negatives developed with ferrous oxalate. It is based upon the observation that the green crystals which are formed in all old oxalate developers, if dissolved in hyposulphite of soda solution, form a ready means of reducing too dense negatives which have not been intensified.

The pure solution of the green double oxalate of iron and potash will not attack silver, and, therefore, even if left for hours in contact with a negative, will not weaken the film.

But a mixture of the double oxalate of iron and potash with hyposulphite of soda does attack silver, the iron salt yielding up its oxygen to the silver, and forming silver oxide, which in a nascent condition is at once dissolved by the hyposulphite.

Herr Belitzki dissolves from 5 to 10 parts of the green double salt in 100 parts of hyposulphite solution freshly prepared (ordinary concentration); but as he prefers to make use first of all of a weak solution, only five per cent. of the green double salt is employed to commence with. The mixture is employed in daylight; it is poured into a dish, and the fixed negative, which need not be washed, is then put in, and taken out from time to time to be examined as a transparency. As the weakening of the negative goes on for a little while after it is put into water and washed, Belitzki recommends that the film be removed from the bath before it is quite thin enough.

The mixture of the green double salt and hyposulphite of soda may be preserved in a dark place most perfectly, and can be used again and again. As soon as a yellow precipitate makes itself seen, the liquid should be filtered, and when it gets too weak, it is strengthened by the addition of a few more crystals of the green salt. That a portion of a negative may be reduced in intensity with the solution is but a matter of course, a pipette or brush being used for the purpose. The stronger mixture, containing ten per cent. of double salt, may be employed for taking stains out of linen, shirt-cuffs, &c.

This observation of Beli zki's at once explains how it is that negatives developed in old and often-used ferrous oxalate solution have usually such thin films. It teaches us, therefore, that all who develop with ferrous oxalate should always employ freshly-prepared solutions; too much density can always be cured afterwards in the way we have just shown.

DIFFUSED LIGHT IN THE DARK-ROOM.

A FORTNIGHT since, we described some experiments undertaken to secure a pleasant and safe light for the developing room, and we showed that an ordinary fish-tail gas-burner at a yard distance could be trusted for the space of two minutes behind a screen of:

1. Four sheets of "stout buff" paper.
2. Three sheets of lumberhand paper.
3. One sheet of thick Harvey Reynolds yellow paper.
4. A sheet of orange glass and a sheet of ground glass.

As daylight varies so much from time to time, there cannot be a doubt as to the advantage of employing artificial light for developing; and certainly one of the best methods of dark-room illumination is to have the flame outside the room, although controlled from the inside. All vapours and gases are thus excluded from the apartment in which the photographer finds himself.

There is no difficulty about adapting the orange and ground glass window to any artificial light, and by making use of an additional orange plate and a second ground glass any ordinary source of illumination may be so tempered as to be perfectly safe within twelve or eighteen inches of a plate.

Still, there cannot be a doubt as to the comfort of daylight as an illuminaut; and as most dark rooms get their light in this way, we have made a few experiments with orange and ground glass to ascertain how these can be safely applied to such apartments. No one is likely to have the full glare of the sun falling upon his dark-room window, so we did not start with these conditions. We took for our experiment a developing room having windows looking into a well-lighted studio, the windows in question measuring 24 inches by 30 inches. These were glazed with a single sheet of orange and ground glass, with the result that the so-called dark-room became almost as light as the studio adjoining.

A plate exposed (covered with a strip of cardboard) for two minutes in this room, one yard from the windows, showed very distinct traces of light.

Half the window was now temporarily blocked up with a deal board, and the other half covered with a second sheet of orange glass. There was now a window measuring 24 inches by 15 inches, of tolerably large dimensions, therefore, which was glazed with two sheets of orange glass, and one sheet of ground glass.

A plate was put into a dark slide, and placed six inches from the window; the slide was pulled up one-third for a quarter of a minute, and at the lapse of this time, pulled up two-thirds for half-a-minute. Afterwards it was developed, one-third of it having been exposed forty-five seconds, and a second third thirty seconds, within six inches of the window: the plate developed clean.

A plate exposed in the room for sixty seconds at a distance of one yard from the window, also developed clean.

There was no doubt, therefore, that the pleasant yellow light afforded in these circumstances was perfectly safe. In case of a casual increase in the light, a curtain of tammy would, doubtless, furnish any further protection that might be necessary.

A further experiment may be mentioned, however, which will show how much more light may be employed with a little judgment. The board blocking up half the casement was taken down, and now, in addition to the former window, there was another equally large (24″ × 15″) glazed with a single orange and ground glass, and admitting therefrom a vastly increased amount of light. A plate was taken out of a dark slide, and a strip of cardboard held against it, at the back of the dark room, at a distance of five feet from the window (where you might have easily seen to read a newspaper), and kept in this way for thirty seconds prior to its development. The experiment, which may be said to resemble the work of a clumsy operator, proved successful, for the plate developed clean. We cannot help thinking, therefore, that for a developing room, ruby light is not actually necessary; if your yellow light is too powerful at any time, temper it by adding another sheet of orange glass, or by employing, as in the old wet process, a curtain of tammy.

THE ELECTRIC SPARK CONSIDERED AS A STANDARD LIGHT.

SECOND ARTICLE.—THE VOSS ELECTRICAL MACHINE.

THE Voss machine differs from the older types of electrical machines inasmuch as its action is not dependent upon friction, but it acts simply by induction, in a manner analogous to the induced and accumulated energy developed in the dynamo-electric machine. In the dynamo there lurks a minute initial charge of magnetism, which sets up a current in the armature when that is revolved, and this current intensifies the magnetic field until its utmost limit is reached. So in the "induction" or "influence" machines of Holtz and Voss, the small initial charge present can by mechanical force be caused to accumulate until the potential reaches the limit of the resistance of the circuit.

The machine we shall now describe has a mahogany polished base-board standing on feet, and at the right-hand side there slides out a bar of wood, carrying a pillar of wood, through which passes a brass tube to serve as the bearing of the spindle of the driving pulley, round which passes the driving cord, whose tension is kept up by sliding out and clamping the slotted bar. At the back of the base-board a strong wood pillar is firmly fixed, and this serves to carry the axle of the revolving plate. There are two glass plates; the larger, A, is 12½ inches diameter, and has a hole 2¾ inches diameter. This plate rests on an ebonite rod let into the back pillar, and upon two small ebonite feet screwed into the base-board. The edges of the glass are nicely smoothed, and on the farthest side there are pasted four discs of tinfoil connected in pairs by a strip of foil, as shown at F F. Over these discs two paper shields, B, are pasted, and each pair is also connected by foil with the elbow-shaped brush-holders, H H.

The moving plate is 10¼ inches diameter, and has a hole in its centre for mounting it on the axis. On the face nearest us there are fixed six discs of tinfoil, D, and on each disc is cemented a metallic button. The two plates, one fixed and the other moving, are mounted about a quarter of an inch apart, and it is this air-space that constitutes the induction field between the discs on the two plates. The moving plate is insulated by ebonite from the axis on which it turns. The collectors E E are fixed on to the end of the axis nearest, and are prolonged to the dischargers C C, which rest upon the two small Leyden jars L L, whose outside coatings are connected by a wire beneath the base-board. The upright set of combs shown in the sketch are more correctly termed neutralizers, and serve to discharge the moving plate of any residual charge not taken up by the collectors before the discs on plate come under the influence of the opposite set of discs on the inducing plate. In practice this neutralizer is placed with its upper part more inclined towards the left, and towards the discs F. The brushes H H are bent so that they just tip the metallic buttons on the face of the revolving plate.

The plates and the jars are carefully coated with thin shellac varnish. The machine described is the smallest size usually made, and is not expensive. A far better insight than any written description can be obtained by procuring one of the machines and taking it asunder and then replacing it, and by studying its form and action much will be learned of its principle which would be difficult to convey in a few pages of the NEWS.

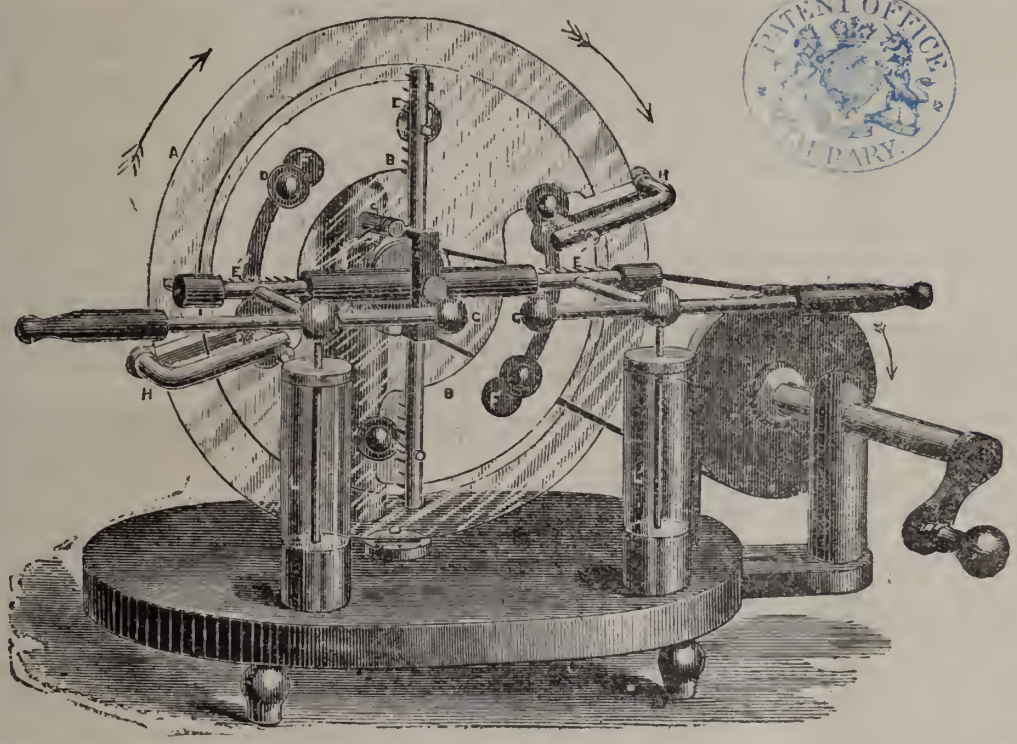
The machine can be used to work vacuum tubes, for which purpose it performs remarkably well—better, we think, than the induction coil. The method of using the machine is as follows:—

A dry and preferably warm room is desirable. In summer the machine will not require so close an observance of this as in winter, when, upon days like last Christmas Day and Boxing Day, the atmosphere everywhere is charged with moisture; this necessitates the warming and drying of the machine, just to dissipate the invisible film of damp which condenses on the glass plates. A film of moisture conducts the electricity away as fast as it is evolved, as may be easily seen by breathing on the plates when the machine is in action; this causes the "current" to cease or reverse its polarity. The machine should be clean—*i.e.*, free from dust—for when a machine is used, so long as it is in an excited condition, it attracts all the dust of the apartment, so much so as to become quite coated over with a black film of dirt, which, of course, interferes with its perfect performance. When cleaning the machine there need be no hesitation in using a damp cloth if afterwards the machine be set near a fire or stove so as to dispel the moisture. As soon as the plates become dry and warm, the machine will perform without any delay; whenever a machine refuses to "take," it may be certain that there is moisture, dirt, or damp somewhere. On dry, frosty days, the machine will usually respond directly, even after standing all night in a cool room, for then no doubt the moisture of the apartment has become condensed upon the windows, especially if the temperature outside is much lower than inside.

The machine being dry and the apartment warm, on turning the handle according to the natural order of things—viz., from left to right in the direction of the hands of a clock—we soon see or hear the machine "take," and the sparks pass between the knobs of the discharger. In a dark-room the whole machine seems alive; it is a beautiful sight to see the violet streams of fire flowing towards the collectors of the discharger, and if we slacken the rate of turning we see the machine "reverse," especially if the distance between the knobs be great, such

as 4½ inches, the maximum length of spark we have been able to obtain with the machine described. If the knobs be drawn beyond one inch apart, the spark is no longer straight, but becomes more or less forked, like lightning, and often the spark traverses a zig-zag path equal to double the distance between the knobs. When the machine is thus strained it would be exceedingly dangerous to interpose the person so as to receive the full force of a discharge of such high tension. A few shocks and smart twinges will soon teach the operator what to touch and what to avoid. Let us now approach the knobs to within one inch of each other, and fix them there so that they will not shake by the jarring of the machine in action; then study the spark at one inch, and observe how very similar each spark is to its precursor.

Now let us remove the two jars which support the right and left halves of the discharger: on revolving the plate, the spark between the knobs is no longer luminous, but appears to be composed of a bundle of thin thready violet-tinted sparks, which convey to the mind the impression that the discharge between the knobs is really a "current," and such we believe it to be. The actinic force of this discharge is extremely low, and proves that the capacity for charge of the machine *per se* may be ignored in our



PATENT OFFICE
LIBRARY.

calculations of the luminous effects to be employed when the machine is used in its normal state, or under a modified form we shall presently point out.

If we place a piece of plain glass, say a quarter-plate, on each of the brass dics from which the jars were removed, and on each piece of glass place a shilling, and connect the shillings with the arms of the discharger by two straight pieces of brass wire, we thereby make two miniature Leyden-jars, in fact, whose surfaces are not above one-fifth of the jars proper. On turning the handle of the machine, we get sparks decidedly more luminous than when no plates were used.

If we replace the shillings by half-crown pieces, we obtain a marked increase in the brilliancy of the spark. This all proves that it is the storage capacity of the jars which influences the luminosity of our spark.

Let us now take two pieces of rather thin glass, say five inches square, and cut four pieces of tin-foil exactly three inches square, and with paste fix a piece on either side of each pane of glass, leaving an inch of margin round each piece of foil. When dry, clean both sides and give each pane a coat of thin shellac varnish, made by dissolving shellac in ordinary "finish" or spirits. We have now made what are termed "fulminating panes," which are really the coatings of Leyden-jars spread out. It is exceedingly difficult to measure the area of the inside and outside coatings of two small jars, but with our two pieces of thin glass the difficulty vanishes, for we can cut our tinfoils exactly three inches square to a hair's breadth; and here, be it understood, is one of the strongest points of our claim to a standard, for what can be more definite than such data as these?

We will now place our two standard panes on the place usually occupied by the jars, and connect their upper sides with the two brass wires to the discharger. On operating the machine, we obtain sparks closely resembling the jar spark, but we have definitely fixed the unit of surface—viz., three inches square.

The law which operates upon this matter is very clear. The limit of charge of given surfaces depends upon the potential of the machine, and the substance of the dielectric (the glass); but these limits are not strained where the striking distance (the length of spark) is small. For small distances, the striking distance is directly proportional to the quantity of electricity, and inversely proportional to the extent of the coated surfaces; in other words, it is proportional to the electric density. The luminosity, also, is chiefly dependent upon the electric density (limited by the area of the condensers), and is influenced by the nature of the bodies between which the spark passes, the atmosphere, and barometric pressure.

Practically, most of these conditions do not influence the result if we work with a view to uniformity, because, with a machine made to gauge, the atmospheric density is about the only really disturbing element likely to interfere.

For the sake of simplicity and uniformity, therefore, we advocate a standard machine, the plates of which can be made to gauge, the brasswork also to patterns, interchange-

able, and, in fact, the whole affair just like so many bullets cast from one mould; the chief care being devoted to the specific inductive capacity of the condensers, and the coated area. Brass may be safely relied upon as a pretty constant article for the metal parts of the machine, and such matters as residual charge and atmospheric pressure may be disregarded. The rest are merely matters of detail.

The data now given will bear examination from a practical, as well as a theoretical, point of view. In the use of the phosphorescent tablet, vast errors may arise in exciting the tablet, but still more seriously in fixing the period between the end of excitation (the period during which the most rapid decline occurs in the luminous surface), and the commencement of the luminous action upon the sensitive plate behind the screen. Further, the distance between the luminous tablet and the screen is about half-an-inch, therefore the thickness of a piece of paper is sufficient to mar the results. In our electric spark system time is not an element: it matters not whether the one hundred sparks be drawn as quickly as the mind can count them, or whether they pass at the rate of one per minute; and can it be supposed that a trifling error at six inches difference between light and screen can weigh with one-hundredth of the force it would do if only separated by half-an-inch? Time being left out of the calculation, if we count one spark too many or one short, it merely makes a difference of one per cent., a quantity totally inappreciable. The hundredth spark will have the same actinism as the first: there is no "decline."

Another careful point to be studied would be the one inch of separation of the knobs of the discharger. We shall eliminate any error here by either making the balls a fixture, or else making the printing-frame and discharger all in one piece, with knobs set inalterably at a fixed inch.

Phosphorescent sulphide of calcium is made which absorbs, and therefore, gives off all the different colours of the rainbow. How, then, can it be pretended that constancy can be claimed for an article of which one tablet may be made giving off a violet, and another a tinge of red? Admit, for the sake of argument, that a luminous tablet is a standard within itself, in relation to itself; that would depend upon the excitant, and the duration of excitation; and maybe a farthing candle would be equally entitled to be considered a standard. Then, again, temperature has a marked effect upon the return of light from a phosphorescent tablet. For instance, if we excite a tablet, and a finger or thumb comes in contact with its back, probably just by the time an exposure is being made the heat of the digit will have penetrated sufficiently to cause that part to give off an increase of light capable of forcing out an additional number or two. No such errors as these are possible by the proper employment of the electric spark system.

It would be quite possible to ensure constancy in the air through which the spark passes by enclosing the knobs in a glass vessel containing pure dry air sealed from the outside atmosphere; but we really do not think this is necessary. If the air of the apartment is such that the machine will perform properly, we believe the spark will be found remarkably constant.

We would suggest that the standard machine should be set under an air-tight glass case, on a stand *à la* sewing machine, and driven by a geared pinion through the base. A tray of chloride of calcium would keep the air dry, as would be indicated by a strip of carbon tissue and a chloride of cobalt test paper suspended within the case. The balls of the discharger could come out through two holes in the glass bushed by ebonite washers. If manufactured in numbers, the capacity of the jars for charge could be measured, and all made electrically equal; in other words, any number of machines could be turned out giving sparks of the *same actinic force*.

This, then, is our Standard Electric Light.

By-the-Bye.

SOMETHING PRACTICAL ABOUT LENSES.

FAR be it from us to decry the theoretical study of optics, especially as applied to the photographic lens. On the contrary, until the photographer has got into his head some idea of the construction of lenses and the laws that govern their focus, he is likely to blunder about every time he ventures upon the simplest of optical problems, and, what is worse still, do inferior work, by reason of ignorance of the tools he possesses.

But there is no use in acquiring knowledge which fails to stick in one's memory. The school-boy is pat at his dates while at school, and can tell you quickly the year Edward the Black Prince died, or the day that King Henry VIII. proclaimed himself Defender of the Faith. Unfortunately, unless he gets something more than the mere theoretical date by heart—unless he takes, for instance, an interest in some fact or event in connection with that date—this gradually fades away like a latent image that is never developed, and his mind is once more a blank. So it will happen to the photographer who only takes optics theoretically, and never experiments practically with his lenses; and our object at the present moment is, while leaving theory to take care of itself, as it is quite capable of doing, to demonstrate how a few hours of the dull weather may be profitably spent in learning something practical about one's lenses.

Some photographers are in possession of a whole battery of lenses; others manage to do a vast amount of work with three or four. Now, for the sake of argument, we will suppose our photographer has half-a-dozen. They are of various kinds and have different names; but beyond knowing that he usually employs this one for carte pictures, that for out-door work, a third for copying, &c., he knows little definitely about them, and his assistant probably less.

Now a straightforward way of comparing the capacities of lenses in a practical fashion, is to adopt some common object, say a two-foot rule, and to look at this on the focussing glass of your camera at a medium distance, say twelve feet from the lens. You have then always a measure of the capacity of a lens in your eye. My No. 1 lens, you will say to yourself, makes the two-foot rule, at a distance of twelve feet, appear exactly 5½ inches long, while my No. 3 lens shows an image of 3⅜ inches, and my No. 7 gives an image of but 1 inch. To make matters quite clear, you try all your lenses, and note the results on a card, thus:

COMPARISON OF LENSES.

Size of a two-foot object at 12 feet.

No. 1.—Copying lens (focal length 26½ inches)	...	5½ inches
No 2.—View lens (focal length 20½ inches) ...	...	4 "
No. 3.—Portrait lens (focal length 17¾ inches)	...	3⅜ "
No. 4.—Portrait lens (focal length 12 inches)	...	2 3/16 "
No. 5.—Wide angle, view (focal length 7 inches)	...	1 5/16 inch
No. 6.—Portrait lens (focal length 6 inches)...	...	1 1/16 "
No. 7.—View (focal length 6 inches)... ...	...	1 "

Two or three copies of this card are made and put up in the studio, work-room, and elsewhere, where it is in view of everyone in the establishment. In this way, a practical acquaintance with the lenses is soon made, and when some picture has to be taken beyond, say, the ordinary carte portrait, the photographer, whether he is principal or assistant, has in his mind what lens is most likely to fulfil the conditions required. He has but two factors to bear in mind—the two-foot rule and the distance of twelve-feet—and he can at once give a good guess which of his lenses to screw into the camera forthwith.

Of course, there are the peculiarities of the portrait lens and the landscape lens to be taken into consideration; but the distinctions here are not so marked as they used to be before the days of gelatine. The out-door photographer,

who has many lenses, employs that which embraces the view he wants, and is of longest focus, that is to say, if he desires the largest picture he can get. But sometimes space is limited for the camera—he cannot get back far enough—and then he must needs employ his short-focus instrument, and put up with abnormal effects in the foreground. At the same time it is well to bear in mind that the rule to employ as long a focus lens as possible has exceptions, and a very important one came under our notice the other day. A technical dispute arose as to the abrasion of a metal surface; it was so slight that to the uneducated eye the abrasion could not be distinguished from ordinary tool markings, and a photograph taken with a long-focus lens, to get the image as big as possible, scarcely assisted the disputants. But when a short-focus lens was employed, the sweep of the abrasion was concentrated, and a smaller but much more sharply-defined image of the defect was at once produced.

A practical experiment touching the focus of lenses will also impress upon the mind of the photographer a fact otherwise not sufficiently appreciated. If a map or plan has to be reproduced, to take an example, the photographer, naturally enough, takes out his copying lens to do the work. He stretches the map upon a flat drawing-board, gets his camera level, and focuses. Now he is usually enjoined not to focus the lens on the very centre of the map, nor on the outermost margin, but at a spot midway between these; in other words, if the map has a diameter of four feet, he is to focus one foot from the central point. This is the advice, we say, generally given in handbooks and manuals. Now a simple experiment will demonstrate the falsity of this, and he will ever after bear in mind the lesson taught him.

Let him take his No. 1 lens with its 26½ focus, and at a distance of, say, twelve feet, set up a dozen slips of card, each of them half-an-inch apart. A deal board with cross cuts half sawn through, will do to stick the cards in one behind the other, each succeeding card being a little higher, so that all are seen from the front. The cards are one and all marked with a fine cross in Indian ink and a consecutive number, the card nearest the lens bearing the figure 1. The focus is accurately adjusted, we will say, on No. 6, and a picture is taken. What is the result? Why, what any photographer with a moment's thought would have foreseen. The cards 5 and 4 are tolerably in focus, to judge by the Indian ink crosses, but 3, 2, and 1 are altogether blurred; on the other hand, not only are 7 and 8 in tolerable focus, but so are 9 and 10. In short, at this distance—12 feet—our copying lens may be said to blur an inch in front of the focus and about two inches behind the focus, the intervals varying, of course, with the distance of the lens from the object.

Now there is nothing new in this. Everyone, as we have said, who has considered the subject, would say the result was exactly what he had expected. And yet the general advice given in copying a map or plan has always been to focus half-way between centre and margin; in other words, to throw half the object in front of the focus and half of it beyond. This, under any circumstances, cannot be right, and the photographer who once will practically make the experiment we have suggested will never fall into the error. He will know that one-third before and two-thirds beyond the focus is generally much nearer the mark; and having learnt this lesson, he will find it to be a valuable one almost every day of his life.

In what way one lens varies from another lens may be made evident to the meanest capacity by simply photographing a diagram through a transparent scale. This transparent scale may be produced upon a glass plate covered with matt varnish, or a film of albumen, and consists of a series of true squares and true circles one inside the other, &c. The scale is produced either by means of a pencil and ordinary drawing instruments, or by transferring from lithographic paper to the glass by the aid of transfer ink. This scale is put into a dark slide and used as a focussing glass, in the first instance, the object to be photographed being a large diagram similarly marked with a series of true circles and true squares, only larger, easily produced by any one in the possession of a set of drawing instruments. One of the squares or circles of the diagram is made to coincide—as well as may be—with one upon the scale, and then a sensitive film is adjusted immediately behind the transparaut scale, and a photograph taken. The resulting image will be naturally "out ofdrawing"; that is to say, the square photographed through the lens will not tally with the square photographed by contact. The latter image will be true, the former more or less distorted, and any one wishing to test two lenses for distortion, has here set before him a plain unvarnished story that cannot fail to be appreciated. If he wishes to know in what way a portrait lens differs from a view lens, or how far he can trust his wide-angle instrument, he has but to secure a photograph of his standard diagram through his standard scale to find out. It is well for the photographer to keep by him a scale result from each lens—taken at a given distance—which will aid as much as the other card we have mentioned in keeping him acquainted with the capacities of his lenses; while the fact of his having made a practical experiment is more likely to fix the knowledge in his mind than all the reading in the world.

The "By-the-Bye" next week will be "Studio Dressing Rooms."

Review.

A DIGEST OF PATENT LAW, and Cases Incorporating the Provisions of the Patents for Invention Act, 1883. By H. A. GRIDLEY, M.A., Barrister at Law. (*Marcus Ward and Co.*).

SO-CALLED manuals of patent law issued by patent agents exist in abundance; but as these are ordinarily written with a view of bringing clients to the agencies issuing them, it is not desirable that too much reliance should be placed upon them. The hand-book of patent law now before us is, however, a work of a very different character, as it is an exhaustive treatise written mainly for the use of the legal profession; but the language used is so clear and free from unnecessary technicalities, that it is difficult to suppose that any person should misunderstand it.

The concise abstracts of leading cases are of especial value, as in legal matters it is quite as important to consider the interpretation which judges put upon the law as it is to study the law itself.

THE SPECTROSCOPE AND ITS RELATION TO PHOTOGRAPHY.

BY C. RAYS WOODS.

No. 1.—INTRODUCTORY.

IN the early part of the present century, when Wedgwood, Niépce, and others were making some of the earliest attempts at producing pictures by the aid of the sun, a new method of investigating* the nature and properties of light was brought about by the use of a triangular glass prism combined with a narrow slit. Spectroscopy and photography may almost be regarded as twin sciences, for though the former was the first to assume a really practical shape, the births of the two sciences were contemporaneous, and from that time to the present many of those experimenters who have given their attention to the one have been equally ardent disciples of the other. Both studies have been mutually dependent on

* The writer's attention was drawn to this experiment by Professor C. H. Hastings, Ph.D., of John Hopkins University, Baltimore, U.S. As to whether it originates with him, I am unable to say.

one another, and it would be exceedingly difficult to say which is the greater debtor; if photography has had to go to the spectroscope for explanations and revelations concerning many of its obscure points, the spectroscope is, in its turn, no less indebted to photography for its recording power, so much more trustworthy than human vision. Either science might have progressed independently of the other, but, happily, such misfortune was rendered impossible by the facility with which men, almost intuitively, perceived the relationship.

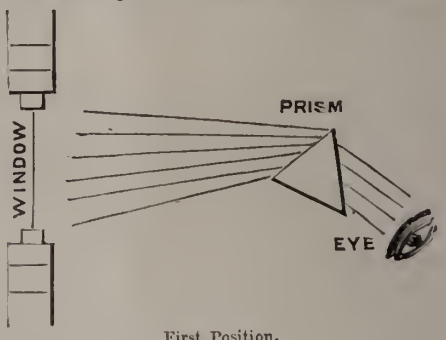
This partial independence of two branches of science, both dependent on one common phenomenon—light—is, unfortunately, however, the reason why some at least of the votaries of the one pay but little attention to the other. Photographers, it must be admitted, are the worst sinners in this respect, nor can it be wondered at, considering that their science has assumed a commercial aspect, and has thus become an art. The wonder is, after all, that so many photographers follow with interest the accounts continually being published about spectroscopic work. And yet, except when these accounts are chiefly intended for photographers, and occasionally even then, they are necessarily somewhat technical, and correspondingly difficult to be understood by those who do not make spectroscopy a special study.

That a large number of workers do not interest themselves in such matters is, under the circumstances, scarcely a matter for surprise. It is for this class that the writer proposes to give a short series of articles on the "Spectroscope and its Relation to Photography," as the reader will see by the title at the head of this column. Whilst endeavouring to make the subject clear, it is proposed neither to write a comprehensive treatise for those already interested in the subject, nor yet an excessively elementary account for that much-catered-for entity, "the meanest understanding,"

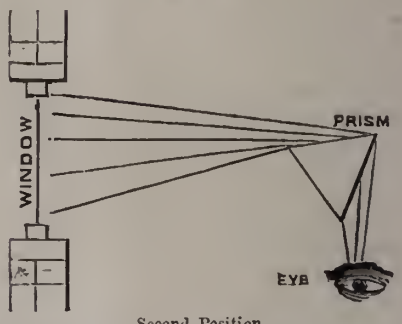
The individual of fairy legend and folk-lore, who went to sleep for a hundred years or so, seems to have a counterpart in the annals of science. The "sleeping beauty," which, under the hand of Newton, bid fair to arise and astonish and attract the world, was scarcely even unveiled till the touch of Wollaston roused the dormant power, and brought it into a world of life. Why Newton failed to discover the spectroscope the reader knows; he used at first a round hole, and then a wide instead of a narrow slit, and for a century and a quarter the man of science went on repeating the experiment, and the artist glibly talked about the primary colours, without getting one step further. Newton's simple experiments can be readily repeated with even a common chandelier prism. A ray of white light from a hole in the shutter of a darkened room is allowed to pass through a prism, and fall upon a screen. It is then seen to be split up into seven different colours. A spectrum thus formed is, however, a very impure one, for the different colours overlap one another.

When Wollaston substituted a fine slit for the circular aperture, he not only got a purer set of colours and better gradation of tint, but he found that the spectrum was crossed by a number of fine black lines. Only twelve years elapsed before 576 of these lines were mapped out by Fraunhofer, in honour of whom they are called Fraunhoferic lines. These lines may be seen with the very crudest piece of apparatus; the rough prism used for ornamental purposes referred to above will show them, although the glass is not so dense and so uniform, nor the surfaces as well polished, as in the prisms used for spectroscopic purposes.

Draw down the window blind till the light only comes through a narrow chink. Take a triangular prism, with two sides at an angle of about 60° if handy; go to the end of the room opposite the window, and look through the prism, holding it in a horizontal position. Some of the darker lines of the solar spectrum may then be seen. Another way of seeing these lines, and one which may be new even to many of those familiar with the subject, is to use, not a narrow chink, but a hole of any shape, or even the whole aperture of the window. Standing at the further end of the room, and holding the prism vertically, get the eye and the prism into such a position that the whole of the window is seen. It will appear white along its main breadth, with the edges of the framework fringed with colour. Now turn the prism round till one edge is nearly at right angles to the window, slightly shifting the position of the eye at the same time. As the position of the prism is altered, the window will appear gradually to contract till its opposite edges meet, when the dark lines will appear—the accompanying diagram showing the two positions; the diagram is made in plan—that is, looking down from above



First Position.



Second Position.

As mentioned, a prism of ordinary glass is quite sufficient for the purpose; in fact, with very dense glass, the effect is not so readily obtained. If the observer, instead of using an aperture such as a window or doorway, looks at the sun in this manner, he will be able to see a very large number of lines, and this, remember, without the aid of a slit. The reader would not thank us for the mathematical explanation of this, but will doubtless be able to see that what takes place is, practically speaking, of the nature of foreshortening.

But to return: Fraunhofer, in A.D. 1814, mapped 576 lines of the solar spectrum, his apparatus consisting only of a slit and a prism. A further addition was made by a famous optician, Mr. Simms, who added what is known as the collimator and telescope. The first consists of a lens placed in front of the telescope, and so arranged that the slit is in its focus. The utility of this will be at once apparent, for all light passing through the slit and falling upon the lens is rendered parallel, and is thus utilized, instead of the small amount of parallel rays that pass through a fine slit. The object of the telescope is to collect these rays and pass them all through the small aperture of the pupil of the eye. The principle of the telescope here is the same as in viewing a distant object—a landscape or a celestial sphere. The object-glass of the telescope brings the rays to a focus, and forms an image of the spectrum. This image the spectrum photographer receives upon his plate; the observer adds the eyepiece of the telescope and magnifies it. This is still

the usual form of spectroscope, and in our next article we purpose showing in detail the construction of such an instrument suited to the requirements of a photographer, and the adjustments necessary in order to obtain the best results that the apparatus will give.

FRENCH CORRESPONDENCE.

PHOTOGRAPH OF THE SOLAR CORONA—SHAPE OF A POCKET-CAMERA—THE LENS FOR SAME—CONSTRUCTION OF THE DARK SLIDES—BITUMEN OF JUDEA.

M. Janssen's Photograph of the Solar Corona.—The annual number of the *Bureau des Longitudes for* 1884 contains a photograph of the sun's corona during the total eclipse of May 6th, 1883, taken by M. Janssen, of the Institute of France. The picture has been neither retouched nor enlarged. It was taken in an instrument mounted in the direction of the parallax, with a lens eight inches in diameter, and 1·20 metre focal length. The exposure lasted during the whole of the eclipse, about five minutes. M. Janssen says that his photograph shows a more extended corona than was visible in the telescope. The photometric measure of the intensity of the corona's luminosity at Caroline Island was greater than the illumination from the full moon. This shows the importance of photography in astronomical observations.

The Shape of a Pocket-Camera.—As is always the case in foggy weather, at this moment there is very little doing in photographic matters. It is therefore fitting to discuss in a few words the interesting subject of pocket-photography. Up to now I have never met with a so-called "pocket-camera" really fulfilling its name with regard to absolute portability and power of taking a number of prints. Most of them have been constructed for use with glass plates, a very serious drawback to both essential qualities. The first thing is, what shape is more suitable for this desideratum—the opera-glass or revolver? The answer must be a negative one. The opera-glass form has the objection of allowing such a small space to be utilized. The square inscribed within the circumference of the glass is, as the annexed diagram shows, very much

Fig. 1.

smaller than the circle, so that with the thickness of the grooves, glasses, &c., the whole space at command is scarcely half the area of the circumference. It is necessary at all times to get a result large enough to be clearly legible without resorting to enlarging. The same objection is to be met with in Enjalbert's photo-revolver—negatives 4 centimetres square, however sharp,

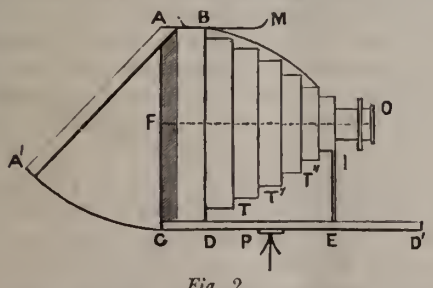


Fig. 2.

are not large enough. This disadvantage obliges me to reject both forms, and I greatly regret that the opera-glass form cannot be employed, as anyone using it would not excite suspicion. A monocular form of field-glass might be adopted, perhaps, allowing of a slightly larger negative to be taken, but one would have to look through the large end, the lens being at the smaller end. I have therefore abandoned all idea of simulating a field-glass or firearms, and have returned to a rectangular shape. By referring to diagram (fig. 2) the construction of my pocket camera will be seen. T T′ T″ represent the drawers, similar to those of a telescope, the space A C encloses a dark-slide shut in by the back A A′. The base D D′ is firmly hinged on to C D, and at E a little upright support, E I, allows of the exact focal distance O F being preserved. Negatives of 6 by 6 centimetres may be taken in this camera measuring 95 by 75 by 15 millimetres. The dimensions of the light double dark-slides are 90 by 65 by 2½ millimetres, six of which may be easily enclosed in a box, two such boxes containing twenty-four sensitive pellicles.

Lens to be Used with Pocket Camera.—I prefer to use an aplanatic lens for groups, views, monuments of 8 to 10 c.m. focal length, and exposed in the place of the diaphram by a rapid drop-shutter acting by a litttle bolt or trigger. The lens and shutter should be carried separately, and fixed on the camera when required for use. Along A B is a rule, so that the object aimed at may be properly centred, while the ledge A M has a screw at each entremity, so that the two knobs are in a line with the object when exposing.

Construction of the Dark Slides.—With regard to the dark slides, they are constructed of pasteboard ½ m.m. thick, the slide bearing on each side a pellicle 6 by 6 c. m. adhering to the surface by means of diachylon (as previously described in my last letter). The base of the actual slide is held down by the back lid while the enclosing case can come out at an opening at the side up to a certain length; when it is stopped, all light is prevented from entering by two springs covered with black velvet tightly clasping the exterior of the slide. Boxes containing the slides in sixes, have sliding openings at the top and bottom, to ensure the same plates not being exposed twice over; they should be put in at the top and taken out at the bottom for use, the words "in" and "out" being written on the respective lids (see fig. 3).

Fig. 3.

This whole apparatus may be really used with precision, not treated as a plaything. It is completed by the addition of a walking-stick. The camera may be carried in a leather case, to keep out dust, &c.

Bitumen of Judea.—Many who use bitumen of Judea for impressions on zinc are not aware that its properties may be considerably increased by the addition of a small quantity of coal-tar; I have used it with success in solutions of the bitumen in benzine. LEON VIDAL.

Notes.

A Arte Photographica is the title of a new monthly magazine published in Oporto, in the Portuguese language. M. Carlos Relvas and Mlle. Relvas, two distinguished amateurs, are on the editorial staff.

The annual meeting of the Photographers' Benevolent Association will be held on the 30th inst.; the Society has, so we hear, increased its balance at the bankers during the past year.

We are glad to hear there is a prospect of Professor

Donkin becoming the honorary secretary of the Photographic Society; no better choice could be made.

Our proposal to use orange and ground glass in the dark-room, so as to ensure a minimum of actinic and a maximum of visual light, is finding favour on many sides; on another column we print a letter from an able amateur—Mr. Blake, late M.P. for Leominster—who seems to have had little difficulty in adapting the combination to a daylight window.

Mr. Francis Galton, F.R.S., whose name, at any rate in connection with composite portraits, is known to most photographers, has recently published two works in connection with family records. The first, namely, "Record of Family Faculties," is little more than a collection of blank forms, in which the owner is to fill in data about his great grandfather and mother, &c., &c., and, in fact, give the most exact records he can about his family, and Mr. Galton will give prizes to the value of £500 for the best writing up of these records. The other book is the "Life History Album," which the owner is also to keep up and illustrate with photographic portraits of himself.

The "Life History Album" will represent a man's or woman's life from birth to death. It is divided into periods of five years, up to 75 years of age. The first periods will be filled up by parents, and only when you have arrived at years of discretion are you to write in details about health, occupation, diet, habits, &c. Every five years you are to be photographed and a portrait pasted in the book, so that when you have passed the three-score years and ten, there will be before you a little picture gallery showing how you have reached the meridian of life and gradually but surely declined afterwards. The volume will hardly be lively reading to its owner, and we are quite sure the illustrations will not raise his spirits, for over and again he will be looking at the last page and wondering when it will be filled. A man feels little interest in his decline and fall off, and less still will be felt when he is dead and gone.

Baron Karl von Jagemann, one of the court photographers to the Emperor of Austria, has died at Vienna. He received from the State the large gold medal of science and art.

Does the first-class professional photographer abroad occupy a higher position than his brother in this country? We think so. For instance, there is no photographer with us equal in rank to the late Herr Karl von Jagemann, of Vienna; and the same may be said of M. Levitsky, in the gay capital of St. Petersburg, who is an undoubted member of the aristocracy. In Paris, in the days of the empire at any rate, several of the best photographers moved in high circles; and the same may be said of the most distinguished men in Stuttgart and Dresden. Indeed, as we go further afield, the rank of the photographer seems to increase, for there is a Persian Prince who practises photography, and the brother of the Mikado of Japan is also said to be in the profession.

M. de Maupas is publishing the history of the Coup d'Etat in 1851, which he, as Prefect of Police in Paris, was instrumental in carrying out. The barricades and their defence in Paris, at that time, were never quite believed in, and some say that Napoleon had a hand both in setting them up and breaking them down. In those days photography was not sufficiently advanced to take note of these things, or M. de Maupas might have illustrated his book; though, possibly, such records would not have been welcome, after all, for camera pictures have a way of interfering very seriously with the romance of a story.

The barricades of the Communists in 1871 were not only photographed, but were depicted while in course of construction. We are in possession of a series of these pictures, one of the most interesting being a photograph showing the barricade stretching across the Rue de la Paix, above which is seen the pedestal of the Vendôme column, for the column itself is not there. It was these photographs that afterwards gave the most damaging evidence against certain Communists, who could not deny their portraits when they were shown themselves superintending the work of obstructing the streets. Perhaps, if similar photographs were in existence of the making of the 1851 barricades, M. de Maupas would not find his writing go quite so smoothly.

With reference to incandescent lighting, we said (p. 386 of our volume for 1882):—"If it could be made practicable to work incandescent lamps at a high temperature, as in the case of our experiments, the cost of incandescent lighting would immediately fall to about one-fortieth that of gas, as the high incandescence does not require a correspondingly increased consumption of electrical energy." Professor Adams, in speaking at the Society of Telegraphic Engineers the other day, pointed out the same thing; but he did not say that we were the first to call attention to the fact.

A photographic partnership was the cause last week of a singular instance of disagreement between judge and jury. The case was heard at the Sussex assizes, the plaintiff, Mr. Wing, a photographer of Tunbridge Wells, suing the defendant, Mr. H. Barmach, to recover £50 as damages for non-fulfilment of a partnership agreement. The plaintiff's case was that he negotiated with defendant for some time, but ultimately it was arranged defendant should purchase a half share of the business for £500. The deed was drawn up, but at the last moment the defendant refused to conclude the contract, alleging that he had not received sufficient evidence of the stability of the concern. The defendant, on the other hand, gave evidence that he refused to sign the agreement until the stability of the business had been proved to his satisfaction, and the plaintiff had refused to go into the matter until he had become a partner. It was also contended plaintiff had really put an end to the agreement by writing

that if the agreement was not signed by a certain date, he should not accept him as a partner. The jury found a verdict for the plaintiff for the full amount; but the judge was of opinion that the verdict should be for the defendant, and ordered judgment accordingly.

Travelling photographers should read Mr. B. H. Buxton's letter in another column. During a journey to America, in re-packing his exposed plates, he "laid the first plate film downwards on the packing paper, and the other plates film downwards upon each other with nothing between them." The plate next the packing paper, it appears, got scratched sometimes, but the others were none the worse. However, Mr. Buxton's travelling experience—and it is not small—seems to show that the best mode of packing plates is film to film with a thin sheet of blotting-paper between.

Some of the Berlin photographers complain that after sensitizing albumenized paper, the silver solution sometimes runs off in rivulets, as if the surface of the paper were greasy, and in this way wave-like streaks are produced. A remedy for the defect, according to Herr Roloff, is to blot off, immediately after sensitizing, with bibulous paper, a plan, as everybody knows, frequently adopted in this country.

Since photographers are as seriously injured by piracies as painters and engravers, we may well be believed when we say that we heartily sympathize with the recent complaints in the *Times* against the wholesale traffic in unauthorised photographic reproductions. But we do not think, with the Fine Art Society, that if the pictures of our Royal Academy were photographed and sold in open market immediately after the Academy opened, that "the value of artistic copyrights would tumble from hundreds to tens of pounds in a day."

On the contrary, we are convinced that if a few artists with big names suffered from such a course, the great majority of painters would be considerably benefited. Where one engraving of a painting is now sold for a few guineas, hundreds of photographs would be disposed of for, say, five or ten shillings a-piece—supposing the photographs were thoroughly well executed and of handsome dimensions. In Paris the plan has been in operation for some years, and large numbers of the favourite pictures in the year's *Salon*, whether these are by known or unknown artists, are sold. That such a state of things may be to the detriment of engravers and to the publishers of engravings, like the Fine Art Company, unless the latter march with the times, is exceedingly likely, but it is a change that must come sooner or later, especially as both France and Germany are well on the way towards it.

We even doubt whether the great artists would suffer by the wider publication of their works by the aid of some photographic process. But the advantage, as we have said, would be with the rising artists, who would thus get "published" to the world forthwith, and realise something for the copyright of their paintings. In a word, a rising painter, no matter how young or obscure, if he produced an attractive picture, would have equal chances with the élite of his profession, of reaching the public eye.

The *Pall Mall Gazette* evidently does not study the PHOTOGRAPHIC NEWS as it should. Last week appeared an article a column in length detailing the woes consequent upon paterfamilias announcing in the *Times* an increase to his family. Among other troubles, he refers to the pertinacious offers of photographers who photograph the printed announcement, and send him a copy begging for sixpence in return. Paterfamilias says he is the first who has called attention to the grievance, but in this he is wrong, for a correspondent did the thing before him in our "Notes" of June 22nd last year.

Photographic apparatus forms a part of the very complete balloon equipment which has just been despatched by the French Government for China.

Photography is not exempt from the law of political economy. When the retouching of negatives was first introduced, the demand for skilled retouchers was far in excess of the supply, and high rates of payment could be obtained. That happy time is passed, and the supply of retouchers now exceeds the demand. Wages for this class of work are, we are informed, about one-third less than they were three or four years ago.

It seems more than likely that photography will be pressed into the service to measure electric light. More than two years ago, it may be remembered, we published some tests made to ascertain the light given by various Swan lamps in this way, and the results were exceedingly promising. The photographic record would always be useful in confirming the ordinary photometric test, for electric lights are frequently difficult to estimate correctly.

Patent Intelligence.

Applications for Provisional Protection.

1497. DAVID HOYLES CUSSONS, 79, Bold Street, Liverpool, photographic chemist, and WILLIAM TULLIFFE TURNER, 79, Bold Street, Liverpool, apparatus manufacturer, for an invention for "Increasing the focal length or range of an ordinary photographic camera by means of a collapsible extension front."—Dated 16th January, 1884.

1622. ALEXANDER CRAWFORD LAMB, of Reform Street, Dundee, in the county of Forfar, hotel proprietor, for an invention for "Improvements in photographic cameras."—Dated 17th January, 1884.

1794. ROBERT BOLES GARDE, engineer student, Training School for Engineer Students, Devonport, Devon, for an invention for "The improvement of photographic shutters."—Dated 21st January, 1884.

1814. FREDERIC WILLIAM HART, of 8 and 9, Kingsland Green, London, in the county of Middlesex, manufacturer of scientific instruments, for an invention for "Portable folding tripod stands; improvements therein."—Dated 21st January, 1884.

Notice to Proceed.

4471. RICHARD BROWN, and ROBERT WILLIAM BARNES, and JOSEPH BELL, all of Liverpool, in the county of Lancaster, for an invention of "Improvements in means for, and method of producing designs upon paper or other fibrous or soft material." Dated 19th September, 1883.

Specification Published during the Week.

2677. ALEXANDER MELVILLE CLARK, of the firm of A. M. and W. Clark, of 53, Chancery Lane, in the county of Middlesex, Fellow of the Institute of Patent Agents, for "Improvements in, and in apparatus for, changing and storing photographers' backgrounds and other movable scenery." Communicated to him from abroad by William Evans Lindop, of St. Thomas, in the province of Ontario and dominion of Canada.

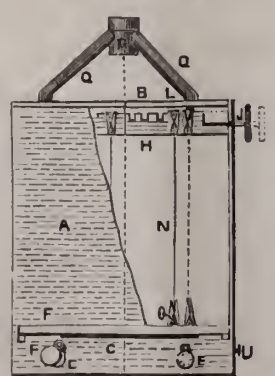
This inventiou consists of a gate or switch-like frame provided with rails at top and bottom, together with a series of stalls, each having rails at corresponding heights to those of the gate to receive a background, the gate or switch being so pivoted that it may be brought opposite to any one of these stalls so that the background therein may be readily run on to the gate for use from any one of the stalls, and *vice versa*. The backgrounds have rollers at back, which run on the rails of the gate and sustain the background in position, and the gate is pivoted or hinged to any suitable support at one end or at some intermediate point, and its hinge rod made double-jointed or cranked in order to enable the gate to be shifted about for altering the position of the background. The stile of the swinging end of the gate is provided with one or more spring catches to engage with the posts of the stalls to hold the gate while changing the background. A spring holds the other end of the gate at the same time, said spriug beiug attached to the floor to receive the bottom part or crank of the hinge rod, and fastened at oue end only, in order that the other eud may slide along the floor and be depressed by the crank which passes into a notch in the spring, whereby the hinge rod is held in the required line with the stall. Where space will allow of it the stalls will be extended in a straight line, and backgrounds of said construction employed; but to provide for storiug the backgrounds in less space they may be made flexible by means of narrow strips or slats properly jointed together, the stalls being curved so as to turn corners or run in circles, or nearly so if desired. The rollers on the backgrounds are grooved for running on the rails; but grooved rails may be employed with rollers to ruu in them if desired, and other modifications of the details may be made. The gate is provided with a castor wheel on its free end to preveut it from sagging, and by preference the lower guide-rolls on the backgrounds (when used) will be located under the lower rails of the gate to have better effect in bending the flexible backgrouuds to the rails.

Patents Granted in America.

291,544. IRVING B. SNELL, Philadelphia, Pa., "Process of colouring photographs."—Filed July 12, 1883. (Specimens.)

This *invention* consists in the use of "Diamond package dyes" in conjunction with gum and sugar.

291,722. BENJAMIN F. HALE, Rochester, N.Y., "Apparatus for drying photographic paper."—Filed May 9, 1883. (No model).



Claim.—1. The herein-described apparatus for drying photographic paper, consisting of the box A, provided with suitable air inlet and outlet passages, the reciprocating frame I, bars K, having paper-clips L L, and one or more heating devices, T T, substantially as and for the purposes set forth.

2. The combination, with the box A, provided with suitable air inlet and outlet passages, of the reciprocating frame I, adapted to support the paper during the drying operation, the removable screen G, and a suitable heating device, T, substantially as and for the purposes set forth.

PRINTING.

BY W. M. ASHMAN.*

FUMING, for some reason or other, is not looked upon with much favour in this country, but why, I cannot say. My experience commenced in this city fully twenty years ago, and I have continually practised it both here and in America since that time. It has been said that the climate of America is of such a nature that fuming is necessary, but here there is no advantage gained. This is simply nonsense; America is far too large a country to be placed in the catagory of auy particular climate. She possesses climates of all sorts, and as my experieucc of fuming extends over some thousands of miles, I hold that fuming is desirable in auy climate.

When hydrate of ammonia is exposed to the atmosphere, pungent fumes of the gas are given off. If these fumes be collected in a closed box, and sensitized paper is placed therein, the sensitiveness is considerably increased—in fact, nearly doubled—and the colour of the print becomes purple, or blue, according to the energy of the gas, and the duration of its action. Among other advantages, fuming permits less concentrated silver solutions to be employed in sensitizing. Less time is occupied in printing, also toning, meaning economy in time and material, and mealiness is uever seen. It is for this latter reason that pictures printed ou fumed paper give such better results in copying than those pictures which are printed on unfumed paper. I strongly advotate the adoption of ammonia fuming by all those engaged in printing from gelatine dry plates, being convinced that it only requires a fair trial to render its use general. Purchase liq. ammonia fortis s.g. ·880, in capsuled bottles or Winchester quarts. The present price is not more than sixpence per pound. Use a measured quantity, say 2 ounces, in a saucer placed at the bottom of an air-tight box; lay the sheet to be fumed on netting stretched an inch or two below the lid; the distance between the liquid and the surface of the paper should be fifteeu inches at least. To ascertain the proper time to fume any given sample of paper—for the different makes vary enormously—it is better to start by exposing the paper in the box for one miuute; cut off a corner and expose it to daylight. If the colour is red as it darkens in the light, the action has been insufficient, and it will be quite safe to return the paper for at least another miuute; at the end of this time another small piece may be cut off and exposed as before. This time it may print grey, afterwards becoming purple; this is an indication that the paper is sufficiently fumed for all ordinary purposes. This sample of paper we have been using for the last few months requires thirty minutes' fuming, and a few years ago we were using paper which required an hour and a-half. Wheu there is much moisture in the atmosphere, and a weak silver bath is employed, a peculiar mottled appearance is sometimes seen, although the purple colour has been attained. This indicates the necessity for a longer period of floating on the silver solution, followed by a prolonged fuming until the blue stage has been reached. As a rule, paper should be floated until it is seen to lie perfectly flat on the solution, whether it requires three minutes or ten to obtain that result. When paper has been acted upon too long by the ammonia, also when not quite dry, a grey metallic lustre and generally flat appearance is obtained. Such prints will not tone well, neither will burnishing improve them very much.

On the subject of preserved sensitive paper I can say but little. Like others, I have made many experiments, ranging between citric acid of at least fifteen years ago, and carbonate of soda leaves of a later period. Although I have preserved paper perfectly white for more than a year, I cannot say the results are preferable to those obtained on paper freshly silvered every day. The formula used for preserving the paper I have just alluded to is as follows:—

After sensitizing in the ordinary way, and while the sheet is still wet, the back of the paper should be floated, for the space of five minutes, on the following solution:—

Picked gum-arabic	3 ounces
Water	100 „

When dissolved, add—

Citric acid	2 ounces
Tartaric acid	2 „
Stroug hydrochloric acid	2 „

The paper should be dried, and packed in a closed metallic case.

Vignetting is a troublesome operation unless onc is constantly practising; and amateurs, as a rule, would rather print their

* Continued from page 43.

pictures plain, than be bothered with cutting out and adjusting masks, without any very certain knowledge as to the results they are likely to obtain. Probably the shape is suitable enough if it were looked after; but the system of placing it in position, and leaving it to the glorious uncertainty of chance, is not a system favourable to good work. Who among us has not occasionally forgotten or neglected a vignette, and upon removing the print from the pressure-frame discovered too much this side, or too little that—a sort of one-sided effect.

I won't ask your permission to let me wade through the dozen and one different ways of obtaining a vignette, since a recent description of every practical method has been made familiar to us in the NEWS; but will merely mention that any suitable shaped opening in an opaque substance would give all the blending that can be desired, if placed in a diffused light at sufficient distance from the negative to produce a well-softened outline. An arrangement similar to the one I now show you answers very well for ordinary negatives.*

Example 5.—In a case of very thin or under-exposed negatives the opening may be covered with tissue paper, ground glass, or a plate coated with purple dye dissolved in collodion and spirit varnish. When the picture is half printed, should there appear to be any deficiency in blending, the smaller mask may be replaced by a larger one, and for some subjects a brief exposure may be given, removing the vignetting mask entirely. Some negatives will not give such good results printed out to the extreme limit of their dimensions, and it is not desirable to vignette them, neither is it convenient to print only so much as is really good, thus reducing the size materially. Under these circumstances a mask of the required size and shape, with plenty of margin, is secured to the faulty negative. Prints from this masked negative will have white margins. In everyday practice this white margin is given a tint somewhat lighter than the general depth of the subject. This is done in the following manner:—

Example 6.—The zinc shapes now being passed round wilbe found to exactly fit the paper masks, any number of which may be easily cut with a sharp penknife.

Two blocks of zinc are cut to the size of every shape used, one being a little smaller than the other. A mask is cut from sensitized paper from the larger zinc block, and the counter-part or inner portion is cut from the smallest block; the difference in the size of the two blocks being sufficient to enable the smaller one, attached to a glass plate, to block the picture entirely, and thus enable the margin to be printed deep enough to produce a pleasing effect without the necessity of a white line.

Cloud effects are produced in a variety of ways, the most practical being, to obtain a series of good cloud negatives, selecting the most suitable for the subject. Without wishing to dictate in any way as to which is the best method of printing in clouds from a negative, I will tell you which I think is the easiest.

Negatives having good density in the sky portion rarely require stopping out beyond ordinary shading. When the subject will allow it, a duster, or strip of thin sheet lead suitably arranged outside the pressure frame, will stop most of the light from passing through that portion of the negative. Some landscape and architectural subjects would be difficult to vignette in this way; nothing short of obscuring the whole of the sky by means of an opaque substance will be found to answer. The best medium I know of is black varnish. Care must be taken not to use it too thin and allow it to spread beyond the parts to be covered.

Example 7.—Having a print such as I now show you, it only requires to be exposed under a sky negative for a short time in diffused daylight, covering up the picture as much as can conveniently be done. The sky negative should overlap the subject a little, unless there are special reasons for not doing so.

Heavy shadows may be softened very effectually by means of dabbing an old brush slightly charged with black varnish on the negative. To facilitate working in foliage when insufficiently indicated, several retouching pencils may be bound together, thus multiplying the number of strokes with considerably less labour to the operator, and better effects are obtained than by using an ordinary stump and powdered graphite. Some photographers grind the back surface of their negatives to facilitate retouching; others attach tracing paper with the same object in view.

* A sketch will be found on page 631 of our last volume.

Combining portions of one negative with portions from another requires both patience and skill. It is easy enough to print the head from one negative on the shoulders from another; but it does not always look well, either a white or dark line caused by over-lapping or the reverse being very often too evident; vignetting does not produce any better result, and sometimes grave errors are made in the lighting. I have always succeeded better by cutting out accurately the portions required from untoned prints of the various negatives, using a sharp pen-knife for the purpose. If a line of any kind is perceptible when the parts are combined, it is better to let it be a white line, for this can be easily removed in the finishing.

There are a great many matters connected with this subject which might occupy the attention of our Society for several evenings. It is manifestly impossible for me to deal with more than a tithe of them just now.

Before closing, I wish to call your attention to a method of testing the quantity of silver contained in any given solution, preferably an acid solution. In this tube is placed some pure solution of nitrate of silver, and in this one silver solution plus nitrate of potash.

Example 8.—This mercury bulb, termed an argentometer, is so indexed that floating in distilled water at 60° F. it stands at zero. If 100 grains of silver nitate be added to each ounce of distilled water the bulb should register 100°; if I were to add barium or ammonium nitrate instead, I should get a very different result. The solution I am now operating with contains 10 grains of silver nitrate to each fluid ounce of distilled water. We shall find upon testing it with the argentometer that it does not register 9 grains. If this is so in the case of a pure solution, what degree of certainty can there be when operating with an old bath containing nitrates and albumen? I have also another solution composed of ammonium thio-cyanate 78 grains in 17 ounces of distilled water; this is the equivalent proportion to react, volume for volume, on a ten-grained silver solution. These burettes are graduated in cubic centimetres; I will run off 5 cubic centimetres of silver into this beaker, to it I will add a few drops of dilute nitric acid, and a colour indicator such as ammonia ferric alum. I will now run into this mixture exactly 5 cubic centimetres of the re-agent, and you will see the reaction is complete the moment the colour remains. Having a stock of the re-agent made at any convenient strength, preferably normal or deci-normal, the greatest accuracy is obtained in testing any given solution containing silver. Those who employ the French system of measurement will find it more convenient to use decinormal solutions, viz., 17 grams of silver nitrate per litre of water, and 7·6 grams of ammonium thio-cyanate per litre. The silver solution is merely used as a standard test for the re-agent. Each c.c. of the re-agent is equal to ·017 grams of silver nitrate, or ·0108 of pure metallic silver; thus in testing we multiply the number of c.c.'s employed to act on each c.c. of the silver solution by that number of times ·017. An easy way to ascertain how many grains per fluid ounce contained in a definite number of grains per litre, is to multiply by 70, and divide by 160; thus the decinormal solution of 17 grams of silver multiplied by 70 and divided by 160 equals 7 and $\frac{7}{16}$ grains per ounce—practically, 7½ grains per ounce.

CAMERA LUCIDA—PALETTA OBSCURA. A STUDY IN LIGHT AND SHADOW.

BY HUME NISBET.*

ALL good original work is got from copying and following those who have gone before. I could quote scores of painters since the days of Durer, Rembrandt, and Teniers, down to the present hour, who gain fame only through being Durerites, Rembrandtists, or Tenierians, with a little of their own personalities thrown in, as those old masters did. Durer flung in and mixed up a part of himself (which he could not keep out) along with the training of Michael Wolgemuth. Rembrandt hashed up Zwanenburg, Lastman, Pinas, with a host of others, along with the son of his own mother, to produce the mightiest giant of the art race, which we all try to copy whenever we want to feel free from the feeding bottle. It is the fate of all great men to copy. Blake says, "The difference between a bad artist and a good is that the bad artist *seems* to copy a great deal, and the good one *does* copy a great deal."

To imitate Rembrandt properly get hold of the first High

* Continued from page 39.

Street, Cowgate, or Leith basket woman that you can chance to meet—a herring or orange vendor will do—take her as she sits without arranging a single fold, adding to, or removing one iota about her; take her on the street or in the close, or as she squats down inside the half-darkened doorway of her own little shop. She can neither have too little nor too much about her if she struck you distiuctly while you passed as being picturesque. Never mind the lighting, or think to be original; as she stands, or sits, or squats, she is the woman for your camera; out with it, and secure her before she can wink or know what you are up to, and you have caught the whole secret of Rembrandt's power and realistic talent.

In patching and touching your plate, which to me seems to represent the second working, think upon all the dodges of the etchers—Hayden, Hamerton, Herkomer, Whistler, &c. If you have a chemical to eat down certain parts of it broadly, leaving the prominent parts (be sparing of prominent parts) standing out dense, do not niggle with your pencil point over much, except it is to blur out an accessory which may be too distinct. I do not know much about printing photographs, yet I am inclined to think it is here that the genius of the photographer may be brought out. If I were a photographer I'd never leave a plate while it was printing for a second. I'd try all sorts of dodges upon the sun with pieces of paper having little eccentric holes torn out where I wanted an artificial shadow to fall across my plate, by exposing the print altogether at times so as to mellow any extreme lights, painting touches of white on it to bar out the sun altogether where I wanted a mysterious gleam, whether it was on my picture or not, and never rest until I had made it my own. I may be wrong, of course, in all this; but it is the idea which now strikes me; or all that may be done already, or considered *infra dig.* or illegitimate; yet here, I think, as in the treating of a painted picture, I imagine the photographer can liberate himself entirely from the trammels of custom, and never be at a loss for fresh tracks.

In landscape photography I constantly observe good pictures rendered imperfect through the fatal power of the camera, which must print every object before it, and yet in the printing, even more than in the sorting, of the plate I think much, if not all of this, might be obviated by a careful study and following up of the tricks of Rembrandt. If it is the foreground which is too plainly marked, why not take another foreground plate, and clearing off all not required, place it over the other plate, and so let the sun strike through both and blurr that corner; or make a dark shower cloud, as in the engraving, "The Three Trees," by covering boldly portions of the plate with paper and allow the rest to print darker, or by adroit covering and exposing simplifying the whole arrangement and create divisions where you want them; a ray of light, or a part blackened, or any device that occurs to you, which is what we call inspiration?

The magic of Rembrandt rests in this, that he seldom creates, *but he takes advantage of circumstances and local incidents* to intensify the story he is telling you.

To return to Teniers (for a moment in passing), I cannot bring to mind one of his pictures which I have seen that could in any way be improved in the composition, added to, or taken from; every accessory tells its own portion of the general story, and this I would once more point out to the composer of a picture, along with a few wise laws which occur to me while I write. The principal object is the first object which rises up before the mind's eye, and fixes the composition when the story is heard or read; therefore the main object to be considered and first set up or drawn in. After we get the first object set up, the others all fall into place to suit that central or main object, and this rule holds with the arranging of light and shadow, as well as form—one minute centre of light through which the half-lights range—and the deepest shadow when you can best afford it. The central form, the central light is of paramount importance, all the rest a matter of convenience, chance, and discretion. Think less about what you may put in to help your picture as upon what you may keep out, to give it importance and repose.

Every sitter has a fine point about him or her—find it out. The best side of the face, a nice arm, or good hand—they will reveal it to you unconsciously, before you have sighted them; and make that your first object, and all the rest subordinate, and to help that out. Don't seize two points in one model; decide which is the most useful, and take that without regret, discarding all the others. It may be that the only good bit is a hat, or a feather, or a pair of gloves, or a brooch. The point that first attracts your eye pleasantly is the point upon which to make your centre of vision, and around which you will arrange the rest. If it is an article of dress, of jewellery, then bring the light to bear upon it, and make all the rest in half-shades.

Study nature for ever, if you would have any photographs you take different from the last photograph. Never take a sitter at once; leave them alone to knock about your studio while you pretend to be sorting something else, but watch them unawares; you will see a natural touch before long, a peculiar habit which they are not aware of, but by which many of their friends know them. Fix on that as your character key-note, and work up features, position, and accessories, so as not to lose sight of this peculiarity; and with this borne always in mind, and a good knowledge of face and neck anatomy, without which I cannot see how anyone can touch up a negative properly, I know of no reason wherefore a photographer should not give us as complete a character study as any painter, ancient or modern, from Millais back to Albert Durer.

Yet, before that state of perfection can be acquired, permit me, as one of the public and also as a frequent sufferer, to enter my protest against head-rests and long sighting, to those who still practise these abomiuations. No natural expression or easy posture can ever be gained until instantaneous plates are used for every one. Before they can well settle in their self-chosen places and posture, have them down and risk it—the chance of a spoilt picture is better than a conventional position; also this debasing system of smoothing away wrinkles, and blotches, and character traces. I never can see a real harsh, wrinkled face now-a-days, except in some of the tin-types.

Of course I know the cry is raised that the public will have those wax productions; but as one of the public I have not yet had my own likeness taken quite right. For instance, in repose, I hang my head on one side, and I have always been made to hold it straight up, like a soldier at "attention." Again, my nose is neither of a Greek nor Roman caste, and yet I never do get that nose put in as I see it in a mirror, or as its humpy shadow is cast upon the wall; or, as a gentleman once closed up a wordy, if not very convincing number of reasons against my having either the qualities to make a poet, painter, or passable labourer, by exclaiming, "Why, just look at your nose; did you ever know a clever man with a nose like that?" This photographed nose of mine has afforded me and others some amusement; sometimes it has been so refined that I fell to reviling Nature for being so far inferior to the artist who finished it off so well. Once it came home a splendid Roman, with the light upon it so intensified by pencil work that it stood out in bold enough relief to have won a Waterloo, if big noses could have done that. I have one portrait which I am keeping to leave to posterity; it is so Byronic and *spirituelle* that future young ladies will no longer wonder why my wife has married me. This refined likeness, and my love songs together, ought to do the trick.

Yet I have some photographs very near perfection. One representing my two little daughters, done by our friend Mr. Tunny. Professor John Ruskin writes:—"The face of the child on the spectator's right hand is the loveliest in expression I ever saw in a photograph." Also some by my friend Mr. John Foster,* of Coldstream, cattle piece, and landscape breathing of balmy atmospheric effect. He gets up to work outside, at three o'clock on summer mornings, the hour when Nature is like a blushing virgin, all dewy loveliness and purity. I have also works done by Mr. William M'Ghee,† of O. Davis, strong and massive, some by our member,‡ Mr. Samuel Tamkin, of Wood and Co., some by Mr. Pope, instructive and graceful; also one of Newhaven Fish Market, 8 o'clock a.m., by Mr. Knolles, the best group of artistic positions I have yet seen; and for the natural swing of one figure in it, to me a treasure priceless. Of course, I merely specify the works of those friends, as they are the only members whom I am yet acquainted with, or have specimens from, knowing well at the same time that they are only individual members out of a great Scottish army of earnest, original workers in art.

* The snow scenes are exquisite, and one exhibited of a camp fire with figures, a perfect triumph of misty refinement; the faces seen through the smoke particularly to be observed. I would also call the reader's attention to his cattle studies, and the printing done on rough hand-made paper, flat, and like sepia and Indian ink work, only far more refined than hand work could be.

† The two studies shown by Mr. M'Ghee are art portraits of my youngest daughters, a head thrown purposely (at my request) a little out of focus, so as to soften the effect.

‡ This enlargement, by Mr. Tamkin, is exhibited for the artistic vagueness and suggestiveness of this process when done with care and skill as in this case: the feeling of an Indian ink or charcoal drawing is thoroughly given.

In France there is a school rising—who with the brush are trying to compete with the camera—*the Impressionists*, who, along with the camera, are yet fated to produce a great revolution in art. They aim at giving the impression, effect, or sensation of an instantaneous action or emotion or phase; not the phase exactly, but the swift impression which it leaves upon the mind of the spectator, with form, as it were, that is, with paints and brushes striving to embody the soul of Nature, and when the two are joined, the result will be—*perfection*.

Correspondence.

DIFFUSED LIGHT FOR THE DARK-ROOM.

DEAR SIR,—Encouraged by the very satisfactory tests as to efficient dark-room illuminatiou in a recent number of the PHOTOGRAPHIC NEWS, I removed the two thicknesses of ruby glass from the window of my developing room, and replaced it with orange and ground glass, as you recommended. The orange used was, I suppose, of too pale a colour; at any rate, I found it admitted light enough to give me very fair transparencies by contact printing in frames, and I begin to think I must replace the ruby. To-day I tried another thickness of the same light-tinted orange, the ground glass being sandwiched between the two panes of orange. The result has astonished and delighted me. I can see to read diamond print six feet from the window; yet, on testing six of Rouch's rapid gelatine plates, by placing them in backs, the shutters of which were each half opened, and placing them *close to the window* for two, four, six, and eight minutes, each plate, when immersed in the hypo bath, showed clear glass, and had no trace on either of them as to which portion had, or which had not, been covered by the slide or shutter of the back. This trial was made at 1.30, when the sun was shining very brightly. It is right that I should add that my window has a northern aspect, but it is not screened by either trees or buildings.

I feel that I owe you a very large debt of gratitude.—Yours very gratefully, THOMAS BLAKE.

Lebanon, Ross, Herefordshire, January 17th.

LIGHT FOR THE DEVELOPING ROOM.

DEAR SIR,—A brief paragraph in your last issue has brought me a number of letters from persons interested in the proper illumination of the developing room. It is quite correct that gas lanterns, covered with one thickness of cherry fabric, having white tissue paper outside, have been in successful use here for a long time. The lanterns have glass about 12 by 8 inches, and the fabric is put on by pasting it round the edges in contact with the white glass. Then place the tissue paper on in the same way. The object of the tissue is to soften the light coming through the small openings in the texture of the fabric, and blend everything in one uniform tone.

I was probably misunderstood to have said this is also used in the dry plate works. This is not so. The most rapid plates may be developed close to such a lantern without danger. Probably some experimenters will try exposing a plate a short distance off for a long time, and then find it fogs. I am aware of that, and for that reason neither I nor ordinary people would keep plates close to it without occasion. The dark slides are of course some distance off the lamp, and the plate is quickly placed under developing solution, and all goes well.

Like many others, I have read recent utterances on the injurious effects of ruby light with some surprise. I thought that every one was now aware that ruby was unnecessary. From my own knowledge, I can say that in all the large establishments it is the practice to use large fixed lanterns with either gas or petroleum lamps, and either glass of lightish colour, or cherry fabric, to develop by. I should have said the use of ruby was abandoned.

In the Midlands it is the habit of most large houses to use lamps covered with canary medium, a piece of which I enclose. Notwithstanding its very light colour, it is perfectly safe, and may be used on a large scale. Searchers after "cathedral green" may save themselves trouble by using one or other of the above well-tested means of illumination.

Permit me just a word on the alleged injury to the human eye of the colours of lamps used in dry-plate photography. It is erroneous to suppose ruby or red injures the eyes; on the contrary, the optic nerves have an almost entire rest in them. Nor is it true that the focus of vision is changed. What really injures the eyes is the everlasting reading, writing, smoking, and glare of gas-light on white paper of modern life. Under the dry-plate system the life of the photographer is infinitely more hygienic than under collodion—the nerves are relieved from endless strain of worrying details of baths and collodion. Of course more spectacles are wanted as we all get older; but the number is not increased by the use of dry plates.—I am, very obediently, SAMUEL FRY.

PACKING PLATES.

DEAR SIR,—It may interest travelling photographers to know I have just finished developing about 120 ten by eight gelatine plates, exposed in British Columbia and the Rocky Mountains in the summer of 1882, and from which I have now about one hundred negatives, more or less good. The plates were packed in dozens in the ordinary way, each dozen put into a waterproof bag, and then packed with straw, in two one-inch boxes lined with tin, which were soldered up when done with. On repacking after exposure, I laid the first plate film downwards on the packing paper, and the other plates film downwards upon each other with nothing between them. The plates with the film next to the paper got a good deal scratched, but only in two or three cases sufficient to show upon the print, whilst the others were not at all the worse. I had not a single case of leakage, although on one occasion, both boxes, together with the horse on which they were packed, rolled about thirty feet down a steep rocky incline. Nor did I get any of the plates fogged, though I often had to change under a blanket in a tent in bright moonlight.

When rightly exposed and developed, the plates do not appear to have suffered the least from the long time which elapsed between exposure and development.

As a result of two years' travelling experience, I intend this year to take for a six months' trip in America, an 8½ by 6½ camera, 20 inch single, 13 inch rapid, and 8 inch portable symmetrical lens, 20 dark slides, charged before leaving home, each one in a waterproof bag, and every two in a telescoping tin case, with a tight india-rubber band round the join.

Besides these I shall take forty-two plates packed in half dozens, film to film, with a mask of thin blotting-paper between each plate, and shall repack them in the same way. Each half dozen will have its own waterproof bag, and the seven bags will be packed with straw or tow in a three-quarter inch wooden box lined with tin and soldered down. I shall thus only have to change plates once during the whole journey, which will save an immense amount of aggravation and bad temper.—Yours truly,

B. H. BUXTON.

NOTE ON PHOTOMETRY.

SIR,—I would like, with your permission, to correct an error appearing in your report of the last meeting of the Photographic Society, in reference to the adjourned discussion upon my paper on a "New unit of light in connection with sensitometry." My reply was to the effect that, having tried various sources of illumination, my experience enabled me to say, that with plates of *uniform* composition, but differing in sensitiveness, the relative time

required to produce a corresponding minimum effect upon either of them remained constant, the result being independent of the composition of the light employed. On the other hand, when comparing plates differing in their composition with any given source of light, the relative time necessary to produce a corresponding minimum effect upon each does not remain constant when a comparison is made with any other source of light differing in composition to that employed. This difficulty I propose to surmount by employing a constant. The result obtained when comparing plates with any given source of light would then have to be multiplied by the constant corresponding to the difference that exists between the light used, to that you intend to employ with the plates.

Kindly allow me to add in reference to the above that I have been giving great attention to this subject for the last three years, with the result that I have more complete apparatus than that described, which is based upon the same principle.—I remain, yours truly,

JAMES B. SPURGE.

P.S.—These conclusions are embodied in my paper printed in the Society's Journal, vol. vii. (new series), page 160, lines 16 to 35.

THE MIXED HYPO AND GOLD BATH.

SIR,—I am glad to see our old friend, the mixed bath, is being stirred up again. Old photographers are beginning to find the prints they made five-and-twenty or thirty years ago retain their colour and tone much better than those of more recent date.

Since the discussion on Mr. Ashman's paper, I have looked up some prints I made over twenty-three years ago. I am able to fix the date to a day, as they were printed and hurriedly finished with very little washing, to take with me to Dublin; as I sailed and crossed the Channel the same night the *Royal Charter* was lost on the Welsh coast, I well remember the time. These prints were made the day previous, and would be in October, 1859.

The prints have, as Mr. Ayres remarked, been kept "anyhow." Others in the same scrap-book, toned by the alkaline method, though not half the age of these, are anything but satisfactory.

The danger of returning to the old method is, in economical or inexperienced hands, the toning with sulphur instead of gold, as upon the exhaustion of the gold, the bath seems to tone equally well. Only allow a certain quantity of gold per sheet of paper, and I think we need not be afraid fading prints will be returned to us during the time even the youngest photographer amongst us will remain on duty.—I am, yours, &c., T. G. WHAITE.

Proceedings of Societies.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

ON Tuesday last, the 22nd inst., the mid-monthly meeting was held in the Gallery, 5A, Pall Mall East, Captain ABNEY, Vice-president, in the chair.

Mr. H. J. NEWTON'S method of accelerating, as described on page 35 of our issue for last week, was brought under discussion, and both Mr. Cowan and Mr. Ashman, who had very carefully tried the method, came to conclusions identical with those which we had previously arrived at, the addition proposed by Mr. Newton acting merely as an intensifier, and not serving to materially reduce the exposure required. A practical disadvantage is, however, the circumstance that a precipitate of subiodide of mercury forms, and settles upon the plate. The deposit thus formed appears itself to become intensified in some way, and firmly fixed to the film. The addition proposed by Newton is, however, not to be recommended under any circumstances until the image is well out.

Mr. DEBENHAM then brought forward a lantern in which one side was glazed with a thickness of orange glass and one of ground glass, covered with a thickness of stout white paper; another side of the same lamp being provided with a thickness of cathedral green and yellow paper; these gave a light about equal as to visual brightness, and experiments made by Mr. Debenham indicated that the actinic action of each was about the same. A thickness of cherry fabric and one of tissue paper gave a light somewhat difficult to compare with those previously mentioned; however,

Mr. RAY WOODS thought it more brilliant, but the actinic action was certainly greater.

The CHAIRMAN referred to the chromates of lead as non-actinic media. He had tried them made into gelatinous emulsion and precipitated into the pulp of paper, and had not found them very satisfactory. He pointed out that ordinary white light may be used in the developing room if it be considerably reduced in amount, and precautions be taken to prevent undue exposure of the plate; indeed, he had often developed a plate in full gaslight by taking the precaution of keeping his back to the light. The canary medium by itself is not good when iodide plates are used, as much green passes. On the whole, the Chairman considered the so-called stained red to be one of the best mediums to employ when a single thickness only is used. Ordinary ruby allows so much blue to pass as to make it a very unsafe medium.

Mr. COWAN had obtained an excellent and very safe light by allowing gaslight to impinge on a sheet of tin plate, and after reflection to traverse yellow paper and cathedral glass.

A question was then read, having reference to the desirability or otherwise of soaking a plate before development, and the

CHAIRMAN said that, when working in extremely hot and dry climates, there is a decided advantage; indeed, if the film be not soaked, one practically loses the effect of half the exposure.

GLASGOW PHOTOGRAPHIC ASSOCIATION.

THE sixth general meeting of the Association was held in the Religious Institution Rooms on the 10th inst., Councillor ROBERTSON in the chair.

The minutes of last meeting and of the conversazione were read and approved of.

The CHAIRMAN then invited the members to inspect a number of platinotype prints lent by the Platinotype Company. These were very much admired, and several gentlemen testified to the simplicity and workableness of the process.

Mr. PATON said it was the simplest process he had ever tried. He had had no trouble from the very first, and showed some excellent specimens of work in proof of his statements. He also showed some portraits printed both on albumenized and platinotype paper for comparison; but the general feeling of the meeting was that the gloss of the albumen print gave it an advantage over the platinotype for portraits. Mr. Paton said he had twice tried to enamel the platinotypes, but had not been successful; he thought the paper supplied by the Company was not suitable. The prints always had a greasy appearance after enamelling.

The question was then asked whether solar enlargements could be done on platinotype paper?

Mr. MCLELLAN said it would be quite possible to do it, but that a very long exposure would be required. It would be much more satisfactory to make an enlarged negative, and enlarge from that.

Mr. PHILSON showed some enamelled silver prints in accordance with his promise at the meeting on the 22nd November, when a discussion arose as to the best method of mounting enamelled photos. Some of the prints exhibited (Mr. Philson explained) were mounted with starch before being stripped from the glass. The others were mounted with gelatine along the edges; the surface of these were slightly dulled, however, where the gelatine touched the back.

Mr. PATON also showed some enamelled prints mounted with gelatine. These showed no mark of the mountant, owing to his having used a thick paper to back up the print when enamelling.

Some discussion then took place concerning the permanency of enamelling photos, and the general opinion of the meeting was that enamelling very much increased the permanency of silver prints.

The CHAIRMAN said he had noticed a camera advertised by the Scovill Manufacturing Company, in the *New York Photographic Times*, the principal feature of which was the revolving back, which enables the operator to make either an upright

or oblong picture after he has the plate in the slide. This was advertised as Hanning's patent, a truly novel instrument. He said that statement was hardly correct, and exhibited one on exactly the same principle made for him fully twenty years ago, which had also the advantage of moving, so as to take eight pictures on one plate without changing the position of the lens.

Mr. BLACKLEY said he had heard neither of Councillor Robertson's nor the Scovill Company's cameras, but he had had one made quite recently on the same principle, which he would exhibit at the next meeting.

Votes of thanks were then awarded to the Platinotype Company, to Messrs. Paton and Philson, and to the Chairman.

The meeting then terminated.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

A MEETING of this Society was held on Thursday, the 17th inst., Mr. A. HADDON occupying the chair.

Mr. W. E. DEBENHAM showed a wood dipper intended for vertical fixing baths, somewhat similar to Mr. Henderson's sliding stud dipper, the base or cross-piece being much wider in this case, thus enabling two 20 by 16 inch plates to be fixed at one time. Two grooves in the base, and transverse slots running at measured distances from the main slot, enable the plates to be firmly secured by the stud.

Mr. A. COWAN exhibited a 7 by 5 camera on behalf of Mr. York, the novel feature consisting in being able to swing the bellows (conical) whenever it is desired to alter the position from vertical to horizontal, by means of a revolving plate attached to the sliding front, a sliding piece in baseboard permitting the range of focus being extended from $2\frac{3}{4}$ to $17\frac{1}{2}$ inches, at the same time conferring rigidity. He (Mr. Cowan) considered it a most compact camera, and having neither swing front or swing back, should, after the recent discussion, be named the "York camera."

Mr. J. N. HARE: Does not the small conical bellows cut off a portion of the picture? He had seen a form of reversible gusset simpler than the one shown.

Mr. COWAN said it did not matter how small the cone of the bellows is, provided it does not obstruct the margin of the lens.

Mr. A. MACKIE: Is there any advantage in using a swing and rising front over a swing-back?

Mr. COWAN: The amount of back swing would be more than the front; he noticed that a swing of a quarter of an inch in front produced apparently greater effect than the same amount of swing at the back.

Mr. MACKIE: In the cases of swinging the front and raising it, the central line of rays would reach the centre of the plate.

Mr. DEBENHAM contended that the effect of swinging either the front or back of a camera would practically be the same, and illustrated his views by means of diagrams on the black board, in which he clearly showed that neither had an advantage over the other.

Mr. MACKIE said that in using a lens that would only just cover the plate, he thought that in photographing a high building there would be an advantage in using the swing and rising front over tilting the camera and swinging the back.

A discursive discussion ensued, in which both Mr. Debenham and Mr. Mackie illustrated their remarks with diagrams.

Mr. H. S. STARNES brought a modification of his lamp before the meeting, the sides of which were of cardboard or stout brown paper instead of wood; the upper and lower portions are made of block tin, so arranged that the paper or cardboard can be easily fixed in position when required; an ordinary visiting card placed in front of the candle flame shields the room from white light. The body of the lamp being lined with transparent tissue paper of a suitable colour is said by Mr. Starnes to emit a safe light into the apartment.

Mr. R. E. Wilkinson was elected a member of the Association.

AUCKLAND PHOTOGRAPHIC SOCIETY.

AT a meeting held in Rolison's Commercial Rooms, Auckland, New Zealand, on the 2nd of November, the Auckland Photographic Society was formed, and the following officers elected:—

President—J. M. Clarke.

Vice-Presidents—W. J. Hurst, M.H.R., and John Chambers.

Secretary—J. H. Sinclair. *Treasurer*—Clement Bartley.

The first field day of the Society was held on Saturday, the 24th of November, in the Domain, and the weather being fine, a number of photographs were taken.

Talk in the Studio.

MESSRS. NEGRETTI and ZAMBRA forward us their new catalogue of photographic apparatus, which, among other matters of interest, contains particulars of reversing prisms for photo-mechanical work.

THE DECAY OF ENGRAVING.—The *Daily Telegraph* confirms the plaint of the Fine Art Company, that photographic piracy is destroying the art of engraving. "The extent of the evil done may," says the *Telegraph*, "to a slight extent be guessed when we find the representative of the Society stating that, in the course of four years, his firm have published six engravings, for the copyright of which the artists received more than seven thousand pounds, while the cost of the engraving amounted to over ten thousand. Within a month of the issue respectively of these prints, photographic copies of them were hawked about for half-a-crown apiece." It then continues to say, that "engraving on metals is, at the present day, menaced on all sides. It is threatened by 'photogravure,' a process of which it may be said that 'it would be engraving if it could,' and, again, by etching, the development of which during the last twenty years has been simply astounding. But the most formidable and the most unfair competitor of chalcography is the sun. Photography will never completely kill portrait-painting, for the reason that human vanity is eternal, and that the sun never flatters—indeed, in association with the lens of a camera, it often distorts, exaggerating facial uncomeliness and putting arms, legs, and hats disastrously out of focus. The sun, however, when it is an engraving that has to be focussed, is a pitiless and unerring forger. With microscopic fidelity the minutest touch of the dry point, as well as the boldest stroke of the graver, will be transferred to the plate of the negative and thence to the paper of the the positive. Finally, the sun is wondrously successful in forging engravings executed in the 'mixed' manner—that is to say, in a combination of etching, line, stipple, and mezzotint. It seems clear enough, however, that if photographic forgeries of costly engravings continue to be sold by the 'sneak' pedlars at half-a-crown apiece, we must be within measurable distance of a period when there will be no more new engravings for the sun to forge. The print publishers will abandon the unequal contest in despair; and the artists will cease to net handsome sums by the sale of their copyright." Seeing that the Fine Art Company, on its own showing, has only published six engravings in four years, few artists will suffer, even when the present state of things do come to an end. Our contention is, that if painters, as in France and Germany, published more frequently through photography, an enormous majority of them, and not only a few, would benefit by their copyrights, while piracies would be far less frequent.

EMPLOYES DINNER.—On Thursday evening, January 17th, by the kind consideration of Mr. Norman May, photographer, his employés, with a few of their friends, were enabled to spend together a few very pleasant hours of social recreation. The party numbered in all about 25; they assembled in the new, handsome, and spacious rooms of the Beauchamp Hotel, where a bountiful and elegantly-served repast was provided. The time that remained after dinner was filled up with mutual congratulations, songs, and merry chat; all enjoying themselves heartily. —*Malvern Advertizer*, January 18, 1884.

DETECTION OF CHLORINE, BROMINE, AND IODINE.—Mr. Francis Jones, F.R.S.E., writes:—"I have lately introduced a method (suggested to me by the process employed on the large scale for the manufacture of iodine and bromine), which is based on the same principle, but carried out in a simpler and more convenient manner, and which serves extremely well for the detection of the three elements. The process is carried on in the following way:—Place a *small* quantity of the mixture to be tested in a good sized test-tube, add a few pieces of manganese dioxide, and then a little water. Add now *one* drop only of dilute sulphuric acid (one part acid to ten of water); a brown tinge indicates the presence of iodine. Boil the mixture, and confirm the presence of iodine by the violet vapours in the upper part of the tube. Continue the boiling till these vapours cease to appear, then add another drop of sulphuric acid and boil again till they cease. If necessary, repeat this addition of acid and boiling until violet vapours have entirely ceased. Now add about two cubic centimetres of the dilute acid and boil again: brown vapours indicate bromine. Continue the boiling until the vapours no longer smell of bromine, then add one cubic centimetre dilute acid and boil again. When the vapours no

longer smell of bromine, allow the residue to cool *completely;* add an equal bulk of *strong* sulphuric acid, and warm; a green gas, bleaching a piece of moist red blotting-paper at the mouth of the tube, indicates chlorine. Occasionally some bromine comes off on addition of the strong acid, but if so it is soon got rid of, and is succeeded by the chlorine, which is chiefly evolved on warming the mixture. As, moreover, moist red blotting-paper is far more quickly acted on by chlorine than by bromine, there can be no difficulty in distinguishing between the two elements. I have compared the results obtained by my students when using this and other methods, and find they are far more successful with the new method."

PHOTOGRAPHIC CLUB.—At the meeting on January 30th, the subject for discussion will be "The Preparation of Lantern Slides." This being also an evening devoted to the exhibition of slides in the lantern, members and visitors are invited to bring interesting subjects to be shown.

To Correspondents.

*** We cannot undertake to return rejected communications.

*** *Reprint of the first number of the current volume.* Subscribers are informed that this is in hand, and will be ready shortly.

JOHN WHITELAW.—The sectional drawing which you send corresponds to an ordinary quarter-plate portrait lens, and it may serve very well for a beginner. If you find it on trial to be a fairly good lens, it may probably be worth 20*s.* or 30*s.*; but if you simply purchase it at a shop, and take the risk of faults, you should not give more than 10*s.* to 15*s.* The front lens, if placed in a reversed position in the back of the mount, will serve for taking views on 5 by 4 glasses, or even on half-plates.

SOUTH DEVON.—1. You will find a drawing and all the information you require on page 449 of our volume for 1882. 2. From any dealer in photographic apparatus.

J. CHAMLEY.—1. They are not manufacturers, but merely described the method of working the process. Write to the Platinotype Company.

THOS. BLAKE.—1. We cannot altogether agree with the opinions of the writer referred to. 2. Mischief is not likely to occur unless the plate contains chloride of silver; but in any case it is well to take the precaution of examining them in a subdued light.

W. S. MOON.—Reference was made to his papers on photo-lithography, most of which were published in the PHOTOGRAPHIC NEWS during the past year.

E. WILLIAMS.—The difficulties you refer to are very real; but you must not expect too much of an extremely rapid lens.

A. H. E.—Nothing is better than a strong mucilage freshly made from the best gum-arabic.

AMATEUR (Croydon).—It is a solution of bitumen in benzole, a small proportion of fine lamp-black being usually ground up with the mixture. The "liquid jet" sold by Messrs. Hopkin and Williams is a simple bituminous varnish without the pigment.

THOS. R. WEST.—It should not be so hot as to be unpleasant to the back of the hand.

F. STOKOE.—We cannot tell you of a certain method of reducing it under the circumstances; but the knowledge you have gained will serve to prevent the occurrence again.

INQUIRER.—1. You may probably obtain them by advertising for them. 2. Quite a matter of opinion.

X. Y.—Simply a false pretence: difficult to detect, certainly, but punishable as a fraud, if money is obtained by the untruthful representation.

B. AND G.—Write to Mr. Eastman, Dry Plate Works, Rochester, New York, U. S. A.

S. K. HUGON.—From the Willesden Waterproof Paper Company, Willesden Junction, London, N. W.

A. B.—1. We will consider the matter, but should not undertake it without making a series of experiments in order to clear up certain points which appear doubtful at present. 2. As much fluoride of sodium as will rest on a threepenny piece, dissolved in 10 ounces of water, and about a drachm of bisulphate of potassium, will serve as a convenient substitute.

OPERATORS' SPECIMENS.—Specimens forwarded by the following in answer to advertisements, may be had on application at our office:—E. Trapnell, W. James, E. Spencer, and J. G Pratt.

AGRICULTURIST.—1. The camera you describe is evidently an extremely old-fashioned one, and it possesses but little commercial value. We should recommend you to purchase one of the cheap quarter-plate cameras which are now in the market. 2. You will find the addresses of several firms in our advertisement columns.

J. S.—You would find it convenient to arrange with a patent agent as regards the foreign patents. Most agents issue some kind of scale of fees, inclusive of agency charges. Consult the Directory for list of agents.

S. SAMUELSON.—1. Try the effect of considerably reducing the exposure. A very good method will be to draw the shutter one-fourth of the way up, and to expose one second; after which you can draw it up half-way, and expose for three seconds, and so on. 2. Iron sash bars will take the putty very well if they are well painted before they become rusty. 3. Chloride of copper.

COLLOTYPIST.—Chrome alum may be added, but you must be careful not to overdo it. A convenient way is to make up a solution containing 5 grains to each ounce, and to add them as required. Under ordinary circumstances your batch of mixture should not require more than half a drachm.

M. T. R. DUTTON.—The silver solution has doubtless penetrated the porous body of the ware, and rendered the vessel quite unfit for further use; glass is much to be preferred.

CHROMATE.— It is nearly insoluble in strong alcohol, but a mixture of equal parts of alcohol and water will dissolve sufficient for your purpose.

J. HARVEY.—1. We have never heard of large surfaces being covered under such circumstances. It would be better to retouch the negative. 2. They answer as well as anything we know of.

J. F.—We cannot judge unless we know something of your qualifications.

C. G. TODD.—1. There is often a tendency to blister if the paper is extremely dry when floated on the sensitizing bath. Try the effect of hanging the sheets up in a cellar or other damp locality for an hour or so before sensitizing. 2. The collodion is probably over-iodized for the bath you are using, and the remedy is either to increase the strength of the bath, or to use a little less iodiser in mixing your collodion. 3. Chloride of silver dissolves readily in a solution of ammonia, hence the result which appeared so incomprehensible to you. 4. It should be prepared by dissolving unvulcanised india-rubber in benzole, and the solution ought to be of such a consistency as to flow slowly over a plate. The most suitable rubber to employ is that which is sold as "masticated rubber," and care must be taken that real benzole is used, and not the light petroleum which is sold under the name of benzolino. 5. The most satisfactory method of preventing the adhesion of the electro deposit is to silver the original, but an extremely thin film of silver will answer the purpose. To a thirty-grain solution of silver nitrate, add sufficient of a saturated solution of cyanide of potassium to re-dissolve the precipitate which is first formed, mix the liquid with sufficient whiting to form a thick cream, and rub this upon the copper by means of a tuft of cotton wool.

C. BURLSDEN.—1. Ultramarine is ordinarily used, and it is merely intended as a "foil" against the yellow tint of the material.

The Photographic News Registry.

Employment Wanted.

Salesman to photo. & frame makers.—L. W., 18, Plantation-rd, Oxford.
Operator, colourist, &c.—S. George, Sherwood-villa, Brunswick-pk., N.
Neg. Retoucher, lady.—M. F., Gaskell's, 15, Sussex-rd., S. Kensington.
Reception-Room or Shop.—C. M., 2, Dover-ter., Dover-st., Sittinghourne.
Retoucher, Lady, first-class.—E. M., *Photo. News* Office.
Spotter & Mounter.—Miss Stewart, 2, Albany-ter., Bournemouth.
Retoucher & Spotter.—L. F., 30, Swanmore-rd, Isle-of-Wight.
Silver Printer, first-class.—F. G., *Photo. News* Office.
Reception-Room, Lady.—F. W., 16, Chrystell-rd., Brixton.
Retoucher (Lond. only), c/o. J. S. Cockerton, 2, Hanover-pl., Regent's-pk.
Retoucher & Assistant Operator.—Artist, 19, Waterloo-st., Southsea, Hants
Carbon Enlarger, Painter, &c.—G. Fischer, 54, Berners-st., W.
Recep. room and manage (Lady).—Rembrandt, 5, High-st., Ryde, I.W.
Retoucher, work-up black-and-white (Lady).—W. J., *Photo. News* Office.
Operator, manager.—A. E. Walker, 118, Abbeyfield-rd, Pittsmoor, Sheffield
Operator or manager.—W. D., 2, Nursery-vils, Bounds-grn, New Southgate
Assistant (Lady), tint, spot, &c.—A. G., 5. Heaton-vil., Heaton-rd., S.E.
Collotype Printer, expe.—E. Birch, 3, Alpha-ter., Boston-rd., Hanwell.
Operator and Retoucher, or to manage.—Operator, 18, Telford-rd., W.
Mounter, Spotter, Books (Lady).—A. E. G., *Photo. News* Office.
Opera. & Retouch, all branches.—Pyro, 1A, Prince-of-Wales-rd., Norwich.
Operator and Retoucher.—Manager, Eastover House, Bitton, near Bristol.
Assistant Operator.—A. G. R., Rosetta Cottage, Weeks, Ryde, I.W.

Employment Offered.

Enlarger for general work.—D. S., *Photo. News* Office.
Dry-plate man, first-class.—Dry plate, 37, Thornton-st., Brixton.
Operator and retoucher.—F. Baum, c/o Disderi & Co., 4, Brook-st., W.
Female Assistant Printer.—F. Baum, c/o Disderi & Co., 4, Brook-st., W.
Painter in Oils, Club work.—K., *Photo. News* Office.
Printer & Toner, good Vignetter.—Mr. Vanderweyde, 182, Regent-st., W.
Photo-litho. Oper. (transfers, collotypes.).—Stewart, *Photo. News* Office.
Lady, Youth, and Apprentices.—2, The Pavement, Clapham Common.
Assistant Printer, to reside in house.—W. J. Anekorn, Arbroath, N.B.
Youth, to sensitize, mount, &c.—Turner & Killick, 10, Barnsbury-pk., N.
Saleswoman and Stock-keeper, to spot, &c.—J. E. Bliss, Cambridge.
Retoucher, first-class.—W. McLeish, 71, Northgate, Darlington.
Young Lady Printer.—Gartside and Risley, *Photo. News* Office.
Retoucher, clever.—J. Hawke, George-st., Plymouth.
Dry-Plate Coaters, experienced.—Prestwich, 155, City-rd., E.
Photo-lithographer, experienced.—Photo., 150, Queen Victoria-st., E.C.
Photo. expe. largest cameras.—E. Meyerstein, 280, High Holborn, W.C.
Retoucher, for high-class work.—Mavius and Vivash, 49, Ann-st., Belfast.
Operator for N.W. Provinces, India.—India, *Photo. News* Office.
Photo. Artist, first-class, all-round hand.—W. Knight, 47, Coney-st., York.

VOL. XXVIII. No. 1326.—*February* 1, 1884.

CONTENTS.

VARIOUS CLEARING SOLUTIONS FOR NEGATIVES.

THE past year has seen a considerable advance in the means placed at the disposal of the photographer for obtaining negatives developed by the alkaline pyrogallic method which show none of the yellow colour that, until recently, was considered a necessary quality of a pyro-developed gelatine negative.

All must well remember the plaints of the poor printers about three years ago, when the use of gelatine negatives became general, and how they grumbled about the deceiving appearance of the negatives, and the time it took to get a dozen prints. In enlarging, the drawback of the bad colour was felt almost more than in printing.

The matter is changed now. We venture to say that in the greater number of the best photographic studios the pyro-developed negatives which are handed to the printers take little, if at all, longer to print than did the wet plate negatives of the olden times.

The habit of always using the alum bath, which was first introduced merely as a means of preventing frilling, has had much to do with the change. Many kinds of plates, if simply treated with alum between development and fixing, give a colour as good as can be desired, but it is to be noted that some require a little more than this. It is not generally known how much difference there may be between one film and another in regard to their liability to take the yellow stains of the pyro developer. We have exposed two plates by different makers for the same length of time in the camera—the sensitiveness was about the same—and have afterwards developed them side by side in the same dish. The development went on at about the same rate in each case, and no difference was noticeable between the one plate and the other till after fixing, when one was found to show only the faintest trace of a yellow colour, whilst the other was almost brown in the shadows.

Treatment of the first plates with alum before fixing made them give negatives of perfect colour. The others still showed considerable yellowness, even when treated with a neutral alum solution.

This difference was not merely accidental, but was noticed at all times between the plates of the two makers.

We have found that even those films which tend most of all to yellowness will give a good colour if the alum used before fixing be rendered a little acid. An alum bath so strongly acid as is often used for clearing after fixing, has the effect of very materially reducing the density of the negative if used before fixing; but one composed as follows does not have such an effect:—

Saturated solution of alum	1 pint
Citric acid	1 dram

We have advantageously used such an alum bath before fixing, and have found the result to be that all plates gave us negatives of excellent colour. It is necessary to be careful to wash the plates thoroughly after they have gone through this bath, and before they are placed in the fixing solution, otherwise it would appear that the acid has some decomposing action on the hyposulphite of soda. If a plate which has been treated with the acid alum solution be rinsed but slightly, and then be placed in the fixing bath, a powdery deposit may form on the film. This is presumably some form of sulphur.

As regards clearing solutions to be used after fixing, we have found that of all the various mixtures of alum solution and acids which have been proposed, few give a better result than the following:—

Saturated solution of alum	1 pint
Hydrochloric acid	1 ounce

This mixture appears to act quite as well as one in which the hydrochloric acid is replaced by citric acid, whilst it has the advantage of being much cheaper.

This acid solution, like all others that we have tried, has the property of somewhat reducing the density of the negatives which are treated with it. This may be a great advantage at times, but at others it is the very reverse.

Mr. B. J. Edwards recently introduced a clearing solution, for which he claimed that, whilst it gave a favourable printing colour to a negative, it in no way reduced the density. The solution which Mr. Edwards recommends is mixed as follows:—

Alum	1 ounce
Citric acid	1 „
Sulphate of iron	3 ounces
Water	20 „

The negative is to be treated with this solution immediately after fixing, and slight rinsing under the tap; that is to say, the hyposulphite of soda is not to be entirely washed away.

We have recently been using this solution, and find that, applied as Mr. Edwards directs, it leaves nothing to be desired. Used in place of the ordinary acid clearing solution as the latter often is—that is to say, on a negative which has been fixed, thoroughly washed, and possibly dried—it appears to have little advantage over the older method.

We have also been more successful in performing silver intensifications with this solution than with any other which we have tried. The negative to be intensified is *thoroughly* washed to get rid of all hypo; it is then placed for some minutes in the solution, the formula for which we have just given, and afterwards flowed with a small quantity of the same solution, into which has been dropped a little of a twenty-grain solution of silver nitrate.

If the negatives to be intensified be quite clear in the

shadows, we have found no difficulty in intensifying them in this manner up to any desired extent. But if they be even a little fogged we have found great difficulty, as, in such a case, the shadows appear to intensify almost as much as the high-lights.

There is a stain quite different in nature from the ordinary pyro stain, which, although it resembles it somewhat in appearance, is in reality a much more objectionable phenomenon. It usually comes when a negatives has been imperfectly fixed—when, perhaps, all the visible bromide of silver has been dissolved away, but when there has still been left in the film a certain portion of some silver compound. The colour is not evident at first, but comes on after the negative has been exposed to the light and air for a few days. It is rather a fog than a stain. A stain covers a negative as well in the denser as in the more transparent parts, although it may be most visible in the latter, and therefore has no effect but to make it somewhat slower in printing. A fog, such as the one in question, appears to attack the shadows only, or at least more strongly than it does the high-lights, and thus, reducing the contrast, ruins the negative.

The ordinary yellow pyro stain is generally pretty evenly distributed over the film. The fog which we mention is usually confined to one portion, namely, the one which has been the last to fix. For this reason it is more detrimental than it would otherwise be.

It is not acted upon by either citric acid and alum, or hydrochloric acid and alum. We have, however, found that it will generally give way to a solution prepared as follows :—

Saturated solution of alum	1 pint
Nitric acid	1 ounce

PRESERVING SENSITIZED PAPER.

THE custom existing some fifteen or twenty years ago, to employ a concentrated solution of silver nitrate for the purpose of rendering albumenized paper sensitive to the rays of light, can by no means be considered an axiom only of the past, since we have it recorded quite recently that practical men—such as Valentine Blanchard, Frederick York, and others desirous of conferring keeping properties to the sensitive surface—invariably start with a liberal quota of the silver salt. An analysis of all the published methods will be found to result in a general average of sixty grains of nitrate of silver to each ounce of the sensitizing solution.

Besides the evidence adduced by those practical photographers who preserve their paper, and make no secret as to the way in which they do it, we find the commercial papers themselves are rich in silver nitrate, giving a further proof, if such were wanting, that the best results are only obtained by a judicious, and not a cheeseparing expenditure of silver. There is no necessity to go to either of the extremes, such as sensitizing on a bath 80 or 100 grains strong, as at one time almost universally employed for ordinary work, or the excessively dilute five-grain bath mentioned at one of the recent society meetings. That a reliable method of preserving sensitized paper in a most perfect manner is not generally known, must be apparent to most of us. We all understand the method of preserving with citric acid, and, perhaps, some may have found a little difficulty when the operation of toning took place ; this little trouble may be easily avoided by adopting Mr. York's suggestion, viz., to soak the prints in an aqueous solution of carbonate of soda, after washing away the free silver, and before toning. One per cent. will be found a good strength to make the soda bath, and five minutes will be ample time to neutralize any acid left in the pores of the paper.

Many other acids have been from time to time recommended, such as nitric acid, oxalic, perchloric, also some of these acids combined with an alkaline base, together with alum, camphor, borax, various gums, glycerine, and other substances. We have also the bicarbonate of soda method published in these columns as far back as 1871, and which is, perhaps, the most convenient plan of all. A neutral sensitizing bath is employed, the exact strength of which is not very important, so long as good prints can be obtained in the ordinary way. The most important thing to observe is, to well dry the paper before packing away between the sheets of bibulous paper, which have previously been soaked in a seven or eight per cent solution of bicarbonate of soda, and thoroughly dried afterwards. If carefully packed away in a moderately air-tight case, such paper will keep a long time ; the bibulous sodic papers doing duty over and over again.

There is no difficulty whatever in toning prints which have been preserved by means of the sodic paper ; but there is at times a mottled appearance, caused either by acidity of the sensitizing bath, or dampness, or both. Possibly the occurrence of this defect occasionally may be the means of deterring many from adopting this method, for the convenience to have paper always ready is great indeed. We are inclined to think albumenized paper keeps white after floating for a longer period than formerly without any extra precautions being observed. If it were washed and fumed in the manner we advocated some years ago, we see no reason why sufficient stock could not be prepared on a dull day to last three months or longer.

ISINGLASS, GELATINE, GLUE, AND SIZE.

A DISTINCTION is often made between the above-mentioned substances ; but, in reality, no very sharp line of demarcation can be drawn, and the term gelatine fairly includes all of them. Of the chemistry of gelatine we propose to say nothing, except to remark that it is a highly nitrogenized animal substance, and therefore quite distinct in its nature from the so-called vegetable gelatines, such as agar-agar, Irish moss, or the so-called thio. We shall have a few words to say about these *quasi* gelatines on a future occasion, but shall now confine our remarks to the true gelatines of animal origin.

Isinglass, which is the most expensive kind of gelatine in the market, is the swimming-bladder or sound of various kinds of fish, and the principal yield is obtained from the sturgeon. Isinglass is used by some for the preparation of collotypic plates, and the circumstance that it yields a very structureless film is in its favour. We are not aware that it has been employed to any great extent for emulsion work ; but some years ago we prepared some plates with isinglass instead of the cheaper gelatines, and the result was very satisfactory, the films being extremely uniform, and no tendency to blistering was noticeable. Considering the small quantity used in plate making, the high price of isinglass should not prove an obstacle to its use.

Ordinary gelatines may be classified into bone gelatines on the one hand, and skin gelatines on the other, the former being ordinarily made by soaking the bones in dilute hydrochloric acid to remove the mineral matter (principally calcium phosphate), and boiling the residue with water until solution takes place. A little alum is generally added in order to separate fatty matter, and the hot solution is allowed to set, after which the jelly is cut into flakes, and allowed to dry in a good current of air. Skin gelatine is made from cleansed hides in a similar manner, only the preliminary treatment with hydrochloric acid is not required ; but it is very usual to fume the skins with sulphurous acid in order to whiten them. Excessive heating is carefully avoided in the manufacture of gelatines, as, otherwise, the setting power of the material becomes less, a considerable proportion passing over into the condition of soluble gelatine or meta-gelatine ; when a gelatine is made from dirty or partially decomposed

material, or if an undue heat has been employed in its production, it passes into commeree as glue. Many impurities may be removed from gelatine by mixing white of egg with the slightly warm solution, and then heating to about 160°, in order to coagulate the albumen, which then separates as a kind of scum, and carries with it fatty and other impurities. The white of one egg will serve to clarify half-a-pound of gelatine. In ordinary cases, manufacturers do not clarify even the fine kinds of gelatine with egg albumen, but they make use of the low-priced albumen obtained from blood.

The commercial value of a gelatine depends mainly on its setting power and the strength of the jelly produced. Eder's method of testing gelatines, which has already been fully described in the PHOTOGRAPHIC NEWS, may be again briefly described.

The samples to be examined are dissolved in nine parts of water, and all the jellies are allowed to set in similar beakers, the temperature being adjusted as near to 15° Centigrade as possible. The resistence of each sample is now measured by a convex disc or cup about half-an-inch in diameter, to the inside of which is attached a metal stem surmounted by a funnel. The convex disc is now laid on the surface of the jelly, and the stem is steadied by a suitable guide, while the funnel is gradually loaded with shot until the disc breaks into the jelly; the sample which resists the greatest weight being the best.

DIFFUSED LIGHT FOR THE DARK-ROOM.

DR. VOGEL writes us:—"I have repeated your interesting experiments on the illumination of dark-rooms, and in the main with the same results; but I must remark that all kinds of orange glass are not suitable for the purpose. The first I tried was lightly tinted, and I did not succeed with it at all. Another darker kind, which absorbed all the most refrangible part of the spectrum, was better; but I must confess that I cannot agree with you when you say that the spectroscopical results contradict the photographic ones. It seems so, but it is not so.

"I compared carefully the absorption of the ruby glass and the orange glass for the red part of the spectrum, and observed easily that the orange glass absorbed *decidedly more* of the red rays than the ruby glass. That gives an explanation. Red rays do really act on the ordinary gelatino-bromide film (I obtained a photograph of the red line of the hydrogen spectrum three years ago), and therefore it is easy to suggest that the very bright red light which a ruby glass lets pass will have about the same chemical action as the dull red, yellow, and green rays together, which an orange glass, combined with ground glass, allows to pass.

"I worked nearly in the same way as yourself. I exposed bromide plates under a Warnerke screen for two minutes, to a fish-tail burner, at a distance of a meter, and covered the screen with ruby glass first, then with orange and ground glass combined. In both cases I got the same number (10). The illuminating quality for the naked eye I determined by covering one of my paper photometer screens with the glasses above mentioned, and observing the last number, which I could recognize when looking through. In this way I could recognize No. 6 behind the ruby glass, and No. 8 behind the orange and ground glass combined.

PHOTO-ENGRAVING PROCESS.

OUR readers will remember the specimen of Klic photo-engraving process which we issued with the YEAR-BOOK for 1882.

The process itself was a secret at first, but we are informed that the principle of working is as follows:—

A copper plate is dusted with powdered asphalt, and the plate is heated, so that the asphalt becomes nearly melted. A negative carbon print is now transferred on to the copper plate, and the plate, now covered with the negative in carbon, is etched, at first by a strong solution of perchloride of iron, which penetrates only the thinnest parts of the picture; then by a weaker solution of the same salt, the solution etching through the thicker parts. By employing more and more diluted solutions, it is possible to etch through thicker and thicker layers of gelatine, so that only the high-lights remain unetched.

One advantage of the Klic process is the circumstance that the plates are very quickly finished. Goupil, who takes an electrotype from a grained relief, requires several weeks for depositing metal of sufficient thickness. The etching process of Klic is rapid, and plates may be produced in a day or less.

Obernetter's Photo-engraving Process.—The eminent photographic chemist, Obernetter, of Munich, to whom we are indebted for so many improvements in photographic matters, has invented a quite new process, which gives results like Goupil photogravure. He has sent excellent proof-pictures by his process to the Society for the Advancement of Photography in Berlin.

The most striking feature of the Obernetter prints is the richness of the tone in the lights, and the principle of the method is stated to be as follows. A diapositive is made by the Obernetter method on a plate containing a maximum of silver and a minimum of gelatine, and the film, having been stripped, is treated with a mixture of perchloride of iron and chromic acid, so as to convert the whole of the silver into chloride. This film, charged with chloride of silver, is now placed in contact with a copper plate, and the copper gradually decomposes the silver chloride, metallic silver being liberated. This decomposition of the chloride is of course accompanied by a corresponding etching of the plate.

The new principle now published is an important one, and we have found that if a collodion positive or an ordinary gelatino-bromide transparancy is converted into a chloride picture by suitable means, it easily etches a copper plate with which it is pressed in contact. We found the method described by Mr. E. de Zuccato in these columns to be the most convenient for converting the silver picture into chloride, viz., treating with a mixture of dilute hydrochloric acid and bichromate of potassium.

If the film, before being placed on the copper, be moistened with a weak solution of chloride of zinc, the etching proceeds more rapidly than otherwise.

We are not aware that the new method of etching copper plates has been patented in this country, and we hope our readers will try a few experiments with the process, and let us know the result. It is scarcely necessary to say that the method is also adapted for the production of high or typographic plates, but in this case the lines of the chloride of silver picture must correspond to those parts of the block which are required to print white.

Those who are interested in producing typographic etchings on copper will find an article treating of the subject on page 338 of our last volume.

By-the-Bye.

STUDIO DRESSING ROOMS.

THE studio dressing room is a more important feature of the studio than people imagine. Even photographers who have shown taste and tact in the fitting of these retiring rooms often have but limited ideas as to their use, while many more regard them as altogether superfluous. Of course, the sitter who pays but five shillings a dozen for his pictures can hardly expect the same appointments and the same handsome fittings as are found in studios where one or two guineas is the fee simple; but he may be treated

with precisely the same consideration, and the best the studio affords should be given to him as to every visitor alike. In a word, whatever the rank or degree of the studio, there is no reason why order, neatness, and discipliue should not be rigorously observed; these have nought to do with the wealth or poverty of the establishment, but are simply the signs of a good and painstaking manager.

We have always regarded the dressing-room as a ready means of showing the sitter polite attention. Your reception room may be gorgeously upholstered, hung with attractive paintings, and furnished with luxurious settees and sofas; but all this is done for the glorification of the establishment, rather than for the comfort of the visitor. In a way, it is a species of advertisement. The sitter regards it all with something of admiration and awe, and communes with himself over the prosperity of the establishment. Nay, the graudeur around often tells plain Mr. Smith that the least he can spend, in these circumstances, is a five pound note, and presently he hands over this amount with a smile to the young lady in charge of the books, although but ten minutes before, as he came up stairs, he had fixed his outgoing rigidly at a guinea. We repeat, money spent upon a grand reception-room is disbursed with something of the same feeling that prompts the physiciau to set up his elegant carriage and pair, and causes the secretary of a public company to secure handsome premises in a handsome thoroughfare. The reception-room is part and parcel of the business concern; the dressing-room on the other hand, let it be as elegant as you please, is a sort of discount to the payment, and a welcome solatium in case this payment is deemed high. You desire, or at any rate you should do so, to render your sitter every attention—to assure him, that since he has placed himself in your hands, you will take every care of him, and treat him courteously iu return for his confidence. How can all this be done better than by placing at his disposal a neat little private room? A sitter feels at once that there is something here tendered him outside the hard-and-fast bargain, and he values the attention highly. It is like giving a man a good cigar; it is one of the cheapest, as it is also one of the most genuine, compliments you can pay.

As well-appointed dressing rooms form part of nine studios out of every ten, it may seem that these remarks of ours have been forestalled by photographers. This is not so, however. We are well aware of the existence in most establishments of dressing-rooms, and in our "Studios of Europe" we have again and again complimented photographers on the taste and elegance with which these are fitted. In Mr. Fergus' studio at Largs, we found no less than five dressiug-rooms *en suite*, all of them bright, clean, and admirably appointed. In like manner the chief studios of London, Paris, Berlin, Vienna, &c., were supplied with suitable dressing-rooms, the principals in most cases, indeed, taking exceptional pride in this part of their establishment. But to judge from our experiences on the other hand, as one of the public, it is very certain that many photographers do not make proper use of the charming little boudoirs into which we have been ushered time after time, on presenting a card with the name of this journal upon it. We fear, sometimes, the manager is too careful of these private apartments. He dreads letting everybody into the well-furnished little chambers, and so it happens that only now and again a sitter is shown into them. At any rate, this fact speaks for itself: that of six London studios visited by us last year, as a paying sitter, in only one case was the invitation extended to us to walk into a dressing-room.

We have little doubt that a lady, entering the half-dozen establishments we visited, would have been differently treated in this respect. But it is not this point at all that we want to urge on the attention of photographers. In no case were we received otherwise than with courtesy. What we want to urge, however, is, that a studio which does not make full use of the advantages it possesses, acts with unwisdom. Here it is, in a position to confer certain compliments and attentions, and yet fails to do so. Not once in a dozen times, probably, will a gentleman sitter find it necessary to make any alteration in his dress, but he none the less desires to look at himself before posing before the camera. This, it is true, he can do very well in the studio itself, at a glass usually placed for the purpose, and if his hair wants brushing and smoothing, the latter operations can equally well be gone through while the assistant waits beside him. But human nature tells us all this will be hurriedly and awkwardly done, and often at some self-sacrifice of respect. A grown-up man doesn't like everybody to watch his toilet: he is much more reticent over it than his wife or sister, for he is not supposed to possess those little vauities and conceits that woman is heir to. Nevertheless, when a solitary wisp is all that is left of his raven locks, or the grey whiskers require a comb to lend them the ambrosial curl of yore, he prefers to make the best of what is left him unwatched and unseen. There is very little to do, perhaps, but he does not care to parade his weaknesses, for all that. Besides, he wants to put his cravat straight, to be quite sure his collar is down at the corners, and that his shirt front has not that crease across the breast where he knows it inevitably comes if he does not mind. A lady would use powder and hare's foot with the greatest nonchalance, where the lord of creation shrinks to comb his moustache. Now all this, of course, is very childish, and very petty; unfortuuately, it is a fact, and it is a pity, therefore, photographers do not recoguize it. That they do not, is proved by our own experience, for we found that in most instances a lookiug-glass and brush and comb in the studio are deemed to fulfil every requirement. If a gentleman, when he comes, hurriedly looks into the mirror, and sits down in the posiug chair without delay, he does this as much from nervousness, or from a fear of appearing ridiculous, than from any other reason.

The photographer prides himself on the idea that in posing, he himself takes eare that nothing in the sitter's toilet is awry, but the former knows nothing of his visitor's idiosyncrasies or tender points. At any rate, the photographer cannot value the persoual fads of the sitter so highly as the latter, and therefore a little thing that escapes the artist's glance may condemn the picture in the eyes of the model. For this reason, we hold that gentlemen and ladies alike should be invited to enter a dressing-room, if the photographer desires them to receive every attention.

There is an intermediate plan which is sometimes adopted on the Continent, and which is certainly better than the looking-glass and brush-and-comb arraugement. This is to have a recess or alcove iu the studio, into which the sitter may retire for a few moments while the assistant is getting ready. The sitter is out of sight of the photographer while making a last survey of his features and dress, and there is not the formality or loss of time involved in entering a dressing-room. Only, it is very necessary in this case, as the alcove is apt to get dusty and dingy, that scrupulous care is taken to keep everything here neat and clean. Better, a thousand times, have no toilet conveniences at all, than have them doubtful as to cleanliness.

In some studios it is customary to have a moveable toilet table, which, after changing a pose, is wheeled in front of the sitter, in case she (for it is rare that a gentleman requires the aid of a mirror and powder, or hair-brush, at such brief intervals) may wish to re-arrange her headdress or make other alteration. In this case the toilet-table must be of elegant shape and fitted with taste and exceeding care, for the fierce light that beats down into the centre of a studio displays unmercifully any signs of slovenliness.

But we have no need to insist upon neatness and cleanliness—there should be, by-the-bye, as few things as possible in the dressing-room—for a want of these has never proclaimed itself in any studios we have visited. Our principal aim has been to point out the shortsightedness of photographers who possess well-appointed dressing-rooms, and do not use them; to all sitters alike, gentlemen as well as ladies, should the invitation be given to enter them, for it does not by any means always follow that those who seem least to care for personal appearances are least fastidious over their toilet. The photographer should remember that the very essence of the sitter's visit is to perpetuate his personal appearance, and it would be strange indeed, therefore, if he were absolutely indifferent about his toilet on such an occasion.

The By-the-Bye next will be "Success in Photography."

A Dictionary of Photography.

ALBUMENIZED PAPER (Printing on).—*Continued.*

Washing by simply soaking in a tub or pan with frequent changes of water is a method largely practised, although somewhat tedious and laborious; but a simple expedient of attaching one corner of each print to a cork, as suggested by Major Senior in a communication to the Photographic News, is a valuable one, as this arrangement tends to keep the prints vertical in the water. Major Senior says:—

Arrange a cask, A, and a tub, B, as in drawing, regulating the run of the water from the two taps, C and D, so that as much water will run off at D as enters the tub B at C. The tub, B,

Fig. 3.

must be full of water, and the prints, having been toned, fixed and washed in one or two changes of water, so as to get rid of the superfluous traces of the soda, they are suspended by one corner to clean corks by means of pins; two pictures to one cork, as a rule, will be best—viz., one on either side of the flat ends. Common sense will suggest to the operator to attach the pictures so that the surplus portion of the paper of the print will be near the cork, and to do the trimming after the washing and drying.

Major Senior's idea may be improved upon by not only pinning one corner of each print to the cork which is to serve as a float, but also pinning to the diagonally opposite corners of the prints to the loaded corks. The best way of loading the corks is to cut a piece of lead tubing into rings by means of a saw, and to slip one of these over each cork. Small phial corks may be used in each case. Unless one corner of the print is loaded it sometimes happens that air-bells which form upon it cause it to float up and lie horizontally upon the surface.

Hypo Eliminators.—To avoid the tedious operation of thorough washing, it has been suggested to change the chemical composition of the salts left in the paper after fixing, and thereby destroy the property they possess in such a high degree of rendering the print evanescent. It has been shown that this result may in a measure be attained by immersing the print, after fixing, in a dilute solution of either lead nitrate, *eau de javelle*, or common potash alum. As these eliminators are not so much in favour with every-day practitioners as they are with the experimental portion of the community, we will merely indicate the method of employing them, thereby opening up a field of further research for the student if he desires to avail himself of it.

The lead solution is made by dissolving one ounce of lead nitrate or acetate in eight ounces of warm distilled water—two ounces of the above solution to each gallon of soft water will be found to be a workable proportion. A stronger solution will change the tone to a cold slatey colour, and a weaker one will not bring about the required decomposition. That such has taken place may be known by the solution becoming cloudy.

The prints should be immersed in the bath for the space of five minutes, keeping them constantly moved about as in toning and fixing. At the end of the time stated, remove them to a vessel of clean cold water, give them three changes in all, separating each time, when they will be ready for drying and mounting.

Eau de javelle is made as follows. With three quarts of water mix half-a-pound of dry chloride of lime, then dissolve one pound of carbonate of potash in one quart of water; mix the solutions, and filter for use. Four ounces of the above solution to each gallon of water will be a very good strength to use; treat in the same manner as lead nitrate, or acetate.

Alum.—Make a saturated solution of ordinary potash alum; of this use four ounces per gallon of water, and allow the prints to be moved about for ten minutes, then wash in several changes of water.

Mounting.—There are several systems of mounting in vogue among photographers, but they may be all classed under two headings, and for convenience we will call them the dry and wet methods. The first-named of these consists in drying the photograph (an operation to be mentioned hereafter), applying some such substance as good starch paste in a manner calculated to give an even surface free from grit, hard clots, hairs, &c., and either attach it to the cardboard or other support immediately, or permit it to dry spontaneously, attaching it to the mount at any time afterwards that may be convenient. If the amateur desires the latter plan, he must proceed as follows:—Pass a wet sponge twice over the cardboard mount where the photograph is to rest; place the print in the required position, and press it gently to ensure its retaining that position. Having done so, pass them both through a rolling-press, which completes the operation. The photograph should be uppermost, and the operation performed quickly, to prevent any chance of tearing under the roller; one advantage this system has over others being that no unequal stretching takes place in the print.

The second, or what we will term the wet system, may be briefly stated thus:—Each print should be placed separately, face downwards, on a clean wet linen cloth, the superfluous water being blotted off by the same; then the mounting substance applied to the backs of as many as can be conveniently managed—say three or four—after which they are placed in the desired position on the mount, and pressed down by means of a paper-knife and sheet of white paper; the operation being repeated so long as any prints remain on the cloth. Whenever possible, we advise two persons to perform the operation, one to apply the mountant, and the other to attach the print to its support; it will not only make the work more agreeable, but it will reduce the chances of the albumenized surface being touched with some of the mountant, provided both persons are equally careful. Should such a mistake occur, the excess must be removed immediately by means of a wet sponge, as it may interfere with the after-operation of burnishing, &c.

Another plan is to transfer the print from the final washing water to a glass plate, albumen side being downwards (as many as fifty, or more, may lie on the top of each other without danger); drain for a few minutes; the top print may then be brushed all over the back with some of the mountant, lifted by a corner, and placed in its proper position on the mount. It should then be well rubbed down with the paper-knife until even—a piece of writing paper placed between the photograph and knife during the rubbing prevents scratches or tears—apply some of the mountant to the next, and repeat until all are finished. This will be found a very convenient mode when only a few dozen are to be mounted.

Mountants.—For various reasons it is probable that no better mountant is used for attaching photographs to substances such as cardboard than a good starch paste, made in the usual manner for laundry work, viz., mixing Glenfield's, or any other good class of starch, with a little cold water until a very stiff paste is obtained; then add *boiling water* (stirring vigorously) until a clear paste results. Should the paste not be of a good consistency—viz., rather limpid—discard it, and make fresh,

using a little less cold water to mix the starch; and be sure the heated water to be added is at a temperature of 212° F.

Two ounces of dextrine mixed with half-a-pint of cold water, and added to the above starch paste in equal proportions, the mixture being heated on a water or steam bath to 212° F., is said to make a very strong and useful mountant for photographs; it is an excellent adhesive, is not easily affected by moisture, and more useful for mounting photographs in scrap books than starch alone. Next in order of merit is thin glue, to which should be added a small proportion of an antiseptic, such as salicylic acid. Many large firms of photographers have not used any other mountant for years.

PHOTO-LITHOGRAPHY AND PHOTO-ZINCOGRAPHY.

BY MAJOR J. WATERHOUSE, B.S.C.,
Assistant Surveyor-General of India.

CHAPTER XVI.—NEGATIVE TRANSFER PROCESSES.

THE next processes to be noticed are the collochromate transfer process, in which, instead of a greasy image, the colloid ground is transferred, leaving the image itself in reserve on the stone or zinc plate, to be inked up by the application of a roller or pad charged with printing ink, which attaches itself on the lines where the stone or plate is bare, but not on the parts where the colloid coating has been transferred.

One of the earliest processes of this kind was published in the NEWS, vol. vii., page 414, by Mr. Joseph Lewis, of Dublin, who, as we have seen, was an ingenious and fertile worker in the early days of photo-lithography. His method is as follows:—

A jelly is formed consisting of—

Water	...	...	...	4 ounces
Gelatine	...	...	...	1 ounce
Glycerine	...	...	...	1 drachm

with bichromate of potash to saturation at 80° F. The solution is filtered carefully, then spread on glass plates, and allowed to stiffen till the surface will not stick to the dry finger or to the negative plate placed against it. If the upper surface be not smooth, the film may be reversed on to another plate or cardboard. It is exposed to light under a negative for a few minutes, and then laid face downwards on a clean lithographic stone, and gently pressed into contact all over; this requires some dexterity. The time the film should remain in contact with the stone varies according to circumstances. When judged sufficient, the film is lifted off, and the stone rubbed over with re-transfer or printing ink. The ink is washed off with turpentine and gum water, and the stone inked in and printed in the usual way.

The best known of these methods is, however, that patented in June, 1863, by Mr. W. Toovey, of Brussels, in whose hands the process gives very perfect results, both in line and half-tone; but it requires special appliances for giving the heavy pressure required, and some skill in adjusting the amount of moisture to be given to the transfer.

The specification of Mr. Toovey's patent will be found in the NEWS, vol. viii., p. 158. The following is an outline of it. Smooth, even paper is coated with a solution of gum-arabic in pure water, saturated with bichromato of potash. When dry, the paper is exposed to light behind a negative, so that the parts forming the image may become insoluble. The exposed print is then laid face downwards on a polished or grained stone, according as the subject is in line or half-tone, and previously arranged in a hydraulic or other powerful percussion press. Several sheets of damped paper are laid over it, and the whole exposed to a heavy pressure, so that the water in the damped paper may be forced through the photographic print, and dissolve the gum in the unexposed parts of the sensitive coating, which has, therefore, remained soluble. The dissolved gum attaches itself to the stone, while the exposed parts, being insoluble, protect it. When the stone has remained in the press a sufficient length of time to allow of the small traces of gum in the deepest shadows attaching themselves to the stone, the pressure is removed, the stone withdrawn from the press, and the paper carrying the photographic print is carefully lifted up, leaving a bare negative image on a gummed ground. The stone is then well dried, and covered all over with oil or greasy ink, applied with a roller or otherwise. The greasy ink is thus brought into contact with all parts of the stone unprotected by the gum. The coating of ink is washed off with turpentine, and all the surface gum removed by washing. The stone is then rolled in with ordinary lithographic printing ink, which brings the positive image in black, and it may be printed from in the usual way. Owing to the great pressure, the gum and bichromate are forced into the stone to a considerable depth, and prepare it so completely that there is no necessity for "etching" in the usual way with gum and nitric acid, and the stones will stand an unusually long impression.

The same method is applicable to zinc.

Captain Hannot, in writing on this process in his book already quoted, draws attention to the necessity for the gum used in this process being of the most soluble quality, and free from acidity. It is well to take large lumps of the best gum-arabic or Senegal, and having washed off the hardened outside coating with warm water, to use the inside for making the solution; a lump of lime or chalk may be added to keep it neutral.

In vol. viii. of the NEWS, p. 197, there is a description taken from *Les Mondes* of two similar methods of transferring an uninked collochromato print, proposed by M. de Lafollye, as a means of avoiding the loss of half-tone and fine details that occurs in the processes in which the collochromate image is inked and washed.

Paper is coated in the usual way with a solution of gelatine or gum and an alkaline bichromate, and exposed to light beneath a negative.

The exposed print is then floated face upwards on a water-bath so that the moisture may penetrate and soften the unexposed parts of the image, while the solarized parts, being insoluble and impervious to water, will remain dry. At a certain point, to be ascertained by experience, the print is removed from the water, and may be transferred to the stone in two ways.

The first is to place it face downwards on a lithographic stone and apply pressure. The paper is removed, and leaves, as in Toovey's process, a reserve of gum in the lights, while in the shades the impermeability of the surface prevents the gum from adhering to the stone. The stone may now be dried and inked with a roller, but the following method of inking is recommended. A clean stone is coated evenly with transfer ink; a sheet of autographic transfer paper is laid on the inked stone, and being passed through the press receives an even coating of ink. The inked sheet is now laid over the gummy image on the stone, passed through the press, and afterwards wetted so as to be easily removed. The ink will attach itself only to the bare parts of the stone, and not to those protected by gum. The stone is then washed and inked in as usual.

In the second method, which is, however, not strictly a negative process, the exposed print, moistened as before to just the proper point, is placed, image downwards, upon a stone that has been rolled in with transfer ink, and is passed through the press. If the sheet were dry its whole surface would be covered with ink, but it will be found that where the moisture has penetrated the gummy coating the ink will not attach itself to the paper, while it does so in the impervious parts forming the image, and in proportion to the amount of the action of light upon them.

The inked transfer print is freely washed with water to remove the soluble bichromato and any slight soiling of the whites. In washing, care must be taken not to use the slightest friction, which might damage the finest parts of the image. The print is then dried and transferred in the usual way.

M. Lallemand, in his "*Nouveaux Procédés d'Impression photographique et de photolithographique*, describes a method of negative photo-lithography, and observes that by the action of an alkaline bichromate, gum becomes less soluble, while gelatine becomes more so. Papers prepared with gelatine are therefore not suitable for this process as those prepared with gum, either alone or mixed with linseed mucilage, and he gives the following formulæ for the sensitive coating:

1.—Sat. sol. bichromate of potash ... 100 parts
Thick gum (2 gum arabic, 3 water) 50

2.—Sat. sol. bichromate of potash ... 100 parts
Thick gum 40
Very thick linseed mucilage at ten per cent 20

By well heating, the mucilage seems to become thinner, and solution No. 2 is not thicker than No. 1.

Paper is floated over the mixture. For very fine results albumenized paper may be used, or paper coated with a single coat of

Water	..	...	...	... 500 parts
Gelatine	...	...	...	... 50
Alum	...	...	...	... 5

The paper when dry is exposed to light under a negative. After exposure the print is laid in a damp book and taken out as soon as it is limp. It is placed gently on the stone, and made to adhere to it by means of a small roller. The back of the print is then wetted very lightly with a sponge, taking care not to use too much water.

After one or two minutes the corner of the paper is raised to see if it comes off easily, and if an even coating of gum has been transferred to the stone, and when the time is considered favourable, the paper is gently removed. If the operation has been properly conducted, the stone will show a negative image of surprising delicacy and sharpness. The borders are gummed, and when the coating is quite dry, fatty ink (by preference a solution of resinate and oleate of iron in benzole) is applied to the stone, and the other operations are the same as in the processes previously described.

In another method suggested by M. Lallemand, the exposure given to the bichromated gum paper is only a few seconds. The print is damped and transferred to the stone as before. The back of the paper is then very slightly moistened, and it is allowed to dry in the dark-room. After about an hour water is applied to the back of the print, and when the paper becomes detached, the gum is washed off with plenty of water. The stone is left to dry, then inked all over, damped, and cleaned up with the roller. This method is also negative, and the gum prevents the ink taking on the ground, while the layer of insoluble gum forming the image prevents the soluble gum from acting on the stone. When the image has been brought well out with the roller, it is etched with gum and acid, and is then ready for printing.

M. Lallemand remarks that the great point to be observed in all these processes is not to moisten the exposed print too much before transferring it to the stone. If the surface is allowed to become sticky or soft, the fine lines will be blocked up. The paper should just be limp, and the pressure applied will make it adhere to the stone.

(*To be continued*).

AN AID TO THE PERMANENCY OF ALBUMEN PRINTS.

BY WILLIAM L. COLLIE.

I WENT into a sale room the other day, and amongst the books was a work published twenty years ago containing a large number of stereoscopic views of Egypt and its Temples (chiefly) by Frith. I am always curious about photographs, and open to take a lesson. The work was full of the photographs, which, with exception of only several, were all in a fine state of preservation. Frith had always been a careful and good printer, and these prints did him credit. What had been originally pure whites, though, namely the skies, had a light greenish tint, but not spoiled or faded like. The rest of the images, including high-lights (but not the highest as in skies), such as of walls, pillars, statues in pure sunshine, had the original colour—a warm purple white; whilst the half-tones and deepest shades were all tints between a purplish-brown and black. In fact, the images were as rich in tone as they were twenty years ago. No doubt they had been protected in the book from the changing effects of light and heat; but still the prints showed a triumph for albumenized paper.

But what I learnt from these prints was, that the parts (such as skies) that in printing had been entirely shielded from any light by the perfect opaqueness of the corresponding part of the negative had changed to a light pea green; whilst the parts that had been affected in the least degree (or to the deepest), and therefore had taken on even the smallest coating of gold in the toning bath, showed not a particle of change or green tinge; in fact, the contrast between the sun-lighted stonework and the sky was quite striking in every instance.

The two lessons I deduce from the above are, first, that the gold is a perfect protection, not only to the shadows, but also to the very lightest tinge in white that can be produced on albumen; second, that a pure white from corresponding opaqueness of those parts in the negative has no protection of gold, and is found to change to some tint according to the original preparation and composition of the albumen coating. In some cases the changes will be, as in this instance, to a cool pea green; in others, to a light ochrish-yellow tint, &c. This also tallies with a well-known fact that the pure whites round the vignettes require longer or stronger fixing than ordinary lights in prints, otherwise the white quickly changes.

Now the practical observation from the above is—"pure whites are not safe, but must change."

Again, and lastly, the practical suggestion is, "If you want your prints not to change at all, the albumenized paper or print must be exposed all over to light just sufficient to make it take on the least coating of gold in the highest lights. The whole print, you will observe, would thus be protected by gold. The loss of absolute whiteness in the highest lights need scarcely be observed, and in the case of harsh and hard pictures, there would be really an improvement by the method.

Notes.

New Zealand has beaten Australia in forming the first photographic society at the Antipodes; as we reported last week, the Auckland Photographic Society held its first meeting on November 2.

The Society of Photographers' Assistants formed a year ago at Vienna has met with extraordinary success. There are no less than two hundred members now belonging to this body, which has a location of its own, and holds regular meetings for the discussion of techical and scientific progress. The only other active body of this nature seems to be the New York Association of Operative Photographers, although it is true there is in Zurich a Schweitzer Photographen Gehilfen Verein, of whose doings, however, one hears very little.

Those about to build studios may be interested in knowing the experience of a correspondent. He has two studios, an iron-framed one, the other with ordinary wood sashes. The first has been built about seven years, the second about twelve, and both were the best of their kind so far as workmanship is concerned. His experience is that while the iron studio has never leaked since it was first put up, the wood one has been a constant source of trouble, despite paintings and puttyings every other year. It is only just to the wood studio to say that the pitch is not so steep as it might be; but, after making allowance for this, the superiority of iron frames seems evident.

Mr. Norman Macbeth, of the Royal Scottish Academy, has designed an emblem for the Edinburgh photographers, which is likely to find favour beyond the Scotch capital. Here is a description of it on the best authority:—

"Photography is represented in the character of a female figure—as the daughter of Nature, Science, and Art. She is seated with a mirror in hand, having a pure reflection of herself seen in it. She has the greatest abhorrence of everything that is false and concealed. She is represented as having torn the mask (which many would live by) from her face, and, being ashamed of such attempt at deception, she hides it behind her back. Everything that comes from her hand has a relation or bearing on Natnre, Seience, and Art. These are indicated by the presence of the sun, moon, stars, insect life, and the head of Arthur's Seat (the lion), all which make up the motto surrounding her."

We hear a good deal of Mr. Barnum's white elephant, and, so far as "word-painting" is concerned, the portrait of the beast has been before us many a time. Still there is an idea abroad that the elephant is not so white as it is painted. In these circumstances, it is strange that a master-showman of Mr. Barnum's standing should not have bethought himself of the camera, and had his elephant properly photographed. We say "properly photographed" from his point of view, because that point of view might include the application of a little whitewash. Surely Mr. Barnum must have forgotten the dictum of his countryman Artemus Ward, wherein he tells us it is true that the leopard cannot change his spots, but you can do it for him.

Dr. Huggins last week broke a lance with the *English Mechanic*. In a resumé of the Progress of Photography in 1883, our contemporary observed, *à propos* of Dr. Huggins' photographs of the solar corona, obtained from the uneclipsed sun: "It is now suspected that the pseudo-coronal structure visible in his negatives may have its origin in reflection from the dark backing of his photographic plates, such backings being painted on with a brush." This statement brought forward a letter from Dr. Huggins, couched in what the journal itself characterises as "strong language," and elicited the explanation that the editor had not seen any of the photographs, and founded what he wrote "on information derived from a gentleman who had himself examined some of Dr. Huggins's earlier negatives, which, in his opinion, showed indubitable traces of reflection from the backing of the plate." As it appears, however, that the varnish was spread with a flat wooden spatula, and not a brush, the editor admits that his supposition with regard to the brush marks was incorrect.

The following is a good plan of enamelling cardboard or pasteboard, according to the *Papierzeitung*. Dissolve ten parts of shellac in a sufficiency of alcohol, and add ten parts of linseed oil; to each quart of the mixture add also a quarter of an ounce of chloride of zinc. The cardboard may be immersed in this solution, or the latter may be applied with a brush; before application, however, the paper surface must be polished with sand or pumice powder.

The *Times* can be very comic when it likes. Last week we mentioned the fact of photographic apparatus having been dispatched to the French army of occupation at Tonquin, and our leading contemporary now gives further information. The cameras are part of the balloon equipments; for, according to the *Times*, "a complete photographic apparatus is attached to each car, which can turn out 100 impressions a second, and printed instantaneously." This sounds exceedingly important, although scarcely so clear as it might be; but in describing what the balloon equipment and corps is wanted for, is where the *Times* makes its point. "It is intended to act specially in ambuscades, and is attached to the artillery."

Fancy lying in ambush with a balloon! Our American humorists in their wildest fancy never invented anything half so funny, while the ostrich, hiding his head in the sand, appears, by comparison, the emblem of cunning. But the French balloons are evidently not ordinary balloons, for they have no gyration—the knotty problem that plagues all photographers—and will probably be able to do without ballast, for, adds the *Times*, their equipment includes "the new electro-magnetic balancing bar, which prevents the balloon from gyrating, and, it is expected, will be the means of eventually dispensing with ballast." Perhaps "the new electro-magnetic balancing bar," besides doing away with gyration and ballast, also renders the balloon invisible when the detachment is to "act specially in ambuscades!"

A very old photographic swindle has been revived in Leicestershire and the adjoining counties. Fellows have been going about the country pretending to photograph the mansions of the principal residents, and in some cases taking the portraits of members of their families. Of course, in pursuance of the good old photographic custom, the money was demanded beforehand, and this having been obtained, the "photographers" immediately decamped. The police have been on the look out for these gentry, who gave a false business address in Nottingham, but without result.

We can recal an instance, however, where a kindred deception was practised without any swindle being intended. A photographer who could not afford to keep an

assistant was compelled by family affairs to be absent from his studio a whole day. It was in the height of summer, sitters were certain to call, and the loss of a day's takings was a serious matter. Luckily, a friend, who was somewhat of a "cool hand," volunteered his assistance, and cleverly overcame the difficulty. He knew nothing whatever of photographic manipulation, but had been in the studio several times, and was familiar with the procedure of dealing with the sitter. All that he did, therefore, was to disappear in the dark room, come out with an *empty* carrier, gravely pose the sitter, solemnly focus, and equally solemnly take off the cap after going through the orthodox formula of requesting the sitter to "look pleasant." In each case he declared the portraits to be a marvellous success, and great was the disappointment when each person who sat that day afterwards received a note from the photographer, to the effect that the negative, unfortunately, was broken, and would he or she kindly sit again.

A "young and ardent photographer" tells us a "good story," which he declares to be "well-founded." This it certainly is, for the "story" is founded upon certain notes in these columns, published more than two years ago. However, we have no desire to spoil sport further than to make this rectification, especially as it is a harmless tale enough, and destined, no doubt, simply to recal the inconvenience of travelling with silver bath and collodion in the old wet-plate days.

Here it is. Two young friends, all excitement over a prospective photographic excursion, secure a railway carriage to themselves, and pack away their apparatus as safely as they can—the camera on the cushions opposite, the tripod and tent under the seat, a small box of chemicals and the nitrate bath in a stoppered bottle in the netting overhead. Maps are consulted, a note-book brought into requisition, and some points, the results of previous excursions, examined with interest. At one of the stations a passenger enters, with tall collar, broad shirt-front, glossy hat, and blue tasseled cane, one who might have been irreverently termed a "masher," only that mashers had not been invented then. The new-comer, however, does not disturb the young photographers; it is very hot, and in a few minutes he is fast asleep, extended at full length upon the cushions of the carriage.

Presently a soft noise attracts the attention of the photographers. It is like that of rain-drops pattering on the roof. They listen; the sounds are in the carriage itself, breaking up the intervals between the long-drawn sighs of the sleeping beau. In an instant the truth is revealed; the bottle of bath has sustained a fracture, and the liquid is dropping merrily upon the starched shirt-front of their fellow-passenger. Horror! what is to be done? Shall they wake their companion, and brave the wrath of a violent swain, on his way, perhaps, to visit his lady-love? They are brave lads, the young photographers, but they do not dare this. Hastily collecting their impedimenta, they quietly steal from the carriage at the first station, leaving the gorgeous one in the blissful realms of dreamland, and to develop photographically as the sun shone on.

Every month sees photography employed more and more in book and periodical illustration. One of the most spirited pictures in the elaborate Christmas number of the Paris *Figaro*—notable, by the way, in addition, from the fact that the whole of the illustrations are in some form of "process," and in every sense are works of art—is a coloured sketch entitled, "A Gust of Wind." The effect of wind is conveyed in a singularly truthful manner—a circumstance, however, not to be wondered at, seeing that the basis of the picture was instantaneous photography. The *Graphic* has long made use of photography, and the frontispiece in the New Year's number was drawn also from an instantaneous photograph. But, perhaps, the most striking example of a photo-illustrated journal is *Scraps*, a paper which in a few weeks from its birth has attained a very large circulation. All the pictures, with but very few exceptions, are photographic reproductions, the majority from original sketches, and it may be said with truth that without photography such a paper would be impossible.

Herr Ed. Lendemann has been studying the comparative brilliancy of the stars by means of photography, and has submitted the results of his work to the Naturalists' Society of Moscow. His endeavour is to work out a method of photometry whereby the light of all heavenly bodies may be measured by photography. Our readers may remember that M. Janssen proposed to apply the photographic film to the same purpose two years ago.

Patent Intelligence.

Applications for Provisional Protection.

1898. Charles Sands and John James Hunter, both of 20, Cranbourn Street, Leicester Square, in the county of Middlesex, Manufacturers of Photographic Apparatus, for an invention for "Improvements in the construction of photographic cameras."—Dated 22nd January, 1884.

1908. Henry Rafter, Artist, 1, Kingswood Place, Dacre Park, Lee, Kent, for an invention for "Combining process with engraving for relief printing surfaces."—Dated 22nd January, 1884.

Specification Published during the Week.

2799. J. J. Sachs, "Apparatus to be used in the preparation of metal surfaces for etching, engraving, &c."
This invention relates to means for applying the sand blast.

CHAPTERS ON LANDSCAPE AND OUTDOOR PHOTOGRAPHY.

BY H. P. ROBINSON.

No. IV.—The Genesis of a Picture.

It will bring the subject of picture-making more home to the student if I take a picture that has been really done in photography, and describe its life-history from its conception to its realisation in a negative.

And, first of all, how do subjects originate? In great part this question is very difficult to answer. Many of my pictures arise before my mind's eye in a most inexplicable

manner, and remain there till I lay the ghosts by making sketches of them. I see these

"Dreams that wave before the half-shut eye."

absolutely and definitely, and can recall them when I please. They come like a dream, but do not fade away till they are done with. I often try to trace any circumstance that might have given birth to the thought contained in the visual design, but can seldom come to any satisfactory conclusion. But to go much into this part of the subject can have little of interest or use for the student. These visionary images come without rhyme or reason; the designs that will most instruct the learner will be those that come from both these proverbial causes—those, in fact, which have some tangible cause that can be traced and assigned for being born.

Most designs obtain their origin from suggestions found in nature. A picturesque bit of landscape will almost certainly suggest to the artistic eye where a figure or figures should be placed; this will lead on to the questions: What are they to do, how should they do it, and how be dressed? Then the subject ought to appear to the artist, and it will do so if he tries his best to see it; although it might be only a poor or hackneyed one, he will find that experience will improve both the quantity and quality of his ideas. It is astonishing how practice assists the imagination. That art breeds art is a well-known aphorism, and it is as true that subjects breed subjects. The picture you last produced leads up to the next, and the better you make it the better will be those that follow. The student after much practice will find himself half unconsciously storing up hints of wayside beauty and suggestive facts, and composing them in his mind into pictures, always with an eye to their possibility in photography.

In my own practice I never now feel in want of a subject. They seem to come naturally when required, but this is the result of experience rather than a natural gift, for I remember many years ago being for a whole twelvemonth without a single idea. Neither could I work one up by any means. I tried every device I could think of. I read a great deal, visited picture galleries, and tried to borrow thoughts from illustrated books, but all to no purpose; no workable idea would arise. I was fallow for about a year, and then the faculty returned, and has always been more or less present. This I put down to constant use, and I mention it for the encouragement of the young beginner, who may occasionally find that his mind is a blank. It would be almost reasonable to suppose that the more of your ideas you used up, the less you would have; but this is not the case. I know this, not from my own experience only, but from questioning many artists.

Sometimes incidents you meet with in the streets, or in country walks, will suggest subjects, not necessarily the actual incident one sees, but something that may be worked into some other scene, with perhaps many alterations. Sometimes a fine pose may be seen, or a lonely bit of light and shade; sometimes an expression or a quaint costume; and all these things should be noted for future use. No suggestive bit should be allowed to escape; all should be sketched or noted. It is good practice also to try to analyse why the pose is beautiful, or the light and shade effective. This a knowledge of the rules of light and shade and composition will enable you to do, and to do this easily, the student will find an added pleasure to his life—another feather in the wing of his artistic flight.

We will now take a picture that has been really produced by photography, and see how it was conceived and finished. To analyse and dissect a picture in a cold-blooded way, as I am going to do now, is to rob that picture of any poetry it may contain, and leave nothing but a mechanical interest; but I know no better means of conveying the information; I will therefore take one of my own—that one I have called "A Merry Tale" will be suitable for the purpose.

In the PHOTOGRAPHIC NEWS for March 29, 1883, will be found a double page reproduction of this picture by the "Ink Process." A reference to it may assist the reader in understanding what follows.

In the drawing-room of a country house in North Wales five young ladies in evening costume were amusing themselves after dinner. One of them was relating some funny circumstance to the others, who arranged themselves in a picturesque group round the story-teller. Here was the germ of the picture. A few seconds sufficed to make a sketch of the composition. The illustration is a reproduc-

tion of the jotting in my note-book, and I may remark, by the way, that the practice of making rough sketches of composition and light and shade is very useful, especially if accompanied by a few descriptive notes. It teaches the student how to observe, if it does no other good. Correct drawing is by no means necessary; the "effect" is what should be noted. To return to the picture. By an easy transition the mind easily changed the young ladies into peasant girls, and suggested suitable surroundings. A sketch was made of the arrangement, and the dress for each figure decided on. In selecting the costumes, the light and shade of the group, and its relation to the landscape, were not forgotten, neither were the accessories—the baskets, jug, and stick. The colours were taken into account only as to how they would translate into black and white.

It was arranged that the group should form part of our work for the next day; but, as often happens in the mountainous districts in Wales, man proposes, and the weather imposes: the morning opened with a deluge of rain which continued more or less for several days. Those days were not wasted, for young ladies now-a-days can not only play tennis, but some of them can shoot and throw the fly, to say nothing of ratting and ferreting! At last the storms were over, and the sun shone again, but with a great deal more wind than a photographer thinks pleasant. However, we determined that we would have some pictures, good or bad, that morning. We were getting hungry for work, and a conscientious photographer is as anxious to make a good bag as a sportsman, but a photographer's desire for picture-making is nothing to that of a set of really enthusiastic models. Mine, I know, go into the business with the greatest energy. Off we started to a quiet lane about a mile away. The photograph conveys no idea of the picturesque effect of the five girls in their humble but brilliantly coloured garments. The effects of colours under the green hedgerows and through the fields was quite beautiful. The choruses sung on the way had, perhaps, nothing to do with photography; but the foxgloves and other wild flowers the singers gathered came in very useful in the picture. Arrived at the selected spot, the camera was unpacked, and the models placed approximately in their proper places, interfering branches cut away, and everything got ready, so that the last moments might be devoted to the quite final touches, expressions, and other little things. The sun shone a cold

steelly blue, and the wind was so troublesome that we had some thoughts of giving it up after all; but we decided we had taken too much trouble to go home without spoiling, at least, one plate.

Now for the arrangement of the group. The girl to the left was sitting up at first, as will be seen in the sketch, but being a young hand at the business, she could not control herself, and, enjoying the fun, threw herself back on the bank screaming with laughter. This was a happy accident, which much improved the composition, and was seized immediately. She was at once shouted to to keep her place, which, being an easy one, required little further thought on the part of the photographer, who could now turn his attention to the other figures. The next figure, the one in the straw hat, was a steady old stager with plenty of experience and no nerves; she required but a moment's attention. The next figure, always dramatic in pose, and with a charming expression, is, perhaps, in consequence of her other good qualities, rather shakey as a sitter. She required a rest of some kind. The stick was useful here, and was of immense value in the composition. A bit of straight line to contrast a number of curves is always effective. This settled the three figures that were easiest to keep still. The standing figure being by far the most difficult position to keep,—for a standing figure without a rest often sways like a pendulum,—was left until last. The figure telling the story was now settled; the pose of the figure came easy, the model being an admirable story-teller, and thoroughly up to her business; but it was necessary to give all possible effect to the hand, for the hand if well placed would do more towards showing the intention of the picture than anything else in it. It, in a way, leads the chorus of expressions. It emphasizes the situation,—it makes you feel the girl is speaking. It was so arranged that, to make it more conspicuous, it should appear partly in sunlight and partly in shadow, and every leaf or twig that came behind it was hurridly removed. The standing figure, who could not be expected to keep the pose for above a minute or two, was placed last. The jug, basket, and foxgloves, which form the key note of the composition in the foreground, had been previously arranged, and all was ready. But a last glance from the camera showed the photographer that the tree was exactly over the head of the standing figure, and cut the composition into two parts. This would never do. But instead of moving the figure the camera was moved. This corrected the error to some extent. It would have been better to have moved it a little further, but it was feared the other tree would interfere with the story-teller. A few last words—at the special request of the models I use ficticious names—"Now, girls, let this be our best picture. Mabel, scream! Edith, a steady interest in it only for you; Flo, your happiest laugh; Mary, be sure you don't move your hand or all the good expressions will go for nothing. Bee, I will say nothing to you, but leave you to fate, Steady! Done!" and two seconds' exposure settled the matter. I scarcely expected a successful result, the thing was so difficult; but as the wind was blowing almost a gale, I did not care to try another plate. As it happened, I found when I developed the plate a fortnight afterwards, I had got a good negative. The sky was white and black; but the use of a second negative, delicate and not too obstrusively printed, soon put this matter to rights.

This seems a long story to tell; but the picture was exposed in under six minutes from the time the models took their places. This quickness is one of the secrets of success, but when your picture is to include figures it should not have the appearance of hurry, for "hurry hinders haste," and, besides, has the effect of flurrying your models: it should be the result of an perfect knowledge of what you want to do. A model should never be kept waiting longer than is absolutely necessary. It is better to give up little things rather than to lose a fine effect.

LESSONS IN OPTICS FOR PHOTOGRAPHERS.

BY CAPTAIN W. DE W. ABNEY, R.E., F.R.S.

LESSON IX.

To find the Focus for a Narrow Pencil of Parallel Rays at a Spherical Surface.—Let D E C A be a block of glass with a spherical end of which A B C is a section, and O the centre. Let rays from G fall on it. Let us consider one

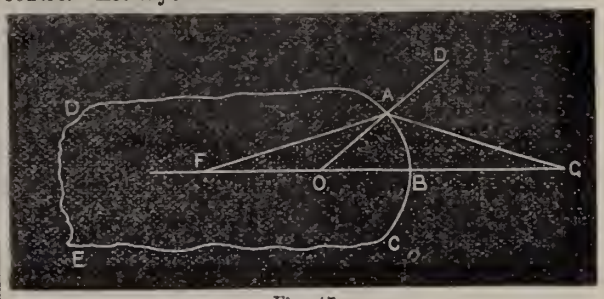

Fig. 47.

ray falling on A; join O A, and produce it to D; then D A G is the angle of incidence; let F A O be angle of refraction* (remembering that O D is perpendicular to the spherical surface); then F B will be the focal distance to find.

$$\frac{\sin DAG}{\sin AOB} = \frac{\sin OAG}{\sin AOB} = \frac{OG}{AG} \quad \text{i}$$

$$\frac{\sin AOB}{\sin FAO} = \frac{\sin FOA}{\sin FAO} = \frac{FA}{FO} \quad \text{ii}$$

But

$$\mu = \frac{\sin DAG}{\sin FAO} = \frac{\sin DAG}{\sin AOB} \times \frac{\sin AOB}{\sin FAO}$$

$$= \frac{OG}{AG} \times \frac{FA}{FO} = \frac{OG}{BG} \times \frac{FB}{FO}$$

when the triangle BQA is small. Let

$$OB = -r \quad BF = -v \quad BG = u$$

Then

$$OG = u - r$$

Then

$$\mu = \frac{u-r}{u} \times \frac{-v}{-(v-r)}$$

$$\mu \frac{v-r}{v} = \frac{u-r}{u}$$

$$(\mu - 1)\frac{1}{r} = \frac{\mu}{v} - \frac{1}{u}$$

Let $u = \infty$, then $v = f$, the principal focus for parallel rays, and

$$\frac{u}{f} = \frac{\mu - 1}{r}$$

$$\therefore \frac{u}{f} = \frac{\mu}{v} - \frac{1}{u}$$

This applies to a concave spherical surface, remembering that in such a case f is positive instead of negative. The case of convergent and divergent beams can also be considered, as we have done at the end of the next problem.

To find the Focus of a Lens.—Let Q be the source of light, $-r$ the radius of DBE, r' of D A E, P the position of focus after one refraction in the glass, F the focus after the 2nd refraction into air. Let

$$BQ = u, \quad AP = v', \text{ and } AF = v$$

From the formula of the previous problem—

$$\frac{\mu - 1}{r} = \frac{\mu}{v'} - \frac{1}{u} \quad \text{(i)}$$

Now suppose the rays to start from F, then it is manifest

* If A B C is concave, or if G is situated nearer to B than the distance of the principal focus, it will be found that the refracted ray would not cut the axis on the left hand side of B, in which case it would have to be produced to cut the right-hand side. The proof would remain the same in every case.

that the focus, after one refraction with glass, must be at P, which is a virtual focus, since it is on the same side of lens as F.

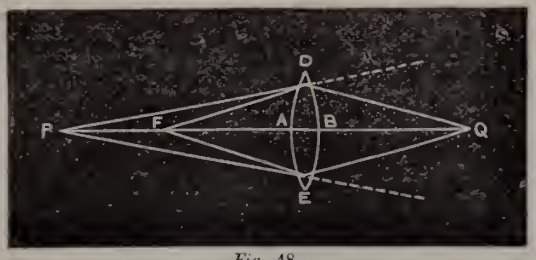

Fig. 48.

Hence, in this case, A Q must be negative. Applying the same formula to again find P, we get—

$$\frac{\mu-1}{r_1}=\frac{\mu}{AP}+\frac{1}{AF}$$

when the thickness of the lens is small, $AP=BP=v^1$.

$$\frac{\mu-1}{r^1}=\frac{\mu}{v^1}+\frac{1}{AF} \quad \text{(ii)}$$

Subtracting (i) from (ii) we get—

$$\frac{1}{AF}=\frac{1}{v}=(\mu-1)\left(\frac{1}{r}-\frac{1}{r^1}\right)+\frac{1}{u}$$

Now let μ be ∞, then $\frac{1}{u}=0$, and v becomes f, the focus for parallel rays, *i e* the principal focus.

$$\frac{1}{f}=(\mu-1)\left(\frac{1}{r}-\frac{1}{r^1}\right)$$

$$\therefore \frac{1}{v}=\frac{1}{f}+\frac{1}{u}$$

A discussion of the last equation will show the following inference.

Convex Lens.—Remembering that u is on the opposite side of the lens to f, v is negative so long as u is greater than $-f$, when $u=f$, then v is infinite. When u is less than $-f$, v becomes positive, showing that the rays proceed from a point nearer to the lens than the principal focus after refraction, are divergent, and that they have only a virtual focus on the same side of the lens as u.

Concave lens.—Remembering that f lies *on the same side* of the leus as the incident beam, and is always positive, it is manifest that as long as $\frac{1}{u}$ is positive, $\frac{1}{v}$ will always be positive—that is, a divergent beam always, on refraction, diverges, having a virtual focus. If u be negative (that is, a convergent beam converging to a point on the opposite side of the lens), v will positive till $f=u$, when it will become negative, and there will be a real, and not a virtual focus. This is often the case when a converging beam from a convex lens falls on a concave lens.

Example.—It is required to achromatize for the indigo and orange rays an equi-convex crown glass lens, whose curves have a 12 inch radius, by a flint glass in contact with it; one curve of the latter to be also of 12 inch radius.

From the table we find—

$$\mu_1=1{\cdot}542\ a=1{\cdot}542-1{\cdot}529={\cdot}013$$
$$\text{and } \mu_2=1{\cdot}660\ b=1{\cdot}660-1{\cdot}635={\cdot}025$$

The focus f of the crown glass, is found by the formula—

$$\frac{1}{f_1}=(\mu_1-1\left(\frac{1}{r_1}-\frac{1}{r}\right. \quad \ldots\ldots(A)$$

Here—

$$r^1=-12 \text{ and } r=12$$

$$\therefore -\frac{1}{f_1}={\cdot}542\times\frac{1}{6}=\frac{1}{11{\cdot}7} \text{ inches.}$$

$$f_1=-11{\cdot}7 \text{ inches.}$$

Now using the formula—

$$\frac{a}{\mu_1-1}\cdot\frac{1}{f_1}+\frac{b}{\mu_2-1}\cdot\frac{1}{f_2}=0. \quad \ldots(B)$$

we have—

$$\frac{{\cdot}013}{{\cdot}542}\times 11{\cdot}7=\frac{{\cdot}025}{{\cdot}660}\times\frac{1}{f_2}$$

$$f_2=20{\cdot}32 \text{ inches.}$$

Again, from formula (A) we have

$$\frac{1}{20{\cdot}32}={\cdot}660\left(\frac{1}{11}-\frac{1}{r}\right) \quad r=114{\cdot}2 \text{ inches.}$$

We therefore have a combinatiou; the radii of the crown glass surfaces are —12 and +12 in, the radii of the flint glass—12 and +114·2 inches. By the formula—

$$\frac{1}{F}=\frac{1}{f_1}+\frac{1}{f_2}$$

the focus of the combiuation is—27·6 inches.

Correspondence.

PERSPECTIVE.

DEAR SIR,—A note to the interesting article in your issue of January 18th, "A Study in Light and Shadow," remarks that however much a painter ought to practise the correct drawing of detail, yet "the photograph is most to be relied on for truth in all *except perspective.*" In this exception truth and error seem to me so mingled—the truth, no doubt, present to the writer's mind, while error will, I fear, be the meaning misapprehended by many—that, if you will kindly permit me, I will venture a few words on the subject.

I will begin by an illustrative experience. One interior I took last summer I felt proud of. The technical difficulty was great, the necessary angle of view enormous. A plate 18 by 15 inches was covered by a lens I had put together of little more than nine inches equivalent focus. Distortion, in the ordinary sense. was fully corrected, all vertical lines being parallel, and—for it is remarkable how few of the faults supposed inseparable from extreme wide angles are really inherent, and how many may be evaded in selecting the best point of view, both as to vertical and horizontal position—the artistic effect has not wanted for admirers. Nevertheless, my assistant heard one admirer of it, as it stood in my window, answered by his friend's remark: "But it's all wrong, you know." To such a critic it is in vain to point out that the perspective *from the point of view selected* cannot err, cannot be really wrong. Nor is it quite conclusive to recommend him carefully to shut one eye, to place the other near the middle of the picture at the proper distance, and observe how perfectly every detail falls into its natural position. He wants a picture to hang on his wall. He has seen an etching or a sketch which pleased him, and, though confessedly coarse and inaccurate in detail as compared with the photograph, it certainly needs no painful adjustment of the eye, but is seen comfortably at any distance. Of course, a man has good right to choose and please himself. But the question is, which is right, and which wrong—the photograph or the sketch? The critic in question is quite sure it is the photograph which is "all wrong, you know." Unfortunately, the inartistic abuse of short-focus lenses too often originates and strengthens this conclusion, for few there be who know how the judicious draughtsman must modify the true perspective that he may produce a result more pleasing, and more like what the brain apprehends through the naturally moving eye, than is the truly representing, but falsely seeming, photograph. But is it fair to the photographer, or to his art, to say just this? Each must work with his tools, and both painter and photographer have noble tools to work with. Let, however, the inimitable perfection of natural vision be better recognized. We see a landscape or an interior, not by simultaneously combining direct vision straight before us with oblique vision all round, but by perpetually turn-

ing our eyes in all directions, and perceiving, as a simultaneous whole, that which is actually viewed directly in successive parts. That he may better represent this effect, the draughtsman so applies his rules as to substitute for the true perspective, from the best *attainable* point, a false one, but which would be true from one, desirable perhaps, but *unattainable*.

I have not touched on aërial perspective. That, to photographers, is, of course, a matter of lighting, of exposure, and of printing. It is our art and our glory, of photography by the shortcomings of its professors, and only thoughtless critics will really judge the capabilities whether they be want of atmosphere, or an ugly point of view. Perspective is one of many points on which photographers and painters may mutually learn the one from the other.—I am, dear sir, yours truly,

W. H. Wheeler.

SOME DEVELOPERS FOR GELATINO-BROMIDE TRANSPARENCIES.

Sir,—The following developers will, I think, be found to give very good results when used with slow plates:—

Ferrous Oxalate.—To each ounce of saturated solution of ferrous sulphate add 20 grains of tartaric acid, and call them "normal ferrous sulphate," and mark it "A" solution. Make up a saturated solution of neutral oxalate of potash, and mark it "B."

Developer No. 1.—This has been recently published, but is repeated here to complete the series. To 6½ drachms of "B" add 1½ drachms of "A," and to the mixed developer, which we will call "C," add 1 to 3 drops of a saturated solution of mercury bichloride. Fully expose and develop. This gives a very rich black tone.

No. 2.—To 1 ounce of developer, "C," add 1 drop of Newton's accelerator (*so-called* "iodo-chloride of mercury"). Colour much as last, but rather deeper.

No. 3.—To 1 ounce of "C" add 3 drachms of a ten per cent. solution of ammonium chloride. This gives a very warm, rich, engraving black tone.

No. 4.—I give this as a key to the action of the others, but do not recommend it in practice, for obvious reasons. Expose fully. Immerse the plate in $\frac{1}{10}$ diluted hydrochloric acid for half a minute, well wash, and develop in developer "C." Colour much the same as in Nos. 1 to 3, but not so intense.

Memo.—Uranium chloride has not as yet given concurrent results in my hands.

Pyrogallol.—3 grains pyrogallol to the ounce of water. 1 ounce of a ten per cent. solution of soda carbonate. Developer "D."

Developer No. 5.—To the 2 ounces of "D" add 3 drachms of a ten per cent. solution of ammonium chloride, or follow the procedure of No. 4. Colour a greenish black tone, which comes out well on the screen, and is considered very good by some who have seen it. I don't like it.

Memo.—The green colour given to negatives developed by Newton's accelerator is probably *not* sub-iodide of mercury, but is due to some pyrogallol derivative, of which more some time.*

Hydrokinone.—A wide range of colour can be obtained with this developer. I confine myself to formulæ which I have sufficiently tested.

No. 6.—Hydrokinone dissolved in alcohol 1 grain to the drachm, and used in the proportion of 1 drachm to 7 drachms of water. Call this "A A." To 1 ounce of "A A" add 1 ounce of a ten per cent. solution of carbonate of soda. The objection to this developer, that it is liable to stain the film a persistent brownish yellow, may be overcome by allowing a full exposure, and stopping development the moment the last details are out, *well* washing the plate before fixing, and taking care that the hypo remains uncoloured. There is hydrokinone *and* hydrokinone in the market. The pure article only should be used.* Colour:—a warm brownish black. The addition of ½ of a grain of sodium sulphite to each ounce of developer warms the tone a little, and allows of longer exposure in the case of a thin negative.

No. 7.—Take of "A A" one ounce, and an ounce of a ten per cent. solution of ammonium carbonate. Allow an exposure of about three times what is necessary in the case of normal ferrous oxalate. Development is very slow, and some practice is required before one can exactly hit the moment when development should be stopped. By transmitted light the transpareucy has a very rich, warm, brown colour, which is very fine on the screen. The silver deposit is very fine grained, and the plate, when viewed by reflected light, looks yellow and very unpromising of good. On the screen, however, it is hardly distinguishable from a first-class well-toned collodion one.

No. 8.—Take one ounce of "A A," ½ ounce sodium carbonate, ½ ounce ammonium carbonate solutions as given above. Development is quicker, colour darker.

No. 9.—Take 1 ounce of "A A." 1 ounce of the 10 per cent. sodium carbonate solution, 3 drachms of ten per cent. ammonium chloride solution. Development is moderately quick, colour a very good warm brown, which is susceptible of a good deal of variatiou by adding more or less of the ammonium chloride to the sodium carbonate.

No. 10.—Take 1 ounce of "A A," 1 ounce of the sodium carbonate solution, to which has been added 3 to 5 grains of citrate of potash. This is perhaps the best of the hydrokinone developers, except that the colour is not so warm as Nos. 7 and 8.

All of the above give very satisfactory results with clear glass where clear glass ought to be. If a clearing solution be required, either dilute sulphuric or hydrochloric acid in alum water may be used, but with care none will be required.

H. Pocklington.

PACKING PLATES.

Sir,—As I see that the question of packing plates is again in your columns, will you allow me to suggest to your readers a plan I have lately adopted. It is at once so simple and efficacious, that, once tried, I venture to think nothing further will be required. It is, in fact, so very simple, that I cannot help thinking it must be in use. At the same time, I have never seen it, or heard it mentioned.

My plan consists merely in clipping an india-rubber band on one or both ends of the plate (an ordinary band as sold in the sixpenny boxes), and placing another on it, film to film. They can then be dropped back into the boxes, or two or more pairs put together and a stouter rubber band placed round them all, which will keep them quite tight. In either case, there is no fear of scratching, as the films are kept perfectly apart. It might be thought that the bands would cut; but I do not find this to be the case unless the very small ones are used.—Yours truly,

C. Pilkington.

LIGHT FOR THE DEVELOPING ROOM.

Sir,—In his letter to you last week Mr. Fry says:—"It is erroneous to suppose ruby or red injures the eyes; on the contrary, the optic nerves have an almost entire rest on them. Nor is it true that the focus of vision is changed. What really injures the eyes is the everlasting reading, writing, smoking, and glare of gaslight on white paper."

My experience differs from that of Mr. Fry. So long as I used cherry medium, I was obliged to wear glasses in the developing room, and if I worked more than a short time, I could not read without discomfort until a long period after I left the room.

* I have satisfied myself that the halogen, and not the base, is the active element in that accelerator.

* That which I have purchased from Reynolds and Branson, Leeds, gives very satisfactory results.

During my recent visit to Scotland, I took so many views that I asked my son to help me in the evening, but after a week's developing he was obliged to desist, as he found considerable injury to his eyes from the red medium.

My son more often uses candles and oils than gas, and his smoking propensities are limited to a few cigarettes a week. I am a non-smoker, and my eyes have not been injured by gas.

Since I have adopted the green and yellow glass, as recommended by Mr. Debenham, I can work in the developing room for many hours, and can read with comfort immediately after leaving it. Moreover, I do not now require my glasses. With reference to the safety of the light, I can only say that I have developed many hundreds of plates by it, and have never had the smallest injury arise from it.

Further, on one occasion, I considerably under-exposed a very rapid plate, and continued the development for a long period, and still no injury was done.—Your obedient servant,

HENRY HARBEN.

EXPANSION OF ALBUMENIZED PAPER.

DEAR SIR,—Here is something of a puzzle. The two prints I send you are from the same negative, and, now they are dry, measure the same exactly. If you soak them in water for an hour, and compare them while damp, you will find that the one will stretch long ways, and the other will get wider. If either of these were mounted it would "stay put," and if a portrait, the face would be either too long or too broad. This is a frequent cause of re-sittings. The expansion is generally supposed to be caused by the direction in which the print is pasted in mounting, but here you will see it occurs before mounting. Prints can now be printed to stretch either way.—Faithfully yours,

PRINTER.

OUT-DOOR PHOTOGRAPHY, ETC.

DEAR SIR,—In your "Notes" a week or two back you mention that it is forbidden to sketch or photograph Battle Abbey.

The same prohibition seems to extend to his Grace of Cleveland's northern seat—Raby Castle. Accompanying this is the result of a shot at the castle from a little distance. The lines seem all at sixes and sevens, but I believe they are not straight in the original. On reaching the Castle gate, camera in hand, the hall porter informed me that no one but a Barnard Castle photographer was allowed to "take" the Castle. However, on my assurance that I was only doing it for my own pleasure, he mollified, and I was preparing to try the old gateway with portcullis still hanging, when a smart shower put an end to my operations.

Is it not time you gave a leader on the smallest useful photographic outfit—a criticism, say, of Stebbing's camera, and the Academy, with specimens of work done by them?

What do you consider the most "put-out-of-sightable" camera stand? A small camera might sometimes be a pleasant companion on a Sunday, but few people would care to be seen carrying a tell-tale tripod. Could one put that mahogany one of Shew's that you saw at Pall Mall, up one's sleeve or into a tail-coat pocket?

Another subject—the ferrous oxalate developer—whether to use it weak or strong, how to judge when the negative is dense enough, and at what period you may hold it up to the gas.—Yours faithfully,

W. S. FOTHERGILL.

NOTE ON PHOTOMETRY.

SIR,—I feel that I must write and thank you for permitting my correspondence to take up your valuable space, although I fear that, owing to the way it has been inserted—viz., by combining under one heading the two separate communications upon two distinct subjects—the readers of your estimable paper will have some difficulty in comprehending it. The latter part of my letter as inserted, referred to the method of photometry devised by Dr. H. Hammert, which was noticed by you and published under "Talk in the Studio," in your issue of January 4th, 1884. This is of importance to me, as I hope to claim priority for that method.—I am, sir, yours truly,

JAMES B. SPURGE.

THE DECAY OF ENGRAVING.

SIR,—We see that you have taken note of our letter to the juries respecting the decay of engraving, and by implication take the side of the contraveners of the law.

Of this we do not complain, but you have misconstrued a sentence in our letter which we should be glad if you would rectify.

The six engravings to which we referred as published by us were merely half-a-dozen *out of a very large number*, which we selected as being those on which we had paid for copyright and engraving a specially large price.

There is hardly an engraver or etcher of note who has not been during the period named working for us.—We remain, yoursobediently,

MARCUS B. HUISH.

LIGHT FOR THE DARK-ROOM.

SIR,—This subject having been brought forward by yourself and correspondents, I should like to make a few remarks thereon.

Doubtless we are all somewhat apt to generalize from insufficient data, which accounts for the varying results obtained by different experimentalists.

The safeness of any medium for filtering the light depends partly on the strength of the light falling on it, the sensitiveness of the films, and distance from the window at which they are developed. I have worked in a room lit by borrowed light from the studio, and found the illumination very unequal, the shifting of a blind, curtain, or background being sufficient to darken the room considerably.

I have also worked (and am again doing so) in a room with a southern aspect, with the consequence that when the sun is out one is nearly blinded, while on a dull day it is a case of developing by feeling rather than sight.

The light is filtered through the thickness of the cherry fabric so much praised by Mr. Fry. My room being narrow from back to front, I have to hold the negative about eighteen inches from the window, and I should be sorry indeed to trust to that protection for the summer, to say nothing of the distressing glare on the eyes. Ruby and red, I take it, differ simply in degree, not in kind. As to the injurious effect of red light on the eyesight, when doctors differ, who shall decide? Mr. Fry says red has no bad effect, but on the contrary *rests* the optic nerves, and does not change the focus of vision. As far as the restful feeling goes, I can't speak very highly of its soothing effect on my "optics;" and how comes it that Mr. Ackland, at the last meeting of the Parent Society, said that working in a red light produced weakness of the ciliary muscle, and that Dr. G. A. Herschell, in a recent paper published by him, says that it *does* tend to alter the focus of the eye, and its power of accommodation for distance through the pupil being continually dilated, while in extreme cases there is danger of colour-blindness setting in?

Mr. Fry is right in his remarks about reading and writing continually with the glare of gaslight on white paper near the eyes—all the more reason for taking the greater care not to tax them unduly during the day.

Cherry fabric is a great advance on the very deep ruby which some have been accustomed to use, but I think everyone who has seen this side by side with the chrome-yellow paper and green glass, as shown by Mr. Debenham, would give the preference to the latter, on the ground of colour and quantity of light transmitted.

Mr. Fry also seems to agree with Mr. Debenham about the yellow, although rejecting the green; but on comparing canary medium with the green glass and chrome yellow paper in front of a light the other day, the mottled appearance of the canary-medium seemed to be a great drawback to its use, while the green glass, along with the other paper, gave a tint which might certainly, in comparison with red, be really entitled to be called restful to the eye. As to the efficieney of the compound, Mr. A. Cowan's experiment leaves no room for doubt.

A Wratten's plate exposed for fifteen minutes close to it, without showing any fog when developed and fixed, is pretty good evidence as to its value for dark-room illumination, though "ordinary people" would not hold their negatives so close in the ordinary way.

I am altering my window so as to have plain white glass outside for admitting white light when not developing; this framework is made to open so as to let in a little fresh air when required. In front of this will be sliding frames glazed with cathedral green glass (the darker shade in this case because of the southern outlook), and over this three or four thicknesses of chrome yellow paper, to be obtained, I believe, at Richards's in St. Martin's Lane. A movable curtain in front of the window will enable me to reduce the quantity of light when the sun shines brightly. In the space between the two windows I shall make arrangement for using artificial light when necessary — either gas, petroleum, or spirit lamp and salt as recommended by Mr. Ashman. It is to be hoped that as new developing rooms are constructed, more attention will be paid to the fact that the successful working of the gelatine process requires elbow room, ventilation, and easy control of the illumination.—I am, sir, yours truly,

CATHEDRAL GREEN.

Proceedings of Societies.

EDINBURGH PHOTOGRAPHIC SOCIETY.

THE first Popular Evening was held in Queen Street Hall, on Wednesday evening, 23rd January.

The exhibition consisted of about 150 pictures, selected from works produced by the members during the past year. Many were of a high order of merit, and the very large audience frequently showed its appreciation by applauding the views, which were exhibited by the aid of Mr. McKean's holder.

The contributors were—Messrs. R. Murray, C.E., William Mitchell, F. Briglmen, A. Matheson, R. Irving, Jas. Crighton, W. Neilson, M. Wane, Fraser, Notman, A. B. Stewart, F. Moffat, Bashford, Crooke, Macdonald, McKean, M. Scott, H. Watson, and S. Tamkin.

The transparencies were produced by "coffee" plates, collodio-chloride, gelatino-chloride, bromide, and by the wet process, and most pleasing effects were also produced by different toning agents. Messrs. Turnbull and McKean manipulated the lantern, and Mr. Bashford occupied the platform.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

A MEETING of this Society was held on Thursday, the 24th ult., Mr. W. COLES in the chair.

Mr. A. COWAN, referring to recent attempts to improve dark-room illumination, had obtained a very safe light by reflecting the light from a gas jet on to yellow paper, thence through three thicknesses of yellow paper and one of green glass. A plate exposed in sections up to fifteen minutes was not affected, and another plate, one-half of which was exposed ten minutes, and then both halves exposed in the camera, the exposed half could not be distinguished from the other.

Mr. W. E. DEBENHAM: Is there as much light as with the ordinary ruby?

Mr. COWAN: Yes, there is more; the advantage gained by reflecting enables a greater space to be evenly illuminated.

Mr. W. M. ASHMAN showed three plates exposed five minutes each under a transparency, twelve inches from an oil lamp, glazed with:—No. 1, ruby glass and orange paper, oiled; No. 2, yellow glass and ground glass, as recommended in the NEWS; No. 3, yellow paper on each side of greenish window glass. After developing twenty minutes, and fixing, no image was obtained. Three more plates were exposed to an ordinary spirit lamp, containing salt, for the space of five minutes, and developed twenty minutes. No. 1, twelve inches from the naked flame, resulted in a very much under-exposed negative. No. 2, eighteen inches from the flame, ground glass screen interposed, very weak image. No. 3, same distance as No. 2, opal glass interposed, image barely perceptible. When ruby glass is interposed, the sodium flame destroys the red colour. Mr. Ashman said no one would think of exposing a plate as many seconds as he had minutes, and he thought the experiments were sufficient to recommend the spirit lamp to travellers.

Mr. J. B. B. WELLINGTON exhibited several lantern slides produced on gelatine bromide plates. At the request of several members, Mr. Wellington gave the formulæ, as follows:—

	A	
Nitrate of silver ...	... ...	... 50 grains
Gelatine	... ...	.. 20 ,,
Water	... ...	... 5 ounces
	B	
Potassium bromide	.. ...	... 40 grains
Gelatine bromide ..	... ...	... 20 ,,
Water	... ...	.. 5 ounces

Convert the silver nitrate into silver citrate by means of citrate of ammonia, re-dissolving with ammonia. Mix A and B at 150° F., allow to cool, then thoroughly wash. The plates handed round, which were very fine, and of different tones, were all developed with ferrous oxalate 1 to 3, with the addition of bromide of potassium, varying from 20 to 80 grains per ounce of developer, according to the colour desired; black tones would not require any bromide. The exposures ranged from thirty seconds to six minutes, six inches distant from a fish-tail burner. Mr. Wellington noticed, when using citrate of potash, to form citrate of silver, and raising the temperature to 150° F., the blue stage was reached in ten minutes; whereas with ammonium citrate, two hours' boiling would not do it.

Mr. G. H. GARRET passed round slides produced on Mr. Cowan's chloride plates, developed with the No. 2 published formula, the exposure being six seconds to diffused daylight at 4 p.m.

Mr. ASHMAN had made further experiments with the sal-soda developer and mercuric iodide, and concluded that there is very little, if any, gain over the ammonia developer. The only effect gained, seemed to be a slight intensity, which could be detected in the negatives and prints passed round.

Mr. COWAN had come to the same conclusion as that arrived at by Mr. Ashman; he made several experiments, cutting down the exposure to a quarter. Varying the amount of mercuric iodide, and the time of its action, he did not consider it an accelerator; its action appeared to slightly intensify the plate, which could be done by other means quite as well.

Talk in the Studio.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.—The next ordinary monthly meeting will be held at the House of the Society of Arts, John Street, Adelphi, on Thursday evening, February 7th, at eight o'clock, when the subject will be, "Willesden Paper and Canvas, and some of their uses in connection with Photography." The following from the question-box will also be discussed: "Are pictures upon 'ready-sensitized' paper likely to be more or less permanent than those upon paper freshly-prepared?"

CELLULOID DEVELOPING DISHES.—Mr. Hart sends us some charming little dishes made of this strong, light, ivory-like material, which ought to become popular in the laboratory. Their strength and lightness should adapt them admirably for travelling.

A CLEAR-VISION THERMOMETER.—The difficulty of reading the ordinary thermometer in a dim light has often been felt, and those who like to keep a thermometer hanging in the dark-room will be interested in an ingenious little instrument which is manufactured by Messrs. Watson and Sons, of Holborn. As the mercury rises, it causes the tube to overbalance, and the tube itself thus becomes the index.

"INDUSTRIAL CURIOSITIES," by Alex. A. Japp, LL.D. (T. F. Unwin).—This volume treats of several industrial matters, such as the production of leather, porcelain, needles, &c. There is also a chapter on photography, but this seems to be merely an advertisement of a Regent Street studio.

RECENT DEVELOPMENTS OF THE WOODBURYTYPE PROCESS.—On Monday last, the first of a series of three lectures on "Photo-Mechanical Printing Methods" was delivered at the Society of Arts by Mr. Bolas. Several modifications of the Woodburytype process were treated of, and Mr. Woodbury's new Stannotype was fully demonstrated. It is interesting to notice that the complete set of apparatus for the Stannotype stood on a table thirty inches wide by six feet long. Next Monday the lecture will be on "Photo-Block Methods."

THE ORIGINAL AND THE PICTURE.—At Stocktou County Court on Tuesday, Mary Ann Best, wife of Edward Best, blacksmith, South Stockton, sued William Baker, photographer, for two guineas, being the amount paid to defendant for a painted portrait of plaintiff. Seven shillings had been paid into court, and plaintiff had received one dozen cartes-de-visite, value ten shillings. Miss Baker appeared for defendant. The portrait was exhibited in court, and its striking contrast to plaintiff created considerable amusement. Miss Baker said the portrait had been executed three years since, and was exactly like what plaintiff then was. His honour pointed out a distortion iu one of the eyes, and an entire absence of colour in the portrait, plaintiff beiug a handsome buxom fresh-coloured lady. Miss Baker remarked, amidst much laughter, that women change a very great deal in the space of three years. A verdict was given for plaintiff, the price of the cartes received being deducted.—*Cumberland Mercury, January 26th.*

THE ILLUMINATING POWER OF ETHYLENE.—Dr. Percy Frankland has obtained results which may be thus briefly summarised :—(1.) That pure ethylene, when burnt at the rate of 5 cubic feet per hour from a Referee's Argand burner, emits a light of 68·5 standard candles. (2.) That the illuminating power of equal volumes of mixtures of ethylene with either hydrogen, carbonic oxide, or marsh-gas is less thau that of pure ethylene. (3.) That when the proportion of ethylene in such mixtures is above 63 per cent., the illuminating power of the mixture is but slightly affected by the nature of the dilutent. When, on the other hand, the proportion of ethylene in such mixtures is low, the illuminating power of the mixture is considerably the highest when marsh-gas is the dilutent, aud the lowest when the ethylene is mixed with carbonic oxide. (4.) That if 5 cubic feet of ethylene be uniformly consumed irrespectively of the composition of the mixture, the calculated illuminating power is in every case equal to or actually greater than that of pure ethylene until a certain degree of dilution is is attaiued. This intrinsic luminosity of ethylene remains almost constant when the latter is diluted with carbonic oxide, until the ethylene forms only 40 per cent. of the mixture, after which it rapidly diminishes to zero, when the ethylene forms only 20 per cent. of the mixture. When the ethylene is diluted with hydrogen, its intrinsic luminosity rises to 81 candles when the ethylene constitutes 30 per cent. of the mixture, after which it rapidly falls to zero when the ethylene amounts to only 10 per cent. In the case of mixtures of ethylene and marsh-gas, the intrinsic luminosity of the former is augmented with increasing rapidity as the proportion of marsh-gas rises, the intrinsic luminosity of ethylene, in a mixture containing 10 per cent. of the latter, being between 170 and 180 candles.

PHOTOGRAPHIC CLUB.—At the next meeting, on Wednesday, February 6th, the subject for discussion will be "On Portable Cameras."

To Correspondents.

*** We cannot undertake to return rejected communications.

FRANK JOLLY.—1. Please read our two articles on the subject again; the last one gives you all the information you require. No yellow fabric, except the well-known tammy, is alluded to. 2. If you will make the description brief, we could find room for it in an early number, and would be much obliged to you for it.

L. L.—1. Yes. 2. To neutralize the acidity. The other points are too many and too complex to answer in this column. Shall we come and stop a week with you?

C. H.—You do not say whether the spots are noticeable as soon as the prints are made, or whether they only appear after the lapse of some considerable time. In any case, we should advise you to change the paper as an experiment. Do not, however, conclude that any sample of paper obtained from another stock-dealer is, of necessity, from a fresh source.

J. L. ROBIN.—It is not yet published, but it will probably be issued in about six weeks.

J. PARKER.—Full details will be found in a series of articles which appeared in our volume for 1881; the first of the series began on page 433. The YEAR-BOOK for 1882 also contains particulars (p. 168).

B. F. T.—One of the best direct copying methods is that described on page 689 of our last volume; and a suitable arrangement for accurately enlarging and reducing plans is figured on page 144 of H. Baden Pritchard's "Photography and Photographers" (published at our office).

J. H. W. B.—It was the fresh gold that put it into working order again; without this addition, we fancy you would have found it worthless.

H. B.—We will do our best to obtain information which may be useful to you, and if we are successful, we will communicate with you by post.

W. B. LOWNDES.—About one-fourth of a grain to an ounce, if it is not to be kept for a very long time. As much as two grains may be added without occasioning any mischievious re-action.

J. FOSTER.—We can trace two kinds of spots: one arising from dust settling on the plates while drying, and the other from careless filtration of the emulsion.

PHOTO.—Perhaps you use water which is uncommonly soft. Try the effect of hardening it by adding an ounce of Epsom salts to a large pailful.

T. B. B.—No doubt some kind of protection is necessary; but we do not think your scheme looks altogether practical.

W. M. DUNN.—So many of the numbers are out of print, that the remainder would be of but little value to you. You had better advertise for a second-hand copy of the volume.

A. A. B.—1. It is the subject of an existing patent, and you must take a licence. 2. The best way is to determine the strength of the solution by a volumetric method. See "A Plea for the Burette" in "Photography and Photographers."

G. FROST ALTON.—1. A symmetrical or rectilinear objective of about fifteen inches equivalent focus. 2. Yes, but you cannot hope to make a good bargain unless you possess some considerable knowledge and experience.

C. T. CHESTERMAN.—Thank you very much for your note, of which we shall gladly use certain portions.

AD. EGGIS.—Write to Mr. Medland, Optician, Borough, London.

R. C. COLSON.—The circumstance that you failed to add sufficient hydrochloric acid to redissolve the whole of the precipiate explains the matter. Most likely there was but a trace of zinc in the solution

V. HALL.—1. Your customer has used you very badly, but in the absence of a written agreement it is hardly likely that you will be able to obtain any redress. 2. It consists of sulphate of barium. 3. Yes.

The Photographic News Registry.

Employment Wanted.

Carbon Enlarger, Painter, &c.—G. Fischer, 54, Berners-st., W.
Recep. room and manage (Lady).—Rembrandt, 5, High-st., Ryde, I.W.
Retoucher, work-up black-and-white (Lady).—W. J., *Photo. News* Office.
Operator, manager.—A. E. Walker, 118, Abbeyfield-rd, Pittsmoor, Sheffield
Operator or manager.—W. D., 2, Nursery-vils, Bounds-grn, New Southgate
Assistant (Lady), tint, spot, &c.—A. G., 5, Heaton-vil., Heaton-rd., S.E.
Collotype Printer, expe.—E. Birch, 3, Alpha-ter., Boston-rd., Hanwell.
Operator and Retoucher, or to manage.—Operator, 18, Telford-rd., W.
Mounter, Spotter, Books (Lady).—A. E. G., *Photo. News* Office.
Opera. & Retouch, all branches.—Pyro, 1a, Prince-of-Wales-rd., Norwich.
Operator and Retoucher.—Manager, Eastover House, Bitton, near Bristol.
Assistant Operator.—A. G. R., Rosetta Cottage, Weeks, Ryde, I.W.
Retoucher & Assist. (Young Lady).—Miss J., 10, Edith-rd., Peckham, S.E.
Lady for Reception-Room, —E. D., 50, Crockherbtown, Cardiff, S. Wales.
Vignetter, good hand, first-class firm.—G. E. Lann, Market-st., Brighton.
Retoucher.—F. Piper, 56, Walford-rd., Stoke Newington, N.
Artist, for Monochrome and Water Colour.—Z. A., *Photo. News* Office.
Operator, clever at lighting, &c.—F.W., 1, Claylands-rd., Clapham-rd., S.W.
Reception Room, Young Lady of exp.—M. A. G., *Photo. News* Office.
Reception Boom, Shop, Books, &c.—W. C., 160, Arlington-rd., N.
Youth, as Assist. Op. or Printer.—L. D., Cambridge-gardens, Notting Hill.
Assistant Operator and Printer.—E. D., 576, Sunderland-st., Pimlico.

Employment Offered.

Assistant Printer, to reside in house.—W. J. Anckorn, Arbroath, N.B.
Youth, to sensitize, mount, &c.—Turner & Killick, 10, Barnsbury-pk., N.
Saleswoman and Stock-keeper, to spot, &c.—J. E. Bliss, Cambridge.
Retoucher, first-class.—W. McLeish, 71, Northgate, Darlington.
Young Lady P inter.—Gartside and Risley, *Photo. News* Office.
Retoucher, clever.—J. Hawke, George-st., Plymouth.
Dry-Plate Coaters, experienced.—Prestwich, 155, City-rd., E.
Photo-lithographer, experienced.—Photo., 150, Queen Victoria-st., E.C.
Photo. expe. largest cameras.—E. Meyerstein, 280, High Holborn, W.C.
Retoucher, for high-class work.—Mavius and Vivash, 49, Ann-st., Belfast.
Operator for N.W. Provinces, India.—India, *Photo. News* Office.
Photo. Artist, first-class, all-round hand.—W. Knight, 47, Coney-st., York.
Young Woman, charge of Painting Room.—W. Winter, Midland-rd., Derby.
Printer and Toner, young, for City.—Viaduct, *Photo. News* Office.
Retoucher, first-class.—Negretti & Zambra, Photo. Dept., Crystal Palace.
Printer & Toner (female) to manage.—Holden & Co., 42, City-rd., Bristol.
Photo-lithog., perm. if comp.—X., c/o Smith & Co., Gresham House, E.C.
Traveller, to Sell Backgrounds.—Photo., 5a, York-ter., Clapham.
Printer, skilful Vignetter.—Morgan and Kidd, Helio House, Greenwich.

THE PHOTOGRAPHIC NEWS.

VOL. XXVIII. No. 1327.—*February* 8, 1884.

CONTENTS.

ZUCCATO'S METHOD FOR THE TRANSLATION OF A PHOTOGRAPH INTO LINES FOR TYPOGRAPHIC PRINTING.

THE accurate translation of the gradations of the ordinary photograph into a black-and-white grain or stipple exactly corresponding in intensity to the lights and shades of the original, is undoubtedly the main problem to be solved in making a phototype block, as, if this grained picture is once obtained, it can easily be reproduced by the ordinary method of making a photo-lithographic transfer, putting this down upon a plate of zinc or type metal, or copper, and etching into relief by well-known means. If the original grained picture is produced in transfer ink, one step in the process is obviated, as there is no necessity to re-photograph, but the grained picture is transferred directly to the metal.

In the course of Mr. Bolas' recent lecture at the Society of Arts, the various methods of translating the photograph into grain or stipple were considered at some length; but especial importance was attached to those methods in which the Woodbury relief becomes a medium or step between the negative and the grained image; methods in which mechanical rather than optical agencies step in for effecting the required translation.

Our readers are familiar with the original method of Ives, in which a surface of grained paper is pressed against a Woodbury relief that has been covered over with printing ink, and the more recent process in which a plaster cast of a relief is inked by means of an elastic stamp, having a surface crowded with minute pyramids, the inked impression being then stripped off on a collodion film; and it is not necessary to do more than allude to the excellence of the work which can be produced by Ives' method.

Mr. Zuccato has recently patented three methods for the mechanical translation of the relief into an ink picture (Nos. 4,152, 4,153, and 4,154, 1883), and these methods were described and illustrated on the occasion referred to above.

According to the first method, a plate of type metal, or similar substance of moderate hardness, is moulded or planed so that its surface is covered with a series of V-shaped ridges, closely packed together, and this plate is inked by a roller or dabber. A sheet of thin transfer paper is now laid over the inked plate, and on this is placed the relief, after which pressure is applied by the hydraulic press. Under these circumstances the inked ridges become crushed down more or less according to the relative thickness of the various parts of the relief, and the imprint of the more or less flattened ridges is transferred to the paper with remarkable clearness of outline. The impression in transfer ink thus obtained is now transferred directly to a metal plate, and this is etched, so as to leave the lines in relief. By this means a typographic block is obtained, which presents many of the characters of a wood-engraving, the lines, although varying in width, being continuous except in the extreme whites, and where they unite to form the solid blacks; but the most important feature is the circumstance that the clear, sharp boundaries of the lines serve to give the blocks most excellent printing qualities.

In other cases, Mr. Zuccato inks a piece of silk or other network, and interposes it between a zinc plate and the relief: a piece of paper being placed on the other side of the inked gauze if necessary. In this way, the stipple depends on the crushing down of the threads, and a cross-barred picture is obtained. Mr. Zuccato's third method consists in pressing the reliefs against a metal plate upon which an ink stipple has been imprinted, and the unequal spreading out of the ink determines the production of the picture.

It appears to us that the second method and the third are quite secondary in importance to the first, as they cannot be expected to give the exceptionally clear-cut lines which have been found to result when the grooved plates of type metal are used.

In connection with the subject, we would call special attention to the "Crayontype" of M. Eggis, a description of which will be found on page 789 of our last volume. M. Eggis lays a sheet of the so-called "carbon" or "manifold" paper or other inked paper on the Woodbury relief, and over this a sheet of grained transfer paper, and he now applies pressure. A stippled picture is formed on the transfer paper, and this may be transferred directly to zinc or to a lithographic stone.

PACKING AND STORING DRY PLATES.

DURING the winter months, a great many photographers, both professional and amateur, will be busy in the preparation of dry plates for use when the finer weather sets in. The mode of packing and storing these plates is, perhaps, as important a detail as any of the many processes connected with their preparation; and, probably, not a few batches, otherwise carefully prepared in every respect, have been injured by want of attention to this final stage of dry-plate manufacture.

In the first place, it is absolutely necessary that the film should be absolutely hard and dry before packing. To ascertain this fact, it is not advisable to rub the fingers over the film, for, even if perfectly clean, the finger is liable to injure the film by its pressure alone. It is a well-known fact that pressure tends to diminish sensitiveness, and thus to produce marks which are rendered plainly visible upon development. If the film appear perfectly

homogeneous and flat by reflected light, and the glass is thoroughly warm, there is little need to fear that the gelatine is not sufficiently dry.

Now comes the important point in packing—viz., the complete separation of the films from one another. Many amateurs are content to place the plates face to face, in pairs, the films being separated by small pieces of paper carelessly placed between each pair. We have even seen commercial plates packed in this manner.

Now, actual experiment performed upon plates packed with a small piece of paper placed near each end, will prove that light-coloured patches may be produced upon each plate, which not only correspond in outline with the shape of the pieces of paper, but which even reveal the ragged fibres which are usually present upon the torn edges of some of the coarser kinds of paper. Of course, in this case, the cause is evident—unequal pressure having diminished the sensitiveness at the points of contact with the paper. If the pieces of paper are carefully folded, so as to form a kind of rack, in which the edges of the plates can be inserted, this effect is of but little consequence; although, even in this case, insensitive bands often appear on the edges of the negative after development, and sometimes of sufficient breadth to diminish the value of the picture. The paper-rack, therefore, should be as narrow as possible in the grooves, and, if possible, should not exceed the breadth of the rim in the dark slide upon which the plate rests during exposure.

When travelling with dry plates, it not unfrequently happens that these pieces of paper slip out when a packet is undone for the purpose of replenishing the dark slides. For this reason, it is preferable to pack up in small batches for out-door work, having not more than four or six in a packet, according to the number of slides employed. By this plan there will be a great saving of time and trouble also; for when once a few plates are taken from a packet, the remainder no longer pack up neatly without considerable trouble, especially as the process of changing has often to be conducted in absolute darkness. Perhaps for out-door work there is no better plan than that of Mr. England. This consists in placing between the films little frames of cardboard, made just the size of the plate; but for large quantities this plan would be a little troublesome.

The method adopted by some professional makers, of separating the films with a sheet of paper, is not always to be recommended, as not only is there some danger of scratching if the films are not perfectly flat, but there is also a possibility that the pressure, being exerted uniformly over the whole film, will cause a general diminution in sensitiveness.

Coming now to the question of storage, the great enemy to be guarded against is damp, which causes fogging and staining by decomposing the gelatine film. Probably, however, either a dry room, or a cupboard near a chimney, will be available in most cases. Still a very hot cupboard is undesirable for storing plates.

Perhaps a few words will not be out of place here upon the storage of negatives. It is not an uncommon thing, for amateurs especially, who have not an endless supply of rack-boxes, to find negatives varnished and packed away with sheets of paper, perhaps newspaper, between them. In this case it generally happens that after a few months, when the negatives are unpacked again, the surface of the varnish is quite spoiled, being covered with matt blotches if the paper used was plain, and with an exact impression of the printed matter if newspaper was used. Now, although the printing qualities of such negatives might not be totally ruined, the presence of these defects, which are often plainly visible by transmitted light, cannot but injure the negative to some extent, and in the absence of rack-boxes it would probably be preferable to stand the negatives on a shelf with nothing between them whatever.

Between exposure and development, it appears that two chief evils only need be guarded against in packing, viz., scratching the film, and imperfect exclusion of light; but in no case should printed matter be allowed to touch the film, nor should two films be allowed to press upon one another; for it has been observed that if an exposed gelatine plate be pressed in contact with another unexposed plate, a second image may be developed upon the latter, the latent image having been communicated from one to the other. Although this statement perhaps requires fuller explanation and confirmation, it suggests the propriety of separating exposed films from one another with as much care as the unexposed plates.

THE SPECTROSCOPE AND ITS RELATION TO PHOTOGRAPHY.

BY C. RAY WOODS.

No. 2.—THE PARTS AND ADJUSTMENTS OF THE INSTRUMENT.

To say that the prism is the most important part of the instrument is almost superfluous. The essential properties of this part of the apparatus are as follow:—Clearness and freedom from inequalities in the structure of the glass, high dispersive power, and accurately plane and well-polished surfaces. Ordinary crown glass is not available, as it does not possess sufficient dispersive power—or, in other words, it does not widen out the spectrum to the most desirable extent. Flint glass is that generally used, and is to be obtained of different densities according to the purpose for which it is required. For photographic purposes, a clear, white quality is the best; and though this has not the dispersive powers of the densest kind, it is as well to sacrifice a little dispersion to purity of colour, the denser glass having an objectionable yellow hue in addition to a liability to tarnish.

Various other media are frequently used for spectroscopic work, such as quartz and Iceland spar, which are often required for special purposes, such as photographing the extreme ultra-violet rays.

Some liquids, such as bi-sulphide of carbon, and certain dense organic compounds, are also brought into requisition; but they are useful mainly for lecture demonstrations. Slight changes in temperature will cause such variations in density throughout a bisulphide of carbon prism, for instance, as to render it useless for fine work.

The principles of optics which give to a prism its chief value as an aid to scientific research are too well known to photographers to need more than a brief glance. When a ray of light passes at an angle from one medium to another of different density, it is refracted, or bent out of its course. A very good illustration of this—but one that is not to be found in the popular text-books—has been given in what takes place when a body of men marching across a piece of solid ground, come to a piece of boggy soil, the boundary of which is not perpendicular to their path. Those who reach the bog first find their movements impeded, and their comrades in the front rank who are still on solid ground get a little in advance. As a natural consequence, when both sides of the rank find themselves in the bog, it is found that their course has been more or less altered. The refraction or bending of a light wave in passing, say, from air to glass is similar to this: "That end of the wave which first reaches the medium will be the first retarded by it, the other portions, as they enter the glass, being retarded in succession."* If the sides of the glass are parallel, an equal amount of bending in an opposite direction takes place, and the ray passes out along a path parallel to that at which it first enters the glass. If the sides are not parallel, as in the case of a prism, yet another path is followed.

But in the passage of a ray of light composed of waves which have not all the same length, something else takes

* Tyndall on "Light."

place. The ray of white light is split up into its many constituents, that light composed of the longest waves being less bent out of its course than the light of shorter wave length. This is shown in the subjoined diagram:

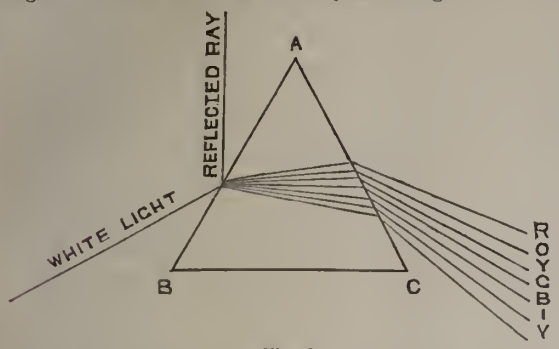

Fig. 2.

A ray of white light strikes the prism at an augle; part of it is reflected, and the remainder passes into the prism and is split up into its several constituents, these different rays being still more spread out on emerging into the air. The violet rays, on account of their shorter wave length, are most refracted, and are therefore called the most refrangible rays of the visible spectrum, the red rays, which are least bent out of their course, being called the least refrangible. Between these come those rays which produce on the retina of the eye the sensations of indigo or dark blue, blue, green, yellow, and orange. At each end of the visible spectrum are rays which are invisible to the eye, and, as will be shown in subsequent articles, have to have their presence made known by other means.

It will be convenient here to mention, incidentally, a little difficulty that the reader may meet with.

Figure 2 practically shows Newton's experiment of passing a beam of sunlight through a prism, and letting it (the light) fall upon a screen, the violet rays emerging from that part of the prism nearest the base (BC), and the red from a part nearest the apex (A). But if the reader employs his eye instead of a screen, as in the experiments detailed in the previous article, he will notice that the reverse of this seems to take place, and the red appears nearest the base. The following diagram will explain this apparent anomaly.

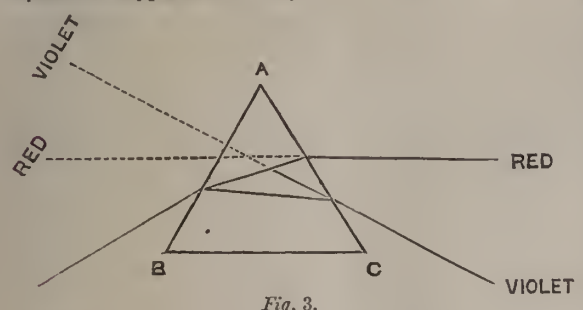

Fig. 3.

The direction of the red and violet rays is shown as in fig. 2, but the experimenter sees, not the band of colour formed by the rays as they fall upon the screen, but the slit itself, displaced and elongated into a band of colour. The dotted lines give the apparent positions of the slit as shown by the red and violet rays.

Next in importance to the prism comes the slit, for on the trueness of this piece of apparatus a great deal of the beauty of definition of a spectroscope depends. The slit plate is usually constructed of brass, the slit itself being formed by two pieces of metal, one of which is mounted in a groove, so that the slit can be opened and closed at pleasure. The edges forming the slit are ground down like a thin wedge, and these edges must be perfectly straight and smooth in addition to being parallel. In the best instruments the edges themselves are formed of a hard alloy of platinum and iridium, and their distances apart are regulated by a screw, to which is attached a circle and vernier to read off the width of the opening. It is as easy to mentally picture a perfect slit as it is to define a straight line, but the practical accomplishment of the former is almost as difficult as the latter. The slightest inequality in the slit, even that caused by a few specks of dust, will show itself. Before commencing work, it is advisable to open the slit, and clean the jaws with a piece of soft wood, such as a lucifer match cut to a point. Where great delicacy is not essential, a slit may be formed by attaching a piece of tin-foil to a piece of glass, and cutting through the tinfoil with a sharp knife or razor.

For the collimator and telescope, achromatic lenses are not essential, though desirable. Lenses of about eight to ten inches in focal length will be found most suitable for a single prism spectroscope. The slit should be placed in the focus of the collimating lens; the right place is most readily found by turning the tube, to which are attached the collimating lens and slit, towards the sun, holding a slip of paper between the jaws of the widely-opened slit, and focussing the image of the sun upon it. Absolute accuracy is not essential. The collimating lens should be large enough to fill the prism, and the lens of the camera, or the object-glass of the telescope (they both amount to the same thing), should be large enough to take in all the light coming from the prism. It is scarcely necessary to mention that the eye-piece of the telescope should possess an arrangement for focussing. The focus varies considerably for different rays, as the photographer will find, especially if he uses non-achromatic lenses, and he must use a very considerable amount of swing-back to get all the rays in focus at one and the same time. Fig. 4 is a

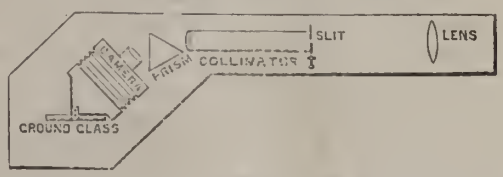

Fig. 4.

diagramatic illustration of a spectroscope used for photographing the corona in 1882, and the amount of swing-back represented there was scarcely more than was required for all the rays from ultra-violet to infra-red. The same diagram shows the relative positions of the slit, collimator, prism, and camera. In the instrument referred to, the rest of the apparatus was constructed of wood. The photographer may readily convert his camera and lens into a temporary telescope for eye observations by turning aside the ground glass, and holding his magnifier in its place.

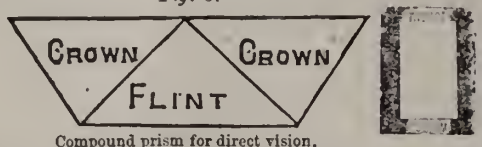
It only remains now to describe the adjustment of the prism, relative to collimator and camera. The prism, in order to get the best results, must be adjusted for what is called "minimum deviation," that is, it should be in such a position that the ray leaves the prism at the same angle at which it enters it. The following is an easy method:—

A source of light is placed near the slit, before the camera or telescope is put into position, and the observer then looks at the slit through the prism. The prism is then slowly turned round. By moving it in one direction the spectrum will move, as it were, towards that side which the violet is nearest to, till at last it moves right out of the field of vision. If the prism is then revolved in an opposite direction, the spectrum will again come into view, and appear to move more and more towards the red till it comes to a standstill; by continuing the same motion the spectrum will then move back again. At the point of rest is the proper position, when the prism will be

roughly, at the angle of minimum deviation. A glance at fig. 2 will, however, show that this angle is not the same for each ray. The photographer will, therefore, watch more particularly the blue rays, and leave his prism where those rays appear stationary. When there is more than one prism, the first one is adjusted, then the second is added, and so on, till they are all in position. It is usual, however, for spectroscopes to possess a mechanical arrangement by which all the prisms are adjusted at once. The camera may then be put in position, and the spectrum focussed on the ground glass.

A handy form of spectroscope with which the photographer is familiar, one suited for eye observations such as examining the light that passes through a particular kind of glass, is the direct vision spectroscope, the construction of the prism of which is shown below.

Fig. 5.



Compound prism for direct vision.

By the use of a combination of flint and crown glass, the rays are made to follow a straight path, whilst some of the dispersion is retained. The action is just the reverse of that of an achromatic lens, in which the colours of the spectrum are done away with, whilst the deviation is retained.

By-the-Bye.

SUCCESS IN PHOTOGRAPHY.

SOME time ago we discussed in these pages the status of the photographer, and we said that he held no recognized position in society any more than did the painter, litterateur or others of artistic calling. In short, like the author who might be Poet-Laureate or penny-a-liner, and the painter who might be a Sir Joshua or a dauber of sign-boards, the photographer simply enjoyed the position his works earned for him. There was nobody for him to lean against, and if he did not make it clear to the world that his work was good, the world held him cheap indeed.

These circumstances the photographer would do well to bear in mind. If he wishes to have name and fame in the eyes of the public, he must act precisely as do his elder brethren. "How do the painter and the author get a position?" he should ask himself, and then he might resolve to act on the same lines to win a standing for himself.

The painter paints a picture, puts his name upon it, and sends the work where it is likely to be seen and to find a purchaser. The author does the same; he writes a book with his own name, or a *nom de plume*, attached, and also takes it where he is likely to find a purchaser. If the painting and the book are good, the name attached to the good work becomes more or less famous, and there is a demand for more such works from the producer of them. Thus, the painter and the author who make good things acquire fame and fortune, while on the other hand, those whose names are attached to works of a mediocre stamp are neglected, and neither secure a standing in their profession, nor little else but bread and cheese to live upon.

Let us turn to the photographer. It is a common thing to hear a gentleman exclaim: "I never send out a picture that is not really good, and I always make a point of destroying bad prints." Now, why does he say this—why is the dictum put forward in a virtuous strain, as if the speaker had done something noble and heroic? Either it is the general way of conducting affairs, or it is not. Yet, to judge from the speech as we often hear it, it really seems that this is not the ordinary way of photographers. Of course we know very well that in very cheap studios there is not the same care taken as in others of higher class, but it is not of the former we are speaking. We here allude to those who have taken up photography as a profession, and who are disappointed if a due share of fame and money do not fall to their lot.

Photographers, we feel sure, too often forget this. They have taken some trouble to produce a brilliant card mount, emblazoned with name and address, and with all sorts of elegant outpourings in the way of promises of performance, and they too often paste upon this mount, which is to go forth to the world and trumpet out their name and whereabouts, a shabby inferior print. There are a dozen pictures to be mounted and sent off, and perhaps fourteen to select from when the batch is brought in for inspection. Six of the pictures are very good, and those you pass at once; another four are passable; and then, to make up the twelve, you select the least bad of the others. In this way you incur little waste, and as the customer is a chance one, or has ordered but a dozen cartes and nothing else, this arrangement you think will do very well. Another and better plan, no doubt, would be to have mounted only the six best, and to have printed another batch, but to do this entails further expense and further trouble; besides, ten out of the dozen photographs are very passable pictures, after all. So your beautiful mount with its glazed back and gilt edges, bearing your name in a magnificent scroll, is put at the back of a little dowdy print, and forth goes the latter into the world to proclaim what?—that you are an artist of only second-rate ability.

Follow the print you send out, be it good or bad, and see what happens to it. The purchaser has bought it and the others that make up the dozen, not for his own album, but simply for giving away. In other words, the dozen pictures you send him are, from one point of view, a dozen advertisements that go into strangers' hands. These strangers, very probably, have no knowledge of your existence as a photographer, but now they look at the back of the smart card given them, and read your name and address. What follows is but a matter of course. If it is a fine picture of friend Jones, or a charming representation of Mrs. Thomson, Mr. and Mrs. Stranger are naturally very pleased; but the strange thing about it—and this our readers should remember—is, that if the picture is a good one, neither Jones nor Mrs. Thomson get any credit; this all goes to the photographer. The latter gains much, therefore, whenever he turns out a good picture, for Mr. and Mrs. Stranger note his name at once, and if either of them want a portrait of themselves or of the dear baby, to the photographer do they go direct, whose picture has pleased them so highly. In fact, the family album, from its owner's point of view, is ofttimes regarded as a book of patterns, and he who has supplied the best pattern in the collection is likely to obtain the most custom.

The sitter himself, therefore, although you do your best to please him, is not really the person with whom you have most influence. He or she has only bought the pictures to give away, and is, in fact, acting as your advertising agent. Unfortunately, this fact is frequently lost sight of, and a photographer thinks that if by hook and crook the customer is satisfied, and pays his money, the transaction is a profitable one. It is nothing of the kind. Sitters there are—not very many, perhaps, but still in goodly number—who do not care a straw how you depict them, so long as the portraits are tolerably well executed, and they give away their photographs just as you send them. They publish your work, so to speak, for good or evil, and you may be quite sure that bad portraits work their producer incalculable harm. The Stranger family may have thought well of you before, because they heard from the Smiths how good you were with children; but since old Brown gave them that hideous portrait of his taken at your studio, they have changed their opinion, and nothing will induce them to enter your doors.

Thus, the selection of good prints, and the destruction of bad ones, is no virtue, after all; it is simply a policy that is not merely honest, but is the only one likely to bring success to the photographer who practises it. It is the policy that is practised every day by the author and by the painter who is successful; wherever your name goes—and the photographer takes care his name goes on every one of his mounts—the work in connection with it must be sterling good. Therefore, if the work is inferior, either destroy it, or do not put your name to it. Dr. J. F. Carpenter, the author of "What are the wild waves saying," and a thousand and one other popular ballads, once gave us an apt illustration of this. His usual fee, after he had become a noted song-writer, was ten guineas for every ballad, and one day, when he called at his publishers, the latter complained of this charge as being somewhat high. "We have got a young fellow just fresh from Cambridge to do some capital sonnets for us, and we only give him a guinea a-piece for them," was their statement. Replied Mr Carpenter: "Well, and I will do you some capital sonnets for a guinea a piece—as many as you like; only, you mustn't attach my name to them."

This is only fair. When you have earned a good name for good work, you must be very circumspect about using that name. Unless the work is in every way first-class, your reputation is sure to suffer. "Just make me a sketch, and put your name to it," is a frequent request made by thoughtless people to artists of standing; while Charles Dickens was frequently bothered by editors of small periodicals for a story, however slight and short, with his name at the top. No one knew better than Dickens "what's in a name," and no one was more chary of depreciating that good name by work of an inferior order than the famous novelist.

So we say that, since photographers are ever ready to put forward their name—and, indeed, make rather a parade of it—they, of all people in the world, should be careful what work is coupled to it. Every print sent out from their establishment is an advertisement of that establishment, and as they sow, so surely will they reap. While they will never lose credit for good work, they will sooner or later most assuredly suffer when bad pictures are inseparably connected with their name; whether it is mere thoughtlessness, or something worse that leads them to adopt such a course, their shortcomings must perforce recoil upon themselves.

DR. EDER'S RECENT RESEARCHES.

BY WALTER B. WOODBURY.

The properties of the ferricyanide of potassium, in combination with gelatine, discovered by Dr. Eder, and mentioned by Mr. Bolas at the first of the series of Cantor Lectures, may possibly cause a complete revolution in carbon printing, and most processes of a kindred nature, where the gelatine has to be washed away, as in the Woodburytype, Stannotype, &c. There are, doubtless, many points to be solved, such as relative sensitiveness to light—principally; although, not having had any experience with this combination, I should imagine that, if insolubility of the gelatine occurs on mixing with the ferric salt, there would at once arise a difficulty in getting either paper or glass coated with the mixture. But if it could be employed, as are now sensitive carbon or Stannotype tissue, there seems to be no difficulty in its use.

A complete reversal of all the processes would naturally occur. The carbon process would require a positive, and the Stannotype a negative to work from, thus completely changing the existing order of things. In the latter process, all that would be required would be to keep sheets of plate glass coated permanently with gelatine, and sensitize as required for use, to expose under a negative, and wash away the parts rendered soluble by light, coating, when dry, with tinfoil, as usual. No reversal of the image would take place, as the surface image from the negative would naturally be reversed, and brought right again in the print. This is a most important feature in all photo-mechanical processes, and formed in the early days of the Woodbury process a serious drawback, until by accident a relief was laid with the wrong surface in contact with the lead (turned inside out, in fact) with no apparent difference in the resulting prints. Since then this method has been adopted in all Woodbury printing, except where film or reversed negatives were handy. In what Mr. Bolas termed the first Stannotype process (although the name was only given to the later) the same difficulty appeared, all prints being reversed, which called forth the remark from a celebrated German firm that this fact took all the cream off the system. This additional reason to those given by the lecturer was the cause of its abandonment.

FRENCH CORRESPONDENCE.

Experiments with Warnerke's Phosphorescent Photometer—Action of Water and Hyposulphite of Soda on Gelatine Emulsions—Non-Stretching Pellicles—Photographic Laboratory at the Museum of Decorative Arts—Physiognomy Album—Pocket Photographic Apparatus.

M. de la Noë's Practical Experiments with Warnerke's Phosphorescent Photometer.—At the February meeting of the Photographic Society of France, Commandant de la Noë, director of the topographical brigade, gave the result of his observations on our friend Warnerke's photometer. After a series of regular observations carried on for a year, it was found to register apparently lower at noon than in the morning or evening. A table of the curves of each series of observations has been drawn up in order to arrive at the conclusion that the action of full daylight upon the retina of the eye caused it to be partially insensible to perceive the true degree of luminosity. For instance, an observer at noon notes the degree visible to him in the open daylight; he sees, perhaps, No. 14. Another observer, having previously remained in a dark place for about a quarter of an hour, on looking at the instrument, was able to see the entire series of degrees on the transparent scale. Evidently this action of light on the retina is an obstacle to the correct reading of the veritable degree. M. de la Noë wished to control these observations by means of Warnerke's sensitometer, and has arrived at the results he had foreseen—that is, to the registering of one degree higher at noon than at 8 a.m. or 4 p.m. The sensitive plate receiving the impression from the phosphorescent is not influenced in the same way as the eye, and manifests an actinic result agreeing with the intensity of light.

Action of Water and Hyposulphite of Soda on Gelatine Emulsions.—M. Audra has been pursuing with success his researches relating to gelatino-bromide. He read an interesting and instructive paper at the meeting, on the action produced on gelatine plates by ammonia, hyposulphite of soda, and water. One half of each plate was treated with the agent, while the other was left under its normal condition. He stated that a hundred thousandth part of hypo in solution was sufficient to show a marked action. A plate was half immersed for a few seconds, and washed, and the whole plunged into the ferrous oxalate, when the portion submitted to the hypo was more quickly developed. M. Audra, therefore, recommends the use of one gramme of hypo in a litre of water as an accelerator. The washing also seems desirable. The action of ammonia is similar, but less active. Water produces a marked effect. The moistened portion of the plate does not give an image so quickly at the commencement of the development, but the water, owing to the salts held in solution, tends to fog the plate. The retardation seen at first is due to the time elapsing before the ferrous oxalate can re-

place the water by acting upon the already swollen surface.

M. Bornstein's Non-Stretching Pellicle.—My last communication on the subject of pellicles has set M. Bornstein to work in the direction of finding the means of producing pellicles not subject to enlargement, and consequent rolling up, during the processes of washing, developing, and fixing. One may thus, according to need, choose pellicles stretching and enlarging themselves, or those remaining their original size.

Foundation of a Photographic Laboratory at the Museum of Decorative Arts.—This Museum is about to be endowed with a laboratory for the photographic reproduction of objects of industrial art which are there exhibited. By this means industrial workmen will be enabled to procure at low prices, through the Central Union Society of Decorative Arts, pictures of articles of furniture and jewellery, porcelain, textile draperies, hanging, &c. The fitting up of the laboratory has been entrusted to M. Davanne and myself; the excellent operator in charge of the work is M. Ferdinand Roux.

M. Chapiro's Album.—M. Constantin Chapiro, of St. Petersburg, has presented, both to our Society and the Academy of Fine Arts, copies of his magnificent album, in which are illustrations, by photography, of Nicolas Golgol's "Memoires d'un Fou." This work is remarkable from all points. It opens out a vast horizon to the application of photography. It consists of scenes in the romance in which a talented actor, M. Andreef Bourlak, throws himself into the part of the hero, and photographed by M. Chapiro. At this first trial, it is a masterstroke, and it is to be hoped that before long more complicated studies will be issued.

Completion of the Pocket Photographic Apparatus.—To return to more personal details, I showed at the meeting my pocket camera and dark-boxes. It has been met with great approval from the numerous photographers, both professional and amateur, who have examined them. The lens, having focal length of 10 millimetres, covers sharply a surface of 7 by 7 centimetres; it is a little gem by M. Français. To complete everything, there only remains the tripod stand, and that I will now describe. I have a bamboo of 25 or 30 centimetres in diameter at the top of the length of an ordinary walking-stick. The cane, split up into three portions, forms the three legs, their lower extremities having an iron spike, and clamping together when closed. In the hollow of the bamboo is another, of nearly the same length as the first, but of one centimetre in diameter. A screw is fixed at its upper end for the purpose of attaching to the camera. At the top of the larger split cane are hinged together the three segments, the slender cane passing up and down to the required height through the centre, where it is fixed by screwing up or unscrewing, loosening or tightening it. When the apparatus is closed, two rings keep the legs together, while a knob screwed on at the upper ends keeps the inner stick in its place. The camera, with double dark-box and lens, weighs only 140 grammes (just under 5 ozs.); the stand can therefore easily support it. I hope, as soon as this is completed, to send an exact drawing to the PHOTOGRAPHIC NEWS, as that will show far better the various details of the apparatus, which I call a photographic *vade mecum*. LEON VIDAL.

PHOTO-LITHOGRAPHY AND PHOTO-ZINCOGRAPHY.

BY MAJOR J. WATERHOUSE, B.S.C.,
Assistant Surveyor-General of India.

CHAPTER XVI.—NEGATIVE TRANSFER PROCESSES.

A PROCESS of this kind was introduced some years ago into the Goot Printing Office, at Sydney, N. S. W., by Mr. J. Sharkey, with considerable success.

From a description given by Mr. E. H. Docken, the details of the process are as follow:—

A sheet of albumenized paper is sponged on the plain side, and laid on a plate of glass, albumen side up. It is then evenly brushed over with a composition prepared by mixing

Starch	1 ounce
Water	1 ,,
Bichromate of potash ...	60 grains
Sugar	60 ,,

When the bichromate and sugar are dissolved, add

Gum-arabic...	2 ounces
Water	2 ,,

and filter through fine muslin.

The paper is dried in the dark, and exposed under a negative as usual.

The mode of transferring varies according as the subject is taken on one negative or several. In the first case, the exposed print is placed between damp blotting-paper till it becomes tacky. It is then placed face downwards on a lithographic stone and passed through the press. The back is then sponged with water until the paper will lift away, leaving upon the stone all the gum mixture which has not been affected by light. The stone is then thoroughly dried, and brushed over with a thin fatty ink composed of

Burgundy pitch	2 ounces
Gum mastic	4 ,,
Bee's-wax	8 ,,
Shellac	4 ,,
Brown soap	2 ,,

melted in a vessel over a slow fire, and burnt for about ten minutes in order to remove a portion of the fatty matter. It is thinned with turpentine to the consistence of collodion, and should be kept well corked.

As soon as the coating of ink is dry, it is washed off again with oil of turpentine; the stone is then sponged with gum-water, and rubbed over with an inky rag, which at once develops the design, and the stone is then ready for printing in the usual way.

If the subject has been taken on more than one negative, the exposed sheets are placed on stones coated with a thin layer of lithographic retransfer ink, to which a little gold size or other drier has been added. The same manipulation as before is gone through, but in this case the paper not only leaves its unchanged gum on the inked stone, but the insoluble lines forming the image take the ink from the stone, so that the design is on the paper in retransfer ink. The sheets are then dried, joined as required, and transferred to another stone.

The manipulation is very easy in both methods, and the stone is ready for the printer within a quarter of an hour from the exposure of the paper beneath the negative. For the second process it is better to use thin bank post paper.

In his treatise on "Photo-lithography," M. Geymet has given a very detailed and practical description of a negative process with gummed paper.

Albumenized paper, the albumenized surface of which has been coagulated with alcohol or by steaming, is floated for three or four minutes on a solution of bichromated gum, made by adding equal parts of a saturated solution of bichromate of potash and thick gum-water containing 100 parts of gum-arabic in 150 parts of water.

The solution must be carefully filtered through muslin, and be free from bubbles. The paper is then drained, and dried in the dark. It must be used fresh, or not more than one day old.

About two minutes' exposure in the shade is sufficient even in a moderate light. The impression should be visible, but scarcely marked. If the exposure is carried on till the image appears of a golden yellow it will be impossible to transfer. By the light of a candle the image should just appear of a green olive colour.

The exposed print is then placed on a sheet of wet

blotting-paper, gummed side up. A sheet of white paper is laid over the gummed paper, and when this begins to stick to the print, the latter is ready to be transferred.

The difficult part of the operation now begins, and success depends on the even damping of the print, which should just be limp and moist without being wet.

The stone should be slightly warmed before a fire or in the sun, and being adjusted to the press the paper is laid face downwards upon it, and covered with five or six sheets of ordinary paper and a sheet of soft cardboard. The tympan is then lowered, and the stone passed through the press some eight or ten times.

A wet sponge, from which the water has been squeezed out, is now passed several times over the back of the paper adhering to the stone. After five or six minutes, a corner of the print is raised gently, and the state of the transfer is examined with care. If it appears successful, the paper should be carefully pulled off the stone; if it resists, it should be sponged and tried again after a few minutes.

A good or bad transfer can be distinguished at once. When the paper is withdrawn, the image should show itself clean and sharp in a brilliant yellow on the white or grey stone.

The edges and all parts of the stone unprotected by gum are gummed, and then, when the stone is thoroughly dry, it is brushed over with retransfer ink rubbed down with turpentine.

A wet sponge is now passed over the whole, and the image appears at once, but may be grey and weak, owing to the thinness of the retransfer ink. This is of no consequence.

The stone is wiped with a damp sponge and allowed to dry, then covered with thick gum-paper, rubbed in well with the hand, and set aside to dry. After some hours the stone is washed, and then brushed over with weak acid and water. It is inked in acid treated in every way like an ordinary lithographic transfer.

In case of an accident, or of its being desired to make duplicate transfers, the original gumming transfer print may be inked by passing it through the press on a stone covered with retransfer ink. It is then washed, and can be transferred in the same way as an ordinary inked photo-transfer print.

(*To be continued*).

A Dictionary of Photography.

ALBUMENIZED PAPER (Printing on).—*Continued.*

Drying Prints.—If we desire to dry prints of large size, it is advisable to keep them as flat as possible, and thereby avoid cracks and tears. Blot off the superfluous water by means of the linen cloth previously recommended. Place two prints of the same size back to back, and suspend by two American clips in the drying-room; but not from the clips used for the sheets of sensitized paper. When they curl at the lower corners, reverse them—that is to say, turn them upside down, but still back to back; when taken down, they will be flat enough for most purposes. Prints of small size may be suspended in strings of two or three dozen, one below another like steps, and when nearly dry, they will drop off; if they are collected and placed face downward under a weight, they will become flat and remain so.

Now let us suppose that the prints are of cabinet size, to be mounted on ordinary cabinet mounts, not reduced to the required size before toning, and we have decided to cut them by means of the glass-shape and sharp knife; under these circumstances the prints must be dry, and the cutting-shape held down firmly on the print to obtain the best results. To mount them, place six, albumenized side downwards, on a clean linen cloth, pass a brush well charged with starch paste over each, separately, working from end to end, and from side to side, being careful not to get any starch underneath, or leave any lumps or extraneous pieces on the print; have ready at hand a pile of mounts, some sheets of clean paper, a paper-knife, and a damp sponge. With the paper-knife raise the first starched print from the cloth, adjust it over, but not touching the mount, until the margin appears equal along the top and two sides; now lower the top edge on the mount, and gradually the remainder. If this has been successfully accomplished, which may be seen at a glance, cover with white paper, and rub the print well down all over with the paper-knife. Should any of the mountant be squeezed out at the edges, it should be removed with the sponge. When the whole of the prints have been mounted, place them, face downwards, on a clean surface in a current of air; they do not alter in shape so much this way as when left to dry face upwards. To prevent the photographs from curling inwards, Mr. C. Keuchel constructs grooved wooden slabs or strips of moulding having a section, as shown in fig. 4, each slab being a trifle over two feet in length.

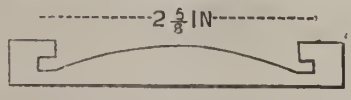


Fig. 4.

The mounts are pushed in this grooving, six, end to end, so that they become arched. After mounting, they are again slid into the grooving, and allowed to remain until dry. When the prints are nearly dry, they are in the best condition for rolling, an operation we will briefly describe, since, for large pictures, at least, the rolling-press is a necessity. The subjoined figure, as will at once be seen, represents a rolling-press, the movable bed being of polished steel, and the pressure, which is capable of acting on the print by means of the roller and steel bed, is regu-

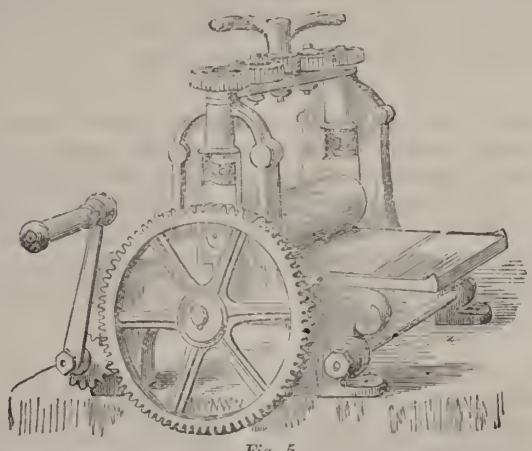

Fig. 5.

lated by the adjusting screws at the top. Brush the surface of the print—also the polished steel plate—with a camel-hair brush, or rub with an old silk handkerchief, to remove particles of dust or paper; place the print, albumen side in contact with the steel plate, and pass it through the press twice, which flattens the picture, and produces an even and polished surface. By heating the plate a more brilliant surface will result. Rolling-presses are manufactured for both cold and hot rolling, and can be procured at any of the stock houses. Where rolling is not permissible, as in the case of scrap-books, a good plan is to attach the print in the usual way to the leaf of the book, damp the back of the leaf slightly with a sponge, and set aside to dry, placing a piece of stout cardboard on each side of the leaf. A strong paste should be used, such as the following, and, when dry, the surface can be very much improved by passing a warm iron over it, substituting plate-glass for the cardboard beneath:—

Best Bermuda arrowroot, or Kingsford's Oswego corn-flour	3½ ounces
Water	28 ,,
Nelson's No. 2 gelatine ...	160 grains
Methylated spirit	2 ounces
Carbolic acid	12 drops

Mix the arrowroot and a small quantity of the water to the consistency of cream, then add the remainder of the water and the gelatine a little at a time; boil on a water bath for five minutes, stirring the whole time, and allow to cool; before quite cold, add

the spirit and carbolic acid. This mixture will keep a long time if well corked.

Another:—

Dextrine	1 ounce
Water	1 „
Methylated spirit	2 ounces

Mix the spirit and water, stir in the dry dextrine, until a smooth paste is obtained; heat on a water-bath until a clear brown solution results.

Notes.

The subject of photography in the new edition of the *Encyclopædia Britannica* will be treated by Captain Abney.

Mr. Colin Hunter, the last elected Associate of the Royal Academy, is an accomplished photographer.

According to the annual report of the Photographic Club, it now comprises seventy-three ordinary members and nine honorary members. The meetings are held at Anderton's Hotel, Fleet Street, every Wednesday evening.

By-the-bye, we see that Edinburgh has now a Photographic Club, which seems to be prospering.

A good deal of interest was felt at Mr. Bolas's lecture on Monday evening, on the subject of the velvet roller and the composition of the ink employed with it, in photo-lithographic work. For this reason we mention that Mr. Newlands, who so skilfully assisted Mr. Bolas on that occasion, furnished the recipe for the photo-lithographic transfer ink given in "The Studios of Europe," for use with the velvet roller.

Mr. W. Webster, junior, an amateur of many years' standing, has taken a landscape illuminated by the beautiful after-glow with which we have been frequently favoured during the winter. The photograph was secured early in December, after four o'clock, the camera pointing west; and there is pretty plain evidence that the sun was well below the horizon at the time. Although considerably under-exposed, the picture is, in some respects, a very good one.

Another recommendation for illuminating the dark-room. Herr Schumann writes in the *Wochenblatt* that he has for some time past abandoned the ruby screen for his lamp, using, instead, orange glass ground on one side. Lately, however, he has employed nothing but brown tissue paper, oiled. Three thicknesses of this paper are usually sufficient, supported upon a plate of ordinary window-glass.

In all these experiments, the principle of "give and take," we repeat, always plays an important rôle. Some light must be admitted, if the photographer is to see what he is doing, and naturally the problem to be solved is to admit a light that does the least amount of mischief. If it were only a question of keeping out every actinic ray, a deal board or brick wall would answer the purpose best of all. As it is, we would recommend the photographer, whether he employs orange or ruby glass, to use a ground surface as well, since the more the light is diffused, the less dangerous is it to the sensitive film. That even two thicknesses of ruby glass will admit plenty of actinic light may be proved by placing them in front of a quick-acting lens; in these circumstances we have secured a picture of a cluster of tall chimneys on a fine day with a three minutes' exposure.

We hope next week to devote a little space to tourist photography, and, if all goes well, to commence a short series of papers "On a Trip to the Great Sahara with a Camera; by a Cockney." We fear there will not be room both for our "By-the-Bye" and for the Cockney lucubrations, and in this case the latter will take the place of the former for a time.

They are still hard at it in Germany threshing out the subject of whether the King of the Belgians did or did not influence the Brussels jury in favour of Mr. Robinson. Why does not Mr. Robinson make a clean breast of it, and tell us frankly what inducement it was he held out to His Majesty? The onus certainly lies with our friend of Tunbridge Wells.

The Photographic Society of Silesia is not dead, we are assured, but suffering from suspended animation.

How to make gold ink. The *Chemist and Druggist* says: Take equal parts of iodide of potassium and acetate of lead; put them on a filter, and pour over them twenty times the quantity of warm distilled water. As the filtrate cools, iodide of lead separates in golden scales. This is collected when the filtrate has quite cooled, washed with cold water on a filter, and rubbed up for an ink with a little mucilage. The ink thus made must be shaken every time it is used.

Two photographic relics of some value have fallen into our hands. It may be remembered that when Nicephore Niépce came to England in 1827, he addressed the Royal Society in respect to his invention, lodging with Mr. Bauer, the secretary, a memoir of his process and a photograph fixed from nature. Mr. Bauer, it was, who subsequently, in 1839, when Niépce was dead and forgotten, reclaimed for the French inventor some of the fame Daguerre had wholly monopolised. The representations of Mr. Bauer, indeed, may be said to have secured to M. Isodore Niépce, the son, a pension of 4,000 francs from the French Government, which awarded Daguerre, on the other hand, an annuity of 6,000 francs.

When Mr. Bauer died, the memoir and the photograph in question passed into the hands of Mr. John J. Bennett, a well-known Fellow of the Royal Society. This gentleman being recently deceased, his scientific collection has been sold, and, in default of a better offer, the two relics in question have come into our possession. They will

form the subject of a critical examination, and furnish the text for a forthcoming "By-the-Bye."

Astronomical observations are attended with a good deal of personal inconvenience, and even risk. For the future, however, they may be undertaken with safety, even by persons of delicate constitution. Mr. Howard Grubb, whose name as a maker to lenses is known to every photographer, described at a recent meeting of the Physical section of the Royal Dublin Society a new form of equatorial telescope, of which all the optical and large mechanical parts were in the open air, while the eye-piece was in a room. Mr. Grubb's designs (pictures of which were shown in the lantern) represented the observer seated in an easy chair, at the side of which were handles controlling hydraulic machinery, by which all the movements of the telescope were effected. An arrangement to attain the same end has been used in France, but is much more expensive and complex than Mr. Grubb's apparatus.

The French Government has resolved to despatch a scientific mission to Java in April next, for the purpose of studying and reporting on the recent volcanic phenomena. A photographer will accompany the mission.

Messrs. Braun, of Dornach, who were the earliest workers in the carbon process, will shortly issue the first part of their series of carbon printed reproductions of the principal pictures of the Dresden Gallery.

Photography is not, it seems, the only process capable of taking an instantaneous portrait. The silk weavers of Lyons, it seems, are able to run it very hard. At the establishment of M. Carquillat, just deceased (who is described as the most remarkable silk weaver Lyons has produced), it was customary, when it was desired to compliment a distinguished visitor, to conduct the latter to the atelier connected with the establishment, and "at a moment's notice" weave a portrait of him in silk. These portraits had acquired quite a European reputation —at least so says the *Echo*.

The discolouration of paper is frequently a source of worry to the photographer. Brownness and yellowness that come simply from the natural action of light upon the paper pulp are oft-times attributed in a photographic print to some chemical reaction, and the photographer is held responsible for the sin. In fact, it is not so long ago that an outcry was raised that carbon prints fade, and it was not until very satisfactory proof was forthcoming that the transfer paper, and not the image, was at fault, that sceptics were prevailed upon to give up the idea.

There are several reasons why paper yellows in time, and, as everybody knows, all ancient pages show the defect more or less acutely. But modern papers discolour yet more quickly than those formerly manufactured, and one reason for this is that many of them contain a good deal of woody fibre. Wood browns in contact with the air comparatively soon, and then there is the disadvantage that the appearance of the paper is spoilt, and it is less durable. In fine papers, such as the photographer uses, there should be no woody fibre at all, or, at any rate, very little, and this is why it is useful to have the means at hand for detecting the presence of wood. The *Chronique Industrielle* gives a very simple test for the purpose, which is, to moisten the paper with a mixture of one part sulphuric and three parts nitric acid; a yellow colour at once results if the paper contains wood, the depth of colour indicating the proportion that is present.

Messrs. Brown, Barnes, and Bell are sending round specimen prints to publishers and proprietors of newspapers, and the qualities their process may possess for book illustration will therefore be practically tested. The weak point of the specimens was, however, at once "spotted" by a shrewd publisher who has had a long experience of illustrated journals. "Yes," he said, "they are very nice, but when the inventors claim that their process will stand the wear and tear of newspaper machinery, and may be printed on rough paper, one ought to see specimens so produced. These samples, printed with care and on first-rate paper with a highly glazed surface, tell me nothing of what the process can do under other circumstances." There is some force in the objection.

Bold indeed could be the sculptor who would venture to set aside old ideas, and represent the horse in action, as Mr. Muybridge's camera depicted him. Indeed, some of the true attitudes are so completely unlike those of the conventional representations, that *Funny Folks* gives sketches after Muybridge, as burlesque suggestions for the new equestrian statues to be erected on Blackfriars Bridge.

Patent Intelligence.

Application for Provisional Protection.

2312. Alfred George Brookes, of 55, Chancery Lane, in the county of Middlesex, Fellow of the Institute of Patent Agents, for an invention for "Improvements in the method and apparatus to be employed in the preparation of surfaces for printing or etching by the aid of photography."—A communication to him from abroad by Edward Kunkler, of St. Gall, in the republic of Switzerland, Civil Engineer, and Jacques Brunner, of Kussnacht, in the canton of Zurich, in the aforesaid republic, Photographer and Art Printer.—Dated 29th January, 1884.

Notice to Proceed.

4705. Richard Brown and Robert William Barnes and Joseph Bell, all of Liverpool, in the county of Lancaster, for an invention of "Improvements in and relating to the art of obtaining by photography definite photographs to be used in the production of typographic blocks and in the art of photo-lithography and like arts."—Dated 3rd October, 1883.

Patents Granted in America.

292,181. Proctor R. Shugg and George Boyle, New York, N. Y. "Process for making relief printing plates or blocks." Filed March 19, 1883. (No specimens.)

Claim—1. The sensitive plate composed of gelatine, albumen, glycerine, resin, and bichromate of ammonia, substantially as set forth.

2. The method herein specified of hardening relief gelatine plates, consisting in treatment of such gelatine plates successively to baths of solutions of bichromate of ammonia, nitrate of silver, sulphate of iron, and ammonium hydrosulphite, substantially as set forth.

CHAPTERS ON LANDSCAPE AND OUTDOOR PHOTOGRAPHY.

BY H. P. ROBINSON.

No. V.—SUBJECTS. THE ORIGIN OF IDEAS.

No writer on art, as far as I am aware, has ever ventured to say anything on the subject of the conception or origin of subjects for pictures or other works of art. Ruskin, it is true, in his seldom-read second volume of "Modern Painters," treats of the Imaginative Faculty, but in this he soars far above the head of the ordinary reader. The origin of ideas is, perhaps, a metaphysical rather than an artistic matter, and should be left to the writers on what is called "pure reason;" but there is, perhaps, a word or two to be said on the subject that may be appropriate here.

In the last chapter I showed how a certain picture originated and was carried out. There are many other ways in which ideas may occur. And I must explain here, that I am not presumptuous enough to be trying to teach the art of imagination, which is impossible, but how the imagination may be encouraged, stimulated, and strengthened. Some people have a sort of dormant imagination, which only wants waking up to be of great value.

Subjects sometimes start up in the most unexpected manner. I well remember one that occurred a few years ago. We were walking through an orchard on our way to photograph a scene that had been previously selected, and had to pass through a door in a fence into the road. One of my models, who had a stick in her hand, ran forward to open the door, and, when it was open, turned round to greet us as we passed, quoting, laughingly, the old nursery rhyme—

"Open the gate and let her through,
For she is Patty Watty's cow."

What a lovely pose she fell naturally into as she spoke! I give a little illustration of it, but the sketch only faintly recals the original. The title was "For the Cows." This must, of course, be secured at once; no sketch, and leaving till another day, was admissible. Thanks to the advantages of the gelatine process, and a camera that is ready for action in little more than a minute, an exposure was made before the pose had lost its freshness or the smile died on the face. But, on the other hand, thanks also to the disadvantages of dry plates as then made, the picture was not good enough to exhibit; the emulsion being much thicker on one part of the plate than another, the picture was not quite up to exhibition pitch. The film was uneven *in the wrong place!* These uneven films sometimes give good effects. I once took a medal with a picture that had very little to recommend it to the attention of the judges except a startling arrangement of chiaroscuro which I attributed entirely to the unevenly coated plate.

In the photograph to which I have just referred, the subject appeared with all its surroundings complete, and did not require any alteration or correction; but some subjects occur in which the figures are not exactly *in situ*, and these must be treated with thought and judgment. Shortly after the "For the Cows" was taken, I saw the same model on the bank of a stream, shouting to her companions, "Can I jump it?" Here was a subject at once; but the background was ugly and unsuitable. Another was at once hunted up, and found. As it happened, the nook in which the figure appears was inaccessible to the model; she could neither jump the water, nor get to the appointed spot in any unaided way. But a trifle like this should never be allowed to stop enthusiastic photographers. My models and helpers are often more enthusiastic than I am myself. In this case, the helper I had with me picked up the young lady in his arms, and waded across the stream with her.

Adaptation from the works of others is a delicate process which I can only suggest in a very vague way. There are some painters who will copy a photograph and call it their own in the most unblushing manner. Even if that photograph should contain a perfectly original idea, something never thought of before, they will argue—"Oh! it's only an accident in nature the machine has met with; it is impossible for it to be the photographer's own thought—they never think, because they use a machine." I would caution the photographer to be honest, or, anyway, not to indulge in wholesale robbery. It is not right, for instance, to dress up a figure exactly like a figure in an engraving, give it the same pose, and, in fact, reproduce the engraving as nearly as your means permit, and then exhibit the photograph as your own original thought. On the other hand, I consider it legitimate to "convey" a hint from a painting or engraving. A slight hint may originate a perfectly new design; but it is nothing less than a crime to carry off ideas wholesale and call them your own.

It is difficult to get quite new incidents even in this kaleidoscopic world of ours; and we should find, perhaps, that they would not be understood if we did. Sir Joshua Reynolds said that it is by imitating the inventions of others that we learn to invent. William Morris, in his

lectures on "The Lesser Arts," boldly says: "I do not think it too much to say that no man, however original he may be, can sit down to-day and draw the ornament of a cloth, or the form of an ordinary vessel or piece of furniture, that will be other than a development or a degradation of forms used hundreds of years ago." If Solomon was right that there was nothing new under the sun, nature also teaches us that everything that has the appearance of novelty is not really new, but simply a variation on some previous form evolved from something that has gone before. Evolution, therefore, in picture-making, I hold to be right; but the picture you produce from the germ you have adapted should no more resemble the original in composition or subject than a man resembles a gorilla. There may be a suspicion of likeness; but it should suggest only a far-off relationship.

Anthony Trollope, in his autobiography, tells us that all his plots were of his own devising, except one which was drawn out for him by his brother. His remarks on originality of subject come in very appositely here. "I mention this particularly," he says, "because it was the only occasion on which I had recourse to some other source than my own brains for the thread of a story. How far I may have unconsciously adopted incidents from what I have read,—either from history or from works of imagination,—I do not know. It is beyond question that a man employed as I have been must do so. But when doing it I have not been aware that I have done it. I have never taken another man's work, and deliberately framed my work upon it. I am far from censuring this practice in others. Our greatest masters in works of imagination have obtained such aid for themselves. Shakespeare dug out of such quarries wherever he could find them. Ben Jonson, with heavier hand, built up his structures on his studies of the classics, not thinking it beneath him to give, without direct acknowledgment, whole pieces translated both from poets and historians. But in those days no such acknowledgment was usual. Plagiary existed, and was very common, but was not known as a sin. It is different now; and I think that an author, when he uses either the words or the plot of another, should own as much, demanding to be credited with no more of the work than he has produced."

Then what vast numbers of subjects are to be got from reading! I like to reduce all I have to say to practice, or to give a definite example. I will, therefore, take a poem, and endeavour to show how subjects are suggested by it. I take Gray's "Elegy in a Country Churchyard," because it is so well known, and has been so well "worked" by artists.

Twilight has not been much used as a theme for photographers; yet it is perfectly easy now to produce all the effects to be noticed at the close of day. What could be more suggestive for pictures of this sort than the opening of Gray's poem? It is so well known that I will not quote it; but can anything be finer or more poetical for a picture than that called up by the lines:—

> "Now fades the glimmering landscape on the sight,
> And all the air a solemn stillness holds."

And there is scarcely a bit of country in England that would not afford materials to illustrate the lines. To London photographers they are especially available—as, if they want literal fact, Stoke Pogis, where the poem was written, is within easy distance, and the actual scenery may be used, especially the "ivy-mantled tower." But the scene that Gray had before him when he wrote the poem is not necessary. A prosaic, fact-giving photograph is not required; the sentiment of the scene is the quality the student must endeavour to secure and represent.

The poem is full of picture-giving lines; some are so plainly descriptive, such as—

> "The ploughman homewards plods his weary way,"

as to require no effort of the imagination to see them at once; others are suggestive, and all the more valuable on that account. Of this kind is the line—

> "Brushing with hasty steps the dews away."

In the poem this line applies to a poetic youth, but the artist is not called upon to literally follow the poem; the line itself may be taken without the context, and there are then infinite possibilities in it for other applications—for instance, it would apply to a village maiden skipping along the fields at the break of day, basket on arm or hay-rake on shoulder.

Milton's L'Allegro and Il'Penseroso are also full of lines that ought to wake the student's imagination, and it would be good practice for him to look for pictures with his mind's eye of the scenes suggested. It would also be useful study for him to look over the titles of pictures in an old Academy catalogue, and when he comes to one that strikes his fancy, to endeavour to make a sketch of the composition as it presents itself to his imagination.

I repeat, and insist most strongly, that the best subjects are those that come spontaneously to the well-practised artist, and the suggestions I have made are only intended to show the student how to stimulate and educate his imagination. He must recollect that if, in taking suggestions from the work of others, he does not get very far from the germ of the thought, and if his design is any more like the original than Monmouth was like Macedon, his design is but second-hand; and even supposing the public does not find him out, there will be his own conscience still left; and if it is anything like a decent conscience, it will be bad for it to be haunted by the ghost of plagiarism.

Correspondence.

OUT-DOOR PHOTOGRAPHY.

Dear Sir,—Your correspondents who complain of the refusal to permit photographers to take views of such places as Battle Abbey and Raby Castle should not be so easily deterred.

I have had several similar experiences, and a letter to headquarters has always obtained the desired permission. The porter in one place referred me to a firm of solicitors in the town, saying that only one local man was allowed to take photographs. On application to them, they regretted very much that they could not give permission. Not satisfied, I wrote to the Duke (not of Cleveland) himself, and by return of post received the required permit from his secretary or factotum. The fact seems to be that the local man has squared with the porter and agents, and a passing photographer may not have the time or perseverance to go farther.

I may remark that nobody has any business to prevent a view from being taken from a public road, and if I remember right (for it is more than thirty years since I photographed there) the principal front of Battle Abbey faces the road.—Yours truly, Russell Sedgfield.

DIFFUSED LIGHT IN THE DARK-ROOM.

Sir,—In reading your article on "Diffused Light for the Dark Room" in your issue of January 11th, I was reminded of the experiments made by Mr. Augustus Marshall and myself in 1880, in which the conclusion was reached that ruby glass *ground* would accomplish the object of transmitting light enough to enable the operator to perform his work comfortably, and would shut out enough to prevent the fogging of his most sensitive plates. It was to remove the objection of the dazzling effect of the red glass that Mr. Marshall suggested the grinding of the colourless surface of the glass. The result is thus stated in an article written for the National Association in

1881:—"It gives the glass the appearance of a deep orange hue, removes the dazzling effect, and, while it cuts off a portion of the light, diffuses what is left in a greater degree than the unground glass."

So you see, Mr. Editor, that your interesting experiments in England in 1884 were substantially anticipated by us in Boston in 1880. You suggest the combination of an orange-coloured glass and a ground glass, and we suggested the grinding of a red until it looked like a dark orange glass. We suggested at the same time that the addition of a ground glass would have the same effect as grinding one of the surfaces of the coloured glass.

In your paper for April 2, 1880, I have given you another instance of similar and simultaneous experiments on both sides of the Atlantic. One of your correspondents, on February 13, suggested the grinding of ruby glass for the developing room, and I received your paper on the same day that my proof of an article arrived from the office of the *Philadelphia Photographer* announcing the same suggestion. I am glad that our experiments brought us both so nearly to the same conclusion.—Yours truly, THOMAS GAFFIELD.

Boston, January 24, 1884.

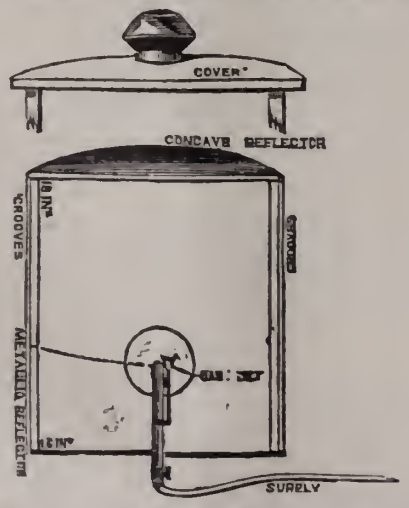
[We are very glad to print Mr. Gaffield's note, who was certainly one the first—if not the first— to advocate the use of ground glass. It is not, however, quite the same thing to "suggest the combination of an orange-coloured glass and a ground glass," and the "grinding of a red until it looked like a dark orange glass." We mean that "orange-coloured" glass and "red" glass are different.—ED. P.N.]

Proceedings of Societies.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

A MEETING of this Society was held on Thursday, the 31st ult., Mr. F. W. HART, F.C.S., in the chair.

Mr. A. COWAN exhibited a lamp combining the principal features of Mr. Debenham's cathedral green glass and yellow paper, with the doubly-reflected rays obtained by Mr. Starnes. The semicircular back upon which the rays are reflected is covered with yellow paper, and forms a safe light for developing at a distance of four feet. When this light is filtered, by sliding into the grooves shown in the sketch one thickness of cathedral



green glass and four thicknesses of yellow paper, it produces no effect on a rapid plate exposed fifteen minutes close to the screen. The experiments reported last week were made with a similar lamp 24 by 18 inches.

Mr. A. L. HENDERSON, referring to his experiments with Mr. Starnes' lamp, said it would be remembered that a wet plate was badly fogged by exposure to that light; he did not think a perfect light had been discovered yet. An Edinburgh photographer was experimenting with complementary colours on a screen, and he believed it would be in that direction a safe light would be obtained. He also passed round some developing trays made of varnished wood with glass bottoms, having a well at one end, similar to the horizontal swing bath; a piece of string being stretched across to prevent the plate adhering to the bottom of the dish.

Mr. W. M. ASHMAN: String would be found a source of annoyance—cat-gut would be better; but neither would be as suitable as fine brass binding-wire.

Mr. J. B. B. WELLINGTON said he forgot to mention in the formula he gave last week that 200 grains of gelatine were to be stirred in as the emulsion is allowed to cool; he showed plates coated with this emulsion, in which halation was very great, and enquired the cause.

The CHAIRMAN: The plates are too thinly coated. Had Mr. Wellington tried backing the plates?

Mr. WELLINGTON had not. With regard to the colour, the developer was modified—viz., ferrous oxalate, 1-8, with the addition of thirty minims of a 120-grain solution of bromide of potassium. The opal picture received two minutes' exposure from an oil Sciopticon; as much emulsion as possible was poured off the plate after coating.

Mr. DEBENHAM and Mr. COWAN thought the shadows were amply rich enough to give a good result with a suitable negative.

Mr. A. MACKIE said, in reference to the swing-back question, he had fully considered it, and must now admit that Mr. Debenham was perfectly right.

The members then resolved themselves into committee to consider the resignations of Mr. C. B. Cutchey and Mr. J. J Briginshaw—the two secretaries.

Ultimately the office of co-secretary was abolished, and Mr. J. J. Briginshaw, Park Villa, Grosnover Park Road, Walthamstow, was appointed secretary.

It was mentioned that the Chairman (Mr. F. W. Hart) would deliver his "lecturette," on Thursday, the 14th inst., on "Residues."

GLASGOW PHOTOGRAPHIC ASSOCIATION.

THE seventh general meeting of the session was held in the Religious Institution Rooms on Thursday, the 24th January, Councillor ROBERTSON in the chair. Besides the usual members, there were present: Mr. A. L. Henderson, of London, and Mr. J. G. Tunny, of Edinburgh, whom the Chairman introduced to the meeting.

The minutes of last meeting having been read and approved of, the question-box was opened, and found to contain this question:—"What is the best method of enamelling silver prints?"

Mr. URIE said the process was exceedingly simple. A glass plate is cleaned, rubbed with French chalk, and coated with collodion. When dry, the collodion is varnished with a thin coating of gum-dammar in benzole to prevent the gelatine mountant permeating the collodion. The print is then mounted down on the plate with gelatine, a thin sheet of paper is mounted on the back of the print with the same medium, and, when dry, it is stripped from the glass.

Some discussion then took place as to the advisability of using varnish on the collodion—the arguments for and against being about equal.

Mr. HENDERSON thought enamelling photographs a mistake altogether. In his experience they faded considerably quicker than plain albumenized prints. He thought the addition of the benzole varnish to the collodion was a decided improvement.

Mr. BLAIKLEY showed a circular camera, constructed almost like an expanding pasteboard collar-box or circular concertina; the lid (on which the focussing screen and slides work) revolving on the body of the box, so that either an upright or oblong picture can be taken without changing the camera. This lid is prevented from coming off by means of four screws or pins working in a groove cut round the box. The front part of camera is, as it were, the bottom of the box cut out. To this one end of the bellows is attached, the other to the inside edge of the box next the lid. The bellows is made octagonal, but the ends readily accommodate themselves to the circular form. The tail-board is simply a flat rod (about one inch broad by three-eighths inch thick), cut in two, and each half hinged to the triangular top of the tripod, so as to fold down against stand when

not in use. When in use they are kept in position by a pinching screw and small plates with socket. The focussing arrangement is that of a rack-and-pinion, the rack being inserted along the bottom of the rod. The focussing screen is not hinged, but slides in the same groove as the dark slide, and is prevented by a check from coming out entirely. A small spring is fixed between the box and lid so as to snap and retain in upright or oblong position. The wood is plane tree ebonized, and, being all turned, the cost is very little.

Mr. McGhie exhibited several pieces of apparatus, including a camera; also a drying box, 21 inch by 12 by 12, which was capable of holding six dozen quarter plates. The ledges on which the plates rest (face downwards) are bevelled. The ventilators, top and bottom, have dust checks; a continuous stream of cold air passes over the surface of the plates, which dry in from six to eight hours; also a dry plate lantern with three distinct forms of light—ruby light with a shade for the eyes, white light for making transparencies; and opal glass for examining developed plates adapted for either gas or oil. He also exhibited a studio shutter, the flap of which was divided in two parts, and opened sideways by a pneumatic arrangement.

Mr. Lorne Campbell showed a picture of a transformation scene in a pantomine; it was exceedingly sharp and well defined in every part.

The Secretary showed the result of some experiments he had made with some extra sensitive ready sensitized paper which he had received from Mr. Otto Schölzig. The experiments proved the paper slightly more sensitive than ordinary paper, but more difficult to tone.

The Chairman then called upon Mr. J. Y. McLellan to introduce a discussion on "The Cause of Fading in Silver Prints."

Mr. McLellan commenced by pointing out the importance of a knowledge of this subject, from a general as well as a photographic point of view. We could not, he said, look over our own or our friends' albums, but we were made painfully aware of the fact that many of the so-called old-fashioned photographs were rapidly fading away. This was all the more to be regretted since these old photographs were often the only remaining portraits of departed friends, and their value consequently increased with years. He remarked that in his opinion, there were two kinds of fading: one which might occur at an early stage in the life history of the photograph, and which could generally be attributed to faulty manipulation on the part of the operator; but the more important form was that which took place after many years, and which could not be accounted for in this way. He had given the matter a good deal of consideration, and had come to the conclusion that the cause of this insidious form of fading was entirely due to atmospheric influence. He said that some years ago he was interested in a chemical investigation undertaken to discover the cause of decay in the leather bindings of the books in a gentleman's library. These books were submitted to analysis, and found to contain considerable quantities of sulphuric acid, and the only legitimate explanation of this seemed to be, that the sulphur compounds in the gas on burning were converted into sulphurous acid, which was absorbed by the books, and ultimately became oxidized into sulphuric acid, and so accounting for the corrosion of the book-bindings. He said that in his opinion this was also the cause of the fading of photographs after keeping for many years. In order to put it to the test, an old faded photograph which had hung upon the walls for fifteen years was torn into pieces and immersed in water; this became strongly acid on testing with litmus paper, and on the addition of barium chloride gave a dense white precipitate of sulphate of barium, proving the presence of a large quantity of sulphuric acid; the water also decolourised permanganate of potash, which suggested the presence of some reducing agent. He said that his experiments up to the present were merely preliminary tests, and that he hoped soon to go into the subject quantitatively, and strongly recommended it to the members as an important subject for investigation. An interesting discussion followed, and several members having intimated their intention to investigate the subject experimentally, the Chairman proposed that the discussion should be continued at the next ordinary meeting on the 21st of February, and it was arranged that Mr. A. Duthie should read a paper on the subject that evening.

Mr. A. L. Henderson was then elected an honorary member, and Mr. M'Kenzie, Paisley, an ordinary member. The meeting closed with votes of thanks to the exhibitors of apparatus, Messrs. McLellan, and the Chairman.

Liverpool Amateur Photographic Association.

The ordinary meeting of the above Society was held at the Free Library, on Thursday, the 31st ult., Mr. B. Boothroyd, President, in the chair.

The minutes of the annual meeting having been read and confirmed, the Chairman, after a few graceful valedictory remarks, vacated his post, and Dr. Kenyon, the President for 1884, took the chair.

Messrs. Cockbain, Irvin, Kerry, Morris, Parkyn, Robinson, Smith, and Watts were elected members of the Association.

The Hon. Secretary read a letter from Mr. Frank Leslie, the chairman of the Executive Committee of the Associated *Soiree*. The consideration of this, on the motion of the Rev. T. B. Banner, seconded by Mr. J. A. Forrest, was deferred till next meeting.

Dr. Kenyon then delivered the following Inaugural Address:—

"Looking at our doings from outside, we find ourselves as photographers engaged in one of the most wonderful of all the wonder-working processes of this eventful age. The dream of the necromancer of the middle ages is well-nigh fulfilled by us every day. If we cannot actually transmute the baser metals to gold, we can transmute inert and sordid matter into the pure gold of ethereal beauty. We can bring to light the secrets of the invisible changes of the minutest molecules. We can seize with a rapidity which would satisfy the recording angel the fleeting actions of time. We resemble those ancient sorcerers in less agreeable ways. Like theirs, our proceedings are not very highly esteemed by the common herd. Fortunately, we receive more compassion than blows; but the fact remains that we are not always so highly appreciated as we could wish. Witness Capt. Abney's story of the Spanish peasant who gave him a halfpenny." The Chairman then, after a very interesting record of his photographic experiences, which was, as he stated, in some degree an epitome of the history of the science, proceeded to remark:—

"I will now say a few words about a rival attraction which is absorbing much attention, and which is not altogether a rival, either, but has special claims upon us as photographers. The development of the tricycle during the last two or three years is comparable with the rise and progress of gelatino-bromide, and, like it, has created a new industry of even national importance. There is a closer affinity between cycling and photography than is at first sight apparent.

"To paraphrase a familiar saying, much though I love photography—great as is the charm of devising and accumulating apparatus and of working the varying and multitudinous processes—I love the objects I wish to photograph even more: the mountains and rocks, the landscapes, the sea, the clouds, objects of architectural interest, and the countenances of one's friends. It is because these are so dear that photography is most beloved as a means of securing a closer communion. And what, I should like to know, more deeply engraves upon one's soul the features of a delightful country than riding through it on a tricycle? The very exertion—nay, toil—of the journey ensures an acute remembrance of its details; and what more promotes good fellowship than the freemasonry of the wheel? As in photography there is scope for exertion, inasmuch as there is a heavy weight to be carried about, and there is a delicate machinery to be cherished with almost humane affection. As in the pursuit of photography, diversified scenery is brought into view. There is abundant scope for ingenuity and invention, both in mechanism and field of operations. What is more to the point: in the tricycle we have a most useful means of transporting photographic apparatus. In the autumn of 1879 I took with me on a "Salvo" tricycle through the heart of Wales a 7 by 5 camera, stand and plates, along with a knapsack, weighing altogether some thirty pounds. On my "Climber" tricycle (a fifty-two inch) I can comfortably carry a Rouch's 12 by 10 camera, and half-a-dozen plates, with stand. As many of the cycling clubs are forming photographic divisions, it might be worth while for us to think of forming a cycling division.

"Passing on to consider the progress made during the past year in the practical working of photography, we have to notice that in the gelatino-chloride process one source of weakness seems to have been effectually removed—a source of weakness due to the very perfection of gelatino-bromide in regard to sensitiveness. In gelatino-chloride we have the means, apparently, of doing with gelatine what hitherto has still to be looked for elsewhere, namely, the perfection of transparencies, whether for lantern purposes, enlargements, or reproduction of negatives. I hope, in direct printing on gelatino-chloride plates, many of us

will find greater ease, certainty, and economy than in the development process. And I venture to hope that, through gelatino-chloride emulsion, we may come to a perfect paper process—one which will give the perfection of a glass transparency on paper, free from the loss of detail and finish sustained in the toning and framing of ordinary paper prints. This, it occurs to me, might surely be attained by some such process as by coating Messrs. Goodall and Stevens' enamel paper with gelatino-chloride.

"The magnificent enlargements, exhibited by Professor Donkin, of Swiss mountain peaks, are a great encouragement for those who look to obtaining from small plates enlarged negatives equal to large pictures taken direct; and here, again, I would suggest that gelatino-chloride will come in useful, for a brilliant transparency may by this process be obtained from a negative otherwise unfit for enlargement.

"There is still much room for improvement in cameras, but serious efforts are being made to supply the want. This, I submit, will only be satisfied with an automatic arrangement for exposing plates or films carried *en masse*, and I would suggest that a great step would be secured if the sliding shutter of the dark slide were replaced by a hinged shutter opening entirely within the camera; this might easily be done.

"In the working of the gelatino-bromide process, valuable additions have been made to our resources in the introduction of the citrates, as a means of obviating the results of over-exposure, and in the improved methods of silver intensification. The use of the carbonate of soda developer appears to be gaining ground, and I have myself had very satifactory experience of its usefulness.

"A great improvement in the illumination of the dark-room for development purposes is now obtained, and this seems likely to find its perfection in the use of a monochromatic light such as is announced from Paris to be obtainable by a mixture of spirit and perchlorate of soda burned in a spirit lamp. This is said to give an abundant yellow light free from actinic influence. For the illumination of dark interiors or portraiture by night, where a short exposure is desirable, we have had brought forward in the oxy-magnesium light the very *acme* of an inexpensive and portable device.

"In this connection I may point out that for copying pictures and small objects, where a longer exposure is admissible, the lens of a graphoscope, for rendering parallel the rays of a paraffine lamp, answers admirably, whilst for making enlargements on gelatino-bromide paper from small negatives the same lens, used along with a smaller, shorter-focus, double-convex lens to act as a condenser, will be found effective with the same simple source of light, the precautions necessary being to place—1. The condenser at or about its focal distance from the lamp. 2. Place the graphoscope lens at or about its focal distance from the condenser. 3. Having placed the negative close to the graphoscope lens in the slide of the camera, to use for making the image a lens of longer focus than the graphoscope lens, and, if possible at least so large an aperture as that of rapid symmetrical type."

Mr. J. A. FORREST proposed, and Mr. J. H. CORKHILL seconded, a vote of thanks to the President, officers, and judges of the past year.

After a discussion on the election of honorary members, it was agreed:—"That the election of honorary members be by ballot, and their re-election annually should not form part of Rule V."

The CHAIRMAN distributed certificates of honourable mention to the following gentlemen, whose pictures had gained prizes in the competition for 1883:—Messrs. Beer, Ellerbeck, Hall, Kirkby, and the Rev. H. J. Palmer.

Mr. ELLERBECK (Hon. Treasurer) spoke at some length on the financial position of the Association, pointing out that, owing to the large and rapid growth of the numbers of the members, and the very large attendance at the monthly meetings, it would be necessary to economise the working expenditure considerably, since it would no longer be possible to give each member a presentation print of the cost of half his subscription, and provide him with tea at each of the meetings.

After some discussion it was decided to present each of the members entitled to it with an unmounted enlargement of the usual size.

The Hon. SECRETARY gave a report of the Society's exhibition at the Associated *Soiree*, gratefully acknowledging the labours of Messrs. Crowe, Forrest, and Guyton in co-operating with himself in the arrangement of the pictures.

Mr. PALMER also related his experiences at Sheffield on his recent visit to the Exhibition there, to which the Liverpool Amateur Photographic Association had contributed a large number of exhibits.

Mr. MCKELLEN, of Manchester, exhibited and explained his new portable and ingenious camera, and received the cordial thanks of the meeting.

The Rev H. J. PALMER wished to make special mention of the kindness of Professor Donkin in sending down for their enjoyment that evening his splendid transparencies of his views in the High Alps, and a hearty vote of thanks was proposed and carried unanimously.

Mr. J KNOT then showed Professor Donkin's pictures in the oxy-hydrogen lantern, and also a number of other slides contributed by Dr. Kenyon, Mr. Newhall, Rev. H. J. Palmer, Mr. A. Scott, and others.

Hearty votes of thanks were proposed and carried to Mr. Knott and Professor Donkin and the other exhibitors of slides.

Mr. A. W. BEER showed a new carrier for the lantern by Mr. McKean, of Edinburgh, for instantaneously changing the pictures on the screen. Its ingenious construction was much admired. Mr. Beer also exhibited a portable adjustable view-meter of fine make and finish, designed by himself and made for him by Mr. Crowe.

The Rev. H. PALMER exhibited some fine enlargements, by Morgan, on gelatino-bromide paper, of negatives taken by him at Chartres and in Switzerland.

The Council finally decided upon an enlargement of Mr. Palmer's "North Portal of Chartres" as the presentation print for 1883.

Some prints on a new doubly-albumenised sensitive paper, by Mr. Scholzig, were to have been exhibited and discussed; but, owing to the pressure of business, these and other matters were postponed to the next meeting.

PHOTOGRAPHERS' BENEVOLENT ASSOCIATION.

THE annual general meeting of this Association was held at the Society's office on January 30th, Mr. W. S. BIRD presiding.

The minutes of the previous meeting having been read and confirmed, Messrs. E. G. Ganly, F. T. Beeson, and W. H. Penn were elected members of the Association.

The SECRETARY then submitted his report, with balance sheet and summary of proceedings of the Society since its foundation as follows:—

Secretary's Report.

In submitting my report of the business done by the Association during the past year, I desire to call attention to the fact, that although the total receipts are not equal to those of 1882, the position of the Society is really improved, a considerable increase of members having been enrolled during the last few months, and the funds of the Association having increased from £139 18s. 1d., to £159 9s. 8d., being a clear gain of £t 9 11s. 7d. during the year.

Receipts.—The honorary members have contributed £24 3s. 6d., the ordinary members £17 5s., and the proceeds from the evening at the exhibition of the Photographic Society £6 6s. 7d., making a total of £47 15s. 1d.; the difference between receipts for 1882 and 1883 (£10 0s. 11d.) are accounted for by the fact that in the former year, several gentlemen combined to hold a soirée and ball, which realized £19 16s. 6d. in aid of the funds. It is to be regretted that the experiment was not repeated for 1883. Further, the proceeds from the exhibition are £3 19s. 5d. below those of last year; it will therefore be seen that the reduction in the income of the Association has not arisen from a decrease in the honorary or ordinary members' subscriptions, which combined are £3 15s. in excess of this source of revenue in 1882.

Expenditure.—The assistance given has been of very moderate amount. Non-members still continue to apply for assistance, and if the rules allowed such applications to be entertained, the funds of the Association would be rapidly reduced; the plea generally given in reply to the query as to why applicants had not joined the Association being, "Oh, I did not know of its existence." It is a matter of surprise how they found it when its help was required. The working expenses have been £22 3s. 6d., or £1 16s. 3d. less than last year.

Board of Management Report.

It is again the duty of the Board to submit its annual statement to the subscribers and to the members of the Association, and to add a few words to the information as to the preceding year contained in the Secretary's report given above. The facts this year are less encouraging than in the previous one. There has been a welcome increase in the receipts from honorary sources through the generous contribution of E. Horner, Esq.

but the receipts from ordinary members exhibit a slight decreasc. Considering the length of time the Association has been in existence, the amount of publicity liberally afforded by the photographic press, and the advantages derived from the annual benefit night at the exhibitions of the photographic societies, your Board cannot but feel that the progress made towards the realization of its aims is but slow. At present the great majority of the photographic professiou, both masters and men. are practically indifferent. It behoves the members to consider whence arises tbis apathy, and what means can be taken to remove it.

The organization of the Society is arranged on an entremely economical scale, and it appears to the Board nothing further can be done in this directiou if auy administration is to be maintained. With a very trifling extra outlay ten times the present work of the Association can be carried on, in which case the proportion of the expenditure to effective results would compare favourably witb any benevolent organizatiou extaut.

The foundation of a Photographers' Beuevolent Association has been laid. There is an accumulated fund of about £160, and an effective administration; but for a real success the hearty co-operation of the members of the photographic profession is absolutely essential.

The Association has been instrumental in obtainiug employment for many of its members, has furnished means to enable them to proceed to the provinces when required, and has rendered material pecuniary assistance to many whom adverse circumstances have placed in the positiou to need it.

Its power of doing good is necessarily limited by the resources at its disposal. It has now entered the tenth year of its existence, aud may, perhaps, claim to merit the largest support it needs for effective working.

Both reports were adopted.

The Chairman then said the report had placed before its members the position of the Society, and stated tbat the Board, which consisted of the faithful few, would be glad to receive co-operation, aud asked for suggestions which would tend to iucrease interest in the Association.

Mr. Ashman said the rule making two classes of members appeared to be a mistake, and to his knowledge deterred some of the profession from supporting the Society. There was no objection to receiving donations from anyone, and to any amount, but why an annual subscriber of one guinea should not participate equally with the half-guinea subscriber seemed a puzzle to many; he would suggest altering the rule. Another matter was the amount of subscription. Why not reduce it to 5s.? Masters and men would gladly pay that amount, who uow withhold a guinea or half-guinea. When employers became regular subscribers, they will have no hesitation in referring needy cases to the funds.

Mr. H. J. Thorne considered the rule admitting two classes of members was one which needed altering; he was not prepared to go so far as the previous speaker, and reduce the subscription.

Considerable discussion took place, in which the Chairman, Mr. Rolph, and others joined. The feeling of the meeting was strongly iu favour of one kind of subscription—only members, in fact, to be on the payment of 10s. 6d. annually. It was felt first that the justice of the case demanded that every member should be entitled to the benefits of the Association; and secondly, that many gentlemen would, in addition to the fee of membership, give further subscription or douatiou. It was resolved that steps should be takeu to alter the rule.

The Association having sustained a loss during the year of two officers—J. H. Dallmeyer, Esq., one of the Vice-Presidents, of whose benevolence the Society has had testimony, and C. G. Collins, Esq., a good working member of the Board—the meeting desired to express tbeir sympathy with the relatives of these gentlemen.

Tbe following are officers for the ensuiug year :—

Vice-President—Rev. F. F. Statham, M.A., F.G.S.

Trustees—Col. Stuart Wortley, Capt. W. de W. Abney, R.E., F.R.S., F.C.S.

Treasurer—H. Baden Pritchard, Esq.

Auditors—G. Taylor, Esq., aud J. S. Rolph, Esq.

Board of Management—W. S. Bird, Esq. (chairman), H. J. Tborne, Esq. (deputy chairman), Messrs. W. M. Ashmau, H. J. Burton, T. Bolas, A. J. Brown, F. H. Berry, E. G. Gauly, J. A. B. Hall, A. E. Hyde, F. J. Mitchell, J. S. Rolph, J. S. Sauuders, and R. E. Wilkinson.

Secretary—H. Harland.

The meeting terminated with thanks to the Chairman.

Postal Photographic Society.

A committee meeting was held February 6th, the President in the chair, aud after tbe minutes of the previous meeting bad beeu read aud confirmed, the following candidates were elected members:—H. G. M. Conybeare; A. Suzanne; Rev. A. M. Macdona; Rev. H. Victor Macdona; Rev. J. Carter Browne, D.D.; Rev. Locke Macdona; John Hollway; Rev. H. Von E. Scott; H. E. Lees; T. Mansell; Harold Sands; F. Pardoe.

It was resolved that, for the future, "All pictures of whatever size, intended for competition, be excluded unless mounted on card of the uniform size of 15 by 12 inches, and uniform thickness, four sheet."

The thanks of the Society were ordered to be sent to the editors and publishers of the Photographic News and of the *British Journal of Photography*, for copies of their respective Almanacs kindly placed at the disposal of the Society.

Competition No. 3, which had completed its first round, was then examined. Mr. Baylis had acted as scrutiueer of the votes, and anuounced the numbers as follows:—

Class I.—Landscapo of size between 5 by 4 to 10 by 8—1st prize, H. H. Cunningham; 2nd prize, G. Bankart.

Class II.—Portrait of member takeu by himself—prize, W. Adcock.

Class III.—Architectural subject—1st prize, F. Gorham Ticehurst; 2nd prize, G. Bankart.

Dr. Horace Day then moved that, in order to raise the quality of the priuts in the albums, a prize be given for the best picture in each album as decided by the votes of the members; but that each member to have one vote simply for the best picture, aud that the prize was to take the form of an enlargement in carbon from the negative; and it was resolved that, so long as funds permitted it, this course should be adopted.

Mr. J. W. Leigh had made a report to the Socicty upon samples sent it of Schölzig's seusitized albumenized paper, and on Scorah's canary medium, and it was ordered he should be thanked on behalf of the Society.

Talk in the Studio.

Photographic Society of Great Britain.—The annual meeting of this Society will be held on Tuesday next, February 12, at 8 p. m., at 5a, Pall Mall East, when tbe report of the council and the fiuancial report will be read, the electiou of officers take place, and other business brought forward.

Photo-Mechanical Printing Methods.—Mr. Bolas, in his second lecture, delivered at the Society of Arts on Monday last, treated of methods of making typographic blocks by photographic agency, and also of photo-litbographic methods. It was pointed out that, at the present time, the production of a transfer in fatty ink, or of a picture in a definite grain or stipple, is equivalent to the production of a block, so well is the method of zinc etching understood. The lecturer said that the more recent improvements depended upon tbe translation of the Wooddury relief into grain or line. Among the principal methods of effecting this may be mentioned Woodbury's metbod of making a grained relief by exposing Woodburytype tissue under a grained positive (see page 667 of our vol. for 1883); the methods of Ives (see pages 498 and 677 of vol. for 1883); Eggis (page 789 vol. for 1883), and the hitherto unpublished processes of Zuccato. Tbese latter methods are fully described on page 81 of our present issue. A transfer was inked up by means of the velvet roller, Mr. Newlands assisting; and the advantages of an india-rubber roller for machine or hand printing were alluded to. The india-rubber roller shown consisted of an outer coating of red vulcanized rubber, a liittle over an eighth of an inch thick, about half-an-inch of fine felt being between the rubber and the stock.

Dinner to Mr. A. L. Henderson.—Mr. A. L. Henderson, of Loudon, was entertaiued at dinner, on the 25th ult., in Young's Hotel, Cockburn Street, by the Edinburgh Photographic Club, when about forty geutlemen sat down to dinner. The chair was taken by Mr. J. G. Tunny. After the usual loyal and patriotic toasts had been drunk, tbe Chairman gave the toast of the evening, "Our Guest, Mr. Henderson." Mr. Henderson, ou rising to respond to the toast, expressed the pleasnre he felt in meeting so many members of the Clnb and other friends. He said tbat on his first visit to Edinburgh, about forty-five years ago, he had neither a shirt on his back nor a

shilling in his pocket. When of suitable age he went to assist a dispensing chemist in Frederick Street, Edinburgh. After being for a time assistant to a chemist, he went to London, and stated how he had saved enough to purchase his first camera and lens, and how, by gradual steps, he attained a position in London. He mentioned that it was while visiting the great Exhibition that he first saw some ceramic photographs, and when examining them he said that he thought he could produce better work; and in a fortnight after, he had produced work which it was thought not only equalled, but excelled that in the Exhibition. Mr. Henderson, in conclusion, advised all photographers above everything to acquire a good knowledge of chemistry. He thanked the Photo Club very warmly for the honour they had done him, and said it was a meeting he would never forget as long as he lived. Other toasts were duly honoured, and during the evening numerous songs were sung.

A MOONLIGHT PICTURE.—An old contributor, Mr. J. Henry Whitehouse, sends us a remarkable moonlight view of a New York Street, and he tells us that it was taken by Mr. Metcalfe from the window of his residence, on the night of December 13th last; the exposure lasting from 6.30 to 11.30. It is quite fully exposed, details being visible even in the deep shadows; but the observer can see at a glance that there is something unusual about the lighting. The picture is bright and well contrasted like a sunlight picture, but it is impossible to trace the general direction from which the light comes. It strikes one as curious to be able to peep into some of the brightly lighted rooms.

AT THE PHOTOGRAPHER'S.—"Chin a little higher, please. There, that is better—look at that nail." "Which one?' "That big nail near those two little ones. Your head is turned again; press it back against the support. There, that is better. I am all ready; now keep perfectly quiet, and assume a cheerful expression." "Beg pardon, but I forgot to ask you what you are going to charge me for these photographs." "Seventeen dollars. Now look pleasant."—*The Eye.*

PHOTOGRAPHIC CLUB.—At the next meeting on February 13th, the subject for discussion will be "Development of Gelatino-Chloride plates."

To Correspondents.

*** We cannot undertake to return rejected communications.

NITRIC.— 1. A solution of perchloride of iron etches both copper and steel very readily, and one advantage is the circumstance that no fumes are given off. 2. Saturate it with iodine, but take care that the solution is quite cold when the iodine is added. 3. Either the collodion has been made with a sample of pyroxylino which possesses unusual contractile properties, or the plate was not properly cleaned. 4. Sulphur answers very well, but care should be taken not to over-heat it, as it becomes viscous at a temperature not very much higher than its melting point.

EDWIN A. JEWITT.—Write to the Willesden Waterproof Paper Company, Willesden, N.W.

EDW. REEVES.—You can easily ascertain if it is a fact by making the following simple experiment. Cut a print in two parts, and attach one-half of the print to a mount from an old batch which has proved serviceable, and the other portion to one of the new mount cards. If both specimens are now kept under precisely similar conditions, you will soon obtain a conclusive answer to your question; and if the new mounts have caused the mischief, you should be able to recover ample damages from the manufacturers.

D. W.—Thank you for the sample of paper, which appears to be excellent.

AD. EGGIS.—We shall be very pleased to receive a description of the apparatus.

T. H. B.—The process is quite open, and unencumbered by any patent. In the "Studios of Europe" you will find full particulars for practically working it.

A. G. B.—1. We do not think that it possesses sufficient superiority to compensate for certain trifling disadvantages. 2. The discrepancy is due, as you surmise, to the difference between the two formulæ.

R. TUNNIS.—Nothing will serve your purpose better than Abney's "Instructions," which is to be obtained from our publishers.

CHAS. LIVERSTONE.—Disregard the threats, as the patent is worthless. We published full details of the same process as early as 1860.

B. R. C.—It is not sufficient, and if you will read the article through carefully, you will understand the reason.

A. HONEY.—1. Either the Collotype or the Woodburytype process will answer your purpose. The Stannotype is a modification of the latter, especially suited to the requirements of the business photographer. 2. Write to Mr. Woodbury.

J. P.—1. The silver can be thrown down from the waste hypo solutions by stirring in a little strong solution of sulphide of potassium. Allow the black deposit to settle, and add a little more of the sulphide. If no more of the black precipitate is formed, sufficient sulphide was added in the first instance. The black precipitate may be reduced to the metallic state by fusing it with carbonate of soda. 2. The waste pyro developer (gelatino-bromide) contains no silver, and is valueless. 3. By the action of heat on gallic acid, air being excluded as far as possible.

A YOUNG LITHO.—You will find full particulars on page 338 of our volume for 1883.

J. MOONEY.—The shilling hand-book published by the Autotypo Company may answer your purpose; or you can obtain the more comprehensive hand-book of Dr. Liesegang, this latter being published by Sampson, Low, and Co.

J. HARVEY.—Aniline dyes, such as Judson's, will answer as well as anything, but they should be considerably diluted with alcohol. It is often better to work with solutions so weak that several applications are required.

A READER.—The exposure given was probably ten or twelve times as much as was required, and "reversed action" set in. It is not very easy to obtain a good negative by the reversed action of light, but it may be done by impregnating the film with bichromate of potassium, and exposing under the original negative for a few minutes.

W. S. ATWOOD.—Thanks for your letter, which shall appear next week.

J. BURNDRED.—From your description we should think that your negatives are not sufficiently dense.

The Photographic News Registry.

Employment Wanted.

Assistant (Lady), tint, spot, &c.—A. G., 5, Heaton-vil., Heaton-rd., S.E.
Collotype Printer, expe.—E. Birch, 3, Alpha-ter., Boston-rd., Hanwell.
Operator and Retoucher, or to manage.—Operator, 18, Telford-rd., W.
Mounter, Spotter, Books (Lady).—A. E. G., *Photo. News* Office.
Opera. & Retouch, all branches.—Pyro, 1A, Prince-of-Wales-rd., Norwich.
Operator and Retoucher.—Manager, Eastover House, Bitton, near Bristol.
Assistant Operator.—A. G. R., Rosetta Cottage, Weeks, Ryde, I.W.
Retoucher & Assist. (Young Lady).—Miss J., 10, Edith-rd., Peckham, S.E.
Lady for Reception-Room. —E. D., 50, Crockherbtown, Cardiff, S. Wales.
Vignetter, good hand, first-class firm.—G. E. Lann, Market-st., Brighton.
Retoucher.—F. Piper, 56, Walford-rd., Stoke Newington, N.
Artist, for Monochrome and Water Colour.—Z. A., *Photo. News* Office.
Operator, clever at lighting, &c.—F.W., 1, Claylands-rd., Clapham-rd., S.W.
Reception Room, Young Lady of exp.—M. A. G., *Photo. News* Office.
Reception Room, Shop, Books, &c.—W. C., 160, Arlington-rd., N.
Youth, as Assist Op. or Printer.—L. D., Cambridge-gardens, Notting Hill.
Assistant Operator and Printer.—E. D., 576, Sunderland-st., Pimlico.
Recep. Room, Mounter, &c.—M. W., 68, Parma-cres., Clapham Junction.
Printer or Gen. Assist. (young man).—Evans, 9, Church-st., Folkestone.
Reception Room, Mount, Spot, Books.—F. W., Chryssell-rd., Brixton-rd.
Printer and Toner.—Printer, 24, Crick-st., Burdett-rd., E.
Operator, Retoucher, Enlarger.—Alpha, 115, High-st., Camden-town.
Artist, well up.—P. Eckhart, 105, Hall-pl., Hall-pk., Paddington.
Retoucher and Colourist (lady).—J. J., *Photo. News* Office.
Artist, medallist.—Miss A. H., 88, Stoke Newington-rd. N.
Operator or Manager.—A. E. Walker, Eastwood, Notts.
Assist. Printer & Vignetter.—G. E. Cann, Market-st, Brighton.
Assistant Operator, or Manage Branch.—H. W., Finsbury-circus, E.C.
General Assist., good all round.—X. Y. Z, 49, Ledbury-rd., Bayswater.
Assist. Op., &c. (town only).—C. H. E., 50, London-st., Tottenham-ct.-rd.
Assist., can print, tone, paint enlarg.—Silver, 40, Gower-st., Birmingham.
Assist., enl. on Morgan's pap.—F. P., 16, Rochester-sq., Camden-rd., N.W.
Assist., retouch heads for publication.—Retoucher, *Photo. News* Office.
Reception Room, as Improver.—X. Y. Z., 5, Jesse-ter., Reading.

Employment Offered.

Saleswoman and Stock-keeper, to spot, &c.—J. E. Bliss, Cambridge.
Retoucher, first-class.—W. McLeish, 71, Northgate, Darlington.
Young Lady Printer.—Gartside and Risley, *Photo. News* Office.
Retoucher, clever.—J. Hawke, George-st., Plymouth.
Dry-Plate Coaters, experienced.—Prestwich, 155, City-rd., E.
Photo-lithographer, experienced.—Photo., 150, Queen Victoria-st., E.C.
Photo , expe. largest cameras.—E. Meyerstein, 280, High Holborn, W.C.
Retoucher, for high-class work.—Mavius and Vivash, 49, Ann-st., Belfast.
Operator for N.W. Provinces, India. India, *Photo. News* Office.
Photo. Artist, first-class, all-round hand.—W. Knight, 47, Coney-st., York.
Young Woman, charge of Printing Room.—W. Winter, Midland-rd., Derby.
Printer and Toner, young, for City.—Viaduct, *Photo. News* Office.
Retoucher, first-class.—Negretti & Zambra, Photo. Dept., Crystal Palace.
Printer & Toner (female) to manage.—Holden & Co., 42, City-rd., Bristol.
Photo-lithog , perm. if comp.—X , c/o Smith & Co., Gresham House, E.C.
Traveller, to Sell Backgrounds.—Photo., 5a, York-ter., Clapham.
Printer, skilful Vignetter.—Morgan and Kidd, Helio House, Greenwich.
Silver Printer and Toner (good).—W. Wilson, 77, De Beauvoir-rd., N.
Photo-Lithographer & Photo-Etcher.—Meek & Co., 4, Cable-st., Liverpool.
All-round hand, wet & dry.—Tune & Co., Warrington House, Tottenham.
Retoucher of first-class ability.—H. W. Winter, Alexandra Rooms, Derby.

THE PHOTOGRAPHIC NEWS.

VOL. XXVIII. No. 1328.—*February* 15, 1884.

CONTENTS.

USING CONCENTRATED SOLUTIONS IN MAKING EMULSIONS.

A LITTLE time ago we made some remarks on the effect of the amount of concentration or dilution of the solutions used in making emulsions. Further experiments in the direction in which we were then working show results that make us wish to add a little to what we said before.

The general tenor of our observations to which we refer, was to the effect that the amount of water used to dissolve the salts from which emulsions are made—that is to say, the silver nitrate and the bromide, and sometimes iodide of ammonium or potassium—has a great influence on the length of time taken to gain sensitiveness. That the less the water—in other words, the more concentrated the solutions—the shorter is the time required for sensitiveness to be gained.

We now repeat this statement, but more emphatically, and even go so far as to say that a variation in the quantity of water used in emulsifying and in subsequent boiling has more influence in the time taken to get a blue bromide of silver, than the variation of any other constituent of the emulsion, so long, at least, as those constituents are used within the limits of proportion which are considered permissible in emulsion work.

To take an example of what we mean, there will be much less variation produced in the time required to gain sensitiveness by varying the excess of bromide from the smallest that is commonly used, than there will be by varying the amount of water used to dissolve the salts, from the smallest given in any formula to the largest given in any formula. And yet we scarcely hear mention of the quantity of water as a factor in the question of gaining sensitiveness. So much is it neglected, that it is by no means uncommon to find formulæ given without any mention being made of the quantity of water in which the salts are to be dissolved.

On the assumption that the solutions are used neutral, the factor which has the next greatest influence in determining the time which will be taken for sensitiveness to be gained, is the amount of excess of bromide which is used. The greater the excess, the more rapidly will sensitiveness be gained, and this is more the case when the solutions are concentrated than when they are dilute. A certain increase in the excess of bromide will enable sensitiveness to be gained in half the time it was before, if the solutions are concentrated. With dilute solutions, the same increase of excess of bromide will have comparatively little influence on the time taken to gain sensitiveness.

The amount of gelatine used in emulsifying and during boiling has much less influence on the time necessary to gain sensitiveness than is generally supposed. Indeed, we have found that we may vary the amount of gelatine used within very wide limits, without much influencing the time required to convert the silver bromide from the variety red by transmitted light, to that blue by the same.

We shall here be more specific, and give two precise formulæ to illustrate the general statements which we have been making above.

	No. 1.	No. 2.
A.—Silver nitrate	200 grains	200 grains
Water	2 ounces	5 ounces
B.—Bromide of potassium	170 grains	170 grains
Gelatine	50 ,,	50 ,,
Water	2 ounces	5 ounces

It will be seen that between No. 1 and No. 2 there is nothing varied except the amount of water used. Nevertheless, if all solutions be used neutral, it will be found that after emulsifying, No. 1 can scarcely be raised to near the boiling point before the conversion from red to blue bromide is complete. Placing the quantity given in a glazed jar in boiling water, ten minutes only has, in our experience, elapsed before a blue and sensitive bromide has resulted. On the other hand, with formula No. 1—which, by the way, is only of use for a precipitation process—we have had to boil from two to three hours to bring about the desired change.

We are now assuming that the solutions are neutral. By making both or one of them decidedly acid, longer time will be necessary to gain sensitiveness in the case of both formulæ; and, in fact, in the case of No. 2, it will be found almost impossible to get it.

The solutions may be made even more concentrated than we have mentioned in formula No. 1; but, in this case, we have found it impossible to get a satisfactory emulsion to begin with, unless we use a good deal of acid. With neutral solutions so very concentrated as, for example, we would have if we used in No. 2 an ounce and a-half of water only, instead of the two ounces given, we have found it impossible to get a ruby emulsion to start with, and have even found it impossible to get the whole of the silver bromide in suspension at all. A bromide greyish blue by transmitted light has been got at once. This is fairly sensitive, if used as it is, but gives plates of very poor quality.

Our present practice is to so proportion the quantities used, that we may get sensitiveness in a time somewhere between the two limits which we have mentioned. We fancy that the best result is obtained when about half-an-hour of boiling is required to cause the change from

red to blue bromide. This is the case with the particular samples of chemicals which we are now using when the following modification of the formulæ just given is used:—

A.—Silver nitrate	... ...	... 200 grains
Water	... ...	... 2½ ounces
B.—Bromide of potassium	...	... 170 grains
Gelatine (Nelson's No. 2)		... 50 ,,
Strong hydrochloric acid		... 1 mimim
Water	... ...	... 2½ ounces

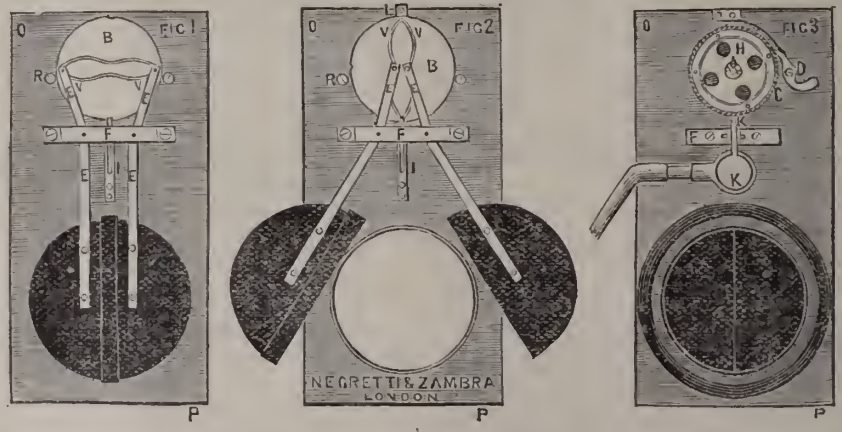
Half-an-hour of boiling with this gives a rapid plate, the conversion from red to blue bromide being then complete. Still greater rapidity can be gained by continuing boiling for fifty minutes or an hour. Boiling beyond this produces fog in our hands.

ZSCHOKKE'S INSTANTANEOUS SHUTTER.

AN ingenious application of the guiding-cam principle governs the opening and shutting of this apparatus, and a very little explanation will serve to make the subjoined diagrams intelligible to the reader.

The actual screens or flaps very closely resemble those of Mr. Spink's shutter, which was figured on page 321 of our volume for 1882; but the mechanical principles upon which it acts are quite different.

B (figs. 1 and 2) is a disc of metal which can be made to revolve on its axis, and in this plate a deep cam-channel, somewhat resembling the outline of an hour-glass, is cut, as shown in the diagram, and the bent arms E E, which carry the half discs, are provided with studs, which can play freely in the cam-channel. Now it is obvious that if the



brass disc be turned round a quarter of a circle, as in fig. 2, the shutter will be open, while a further movement of a quarter of a circle will close it again. A lever and catch (I) serves to fix the revolving disc at either one of two points, one being a quarter of a circle from the starting position, and the other point half a circle from the initial position, and it can be released from either of these positions by a pneumatic ball, situated on the other side, (fig. 3), lifting the catch through the agency of the lever K. It should be mentioned that a spring contained in a box, H (fig. 3), serves to constantly press the disc B back towards its starting point, and this spring can be wound up to any required degree of tension, so that the speed of the shutter may thus be adjusted with great exactness.

It will be seen that the Zschokke shutter combines in itself the main points of excellence which one looks for in such an apparatus—viz., opening from the centre, compactness in relation to the aperture covered, and steadiness of motion. It will give an exposure as short as one-fiftieth of a second, and one as long as half a second. The maker is Steinheil, of Munich, and it has been introduced into this country by Messrs. Negretti and Zambra.

CRAYON ENLARGEMENTS.

THE softness and permanency of enlarged portraits, carefully executed in coloured crayons, renders them very attractive, and specially valuable in many instances, as works of art.

The usual method of producing life-sized crayon pictures is by placing a diapositive in an ordinary magic lantern, focussing the image of the size required on a sheet of paper crayon, and then, in the darkened room, sketching in the luminous picture with great nicety and exactness.

Such a sketch can be finished afterwards by the aid of a guide print from original negative, or better still by one or two sittings on the part of the subject. In the hands of a really good artist such a picture leaves little to be desired, being exceedingly life-like and pleasing. However, the demand upon the artist's power is very great, and the expense, consequently, considerable; and the likeness is sometimes lost; still, if the enlargement be taken on a sheet of bromide paper, by one of the processes recently described in these pages, the likeness is insured, but it is impossible to produce the same soft blendings of light and shade on a paper with a surface so different from that of crayon paper. We have found it comparatively easy to prepare a very suitable paper for this purpose by simply mixing with each ounce of good gelatine bromide emulsion, a small teaspoonful of powdered pumice-stone previously sifted through fine muslin. This is stirred up well, and a large sheet of paper coated therewith by either of the methods we have before suggested. Such an emulsion adheres rather badly to the paper, especially if the latter is used without drying; but this difficulty is soon got over by the use of a substratum. That which has proved satisfactory and most easily made and applied, in our case, is the one described by Captain Abney some two years ago, and is made by dissolving a small quantity of gelatine in acetic acid, by the aid of heat, and then diluting the solution with methylated spirit. We see no necessity for precipitating the gelatine as recommended, and then re-dissolving the precipitate in more acetic acid.

This can easily be brushed over the paper, or poured over if the paper be previously pinned to a flat board. Drying can be hastened by heat. The paper should be wetted in water before applying the emulsion. An exceedingly thin coating is required, as nothing more than a very thin grey image, full of detail, is necessary as a perfect base for future operations with coloured crayons. The emulsion must be well stirred before applying to paper, and we see no reason why the coated sheet should not at once be exposed in the camera or dark-room, as soon as the coating has set. Development should be arrested as soon as detail is out, as no strength of dark deposit should be there to interfere with the purity of the colours to be

applied; only a sufficient faint guide to the artist to render the retention of the likeness certain with ordinary care. Less artistic skill being required, less expense is incurred, and any photographer—professional or amateur—who can make a few ounces of good emulsion, can easily produce a life-size head ready for the hands of the colourist in crayon.

We may mention that, in our hands, the substratum just described has answered perfectly for opal work, either in gelatine or collodion, especially in cases where annoyance is caused by dust, as it can be dried off rapidly by heat before any dust can adhere to it. The emulsion as above can be used for opals, and will give a matt surface as with paper, and, like the latter, they can be coated and used at once, sufficient emulsion only being taken from the stock. It is well in this case to soak plates or paper in water before development, or air-bells may form white spots in the ultimate picture.

TRIP TO SAHARA.

BY A COCKNEY.

On a yellow 'bus in the Tottenham Court Road. Mind you, I don't say that this is the straightest way to the Great Desert. I believe that if, after passing the "Horseshoe," you were to turn into Endell Street, and take Covent Garden on your way, it would be nearer. But then the yellow 'buses from the "Mother Redcap" don't pass that way, and the driver is obliged to go by his usual route, whether you are bound for the Sahara, or St. Martin's Lane. So there is no use grumbling; I pay my twopence at St. Martin's Church like a philosopher, and walk the rest of the way.

Charing Cross. The luggage porter takes a long time looking through the little volume I hand him when he asks me for my ticket. I have begged him to label my bag for Marseilles, and he is now deeply interested in the book of travel they have given me at the booking-office in exchange for £17 18s. "Where is the Girdle Railway coupon?" he presently asks. I am sure I don't know. I should have thought the thick little volume of tickets would have satisfied any reasonable porter, for they are there in English, French, and Spanish. So, after looking over the porter's shoulder for a while, I hazard that it may be among the Spanish sheets. But he is not satisfied, and as he labels the luggage, suggests all sorts of difficulties for me later on.

Out into a London mist across the river we go, our train rather uncertain of its way at first, evidently, for it slows, and halts, and backs at times. But this is only while we are still among the fog and the chimney-pots. By the time we reach New Cross the carriages are spinning along at high speed, and green-turfed Chislehurst and leafy Sevenoaks are past and away before there is well time to settle down to the morning paper.

Bad news from Egypt again! And the Queen's speech as uninteresting as ever. Short disjointed paragraphs Her Majesty adopts, in order to make the stale news she tells us look tempting. Bah! What's the good of saying Gordon has gone to Khartoum, and that the Madagascar difficulty with the French is as good as over? I should think so, indeed. Why, it all happened last year.

Dover. Two sudden dips into darkness under Shakespear's Cliff, and we are on the Admiralty Pier, with the fretful waves washing as restlessly as ever against the granite sea-wall. "The Calais boat opposite; Ostend further on!" shout the men in blue jerseys worked with red; and so we go opposite and down a steeply inclined gangway all wet and slippery with recent swabbing.

A close paint smell in the cabin, as usual. A well-cut ham and plenty of brandy-and-water seem to be the only refreshments, although it is true there are some smart pints of champagne—all gold and white labels—on the table too, but nobody ever touches them. Somehow I never care for high living on board a steamer. I am not a bad sailor, of course—nobody is; but I always prefer to munch a dry biscuit, and to lie down on a couch, if I can. It is a habit I have, that I have acquired by something inside generally telling me it is the best thing I can do.

We are getting on. This black structure of tarred planks, that rises from the low stretch of yellow sand, is Calais harbour, and in ten minutes more our swift steamer, with its sloping white funnels, is running between the high black piles on either side. There is the same crushing, rugs and parcels in hand, to get ashore; the same rush, as of old, across to the line of carriages; the same hoisting and pushing into the comfortably stuffed drab-lined coaches of the Chemin de Fer du Nord.

"Vingt-cinq minutes d'arrêt!" shouts the white-aproned garçon, with a view to induce you to descend. "Twenti-faive meenets!" he adds, when you shake your head; and then, to make the matter quite clear, he rubs a big 25 on the glass with his fingers. At this, as I am getting up my Spanish, I venture, "Habla Espagnol?" doubtfully; he looks up, walks away sulkily, slamming the door after him. The waiter's disgust does not, however, so much matter just now, for as soon as the train starts, one of my friends unpacks a fowl, while I get out my ham sandwiches, and these, with a "demi" of Burgundy, which I had taken the precaution to purchase on passing through the buffet, make up a splendid banquet that we thoroughly enjoy after our sea trip.

And now I am well on the way, I ought to say a few words about my outfit. There is plenty of room here in the comfortable railway carriage for examining it all, and plenty of time, too, before we get to Marseilles to-morrow morning at ten. I have got my camera in a little waterproof case in the netting overhead, so we will have it down to look at. Here it is lying on the cushion, a brand-new half-plate apparatus of shining mahogany and well-polished brass fittings. The fact is, I was rather afraid of my ancient experiences, and have left behind my two little cameras that served me so well in my knapsack journies a dozen or fifteen years ago. One of them weighed 1½ lbs., and the other 2¼ lbs., but they only took 5 by 4 plates; still I have some misgivings about weight and bulk, and, as I look at my shining friend on the seat opposite, I am beginning to think whether I should not have done better to have been a little more modest.

The fact is, the term "tourist photographer" wants to be better defined. I am a tourist photographer, I take it, and as such, thought I, I cannot do better than go to one of the best manufacturers and purchase a "tourist camera." There are several advertisers in the Year-Book, so to the Year-Book I turned for information. There was not much choice as to price or to weight, I found, so a decision was soon arrived at. I have carried a camera into most countries of Europe—to Norway in the North, and Italy in the South—but my last trip was five years ago, before gelatine plates were in every-day use. So, in a way, I am quite a novice as "tourist-photographer," and in these circumstances it behoves one to be humble and to take advice. I have taken it, and hence, apparently, my somewhat uncomfortable position.

Yet stay; I must plead guilty to being obstinate on one point. It is this. My half-plate camera being a "tourist-camera," must, perforce, be all right, and though it weighs no less than four pounds and a-half, and is furnished with as many as seventeen catches and screws of one kind and another, there was nothing for it but to submit. But the case, being a mere article of packing, I was not bound to carry, and so I have left it behind. "I want a mere cover of waterproof canvas with flaps," was my demand, and in satisfaction of this, there was sent home a stout leather cart-horse like equipment with heavy canvas sides, weighing 3 lbs. 3 oz. A friend told me, just before starting, that this sort of cast-iron portmanteau might be useful, after all, in case the camera got kicked

about. But then, I do not mean to kick it about, but to carry it, very carefully; so I have put the apparatus in a thin waterproof-cover, weighing three ounces, and this, rolled up in my overcoat and slung in a coat-strap, will satisfy me. The three pounds of portmanteau my friend will be quite welcome to if he will accept them.

But as to the definition of a "tourist photographer." I don't know if I am right, but my idea of him is this: that he is somebody out for a holiday, and carries a camera with him, much as he would a note-book or album; he wants to have a pleasant trip or tour, and bring home pictorial notes or sketches of that tour. That is my object on the present occasion, and that is why I call myself a tourist photographer. A pleasant holiday is my first aim; to bring home reminiscences of it is the second. Therefore, the photographic apparatus must be subordinated altogether to the pleasuring, and this is not the case if the tourist is a slave to his camera, and is overburdened by his outfit. Of course, if the object were to make the journey a paying concern by means of photography, or if, as amateur, the chief aim were to secure a complete set of views of value from a geographical or artistic standpoint, it would be another matter altogether, and then you would be a travelling photographer more than anything else. The two things, I hold, are quite distinct, and it is because I choose to be the more modest of the two, I do not want to carry an unnecessary burden.

One moment. Here is Paris, with its tall white buildings growing up around us, the acres of whitewash occasionally varied by structures of pale green. Legends in big black letters are written everywhere about the Bon Diable, and the Magasin du Louvre, and Café Estaminet, and Défense d'afficher. But I am not going into Paris, but around the city by the Girdle Railway, about which my friend the porter at Charing Cross was so anxious. It is a long way round, by-the-bye, to the Lyons terminus, but once here, if you have your wits about you, there is a capital dinner to be got, with three-quarters of an hour to eat it in.

But to resume what I was saying about the tourist photographer. Supposing he is satisfied to work with a half-plate camera, I contend that he ought to be able to get an apparatus weighing less than mine does, viz., 4½ lbs. without lens or dark slides. The diligences in Algeria limit the traveller's luggage to 35 lbs., and yet my photographic outfit, restricted as it is, comes to two-thirds of this weight.

Here are the items:—

	lbs.	ozs.
Camera	4	8
Rubber case	0	3
Stand and top	2	2
Three dark-slides (double) ...	1	14
Lens, shutter, and cloth... ...	1	0
Six dozen plates (thin glass) ...	15	0
Divers	0	7
	25	2

My camera, it is true, is not only stout and firm and excellently made, but is capable of being fitted with half-a-dozen lenses of different focus, can be employed for copying, and has every appliance that the most refined photographer desires. But I would willingly dispense with the ability of a tourist-camera to be used for copying, if a pound or pound and a-half of its weight were struck off; and I cannot help thinking most bona fide tourists would say the same. Unless some Arab in the Great Sahara—by-the-bye, this Sahara is a long way off at present, but I suppose if the train goes rattling on in this way for a bit longer, shaking your bones like an unstrapped tripod, I shall soon come within measurable distance of it—I say unless some Arab in the desert should bring a faded carte of his mother-in-law or something of the sort, and express a fervid desire for a few copies, I do not quite see of what use the copying arrangement will be to me. In a word, the so-called tourist camera of to-day seems to me a most delightful, ingenious, and well-constructed instrument, and to be pre-eminently suited for every purpose in the world except that of a tourist photographer.

But it is time for bed now. We left Macon behind an hour ago, and the rattle and din of a P.L.M. carriage is apt to make you sleepy after a ride of a dozen hours. My companions are already in a state of torpor in different corners of the carriage, snugly ensconced against the softly-padded cushions, and twisted up into unshapely masses in their shawls and rugs. Dozing is easy under these circumstances, and it is only when the train comes to a full stop, and strange nasal shouts are heard through the still night that you get awakened. On we go again—on—on—until I begin to see picturesque Arabs around, and palm trees, and the Great Saha . . . . .

No, that big station with the lights was Lyons. I rub the glass and look out at the fierce moustached officials hurrying to and fro in the chill morning air. The last time I was in Lyons I remember was in 1858, when on my first visit to Switzerland, and now I am off to the Great Saha . . . .

By Jove! how bright the daylight is, as it comes in beating in upon us all drowsy, begrimed, and unwashed. That broad river must be the Rhone, hurrying on its way, like ourselves, to Marseilles; and soon afterwards on the left there is a glimpse of the Mediterranean.

Marseilles at last. Eight hundred miles is not bad travelling for the first day. I get together my rugs and parcels, and make ready for the Custom's examination. I shall have to pass my packets of dry plates, done up in half-dozens, and lying perdus in certain articles of apparel in my Gladstone bag. By-the-bye, I want to say something about packing dry plates; the fact is, that you can *say* a good deal, but *do* very little with them, when it comes to packing. I mean that you can't get out of it that they really are heavy and bulky. Now I don't think—"Messieurs à la douane, s'il vous plait."

Pray excuse me finishing just now. The boat for Philippeville starts at 5 p.m., and as soon as I am on board I will proceed.

ON THE VALUE OF DIAPHRAGMS IN PHOTOGRAPHIC LENSES.

BY DR. SCOTT.*

MANY an amateur, on commencing landscape work, is troubled by the various stops applied to the lens he possesses not bearing any definite relation to the fixed aperture of the lens, so that even if he knows the rule to square the exposure for each decrease in size of the stop, he is still in trouble on account of the numbers on them not having any definite relation; and further, if he tries to use another lens after having got used to his own, he is rather worse off than before, for a time at least. All photographers know that different lenses possess different rapidities, but yet this difference is more apparent than real, the whole difference lying in the stops.

In order to define accurately the size of a diaphragm used in any lens, a formula is generally given for it, it being generally written as an italic "f" divided by some number; for example, $\frac{f}{}$. This simply means, assuming that "f" means "focus," the length of the focus of the lens divided by some figure that will give the size of the stop.

Thus, if we have a lens of eight inches focus, and find by measurement that the largest stop be half-an-inch, on dividing the latter into the former, we get 16 as a result. Now write this as $\frac{f}{16}$, and we have the exact relation of the stop to the focal length. If another stop measures quarter-inch, the resulting fraction will stand $\frac{f}{32}$. By this simple means we see at once that the latter stop is one-half the size of the former, and that it will require four times the exposure. Again, should it be necessary to have two different lenses in use, as it may not always be possible to have them of the same class—a short focus symmetrical, and a long focus single landscape lens, for example—some means of comparing the rates of exposure should be at hand. In two

* Abstract of a Paper read before the Photographic Society of Ireland.

such lenses at present in my possession, I find that the full aperture of the single lens is $\frac{f}{13}$, while that of the symmetrical lens is $\frac{f}{15}$. On squaring these, the relation stands pretty near as 1 is to 1½, so that the latter lens requires an increase of exposure in that ratio. From this we see that all lenses possess the same rapidity, *provided the stops bear the same relation to the focus:* the great difference in the rapid lenses over the slow ones being that they can work with much larger aperture.

In order to equalize the various makers' lenses, the Photographic Society of Great Britain have recommended what is termed a "uniform system" of numbering the stops. They recommend that all stops having the formula $\frac{f}{x}$ be stamped with the figure 1, this being the largest aperture that it is at present possible to make, and every other stop with that number which would indicate the exposure in comparison with the standard $\frac{f}{4}$, without regard whether all the stops can be found in the lens or not. The figures would run thus:—

$\frac{f}{4}$	$\frac{f}{5{\cdot}6}$	$\frac{f}{8}$	$\frac{f}{11{\cdot}3}$	$\frac{f}{16}$	$\frac{f}{22{\cdot}6}$	$\frac{f}{32}$	$\frac{f}{45}$	$\frac{f}{64}$
1	2	4	8	16	32	64	128	256

The intermediate ones by calculated in proportion. If this was carried out by all makers, no matter what lens we took up, the exact rapidity could be seen at a glance.

I calculate the formula of the various stops in the lens, and select three or four of those that bear a direct proportion to each other, so that the exposure may be, say, the middle stop, four times the full aperture, and the small one four times the middle, and consequently sixteen times the full aperture.

COPYRIGHT LAW IN BRIEF.

COPYRIGHT means the sole and exclusive right to copy, reproduce, and multiply, by any means, and in any manner, any original painting, drawing, photograph, or other work of art.

Copyright accrues to the *author* of a work of art, by virtue of authorship, and lasts for his or her natural life, and seven years after death.

As soon as the copyright in any work is registered, in accordance with the provisions of the Act of Parliament known as Vic. 25 and 26, cap. 68, it becomes personal estate, and can be sold, assigned, or demised, just the same as any other personal estate.

A properly registered copyright will enable the owner to take proceedings and recover penalties against any one who, without permission, copies or imitates, wholly or partially, the whole or any portion of the original work of art to which such copyright applies.

Under the Copyright Act, an original negative, or the photographic copy of it, is considered a work of art.

A photographer can make a negative of a landscape, of natural objects, of architecture; in short, of any object or objects in which there is no copyright, and the correct registration, according to the Act, will secure to him his copyright in that particular negative or photograph. He cannot, however, prevent any other person making another negative of the same objects, even from the same point of view, and as nearly as possible under the same circumstances.

If a photographer take the portrait of a person of eminence—a member of the Royal Family, musician, actor, &c., &c.—copyright can only be secured by a signed agreement, made at or before the time of sitting, between the person whose portrait is made, and the person who makes the negative. If this be not done, and the names of the parties to the agreement properly filled up in the registration form, there will be no copyright.

If a *group* of persons be taken, it will be necessary to have the signature of every member of the group to the agreement.

Seeing that copyright accrues only to the *author* of the work, a principal cannot send out his operator to execute his commission, and then take the copyright to himself; it will, in every case, accrue to the author of the work.

In the present state of the law, it would seem to be absolutely necessary, that, where a principal does not himself execute the work, or have it done under his personal direction and supervision, he must have an assignment of the copyright from the person he employs, and who, in the eye of the law, is the true author.

Portraits taken in the ordinary way of business have no copyright, except by special agreement; but that does not give the right to the photographer to print from the negative for his own purposes. He is bound to use the negative, if he retains it, only to the order of his employer.

The owner of a copyright picture cannot have it reproduced or copied unless he *also* possesses the copyright.

Authors of original works should secure copyright by registration as early as possible; illicit copying of an original work before the copyright is registered is actionable, and confers no copyright.

In transfers of photographic businesses, each copyright negative must be duly assigned, and the assignment registered at Stationers' Hall; unless this is done, the purchaser of the business does not acquire the copyrights.

Proper copyright forms can be obtained for one penny each at Stationers' Hall.

The penalties for infringement are very heavy, the offender upon conviction being liable to be adjudged to forfeit a sum not exceeding ten pounds for every copy sold, or offered for sale.—*Autotype Notes.*

Patent Intelligence.

Applications for Provisional Protection.

2767. FREDERICK WOODWARD BRANSON, of Leeds, in the county of York, Pharmaceutical Chemist, for an invention of "Improvements in photographic 'shutters.'"—Dated Feb. 5, 1884

2981. WALTER BENTLEY WOODBURY, of South Norwood, in the county of Surrey, for the invention for "Improvements in methods for producing printing-blocks by means of photography."—Dated 8th February, 1884.

2987. ALBERTA MARY FRANCES CASPAR, of 200, Regent Street, in the county of Middlesex, W., Artist and Inventor of Easy Artistic Processes, for an invention for "The easy copying and toning of photographic and other prints."—Dated 8th February, 1884.

3017. JOSEPH NORRIS, of Birmingham, in the county of Warwick, for an invention for "Improvements in the manufacture of ornamental building slabs or tiles."—Dated 9th February, 1884.

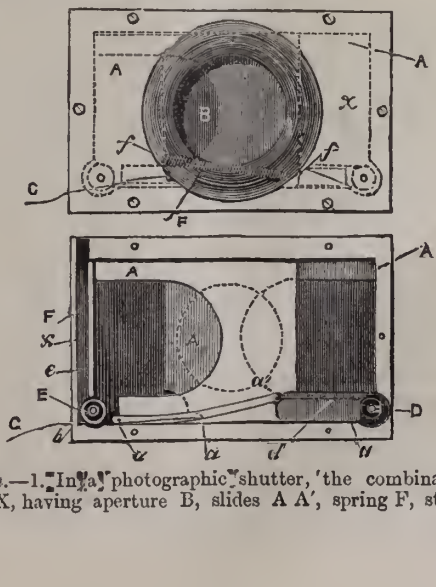
3026. JOHN and ALFRED GEORGE HOPKINS, of Amwell Cottage, Hoddesdon, in the county of Herts, Photographers, for an invention for "A new apparatus for the exposing of photographic sensitive plates in cameras."—(Complete Specification)—Dated 9th February, 1884.

Patent Sealed.

3948. JOSEPH JULIUS SACHS, of 8, Union Court, Old Broad Street, in the city of London, for an invention of "Improvements in the manufacture of pliable plates and surfaces as a substitute for glass for photographic and other purposes."—A communication to him from Messieurs Fickeissen and Becker, resident at Villingen, Baden, Germany.—Dated Aug. 14, 1883.

Patent Granted in America.

92,707. DEXTER B. SWEET, Eaglewood, Ill., "Photographic Shutter."—Filed Nov. 9, 1883. (No model).



Claim.—1. In a photographic shutter, the combination of frame X, having aperture B, slides A A', spring F, studs *f f*,

cord C, cord *d*, and wheel or pulley D, all arranged, operated, and controlled substantially as described, and for the purpose specified.

2. In a photographic shutter, frame X, having aperture B, and slides A A', in combination with spring F, cord *e*, pulley or wheel E, cord *d*, pulley or wheel D, and cord C, all substantially as described, and for the purpose specified.

A Dictionary of Photography.

ALBUMENIZED PAPER (Printing on).—*Continued.*

Burnishing, enamelling, &c.—We mentioned that the object of rolling is to produce an even and polished surface on the photograph. The burnisher acts in a somewhat similar manner to the hot rolling press, but in skilled hands it is capable of producing a more brilliant surface and better tones. The principle of the

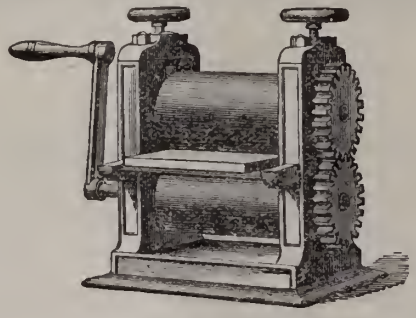


Fig. 6.

burnisher differs only from the hot rolling-press, inasmuch as the print is dragged by a roughened roller over a highly polished and hardened steel bar, which is stationary and heated, instead of passing between two polished steel rollers, or a steel bed and roller, as in fig. 6. Fig. 7 is a sketch of an ordinary burnisher.

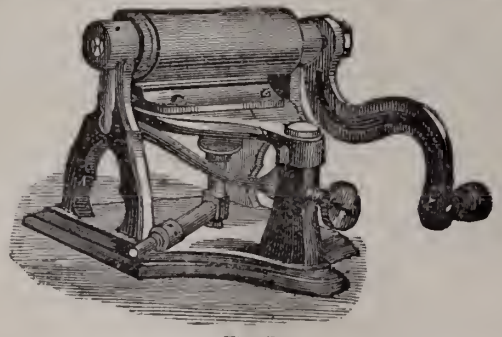

Fig. 7.

To ensure success with the burnisher, it is necessary to lubricate the photograph, and there are several ways of doing this; perhaps the highest degree of polish is obtained with curd soap rubbed on in the dry state by means of a flannel pad. Some prefer using an alcoholic solution of soap made by dissolving sixty grains of curd soap in a small quantity of water, adding methylated spirit to make twenty ounces. Moisten a tuft of cotton-wool with the soap spirit, and rub the surface of the photograph on every part; five minutes afterwards it may be passed through the hot burnisher, care being exercised not to scorch the photograph, or make a halt while it is passing over the heated bar. Care is also necessary to prevent particles of dust entering between the bar and the photograph, as scratches would be produced on the subsequent prints; should this happen, the burnishing tool should be rubbed on an oil stone, with a little powdered emery, finishing on an emery knifeboard to bring up the polish. As many persons object to using soap in any form on the photograph, they will find a very good substitute in wax. The following has been lately recommended as one of the photographic societies, and we have found that it answers well:—

Benzoline spirit	1 pint
Paraffin wax	20 grains

Among other modes of obtaining glazed surfaces on photographs besides rolling and burnishing, so-called enamelling must be mentioned, the finished result giving a very fine glaze, as highly polished as a glass plate. The process consists in placing the albumenized surface of a photograph, in a moist condition, in contact with a polished glass plate, which has received a coating of normal collodion, and a somewhat dilute solution of gelatine; when dry, the print will drop off. For the information of those of our readers who have never tried the process, we will describe the operations:—

Transparent gelatine	1 ounce
Water	8 ounces

soak one hour, then add—

Glycerine	10 drops

heat on a water bath until the gelatine is dissolved; filter while hot.

Normal Collodion.

Pyroxyline	2 drachms
Methylated ether...	8 ounces
Methylated alcohol	2 ,,

These proportions may be altered to suit the cotton used. Mount the photographs by means of gelatine, as above, on thin cardboard; what is known as Bristol board being very suitable. When quite dry, touch out any white spots which may be caused by dust during printing, or faults in the negative, afterwards placing them in a dish of cold water to soften the board. This will take place in about ten minutes, more or less. The prints should remain until quite soft, as success depends in a great measure on their pliability at this stage. The time that elapses while the mounted prints are drying may be occupied in preparing the plates. Patent plate free from imperfections should be cleaned with dilute nitric acid, well washed, and polished with tripoli, or any of the substances usually employed for plate cleaning; powdered French chalk (talc) is dusted on the surface, and removed with the polishing cloth. Pass a camel-hair brush over the plates to remove any particles of dust, then coat them with normal collodion in the same manner as coating a wet plate or varnishing a negative; when set, rear on end to dry. A number of plates may be coated, as they will be none the worse for keeping. We will suppose the mounted photographs have been soaked as directed, and are soft; remove them from the dish of water to a clean damp cloth; blot off the excess of water, and leave them in the cloth until they are required for the next operation.

The gelatine should be re-melted in a flat porcelain dish over a water bath; into the solution immerse one of the dry collodion plates, and one of the photographs from the damp cloth. To bring these two into perfect contact requires a little skill and practice. From our description, however, it should not be found at all difficult. With the left hand hold the plate, collodion side uppermost, just under the surface of the solution; with the right hand lower the print gradually on to the plate, commencing at the bottom and working upwards. The top of the print should be held outwards, so as to form a slight curve; by this means it will be easy to see the air-bells gradually pushed out as the two surfaces come in contact. Having accomplished this satisfactorily, lay the plate down on the bench, and well squeegee the back of the photograph to remove any excess of air and gelatine imprisoned in the paper. When all the prints have been squeegeed down on their respective plates, place them in a current of dry air, and leave them for twelve hours; at the end of that period the prints probably have dropped off the plates; if not, they will come away quite easily if the point of a penknife is passed round the outer edges to give them a start. It is not usual for photographers to deliver these so-called enamelled photographs to their clients in this condition; they are generally stamped up by an embossing press. The margin, after being reduced to the required size (prints intended for enamelling need not be cut until after they leave the glass plate), is fastened with glue to an ordinary thick card mount. When cabinet or larger sizes are produced, the air space between the embossing and the ordinary mount should be filled with cotton wool padding, to prevent the centre falling in by reason of changes in the atmosphere. It will be seen that the highest degree of finish can be obtained by this method. Pictures printed as cameo vignettes, medallions, and cushion-shapes with printed-in margin, as described in a former lesson, are particularly suited to this class of work. Fig. 7 is a sketch of an embossing press. The print is adjusted so that when the pressure is exerted, the metal die fits exactly over the mask line selected in printing; that is to say, an oval used in printing should be of the same dimensions as the die of the em-

bossing press. Do not apply too much pressure, and immediately remove the print, for unless the cardboard be of unusually good quality, it will in all probability burst. Many inexperienced persons fall into error in this particular, and throw the blame on the press or the cardboard. To avoid such failures, allow the print to remain under less pressure for a longer period, say one or two minutes.

(*To be continued*).

SHORTCOMINGS OF PHOTOGRAPHY.

BY DR. TULLOCH.*

In photography, where so much depends upon manipulations and processes, technicalities require, and do actually receive, great attention. The vast majority of papers read, and discussions held at photographic society meetings, are upon technical matters; and while a great deal has to be done yet before our formulæ can be considered perfect, or apparatus all that could be wished for, I think the time would be well spent were we to leave these well-worn grooves occasionally, and, taking a broader view of the situation, consider in what precise direction improvement is most urgently required. This idea was forced upon me the other day, when, having the opportunity of comparing a photographic landscape with an engraving taken from the very same spot, I had to confess that the photograph lacked in a woeful degree the breadth and fine pictorial quality of the engraving. Nor was this due to any liberties which the artist had taken to improve his picture at the expense of truth, as could easily be seen by referring to the photograph. What, then, constituted the difference, and why was there a fine breadth of effect in the engraving, and a particular absence of it in the photograph, when, in both cases, the very same subject had been chosen.

In the following remarks I shall give what appear to me to be the principal shortcomings in a photographic picture, and as the subject is both wide and difficult, I make no pretension to do more than skim the surface. To be concise, and at the same time intelligible, I will consider the subject—1st, as to outline; 2nd, as to light and shade; and 3rd, as to colour.

1st, as to outline. A design, whatever it may be, is forcible in proportion as it is simple. An artist secures breadth by seizing the salient points and presenting them unbroken by paltry detail. For this reason, the photographic outline is too complex to be effective. It must be remembered that, while it is so far a copy of nature, it is a very diminutive copy, and will not bear the same elaboration as the original. Besides, seeing that objects in very different planes have to be adequately represented on the flat as being at different distances, some plan must be fallen upon to do this. One of the most important aids in this direction, is the suppressing of outline here and there, and the simplification of it where it cannot be suppressed. In this way, a foreground may be made to come forward, while the distance seems to retire. Of course, the camera has no such modifying power, and although we often see in the photographic picture an outline which would be better softened, or another accentuated, we have no way of photographically effecting it.

This equally intricate outline over the whole length and breadth of the picture not only destroys distance, but it is not a correct representation of what we see, for it will be found, if the eye be fixed upon a certain object, that the outline grows less and less intricate as it nears the margin of our view. Looking along an avenue of trees, for instance, with our eyes fixed upon a certain point, although we have a vague, general impression of the trees immediately on our right-hand and our left, we do not distinguish every leaf and every little spray as the photographic lens reproduces them. If the eye were in focus at one and the same time upon an object a few feet in advance, and upon another half-a-mile away, our perception of distance would not be nearly so perfect as it is, and yet, depth of focus in a lens is considered a very important feature.

It may be asked, then, if our pictures ought to be blunt or blurred towards the margins? By no means. The impression which the eye receives of objects not precisely at the point of sight, is not a blurred image. The general impression of outline is perfectly sharp, but the eye cannot follow it in all its little tortuosities. If an artist would be successful in conveying the impression which a certain scene had upon him, he must manage to bring the eye to rest upon his canvas precisely where his own rested when the original impression was produced. He does this by carefully working up from simple forms at the margin, to the most complex at the point of sight. In this way the eye is carried forward to the focus of the picture, and finally chooses as a centre the very spot which was the centre of his own impression. I cannot see how the photographic outline, which is as pointed and precise at the margin as in the very eye of the picture, can lead one on into the distance; rather, I should say, is the attention arrested and fixed by what should have been only a stepping stone. The point of maximum interest is never at the margins of my field of vision, and yet I have frequently seen it here in photographs. Vignettes have always been considered the most artistic of photographic productions, and this, I am convinced, simply because the margins are robbed of their undue importance. To recapitulate, then, I consider that the photographic outline, being equally intricate throughout, by scattering the interest, robs the picture of the charm and force of one common centre.

* Read before the Dundee and East of Scotland Photographic Association.

Notes.

A satisfactory balance sheet, and a notable increment in the membership roll, are good indications of the prosperity of the Photographic Society of Great Britain.

The general work of the Society during the past year, as reported at the annual meeting on Tuesday, has not been characterised by any striking innovations, but by steady progress. The Society's Official Journal, under the management of Captain Abney, has cost some £14 less than last year, and some useful pieces of property have been acquired.

Our readers will see by the abstracted report, which we print in another column, that Col. Stuart Wortley becomes a Vice-President, and Prof. Donkin takes the office of Hon. Secretary, while two new names will now find a place in the list of Members of Council.

It is passing strange, to some of us, to hear contemporaries of Daguerre speak of him and his invention when some thirty-three years ago the world was startled with the marvels of Daguerreotype. Our friend Mr. J. E. Mayall, of New Bond Street, was one of the few who depicted the great Frenchman in the camera, and this photograph, our readers will remember, forms the frontispiece to the Year-Book of 1881. But Mr. Mayall's personal experiences are as nothing compared to those of the venerable Secretary of the French Academy of Sciences, for M. Dumas remembered Daguerre in 1827, twelve years before Daguerreotype was known to the world.

"I was a young man then," is M. Dumas' story—M. Dumas, we may mention, was born in the same year as the century—"and must have been about 27, when a message was sent into my laboratory that somebody wished to see me. I asked the visitor in. It was Madame Daguerre. She came to consult me on the subject of her husband's investigations. So far, he had been unsuccessful, and she did not conceal the anxiety under which she laboured. 'Was there any chance of the dream of her husband ever being realised?' she desired to know

'or whether,' she added timidly, 'it would not be well to wean him from them, before it was too late?'' In a word, Madame Daguerre was of opinion that her husband was going mad. Dumas hastily reassured the wife, and soon afterwards, says the venerable chemist, "I had the satisfaction of knowing that I had not been mistaken; Daguerre discovered the solution of the problem he had been searching—a discovery that made him famous." Thus the *Revue Photographique*.

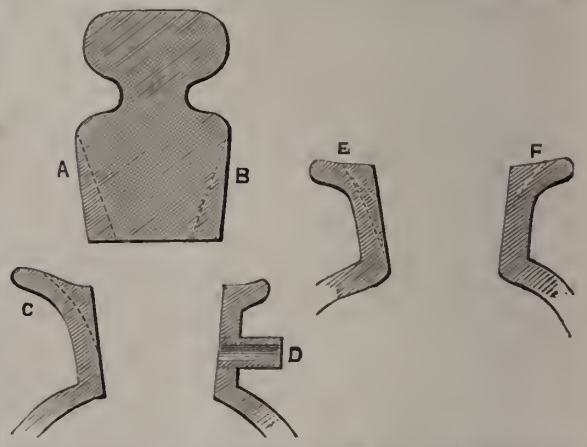
The unfinished appearance so often noticeable in the case of cartes or other portraits coming from the studio of the amateur is mainly due to the circumstance that the mounts are ordinarily blank ones; such, indeed, as no professional photographer would use. As an exception to this usual order of things, we may mention that an amateur photographer, who is a large chemical manufacturer in the north of England, recently sent us some cartes which were on mounts imprinted in quite the business style, there being a place for the number of the picture, and an announcement that enlargements could be satisfactorily made from the negative. The principal line, however, was "Amateur Photographer," not "Artistic Photographer."

Fancy balls and fancy bazaars are great boons to photographers. All the ladies who took part in the Peasant Festival at the Albert Hall this week were previously photographed in the costumes in which they were to appear, and the collection promises to be a very interesting one. Messrs. Elliot and Fry were the photographers.

Photographers who go in for "Club" portraits would do well to be suspicious of over-energetic canvassers. Messrs. Taylor, of Brighton, have, within the last few days, been compelled to prosecute a person in their employ; the circumstances indicating that the "Club" system has to be conducted with great caution to avoid the possibility of fraud. The custom at Messrs. Taylor's establishment was for the canvassers to pay over two shillings on each order, they receiving in return the full commission of fifteen per cent. on the amount of the order. The person in question entered upon his duties in June last, but after a time suspicion began to be excited by the immense number of orders he obtained; and it was afterwards discovered that a large number of addresses in his book were wrong, about £21 having then been paid to him in commission. In the case selected, the prosecution broke down, as it was elicited that the prisoner had repaid by instalments all that was due in this particular instance. It is stated, however, that there were numerous other charges, and the prisoner was remanded on bail.

As the case is still *sub judice*, comment upon it can scarcely be made; but there is a point to which attention may be drawn, as it illustrates one serious difficulty of the club system, namely, the collection of the instalments. A circumstance noticed by Messrs. Taylor was that in the order book of the accused his own address was put down as being the address of several customers. When asked to explain this, he said these customers did not wish to be called upon by canvassers, and he had therefore thought it best to insert his own address instead of theirs, and this explanation was believed. But that it was so, leads to the inference that the firm was aware of the sensitiveness of the public in regard to belonging to photographic portrait clubs. It would be instructive to have the experience in this matter of those who had much to do with clubs, and to learn how the difficulty is best got over.

From Germany we receive an ingenious dropping bottle. In the stopper are filed two grooves, A and B, these grooves extending rather more than half way up. When the stopper is so placed in the neck that one groove corresponds to the lip C, and the other groove to the vent pipe D, it is easy to pour the liquid out in drops; but when



the stopper is turned round a quarter of a circle, the bottle is perfectly closed. We find that an equally efficient apparatus can be made from an ordinary bottle by filing grooves in the stopper as described, and in the neck as shown at E and F. An ordinary rats-tail file, moistened with oil of turpentine, answers well.

Science in the purple has taken the place of the starving alchemist of old. The late Sir William Siemens, who had not many shillings when he came to England thirty years ago, has left property to the value of almost half a million, his personality alone being valued at £380,000. For one scientific man in the last generation whose income was three or four thousand a year, there are a hundred to-day who make as much out of scientific advice and scientific teaching. In the days of Sir Humphrey Davy, and even Faraday, there was, indeed, no such thing as earning a fortune by science, and although the old alchemist was for ever trying to make gold, he never succeeded. Nor was teaching considered a lucrative profession fifty years ago; yet to-day professors may be found in the Scotch and English capitals who, in return for an average of two or three hours' tuition a week, receive an income amounting to thousands of pounds.

The salaries of official scientific men are, certainly, none too high, when we compare them to those enjoyed by other

professions. At the same time, it must be remembered that Government rarely absorbs the whole of a man's time, so that his official salary is usually but a portion of his income. Among the "plums," may be classed the Professorship of Chemistry at South Kensington, held by Dr. Frankland, which is worth £1,609; the Inspectorship of Fisheries and Professorship of Biology brings in the holder £1,500; the Chemist of the Mint, with a second appointment, receives £1,125, while a round thousand each is the value of such appointments as Astronomer-Royal, Chemist to Inland Revenue, Inspector of Explosives, Chief Mining Inspector and Professor of Metallurgy, at Kensington, &c., &c. Be these gentlemen well or ill paid, there were no such lucrative appointments open to scientific men of the last generation.

A contributor, wishing to hire a suitable place for gelatino-bromide experiments, advertised in the *Daily Telegraph* for a dry cellar near Charing Cross, no window necessary. A well-dressed man, whose awkward manner and unready answers at once proclaimed him a detective, called on our friend and said he had such a cellar, but in response to the natural enquiry as to its whereabouts he seemed confused, and ultimately gave a fictitious address. He proved to be one of the new "dynamite staff" of Scotland Yard. If this officer will only take the trouble to revisit our friend's chambers in the Adelphi, he will not only find there abundance of all such materials as are used in making dynamite, but also several very strangely devised pieces of clockwork. At our own laboratory, also, he might find in addition to these, everything required for making bad coin and forging bank notes; and, what looks even more questionable, a full-sized reproduction of the bank note watermark, made by the photo-filigrane method of Mr. Woodbury."

CHAPTERS ON LANDSCAPE AND OUT-DOOR PHOTOGRAPHY.

BY H. P. ROBINSON.

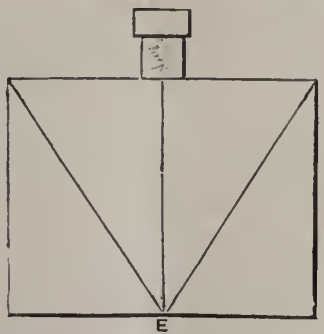
No. 6.—On Sea and Shore.

Before the advent of gelatine plates, photographs of the sea were the unfulfilled dream, rather than the accomplishment, of the photographer. It is true that some very creditable results were produced (chiefly by the aid of double printing), especially for the stereoscope, and, in a few instances, of larger sizes; but nothing to be compared with the marvellous achievements that are now open to the followers of our art.

But with the sea, now we have the means of photographing it, we are doing to-day almost exactly what the earliest photographers did with landscape; we are content to take almost anything that presents itself to us, and think it good if it is sharp. The possibility to get the tumultuous waves in so short a time that they appear in the print to have been quite still, is such a surprise that many photographers appear to be quite satisfied with it, and the simple pleasure of surprise is enough for some people, bearing out the adage "little things please little minds;" but when the novelty of quickness wears off, they will find there is a good deal more to be done than has yet been accomplished. At present there is too much disposition to rely on accident. A photographer will go down to the sea and fire off some dozens of plates in the hope that a few of them will turn out prizes. This is photographing with the hope of a miracle happening, which I need not say is not art.

In producing plates quick enough to receive the ever-changing, restless sea with ease and certainty, the photographer has had placed in his hands weapons with which he may conquer a new realm. And this addition to his conquests will be fortunately more appreciated in our country than any other, for Englishmen love the sea, and are never happier than when on its surface or its shores. Subjects are more plentiful on sea and shore than in other places. Nearly my first experience with gelatine plates was on the sea, during a yachting cruise on the Clyde and among the Western Islands of Scotland.

Plates and shutters have greatly improved since that time, but I was astonished at the wonderful ease with which good negatives could be got even on the unstable base of a yacht in full sail. One of the difficulties was to get the horizon even approximately level. The roll of the boat was not of much consequence, but the pitch, if it happens at the moment of exposure, was often fatal. Recent experiments have convinced me that this difficulty can be modified by using a camera stand with a ball-and-socket joint, with the camera loosely fixed, so that it can be turned about quickly by the hand. With this arrangement, and a finder, combined with a pneumatic exposer, many difficulties disappear. A finder is of great use, for without one the photographer may discover that a vessel has escaped from the field of the picture altogether, or left only her mizen behind her, like little Bopeep's sheep. There are several good finders sold now, but they are most of them too elaborate for my use. I like every piece of apparatus to be as simple as I can get it, and am even prepared to give up some advantages to attain simplicity. The following plan I find to answer sufficiently, and it is always at hand, and never requires separate setting up. The ground glass of my camera is hinged, and, when the slide is in, falls flat on the top. On the glass are drawn three lines, one directly down the centre, the other two



from E to the opposite corners. When the glass is flat on the camera, by placing the eye at E and looking along the central line, as you would along a gun-barrel, you get the centre of the picture, and by looking down the diagonal lines, you find how much will be included in the angle of view. The diagonal lines must be adjusted to the focus of the lens you are using,—and this reminds me that a long focus lens is better for a sea-view than a wide-angle. There are two or three things worth considering in taking ships at sea. I quite believe that all things are possible now-a-days, but some are easier than others. A ship going broadside on is more liable to show movement than one coming end on. The cause of this is plain. If a vessel is going parallel with you, it infinitely more quickly exposes fresh sky behind it than does a ship that is coming towards or going from you. The latter covers the same space for a much longer time than the former, and allows a more prolonged exposure. It is for this reason that photographs of railway trains going at full speed have been so easy,—they are all taken end on. A vessel sailing in the same direction as yourself will allow of a

longer exposure than one that is meeting you, and objects on the deck of the vessel on which your camera is placed will allow of very prolonged exposure even when the boat is rolling considerably, always making allowance for the jerking of the rigging. It will be found that camera, vessel, and all the objects on it roll together, and, other things being equal, have no effect on the definition. The extraordinary photographs of yachts exhibited at the last exhibition of the Photographic Society by Mr. West, of Gosport, showed that marvellous results could be attained. The majority of these pictures were taken while racing from another vessel. There must have been, of course, many failures in taking these pictures, but much as I object to "flukes," when a photographer produces some hundreds of such pictures as these in a season, as I believe Mr. West has done, I cannot put down his success entirely to accident.

But it is on and from the shore that the photographer ought to expect to find his best subjects. Life on the shore is full of pictures. The sailors and their occupations afford plenty of incidents, while the sands and shingle and cliffs supply picturesque surrounding. There is only one aspect of the sea which defies the cleverest painter or artist of any kind to get anything pictorial out of it. A dull smooth sea with nothing on it is the most monotonous, insipid, and characterless thing in nature. It is fortunate that this effect seldom exists for many days together, and the photgrapher who goes to the sea will find plenty to do, if he has the power of seeing what to do, and knows how to do it.

If my reader lives at the sea-side, there ought to be little that I can point out to him; but to the stranger who wants to do real work, I should say select an intelligent boatman, and engage him to carry your camera. Through him you will get to know other sailors. Listen to their yarns and be liberal with tobacco, and you will have a chance of getting pictures that could scarcely be got on any other terms. If you manage them properly, they will become greatly interested in your work, and be always anxious to help, and the assistance they can give is very real. Boats, ropes, lobster pots, and other "common objects of the shore," are heavy to move, and the boatmen are always willing helpers, always supposing you get the right side of them.

I have known half-a-dozen sailors work like slaves launching and beaching a great lugger for the benefit of a photographer; and I must confess, on the other hand, I have seen them very obstructive.

Charming pictures may be made of figures, boats, &c., taken on the beach, using a second negative for the sea and sky. All the precautions necessary for securing truth in a similar kind of picture on land must be more than ever observed in a shore view. The photographer would, of course, not be guilty of the mistake of using a sea and sky lighted from a different direction to that of the foreground, but there are other things that could scarcely happen inland that must be looked to here.

Suppose, for instance, the subject was a group of figures looking out on a raging sea, it would never do to take the group on a calm day; the figures would not be in accord with the sea, and it is very possible that there would be included in the foreground objects such a thing as a boat with its sails set to dry, which would of course be torn to ribbons in such a gale as was represented by the sea.

These observations are very commonplace and trite, but it is astonishing how easily obvious blunders will creep into photographs when they are anything but the ordinary thing done at one exposure. In the last exhibition I noticed several sea views into which the sky had been printed from a separate negative. In these the clouds were seen to go down to and behind the horizon. Now this is an effect that is never seen except in the clearest of latitudes; it occasionally nearly occurs in Cornwall, where the air is sometimes extremely clear, but I have never seen it further North during the observations of many years. There is always sufficient density of atmosphere to give a line of what may be called plain sky for some space above the horizon—that is, between the clouds and the sea.

Many fine pictures can be got of the waves breaking on the shore, from the dash of the giant waves, crashing and smashing themselves into foam on the shingle, to the beautiful effect of long, rolling waves creeping slowly over the wet reflecting sand. The chief qualification a photographer requires for taking this kind of picture is presence of mind combined with ready thought, so that he may be able to say at the instant, "This is good!" and pull the trigger; or, "This won't do!" and leave it alone.

The shore is very fertile in suggestions for subjects. The accessories are so picturesque that they call aloud to be photographed, and pictures containing figures can often be snatched with great ease. The photograph from which the illustration is taken was exposed without the little

girl knowing anything about it. The camera was focussed on the crab baskets, and the little girl came to play with them. The elder girl, who had been acting as model in several pictures, at a hint from the photographer, walked quickly to the baskets, stooped down to speak to the child, and, before she could look up, the picture was taken.

To the artist photographer a fishing village, picturequely situated between overhanging cliffs, presents dozens of available subjects. The space covered may be small, but the ever-varying life of the place presents continual change. On the beach the trawlers may be drawn up high and dry, keeled over on their sides, the fisher-folk mending their nets, or spreading out their tanned sails to dry on the shingle, while children swing and play on the ropes with which the boats are made fast. The odds and ends of the shore always present opportunities for groups and single figures of fishermen and girls following their occupation. The windlasses, piles of lobster pots, creels, bits of rope, anchors, barrels, and tar-covered buildings, all suggest picturesque incident, and dramatic situations. The return of the fishing fleet is full of lively incidents. Before the boats get to land, there are always groups of tarpaulined men, with their wattled creels, waiting to land the cargo. When the boat, after pausing a moment—a fine opportunity—on the top of the last wave, is driven straight ashore, she heels over, and the expecting groups rush to her leeward gunwale to receive the glistening and splashing fish—live soles, giant rays, pollock, whiting, red gurnard, and perhaps a conger or two. Here is a picture that could only come to him who knows how to wait, but which happens daily, and is certainly possible.

Then the sale of the fish on the beach by Dutch auction, the removal of the fish to market, or the packing them in boxes or barrels; all these give subjects. So also do the children on the sand; but this is so obvious, and has been so often done, that I will say no more about it.

ON COATING PAPER WITH GELATINO-BROMIDE OF SILVER.

BY L. DIXON.

Having tried all the ways that have been published for coating paper with emulsion, and others that have suggested themselves as a likely way to attain this object, I have met with but indifferent success with any of them compared to the samples that are offered in the market. The writer's object in recording his experience is to state how each method has failed, so that others may profit thereby who have been working in the same direction. First—we selected the method adopted for coating carbon tissue. By putting an endless band of paper of twelve feet lengths to revolve round a roller at the top of about seven inches diameter, the bottom was suspended by the weight of another roller inside, which kept it stretched into a trough containing the emulsion; turning the top roller caused the paper to revolve, letting the bottom skim over the surface of the liquid emulsion. This method I found would not give an even coating, running in streaks.

I next tried brushing on the emulsion when in a jellified state, and then running the same over a tin containing boiling water. This way dried the paper, instead of liquefying the brush marks and making it run even.

I then tried floating the paper on the emulsion. This gave bubbles and spots of various kinds.

By the next method I got the best results of any tried, getting a wood roller (say) of 1½ inch diameter, and rolling a band of paper as tightly on it as possible; the length of the paper must be the length of the room. Putting my emulsion in a half-round trough, having made a centre hole at each end of the roller, and made the pins to rest on each end of the trough, I take hold of the two corners, and draw the paper off the roller while the same is revolving in the emulsion, taking care to keep the paper flat on the floor. A minute or two by this method will coat a twenty-foot length, if the floor is long enough for this size. The short-coming of this plan is the expansion and cockling of the paper before the emulsion has set.

If this article is not too long I will give another way, which, for those who want enlargements for painting upon, offers on economical grounds an advantage, and very easy to do. Cut the sheets the size you require, dip them over head in water, then place them one over the other; roll all the water out you can; take a sheet off the top and place it on a levelled slab, perfectly flat; pour as much emulsion upon it as will, when spread, cover the head; carry it over with a broad flat brush. This must be done very quickly before it sets. The emulsion must be made rather thin, so that it will prevent setting so quickly.

When the image is thrown upon the paper, make sure the head is where the emulsion is floated. When exposed, hold a cardboard over the part sensitized, while you pencil the outlines of the body; the latter being painted solid, answers the purpose equally well with pencilling instead of having the whole sheet coated.

Correspondence.

READY-SENSITIZED PAPER.

Dear Sir,—As at the present time the question of ready-sensitized paper is being discussed, I should like to bear testimony to the efficiency of the plan mentioned in the last number but one of the News, viz., preserving the sensitized paper between leaves of bibulous paper previously soaked in a solution of bicarbonate of soda.

This plan I adopted soon after its suggestion in the News in 1871, and have continued its use to the present time, and would strongly advise those who have not tried it to do so, and if they use the precautions you mentioned the week before last, I do not think they will give it up, finding, as they assuredly will, the comfort of having a reliable method of preserving sensitized paper, giving the best results, and keeping a reasonable time.—I am, sir, yours very respectfully, W. S. Atwood.

THE PACKING OF PLATES.

Sir,—I was much interested in reading your article on "Packing of Plates," in your last number.

During my summer rambles with the camera, this has been one of my difficulties, and I had such a lesson last August, whilst in Switzerland, that I came home determined to find out some better method of packing than by placing strips of cardboard between the edges. As one has to work gelatine plates in such a subdued light, it is no easy matter to see that the strips keep their place, and if they happen to slip away, scratches and marks caused by the pressure may result.

For the future I intend to use those cheap cardboard boxes which Mr. Edwards sends out with his plates. I always use them for the purpose of storing away my plates, and when on a tour, they render changing a very easy matter; the only possible objection being their bulk. This, I think, might be sacrificed for comfort and perfect safety.—I am, yours truly, W. H. Plaister.

Proceedings of Societies.

The Photographic Society of Great Britain.

The ordinary monthly meeting of this Society was held at 5a, Pall Mall East, on Tuesday evening, the 12th inst., James Glaisher, Esq., F.R.S. (president), in the chair.

The minutes of the previous meeting having been read and confirmed,

Messrs. Norman May, J. S. Knight, J. T. England, and R. S. Kidd, were elected members of the Society.

The following is an abstract of the secretary's report:—The mental activity which has previously prevailed since the introduction of the gelatino-bromide process has now subsided, the dry-plate question having ceased to be a burning one. Although less papers have been read during the past year than in former years, valuable discussions have taken place on matters of general interest. The Council refer with satisfaction to the completion of the standard screws, which will be of great benefit, two sets having been prepared, one in hard metal, and one in soft; their use is now at the disposal of all who consider it desirable to make any change. The Society possesses two optical lanterns made by the late J. H. Dallmeyer—one a sciopticon oil lantern, the other an oxy-hydrogen lantern; these have already done great service in exhibiting slides at the last exhibition. The majority of the pictures shown at the 1883 exhibition were produced by the gelatine process, a very high standard of excellence being attained, many considering it the finest display the Society has yet exhibited. Doubtless the chief factor is due to the rapidity of exposures now permissible. In connection with the awards, photographers alone composed the jurors. The demand for wall space is getting every year larger, and some pictures last year were rejected; as the number of rejections increase, a higher standard of work will probably result. The Society now numbers 363 members, the largest number on the roll for some years past.

The Treasurer's report was then read, on which he (the Treasurer) remarked that the Society had made substantial progress in the right direction. If the Society were in a position to do it, he should suggest investing all subscriptions received from life members; but at present he thought it better to use the funds in such manner as the Council may deem best in conferring benefit on the general photographic community. No doubt in time these advantages would be recognised, with the result of largely increasing the ranks of the Society.

The reports having been read and adopted,

The Chairman proposed a cordial vote of thanks to Mr. Bird (the Treasurer) for his arduous duties, and hoped this year would enable him to devote as much time for the Society's welfare as he had done in the past, and that he would be able to give them as good a report; better he could not.

Mr. ADDENBROOKE, in seconding the motion, said the clear manner in which the accounts and vouchers were laid before him and his co-auditor Mr. C. Ray Woods, rendered their work of the most meagre character. The motion was carried by acclamation.

The CHAIRMAN noted, duriug the reading of the Treasurer's report, that the Society's Journal had cost some £14 less. Although the Editor has been out of health, he has been able to show a very good balance in favour of the Society. He was quite sure they were all very much obliged to Capt. Abney for the able manner iu which he conducted their Journal, and he asked for a warm vote of thanks, which was accorded.

The auditors, Messrs. Addenbrooke and C. Ray Woods, were accorded a vote of thanks.

The CHAIRMAN said, according to the rules laid down for their guidance, the silver progress medal is awarded for scientific research, not only through the past year, but through preceding years also. The medal has been awarded to Dr. Eder for his previous work. In asking the Treasurer to transmit the medal he would couple with it the Society's best wishes for his prosperity, health, and happiness.

The result of the election of officers for the current year to fill the places of those retiring was announced as follows :—

President—Mr. James Glaisher, F.R.S.
Vice-President—Col. Stuart Wortley.
Treasurer—Mr. W. S. Bird.
Secretary—Prof. Donkin.
Members of the Council—Capt. Abney, F.R.S., Mr. F. Bedford, Mr. T. Bolas, F.C.S., Mr. W. B. Bolton, Mr. W. England, Mr. Jabez Hughes.

The CHAIRMAN asked for a vote of thanks to Messrs. Burton, Cobb, Cowen, and Hollyer, for their arduous services as scrutineers, which was accorded.

COL. STUART WORTLEY: Mr. President, Ladies, and Gentlemen,—I am anxious to propose a vote of thanks to our most estimable and worthy President. Although the duty fell on him (Col. Stuart Wortley) last year, he could only say as last, that the success of the Society is due to the President. It would be impossible to find a man who could do the work like him; he was always present, and was referred to for his experience on all occasions; the energy he devoted to the Society was astonishing. His (Col. Wortley) own experience in council made him speak up for their president, and he could say from his heart he hoped their old friend may be spared many years to preside over them.

Mr. J. SPILLER was sure the remarks of the previous speaker were the sentiments entertained by all. Mr. Glaisher was always to be found in his place, and had been so for upwards of twenty years; he heartily seconded the motion.

CAPTAIN ABNEY: It is hardly necessary to put the vote in a formal manner.

Carried by acclamation.

In returning thanks, the PRESIDENT said he should always work to put the Society in the best possible position; but the Colonel must remember what a good council he had to assist him. With such a good council, Treasurer, and Editor, he ought to succeed; towards that end, all in his power he would do. Professor Donkin had been elected on the Council; he is now elected secretary. Mr. Maxwell Lyte has not been able to be with us, although he desired to be. I shall ask the members to pass a vote of thanks to our late secretary, Mr. Maxwell Lyte.

Carried unanimously.

The meeting then adjourned until March 11th.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

THE ordiuary monthly meeting of this Society was held in the House of the Society of Arts, John Street, Adelphi, on Thursday, the 7th inst., the President, the Rev. F. F. STATHAM, M.A., in the chair.

The minutes of the ordinary meeting held in December, and the lantern meeting held in January, having been read and confirmed,

The PRESIDENT announced that Mr. E. Dunmore was entitled to the Society's diplomas, he being the successful competitor, both in landscape and figure subjects, in the January competition; these would be presented later on in the evening. Unfortunately, there was not the interest taken in these competitions they had expected; in fact, one month they had no competitors at all. Some change had been suggested in committee, and he would ask Mr. Bridge to state what occurred, and the decision arrived at.

Mr. F. A. BRIDGE: The President asks me to state what has occurred in committee regarding these competitions. Briefly, I may say that the practice hitherto of passing round blanks each evening, to be filled with a title suggested by each individual member, has been the means of our getting a very large number of suitable subjects, from which only one figure, and one landscape subject, is selected; all the others, however good, being wasted. It has been thought that this manner of proceeding is a loss of force, and that it will be much better for the President to select the subjects this evening for the whole year, drawing them from two hats (one for landscapes, and the other for figures) consecutively, until the whole number of subjects drawn are approved by the majority of the members present. Members will thus have the greater part of the year before them to make their pictures, as opportunity presents itself. The competition pictures are to be delivered iu time for the December meeting.

The CHAIRMAN said it was desirable to make some change, for the present month they had no competition at all. Sending round papers was a trouble to the members; a subject is written, a member (generally a lady) is asked to draw one of the selections; if thirty subjects of each kind have been selected, only one of each are made use of, the others being wasted; so the committee considered it better for the chairman to draw ten of each kind—figure and landscape—from the subjects given, thereby saving trouble to the members, besides giving them the whole of the year to obtain their results. He hoped this arrangement would prove successful. It was really surprising how the competitions had fallen off, as everything has been decided by the votes of the members themselves, and the successful competitor has generally had a very large majority of votes.

The CHAIRMAN: In the absence of a paper this evening, our excellent friend Mr. Bridge has undertaken to make a few remarks on Willesden paper.

Mr. BRIDGE: As I could not get a paper from any of the members, one of whom said, "Try Willesden Paper," I ventured a letter to the manager, and received a very courteous reply. Visiting the Fisheries' Exhibition in common with everybody else, I noticed the roof was covered with Willesden Paper, so started off to Willesden, and was very politely shown over the premises by Mr. A. E. Healey, the manager, who has attended here to-night to answer any questions you may wish to ask him. "Willesden paper" is a paper treated with ammoniacal subchloride of copper. It is water-proof, rot-proof, and almost thief-proof. It is made in 1-ply, 2-ply, and 4-ply thicknesses; 1-ply is not absolutely waterproof, on account of the fine pin-holes not being perfectly closed; 2-ply consists of 2 papers welded together, forming a thicker substance; 4-ply consists of two 2-plys welded together, and so tightly do they stick, that it is possible to boil them for half-an-hour, and you cannot separate them. Here is some portion of a registered envelope with linen at the back, and here is some paper treated at Willesden. These will be boiled for half-an-hour, when the envelope will be nothing but a pasty mass. Here are some samples of Willesden paper which have been soaking in water since the 2nd ultimo, also pieces of ordinary paper which have been soaking the same length of time. The Willesden paper is quite clear, the other is little but pulp. Now what is it used for? We may want to cover a building away from the studio. Here is a dark-room they have taken the trouble to build up here for us, also a boat or trough of 4-ply material with two pails of water in it. Another thing suggested itself to him, and that was, a covering for printing-frames when a sharp shower comes on. It can be obtained a yard and a-half wide, so that the frames could be quickly sheltered. There was no fear of trouble with the Board of Works (which was a wonderful convenience, in his experience), because it is so light and portable. Another use would be a backing for picture-frames. It is also valuable for packing dry-plates. For dishes it is about the handiest stuff he had yet seen, it being only necessary to fold it up and stick the corners with elastic glue. The main question for photographers would be: How about the chemicals acting on the copper and ammonia? He developed a dry-plate that day in one of these extemporized dishes, and detected no difference. Some samples would be passed round coated with lac varnish; also collodion; hyposulphite of soda had been in one of them, but it was easily washed away. A sample of note-paper was also shown, but they had a difficulty in getting it light enough for some purposes. Mr. Bridge also stated that it would be exceedingly useful in making up slides for the lantern, as a substitute for mahogany. There would be a loss of an ounce and a-half in weight on each slide, which meant a good

deal when anyone was travelling with some hundreds of slides. The result of the boiling was then shown; the registered envelope was recognized only by the linen rag which covered it.

The Chairman said he was sure they were all very much obliged to their vivacious treasurer for bringing the subject before them. Even if there were some things not quite photographic, it permitted divers opinions being expressed on them, and valuable ideas followed. From what he had seen this evening, and previously at the Fisheries' Exhibition, he thought the material would be very valuable to photographers, and hoped there would be a good discussion. He remembered Mr. Leon Warnerke telling them that on a trip to Russia a lot of his apparatus was spoilt with water; if it had been covered with material of this kind, no doubt it would have been saved.

Mr. W. M. Ashman enquired whether, in welding the paper together to obtain thickness, it could not be formed into dishes for development at the same time.

Mr. Healey said they found a difficulty in getting a waterproof glue or mucilage with which to hold the surfaces together. The first principle was to volatilize the ammonia by heat; dipping the parts into a suitable solution, they could be stamped.

Mr. W. Brooks: Does an alkali or an acid affect the paper?

Mr. Healey: An acid bath would affect the copper, in which case it would not be water-proof.

Mr. King found the material useful for backgrounds; there is a texture in it which gives the soft effect obtained with woollen backgrounds.

Mr. E. Cocking desired to know if the width was limited to a yard and a half, because, the wider it could be made, the more useful would it become.

Mr. Healey said the outlay would be so considerable for machinery, that he did not anticipate the directors would incur the expense until they saw the absolute need of it.

Mr. A. Mackie: Could any paper pulp be made water-proof by treating it with copper?

Mr. Healey said Mr. Bridge mentioned that in building up the paper there is some of the mucilage between each sheet, which is found the best way of attaching the fibres.

Mr. Brooks thought the paper useful for collodion emulsion work, if a good surface could be obtained.

Mr. F. Howard said many amateurs had abandoned making their own gelatine plates, because of the difficulties of dark-room accommodation. A suitable dark-room built of this material was just what was wanted.

Mr. Healey mentioned that ferricyanide of potassium was the best test for "Willesden paper." This re-agent turns it a rich chocolate, an indelible fixed stain.

A vote of thanks was given to Mr. Bridge, which that gentleman preferred to pass on to Mr. Healey, the representative of the Willesden Paper Company.

The Chairman then handed Mr. E. Dunmore the diplomas for his pictures—"Out in the Cold," and "The Village Church."

The Treasurer passed round samples of albumenized paper, which had been forwarded to him by a gentleman. No particulars were given as to the mode of preparation.

The following from the question-box was next discussed:—"Are pictures upon ready-sensitized papers likely to be more or less permanent than those on paper freshly prepared?"

Mr. Brooks had noticed streaks of a lemon tint in several prints on ready-sensitized paper; these markings generally became apparent after the prints had been kept a few months.

Mr. Harrison's experience had not led him to think ready-sensitized paper to be any less permanent than freshly prepared; he had frequently noticed blue patches in some of the prints, as if unequal toning had taken place.

Mr. Bridge was able to corroborate Mr. Brook's experience, but he should rather call the streaks brown than yellow.

Mr. F. Howard: It has long been the opinion that it is not so much a question of ready-sensitized or freshly prepared paper which confers permanency, as the quality of the negatives. To illustrate his remarks, he now handed round a print with description appended which was printed more than twenty-five years ago; by the description it would be seen that the negative was well-exposed and of good density; toning being, of course, of equal value.

Mr. E. Foxlee could endorse the remarks of Mr. Howard. He (Mr. Foxlee) had several prints over twenty-five years old which were as good as fresh prints. After the lapse of a little time he could always trace prints from thin negatives or dense negatives.

Mr. W. M. Ayres passed round prints made by him twenty-two years ago, the particulars of which we reported last month.

The following subjects were chosen for competition during the year:—Figure 1, "The Shepherd"; 2, "Afflicted"; 3, "Happiness"; 4, Unearthing a Treasure"; 5, "Indecision"; 6, "Mother and Child"; 7, "Wrath"; 8, "Rustics"; 9, "Gone"; 10, "Age and Youth." Landscape:—1, "A Shady Nook"; 2, "Country View, including a Church with Ivy"; 3, "A Study of Leaves"; 4, "Clouds and Trees"; 5, "A River Scene"; 6, "Hay Making"; 7, "The Harvest Field"; 8, "A Roadside Inn"; 9, "Summer"; 10, "Village."

The Chairman suggested that the subject of old photographs be introduced for discussion at the next meeting, and Mr. E. Dunmore promised to open the discussion.

London and Provincial Photographic Association.

At the meeting of the above Society, held on Thursday, the 6th inst., Mr. A. L. Henderson occupied the chair.

Mr. F. W. Hart passed round some developing trays cast in celluloid. They were made in both opaque and transparent material, and had a well at one end to allow of the tray being held up for inspection of the plate.

In reply to a member, Mr Hart said they were moulded in steel moulds under hydraulic pressure, the cost of the mould for the size exhibited, quarter-plate, being £9.

The following question from the box was discussed:—"Are albumenized paper prints, made from citro-chloride of silver, more permanent than prints made on ordinary sensitized paper?"

Mr. Hart, some twenty years ago, had tried organic acids mixed with albumen, but discarded them, owing to the difficulty in toning.

The Chairman asked whether a print pressed with a very hot iron would not be likely to be more permaneut.

Mr. Debenham, as a matter of experience, did not think burnished prints had been found to be more permanent; in fact, it was rather the reverse. Silver became much redder in tone by the action of heat, and gold also probably underwent a similar change. He did not think the change of colour in an ironed print was due to the disappearance of gold.

The Chairman said he thought a Rev. Mr. Read some years ago took out a patent for a marking ink for which he claimed great permanency; in its composition tartaric acid played an important part. Perhaps paper sensitized as described in the question might give more permanent results if subjected to heat.

Mr. Debenham: Tartrate of silver decomposes by heat, and leaves metallic silver in the fibre of the material. Considerable heat is required to reduce it, and an excess of heat will not cause it to become brown in colour. He should not be prepared to accept as a fact, without good proof, that an ironed print on paper prepared on a citrate bath would be more permanent than ordinary prepared prints.

Mr. Haddon enquired if the change of colour took place in a print which was perfectly dry before being put in the burnisher.

The Chairman replied that it did.

Mr. Hart said that when gold was precipitated as fine gold and dried at a moderate heat—under boiling point—it was of a rich brown colour; but when the heat was increased to nearly redness, the metal became much lighter in colour, and that probably prints, when heated, underwent a molecular change, which caused a different reflection of the light.

Mr. Barker thought the image was a compound of silver and organic matter, and that the citrate of silver compound would be the more stable.

Mr. Briginshaw asked the best method of ascertaining the strength of an old carbon sensitizing bath.

Mr. Haddon suggested evaporating a measured quantity and weighing.

The following question was next discussed:—"Is there any method of coating paper with gelatine emulsion, so that after developing the film can be stripped off instead of waxing?"

The Chairman suggested the following as a likely method, viz., coat the paper with a varnish soluble in alcohol previous to coating with the emulsion; the developed negative might be placed in a bath of alcohol, and the film stripped off.

Mr. Barker thought that if a parchment-like paper, similar to that used by Messrs. Morgan, was French chalked, it might answer the purpose; he had been told by a friend that French chalk might be left on a plate very thickly without injury to the film, and he could himself verify the statement from experiments since made.

Mr. BURGESS had also left the chalk on the glass without injuring the film.

In reply to a question as to whether the advantages claimed for fumed paper applied equally to ready sensitized paper,

The CHAIRMAN said in his experience fuming was a great advantage. Ready sensitized paper could scarcely be over-fumed. The operation should, however, be performed judiciously. In his practice, two sheets of paper were put back to back about two inches from the top of a box, underneath them being a saucer containing the ammonia. The paper was laid on a piece of fishing-net stretched across, and the lid of the box was air-tight. No marks resulted from the use of the net, the same piece having been in use some time.

PHOTOGRAPHERS' BENEVOLENT ASSOCIATION.

THE Board of Management held its usual monthly meeting at 181, Aldersgate Street, on the 6th inst.

The minutes of the previous meeting having been read and confirmed, Mr. L. W. Green and Mr. M. A. Wood were elected members of the Association.

Mr. ASHMAN submitted some proposed alterations in the rules which were discussed. It was decided that the meeting of the Board on March 5th should be special, in accordance with Rule 18.

The other business having been disposed of, the meeting terminated.

NORTH STAFFORDSHIRE PHOTOGRAPHIC ASSOCIATION.

THE monthly meeting of this Society was held on Wednesday, the 6th inst., at the Town Hall, Hanley, Mr. C. ALFIERI, Vice-president, occupying the chair.

The minutes of the previous meeting having been read and signed, Messrs. J. Beardmore, W. Woodall, M.P., Inshull, and Taylor were elected members of the Association.

The CHAIRMAN, addressing the meeting, apologised for his non-ability to demonstrate the progress of enlarging from negatives upon argentic paper, on account of an accident which had lately befallen his condensers, they having been cracked, and the new ones ordered not having come in time for the meeting. He would, however, give the members an invitation to his own laboratory next month, when he should have great pleasure in redeeming his promise. In the meantime, he called upon Mr. Allison—who, he was glad to see, had brought some fair-sized negatives—to give a demonstration in printing direct upon this paper.

Mr. W. B. ALLISON said that having heard a day or two previously of their Chairman's accident, in case it should not have been repaired in time for the meeting, he had brought a few negatives and some of Messrs. Goodall and Steven's enamel argentic paper, to prevent entire disappointment. The room having been darkened, printing-frames were filled as usual in ordinary silver printing, and, a gas burner being lighted, exposures varying from one to two minutes were given at about four feet from the frame. The resulting pictures were all developed successfully with ferrous oxalate developer, and were greatly admired both for their vigorous depth and the purity of the whites obtained with this paper, the pictures somewhat resembling platinum prints highly glazed.

This simple printing process was much admired, and a vote of thanks was passed to Mr. Allison.

The CHAIRMAN handed round a splendid set of about thirty lantern slides, made by contact printing upon bromide plates. The quality of the slides, with perfectly clear glass in the high-lights, showed that in careful and skilful hands alkaline pyrogallic development is equal to any other.

A vote of thanks having been passed to the Chairman, the meeting separated.

PHOTOGRAPHIC SOCIETY OF IRELAND.

THE usual monthly meeting of the above Society was held in the Royal College of Science, Stephen's Green, E., Mr. WOODWORTH in the chair.

The minutes of the previous meeting having been read and confirmed,

Mr. Samuel Boyd was elected a member, and Messrs. J. Robinson and R. Brown were proposed for membership, and will be balloted for at next meeting.

The CHAIRMAN then called on Dr. Scott for his communication, "On the Value of Diaphragms in Photographic Lenses" (see page 100).

There was a very well-sustained debate, some of the members having found the system of diaphragms as drawn up by the committee appointed by the Photographic Society of Great Britain of very great value.

By the courtesy of Dr. Scott, who had prepared a table showing the relative value of the stop, and the exposures necessary to obtain good pictures, Mr. Watson was enabled to compare this table with the actual exposures made during a tour in Wales last summer, and on only one occasion was there any difference between this note-book and table.

Mr. GREENWOOD PIM, as also Mr. E. P. JOHNSON, exhibited a collection of lantern transparencies produced on gelatino-albumen plates, the difference between these plates and the ordinary gelatine plates being very marked; the former being much the best for the purpose. Mr. Pim also exhibited some further results he had obtained on "Eosine" plates.

Mr. JOHNSON and Mr. WOODWARD also showed some specimens of enlarging made on gelatino-bromide paper, which were very good.

Mr. J. V. Robinson passed round a C.D.V. portrait which had been taken in an ordinary sitting-room at night, the subject having been lighted by two ordinary gas jets, the exposure being about fourteen seconds.

COVENTRY AND MIDLAND PHOTOGRAPHIC SOCIETY.

AT the ordinary monthly meeting, the chair was taken by the President, Mr. W. ANDREWS, who (after the business of the meeting) called upon Mr. A. E. ROLLASON (Hon. Sec.), to read a paper on "Exposures by the Oxy-Magnesium Light."

Mr. ROLLASON said that this phase of photography was quite new to him. It was suggested that if members would bring cameras to the meeting a few exposures might be made. He had made several trials of the light, and found it very actinic, but somewhat difficult to manage without proper apparatus. The light was too strong for direct illumination, and required the interposition of a medium to soften the light. In this case the light would be much improved if placed in a focus of a large reflector. Reflectors were also required to soften the shadows, which were found to be very dense. As several gentlemen who had brought cameras were now ready, and the President volunteering to sit for the first trial, preparations were at once made for exposure. Two twenty-ounce gas jars were filled at the pneumatic trough with oxygen gas (kindly given for the occasion by M. S. J. Lloyd). The magnesium wire was bent round a test-tube into a spiral form, and fastened to the stopper at the top of the jar. The jar was then placed about ten feet from the sitter, slightly to his left, on a camera-stand about four feet high, while the camera was to the right hand. All being ready, the wire was then removed from the jar, lighted, and re-immersed in the gas. The exposure was as near as possible about eight seconds; the lens, a single landscape of nine inches focus, No. 2 U.S. stop; the plate, W. T. Baynton's "Coventry Dry Plate." This, upon development, proved to be a failure, on account of the size of the stop and slowness of the lens, which the next exposure conclusively proved This was made under precisely the same conditions, same make of plate, exposure, &c., but with a portrait lens. No. 10 U.S. stop was a decided success, and resulted in a capital negative. The last was a group taken on a Wratten and Wainwright instantaneous, with the portrait lens, same stop, but with two lights burning, one at ten feet and the other at fourteen feet from the group. The exposure was thought to be about twenty seconds, and on development turned out fairly good. The plates were developed (at the meeting) exactly alike by Mr. J. M. Danks in a careful and efficient manner, considering the fact that neither the plate nor the correct exposure was known to him.

On the whole the experiment was fairly successful, and several members expressed a wish to further try the capabilities of the light on a future occasion.

After votes of thanks had been passed to Mr. Rollason and Mr. Danks, the meeting terminated about ten o'clock.

THE SHEFFIELD PHOTOGRAPHIC SOCIETY.

THE regular monthly meeting of the above Society was held in the Masonic Hall on the 5th, Mr. Councillor S. FIRTH in the chair. There was such a numerous attendance of members, as to give rise to some talk of a larger room.

It being the first meeting after the Exhibition, many interesting matters were conversed upon concerning it. It was proposed that each member note down such ideas and suggestions on Exhibition arrangements as he may consider of use for next year, as it was unanimously decided to have one.

Mr. W. B. Hatfield then proposed that the Society vote their best thanks to the many gentlemen throughout the country who so kindly contributed to the Exhibition, which was unanimously acceded to.

It was agreed, on the motion of Mr. Taylor, that a special vote be sent to the Rev. H. J. Palmer and the members of the Liverpool Society for their large and interesting contributions.

The following gentlemen were then unanimously elected members:—Messrs. Johnson, Hibbert, Shields, Mottershaw, and Hayball.

Mr. J. H. Rawson then showed a negative with some map-like lines indented in the film, which caused much discussion as to the cause.

It was proposed that the members should commence a competition illustrating a subject to a given word suggested by the President, and the best pictures to be put in the Society's large album, with full particulars of the method of production; the first show of pictures to take place at the monthly meeting in April, and the word to be "Contentment."

After looking over and discussing a number of prints brought by Dr. Morton, J. H. Dickenson, Mr. Seaman, Mr. Pilley, and other members, a very pleasant meeting was brought to a close.

Dundee and East of Scotland Photographic Association.

The fifth regular meeting for the Session was held on Feb. 7th, in Lamb's Hotel, Dundee, when there were about thirty members present.

The minutes having been read and approved, it was arranged that the subject for the next monthly competition be "Portrait taken in Room."

Four new members were admitted, and one new application was handed in.

The routine business having thus been disposed of, the Chairman (Mr. W. D. Valentine) called on Dr. Tulloch to read his paper on "Shortcomings of Photography" (see p. 103).

A very animated discussion then took place, the Chairman leading off with the remark, that it was not fair to institute a comparison, as Dr. Tulloch had done, between an engraving and a photograph, unless the latter was printed on rough paper or in platinotype; and he also said that the widerspread use of highly albumenized paper for large pictures had done much towards preventing the artistic development of photography.

Mr. Valentine remarked, that the greater intensity of the shadows at the edges was in great measure due to the use of wide angle lenses.

Mr. G. D. Macdougald thought that the too great intensity of the shadows could be remedied by a full exposure. Dr. Tulloch stated that in a picture there should only be one point of pure black, whereas in a photograph there were dozens of such points.

The Chairman proposed a hearty vote of thanks to Dr. Tulloch.

Mr. Geddes, Arbroath, then made a few remarks regarding "Halation: its Cause and Cure." In his opinion halation was caused by the space between the back of the plate and the dark slide, and he found that the evil was completely remedied by laying a piece of blackened cardboard on the back of the plate.

The Chairman said he thought this would not be of use unless it was placed in optical contact with the glass.

Mr. Macdougald thought that the cause of halation was that the particles of silver bromide dispersed the light through the film; and he also said that compound lenses were much more apt to induce halation than single lenses.

Mr. Mathewson had got halation in a plate which had even been backed with burnt sienna.

A vote of thanks to Mr. Geddes was passed.

A question was found in the question-box:—"Is there any advantage in fuming ready sensitized paper?" It was the opinion of the meeting that there was a slight benefit to be derived from this, as it neutralized the acid in the paper, and caused it to tone more readily.

Talk in the Studio.

Colotypic Prints.—We have received some excellent prints from Mr. Riley, of Humberstone Road, Leicester, and he tells us that he has turned out finished prints within four hours from the receipt of the negative.

Artistic Photo-lithography.—We have received from Messrs. Eyre and Spottiswood an *Edition de Luxe* of the "Jackdaw of Rheims," reproduced by litho-photography from the artist's designs; the work having been executed under the direction of Mr. George Sims. Although there have been several printings, the register is perfect.

Society of Arts.—Mr. Bolas' third lecture was delivered on Monday last, and recent methods of producing photo-intaglio plates were described, and some experiments were made illustrating the application of photo-engraving to the decoration of pottery.

Bichromated Gelatine for Damp Walls.—*Walzl's Monthly* says:—"This bichromate of potassium is useful stuff for many purposes beside carbon work. A friend of ours occupied a house which boasted of an English basement, and, as is not uncommon with those domesticated cellars, the walls were damp. After having wasted the "substance of years" in trying to introduce the "dry process," he came to us for advice. We suggested bichromate of potassium. He applied this, mixed with size. He allowed a sufficient time for the light to act upon it and render it insoluble before going over it a second time. Paper now "hangs on those *inner* walls," and, as far as dryness goes, a bone is nowhere beside it."

Hawthorne and his Photograph.—Mr. Henry A. Bright, Hawthorne's most intimate English friend, gave the following account to Mr. Julian Hawthorne, in contradiction of a statement that his father was entrapped by Mr. Motley into having his photograph taken. "I went with him," he says, "to a photographer, as he had promised me a photograph of himself. He gave his name, and Mayall came up in a great state of excitement. Hawthorne got very shy, and grasped his umbrella as if it were the last friend left him. This, of course, was taken away from him by the photographer, and a table with a book upon it was put in its place. 'Now, sir, please to look intense!' He was afterwards told to look smiling (at the portrait of a lady!). I chose the 'intense' one, and afterwards had a copy of it taken for Hawthorne's friend, Mr. Fields." After Hawthorne's death, a copy was sent to Mr. Fields, others were sent to Mrs. Hawthorne and Longfellow. The original hangs in Mr. Bright's own room.—*Echo.*

New Paper Material.—Consul Gade, of Christiannia, has submitted to the United States Government a report relative to a new industry, or, rather, the use of a raw material for the manufacture of paper, which will soon be in use in Norway and Sweden. Among the raw materials already employed in the manufacture of paper are rags, esparto, straw, and wool; but all these are expensive, and this new and cheaper one, which consists of white moss, will now be added to the list. The moss is found in immense quantities in Norway and Sweden, but it is not the living plant as it grows in the fields which is used for making paper, but the remains of this kind of moss which have gradually accumulated in the woods. The mouldering which the moss has gradually undergone constitutes a preparation for the paper manufacture made by nature herself. A factory is now building for the manufacture in Sweden, and examination has shown that near this place many millions of pounds of the raw material are to be found; in fact, a quantity sufficient to support a large manufactory for many years. Paper of different thicknesses, and pasteboard made of the white moss, have already been shown, the latter even in sheets three-quarters of an inch thick. It is as hard as wood, and can easily be painted and polished. This manufacture is said to be very well suited for taking the place of wood for many purposes. It has all the good qualities, but none of the defects of wood, as it neither cracks nor warps. The pasteboard can consequently be used for door and window-frames, and for architectural ornaments of all kinds of furniture. —*Journal of the Society of Arts.*

Photographic Club.—At the next meeting, on February 20, the subject for discussion will be "On the best methods of obtaining black and white negatives on dry plates."

To Correspondents.

*** We cannot undertake to return rejected communications.

TYRO.—1. The objective to which you refer would probably suit your purpose better than any other in the market. 2. To the optical centre of the lens.

W. L. G.—We will do our best to serve you, but cannot be quite sure of being successful.

ROBERT SHAW.—If you wish to have the best work, you cannot do better than to go to the maker of the lens for what you require.

J. FOSTER.—We will make the experiment as you suggest, and write to you as to the result.

HEATH and BULLINGHAM.—We do not know the address of the firm, but imagine you might obtain the information by applying to the Autotype Company.

E. W.—1. You should demand the compensation you refer to, but the tardy registration may somewhat complicate the matter if the case comes on for trial in a court of law.

H. P. T.—Thanks for suggestion, which will undoubtedly assist us.

G. M.—1. Perhaps you had better try Spooner's, in the Strand. 2. The maker will doubtless give you all the information if you write to him.

WALTER POLLARD.—1. But little has been done, and that little is hardly satisfactory. Dr. Liesegang, however, publishes a small book on the subject, and if you write to him, he will doubtless send you particulars. 2. We think you have succeeded very well indeed in the case of the fern picture. For a subject requiring more vigour you should size one side of the paper by floating it upon a warm solution of gelatine—say one part in ten of water—and afterwards you should sensitize it by floating it with the gelatinized side downwards. Under no circumstances are you likely to obtain the vigour and full gradations of a silver print.

W. S. S.—The first article of the series appeared on page 482 of our volume for 1882, but as many of the numbers are out of print, it is impossible for our publishers to supply you with a complete set. You had better advertise for the volumes of 1882 and 1883.

G. MACKIE.—Dissolve ten ounces of gelatine in sixty ounces of water, and to one-half add three ounces of chloride of barium, while four ounces of sulphate of sodium are added to the other half. On mixing the solutions, a kind of emulsion is obtained, which is allowed to set, and is washed in the ordinary way. Melt, and add chrome alum solution until it begins to thicken, when enough glacial acetic acid is added to restore the fluidity.

H. E. (Rochester).—We have forwarded the letter as desired.

G. K.—1. Several use it. 2. Write to the Eastman Dry Plate Company, Rochester, New York, United States of America.

M. S. P.—We are not sure just at the moment, but will endeavour to ascertain the address of the advertiser to whom you refer. 2. If you address a letter for Mr. Crowe, to the care of the Hon. Sec. of the Liverpool Amateur Association (Rev. H. J. Palmer, Clare Mount, Wallasey), it will doubtless reach him. 3. We believe not, but a moderately skilled mechanic would have no difficulty in making one. 4. It should not cost more than £2 or £3, and could be had from any dealer in photographic apparatus.

E. A. MAXWELL.—It never came into general use in this country, and we believe the inventor has returned to St. Petersburgh.

S. W. S.—Your case seems pretty clear, and you had better now make a definite claim to cover the loss to which you have been subjected. Of course the other party may reasonably claim facilities for making an exactly comparable experiment, and in your letter making a claim, you should offer to assist him in this. You should claim for loss of business as well as for the value of the goods destroyed. Of course our advice is based upon the assumption that the mounts were supplied expressly for photographic use, and that they occasioned the damage. When goods are supplied for a definite purpose, and by a person who is in the habit of supplying them for this purpose, there is held to be an implied guarantee that they are fit for the purpose.

J. C. L.—You might perhaps do well to write to Marion and Co., of Soho Square.

S. C. RILEY.—Thank you for the collotypes, which are very good; you will find a few words about them in another place.

N. K.—As you are evidently a novice, we should advise you to begin with an apparatus for pictures 5 by 4 inches, and you will be able to obtain information as to prices, &c., from the dealers who advertise in our columns.

P. H. DAVIES.—The lantern you describe will answer the purpose very well indeed, and full information as to the method of working will be found in the YEAR-BOOK.

A. RICHARD.—All depends upon the construction of the lenses, and it is extremely probable that they might not work satisfactorily as a combination. You might try about six inches, as an experiment.

H. JARVIS.—Thank you for your letter, which we shall use shortly.

P.—1. We shall publish a short series of articles on the subject shortly. 2. No; it is generally convenient to leave about 2 feet as a skirting. 3. About 7 feet. 4. Not much less than 10.

LATERNA.—The reflector will not add very much to the illumination, but you had better let it be larger than the condensers.

ENQUIRER.—It looks to us as if the mounts were in fault; but you had better test the matter by cutting some prints in two, and mounting one half of each on the new cards, the second halves being mounted on cards which have proved satisfactory. If all the samples are kept in a slightly damp place and under similar conditions, you may soon obtain sufficient information to justify you in making a claim. See answer to S.W.S.

FRANK LASHAM.—1. If you have purchased the negatives, you must have a proper transfer of copyright for each. 2 Certainly not. 3. Such additions would not affect the copyright of the original, and even if no copyright exists with respect to the original, you can register a copyright as regards the altered pictures. 4. Yes.

DRY PLATE.—1. To harden the water, add a little sulphate of magnesium (Epsom salts)—from one to three grammes to each litre. 2. Simply because it takes a longer time to heat the large quantity, and it cools more slowly. 3. By using hard water, you obtain the emulsion in a more concentrated condition—that is to say, it absorbs less water during the process of washing. An emulsion can be more quickly washed in soft water, and it is easy to harden it by soaking for a few minutes in alcohol. As regards quality of the resulting emulsion, we do not think it makes any difference whether hard water or soft water is used, provided that no specially injurious material is present in either case. Write again if we have not made all clear to you.

W. DAVEY.—We will endeavour to ascertain. Have you Dr. Liesegang's little hand-book on the subject?

W. E. CRAIG.—1. It is sufficient if the precipitate subsides satisfactorily, and you pour off very carefully; otherwise it would be well to wash once or twice more. 2. We could mention several who coat on the bare glass, but some adopt the other method. 3. Add a solution of sulphide of potassium.

The Photographic News Registry.

Employment Wanted.

Retoucher & Assist. (Young Lady).—Miss J., 10, Edith-rd., Peckham, S.E.
Lady for Reception-Room.—E. D., 50, Crockherbtown, Cardiff, S. Wales.
Vignetter, good hand, first-class firm.—G. E. Lann, Market-st., Brighton.
Retoucher.—F. Piper, 56, Walford-rd., Stoke Newington, N.
Artist, for Monochrome and Water Colour.—Z. A., *Photo. News* Office.
Operator, clever at lighting, &c.—F.W., 1, Claylands-rd., Clapham-rd., S.W.
Reception Room, Young Lady ot exp.—M. A. G., *Photo. News* Office.
Reception Room, Shop, Books, &c.—W. C., 160, Arlington-rd., N.
Youth, as Assist Op. or Printer.—L. D., Cambridge-gardens, Notting Hill.
Assistant Operator and Printer.—E. D., 576, Sunderland-st., Pimlico.
Recep. Room, Mounter, &c.—M. W., 68, Parma-cres., Clapham Junction.
Printer or Gen. Assist. (young man).—Evans, 9, Church-st., Folkestone.
Reception Room, Mount, Spot, Books.—F. W., Chryssell-rd., Brixton-rd.
Printer and Toner.—Printer, 21, Crick-st., Burdett-rd., E.
Operator, Retoucher, Enlarger.—Alpha, 115, High-st., Camden-town.
Artist, well up.—P. Eckhart, 105, Hall-pl., Hall-pk., Paddington.
Retoucher and Colourist (lady).—J. J., *Photo. News* Office.
Artist, medallist.—Miss A. H., 88, Stoke Newington-rd. N.
Operator or Manager.—A. E. Walker, Eastwood, Notts.
Assist. Printer & Vignetter.—G. E. Cann, Market-st, Brighton.
Assistant Operator, or Manage Branch.—H. W., Finsbury-circus, E.C.
General Assist., good all round.—X. Y. Z., 49, Ledbury-rd., Bayswater.
Assist. Op., &c. (town only).—C. H. E., 50, London-st., Tottenham-ct.-rd.
Assist., can print, tone, paint enlarg.—Silver, 40, Gower-st., Birmingham.
Assist., enl. on Morgan's pap.—F. P., 16, Rochester-sq., Camden-rd., N.W.
Assist, retouch heads for publication.—Retoucher, *Photo. News* Office.
Reception Room, as Improver.—X. Y. Z., 5, Jesse-ter., Reading.
Assist. Operator, could manage.—F. B., 2, James-st., Illey-rd., Oxford.
Reception Room or Shop (Lady).—A.S., 77, City-rd., N.
Operator, wet or dry.—C. O., 25, Duke-st., Bloomsbury.
Retoucher, first-class.—Artist, 15, Hastings-st., King's Cross, N.W.
Artist in Oil and Water.—J. J. Gibson, 32, Pembroke-sq., Kensington, W.
Op. & Ret., wet or dry.—F. J. M., 6, Brockham-ter., Willsbridge, nr. Bristol.
Operator and Retoucher.—Alpha, 10, Hotspur-st., Kennington-rd., S.E.
Retoucher and Min. Artist.—Miss Lea, 443, Coldharbour-la., Brixton.
Silver Printer and Toner.—F. C. M., 35, Vincent-sq., Westminster.
Gen. Assist., all round.—G. L., 49, Ledbury-rd, Bayswater, W.
Op. & Retoucher, 50/- weekly.—H. H., 116, Cheetham-hill, Manchester.
Gilder, Joiner, Fitter-up.—A. J., 31, Charles-st., Southboro', Kent.

Employment Offered.

Young Woman, charge of Printing Room.—W. Winter, Midland-rd., Derby.
Printer and Toner, young, for City.—Viaduct, *Photo. News* Office.
Retoucher, first-class.—Negretti & Zambra, Photo. Dept., Crystal Palace.
Printer & Toner (female) to manage.—Holden & Co., 12, City-rd., Bristol.
Photo-lithog., perm. if comp.—X., c/o Smith & Co., Gresham House, E.C.
Traveller, to Sell Backgrounds.—Photo., 5a, York-ter., Clapham.
Printer, skilful Vignetter.—Morgan and Kidd, Helio House, Greenwich.
Silver Printer and Toner (good).—W. Wilson, 77, De Beauvoir-rd., N.
Photo-Lithographer & Photo-Etcher.—Meek & Co., 4, Cable-st., Liverpool.
All-round hand, wet & dry.—Tune & Co., Warrington House, Tottenham.
Retoucher of first-class ability.—H. W. Winter, Alexandra Rooms, Derby.
Printer, first-class, to Manage.—Byrne & Co., Richmond, Surrey.
Printer & Toner, dry-plate.—H. Friedmann, The Grove, Stratford, E.
Assist. Landscape Printer.—Carl Norman, Graphic Villa, Tunbridge Wells
Operator for Ireland.—D. W., c/o Marion and Co., Soho-sq.
Printer, young and clever.—J. S. Catford, Art Gallery, Ilfracombe.
Assistant Operator immediately.—P. G., c/o Marion & Co., Soho-sq.

THE PHOTOGRAPHIC NEWS.

VOL. XXVIII. No. 1329.—*February* 22, 1884.

CONTENTS.

FADING OF PHOTOGRAPHS OWING TO HYPOSULPHITE IN THE MOUNTS.

FADING and fugitive as ordinary silver prints are admitted to be, the photographer who works carefully and takes such precautions as are generally recognized to be desirable, may reckon on a life of at least six or eight years for his pictures; provided, of course, that they are not exposed to especially injurious influences such as damp, when fading may set in at a much earlier stage.

A great, and by no means unrecognized evil, is the general use of sodium hyposulphite as an "antichlor," after the bleaching of the paper pulp; and it not unfrequently happens that a large quantity of the deleterious salt remains in the paper from which photographic mounts are made. It is scarcely necessary to say that a print, if attached to such a mount, is calculated to rapidly fade away.

There is no disguising the fact that at the present time a very large proportion of the mounts in the market contain so much sodium hyposulphite as to cause the rapid fading of any albumen print mounted thereon, and photographers are, perhaps, more interested in this matter than may at first sight appear. What, indeed, is calculated to so much damage the reputation of a photographer as for his pictures to fade in the course of a few weeks—or even days?

A ready means exists of testing for hyposulphite, and for testing, a card should be cut up and soaked for about half-an-hour in the smallest quantity of water, and after the water has been filtered off, it should be tested with iodide of starch solution, as directed on page 114 of our volume for 1883. We quote the directions for preparing the iodide of starch solution:—

"To prepare the iodide of starch solution, about twenty grains of starch are mixed with a few drops of cold water, after which a teacupful of boiling water is poured in, so as to break up the grains and form a very dilute starch paste; when this is quite cold, tincture of iodide is stirred in, not more than one drop being added at a time, until an intensely blue liquid is obtained. A little of this is next diluted, until the blue shade is *only just perceptible*, when a teaspoonful is placed in a white saucer; and if a solution containing as small a quantity as one-hundredth of a grain of hyposulphite is added to the liquid in the saucer, the blue colour will disappear."

If it is desired to make the testing very accurately, two white saucers should be used, and the same quantity of the blue iodide of starch solution poured in each. When the addition of the liquor in which the pieces of card have been soaking is made to the contents of one saucer, an equal quantity of water should be added to the contents of the second saucer. In this way the least diminution of blueness becomes visible; the contents of the second saucer serving as a standard of comparison.

If a mount taken from a batch shows any indication of hypo when tested as above, the cards should be rejected without hesitation.

There is no doubt as to the liability of a photographic stock dealer for all mischief which may happen as a consequence of faulty mounts which he may supply; not only substantive loss, but what is far more important—damage to reputation. One essence of an implied guarantee is the supplying of goods for a definite purpose, and when this is done, the vendor is responsible if they are not fit for the purpose. It is scarcely necessary to say that a photographer who buys his mounts from an ordinary stationer or printer has no guarantee, as in this case it cannot be supposed that the person supplying them has a sufficient knowledge of photography to understand what is needed. If, however, the printer is in the habit of supplying photographers with mounts, he would be held responsible for their quality in respect to photographic use.

Before making a claim for compensation, we would recommend that a print be divided into two equal parts, and one part be mounted on a card known to be reliable, while the other half is similarly mounted on the questionable cardboard. If both are now kept under precisely similar conditions as to moisture and temperature, the rapid fading of one may be taken as evidence of the faulty nature of the mount.

We may mention that we have numerous complaints of damage caused by mounts, often several in one week; and the photographic fraternity would be under considerable obligations to anyone who should make those who supply such mounts pay for their neglect.

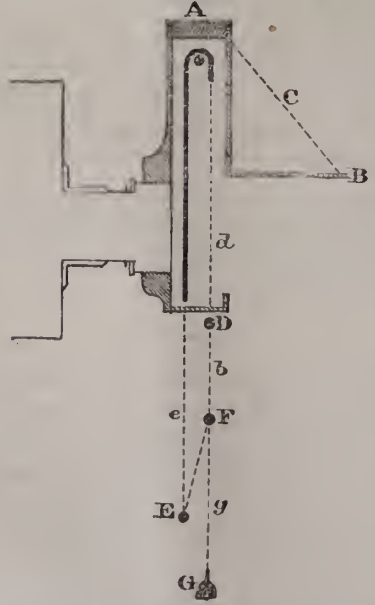
NOTES ON MR. HART'S LECTURETTE.

MR. HART'S lecturette, delivered to the members of the London and Provincial Photographic Association, was as instructive as it was interesting. It is some time since the subject of residues has been considered in a paper brought before the notice of any of the photographic societies, although it is one of those subjects which concerns the professional photographer to a considerable extent, and even now is very far from being exhausted. Judging from the discussion which followed, there is a very wide difference existing among the various practitioners in the percentage recoverable; Mr. Hart averring that in his own practice he is able to recover as much as eighty-five per cent. of the silver and gold employed. Some very practical suggestions were offered; among them we note Mr. Ayres' plan of pouring the liquefied metal into a vessel of water, thus obtaining a granulated form, at once familiar to most of us. In this state the metal may easily be cleansed from impurities should any exist.

Mr. York, who conducts his operations on a large scale, finds paraffine oil barrels of good service for holding the various liquids during precipitation, and he strongly recommended them for this purpose. We know several photographers who have pressed paraffine oil barrels into their service for a similar purpose, and from our intimate acquaintance with their usefulness, we can thoroughly endorse Mr. York's good opinion of them for the purpose named. One great thing in favour of their adoption is the comparative cheapness at which they can be obtained from any oilman's, viz., something like half-a-dozen shillings each; while for durability, they remain unsurpassed. So far as we are aware, no inconvenience has been experienced from the small amount of oil attached to and contained in the pores of the wood; should anyone feel fastidious on this score, the barrels are easily cleansed with a few pails of hot water containing some common potash, following this treatment by a prolonged soaking. An ordinary wood tap inserted about four inches from the bottom permits the supernatant liquid being drawn off without disturbing the precipitate. Probably the majority of photographers are more interested in the most efficient method of collecting the residues than the after operations of refining, which on any but the most limited scale can be so much better performed by professed refiners than by the photographer with limited means at his disposal; and here we may say that the use of common salt in the treatment of washing waters and other solutions containing free nitrate of silver is frequently, nay, nearly always, attended with loss. Hydrochloric acid is far more effectual, both in the matter of time for precipitation, and certainty of result.

A SHUTTER FOR THE STUDIO.

AN old form of shutter, made by Dallmeyer in 1861, has recently been brought again into notice as extremely well adapted for studio work. We take the sketch from the *Journal of the Photographic Society*, November 15, 1861.



A is a small box which fits on the hood of the lens, and the front or flap B is kept up by an elastic cord C; while in this position it serves as a shade for the lens. Inside the box, at the top, is a roller working on points at each end, and over this roller passes the shutter; this being made of a flexible material composed of strips of wood glued on thin leather. In the section the flexible shutter is shown by the thick line. A loop of string, *d e*, depends from the two ends of this curtain, and on the loop three rings, D, F, and E, are fastened, while to the ring F a tassel is attached by means of a string, *g*. By pulling down either the ring D or the ring E, the shutter becomes closed, and it may be opened for focussing or for a long exposure by pulling the tassel *g*, after which it is closed again by pulling either E or D. For a quick exposure, it is merely necessary, after closing the shutter, to pull D or E, whichever happens to be at the top. It will be noticed that the lower part of the lens is uncovered first and covered last, this being, in ordinary cases, no disadvantage. If, however, it is wished to make the shutter open from the centre, all that is required is to make the flexible shutter somewhat longer, and to cut two round holes in it.

By hanging a weight to the ring D or E, as the case may be, and adopting a pneumatic release, the shutter may be made automatic.

Although the above-described shutter is excellently well adapted for studio use, it is not likely to prove very convenient for landscape purposes.

TRIP TO SAHARA.

BY A COCKNEY.*

THE Customs' officer at Marseilles did not think much of me or my luggage. "Rien à déclarer?" he said, briefly, waving a bit of chalk. No, I said, there was nothing contraband about me; I only had a few dozen photographic plates. "Ah! ah! plaques photographiques—si, si!" and he smiled knowingly: "à collodion ou à la gelatine?" He asked the question much as a garçon at Véfour's demands whether you will take your artichokes *à l'huile* or *à la sauce?* Finding him so well grounded in matters photographic, I naturally rejoined that people did not travel with collodion now. "Ah, well, you havn't many, in any case," was his rather disdainful remark. I may add that he scorned to look at them.

Marseilles, with its broad, handsome streets, has several good studios; but the time between the arrival of train and starting of boat for Philippeville leaves you little leisure for anything beyond a stroll in the town and a breakfast in peace and quiet, very grateful after the rattle of an express train.

Algeria is usually visited by taking steamer across the Mediterranean to Algiers; but there is another not less direct route to the town of Philippeville, which is more east than Algiers. The latter route is on the highway to Constantine, the most romantic, as it is the most interesting, of Algerian towns; while a railway, moreover, helps one a hundred miles and more south, towards the Great Desert. The French Government, indeed, promises an extension of this railway right into the Desert—fifty miles over the sands—to Biskra, a large oasis, important on account of its large plantations of date palms, no less than from the fact that it is the junction of three caravan routes going south into the Soudan. Biskra is, in fact, my goal for the present, and at 5 p.m., on the day following my start from London, I am on one of the fine steamers of the *Compagnie Transatlantique*, bound for Philippeville. I think the distance is about 500 miles, but I am not quite certain; all I know is, that, after a most pleasant voyage of two nights and a day, I am landed on the African coast in the grey of a morning.

But I am getting on too fast. A word about the steamer. My London ticket is entitling me to privileges unprecedented, of which I must make some mention. Not only does it give me my meals free, but, from an important document hung up in the cabin, I am told what my strict rights are, so that the steward cannot take me at a disadvantage. Thus, the breakfast and dinner he must serve with napkins "damassées," while my service must be "porcelaine de choix," and my glass "cristal de choix." I am rather proud of this, as I strut the quarter-deck, for

* Continued from page 100.

I know that the second-class passengers (by this same announcement in the cabin) are only to eat off "porcelaine ordinaire," and drink out of "cristal ordinaire." Moreover, this same interesting pronunciamento specifies the hours of meals, and of how many *plats* they are to consist; how I am entitled to coffee and cognac; and, in case there are more than seven first-class passengers (and I am glad to say there are), I am to have the choice of four desserts instead of the three.

But there is a dark as well as a golden lining to my cloud of travel just now, to which I must allude. I mentioned in my first letter how carefully I had cut down every ounce of baggage, for you need not be an old traveller to know that your peace of mind depends upon the state of your baggage. Well, I am carrying into the desert an article which one of my companions designates the "nightmare." It is a dark-room reflector lantern of Marion's, and its history is this. A good friend, whose advice I sought on the subject of a trip to Algiers, said, "Go to Biskra, and I will give you a line to an old comrade I have there just now." The opportunity was too good to be lost, and I wrote to the Biskra gentleman; in my note I spoke of a speedy visit, and asked if I could be the bearer of any little object—photographic, microscopic, scientific, or what not. To him, also, the opportunity was too good to be lost, apparently, and the day before starting came a note, bidding me look on page 10 (I think it was) of the Year-Book, and bring him one of the lanterns there mentioned. I did not know the size of the lantern at that time; I do now. It is half the size of the Gladstone bag I carry, while on account of its fragile character—for glass and all, it is still in the same cardboard box forwarded from Marion's—the utmost care is necessary in handling it. No wonder, then, that I start up in my berth two or three times at night, and cry out about that lamp. "What on earth do you want?" says my companion underneath me in a querulous voice, as he raises himself and his warm clothes. "My lamp," is my reply; "I want my lamp." "Oh! bless your lamp; there it is where you put it, in a corner of your berth."

The captain and doctor breakfast and dine with us, and enjoy their meals so heartily that I cannot help thinking that they are never so well cared for as when passengers are with them to secure damassed napkins, choice porcelain, cut glass, and four desserts. The doctor discovered his wine corked on two occasions, and got it changed by the steward; but I noticed he did not find out the defect until he had drunk three-quarters of the bottle. I noticed, too, despite the magnificence of the catering, the gilding in the saloon, the marble panels, and shining mirrors, there was some sea sickness on board, which the all-pervading grandeur was powerless to avert.

A clear blue sky, and a sea still more blue, there were to gaze upon all day, but from early morn till late into the night not a single craft hove in sight. The whole live-long day passed away upon the silent sea without a speck on the horizon, for it seems that not until you get close to the African coast do you get into the track of vessels.

What will the first glance at Africa be like, and on what will you spend your first plate? is a question I ask myself. Murray in his Guide, I find, says that for every lion you kill you get £20, and I am thinking of recouping my expenses by encountering a monarch of the Atlas. As to photographing lions, I did ask one of my friends before I came away what sort of lens he thought best for the purpose, and he recommended one of long focus—the longer the better, he said. Now, as mine has not a very long focus, I think I shall let the lions be; I shall confine myself to going among the Arabs and taking some picturesque groups. And then it occurs to me that I read only last year of a European traveller in Africa who was stabbed to death by the natives while occupied in focussing with his head buried in the dark cloth. Really I don't half like the prospect before me, and begin to wish I was back again in the Tottenham Court Road.

I wonder, too, whether sand shoes will be any use in the desert—whether the yellow pair I wore on Margate sands last year would have been comfortable wear? Whether—but I had better be off to bed, and look after that dark-room lantern, for we land at daybreak.

Whirr—whirr—whirr goes the cable, and rattle, rattle, goes the donkey engine—we are there. I jump up: the sun has not yet risen, but it is light enough and clear enough. In ten minutes I am on deck to get a first peep of Afric's shore. Alas! no yellow sands washed by the azure sea, no tall palm trees rising straight towards the burning sun, no camels laden with spices of Araby to greet the eye, but instead, a green hill dotted with pleasant white houses, for all the world like Vevey on the Lake of Geneva, or not unlike the smiling Rothsay on the Clyde.

This is Philippeville. I land, my precious (!) dark lantern in hand, and my camera enveloped in an overcoat and encased in light waterproof, strapped over my shoulder. All is quiet on the quay, for it is very early, and not half-a-dozen people are stirring. Still, somebody has left four heaps of old blanketing on the granite parapet, while yet two other similar heaps are lying on the stone steps of the hotel as I enter. These heaps of blanket I find out afterwards are Arabs, to whom, it appears, the country belonged before the French relieved them of the responsibility.

But blankets turning into dusky Arabs is only the first surprise of many. To one who sees an Eastern country for the first time, the early impressions are wonderful. Here comes a whole procession of Ali Babas and their little donkeys, laden with wood; here is Mustapha, the tailor, seated cross-legged at his open shop-window; here is the Grand Vizier on horseback; here is poor little Moock with his big turbaned head and bandy legs; and here are baggy-trousered Ganems by the score.

Outside the town by a dusty road, and there, instead of a quickset hedge, is one of gigantic cacti. The cactus leaves measure fifteen inches long, and the hedge is a dozen feet high—as you look upon it, leaf growing out of leaf, a living example of the error of trying to be independent, and doing without stalk or stem, for the failure is so painfully ludicrous, it reminds you of nothing so much as the wonderful tropical plants they put in the transformation scene of a pantomime; the whole thing is to the Cockney eye so stupidly exaggerated.

I must wait for the night before I can fill my dark slides, so the cactus hedge must wait too. The damp sea-air is particularly injurious to gelatine plates, as everybody knows, so I have had my packages carefully enveloped in tin-foil, which previous experience has told me is one of the best means of assuring from damp. I might make use of the red lamp I carry, for filling my slides, but I prefer to follow Mr. Cowan's advice, and work in the dark. I open my slides and put them in proper order on the bed—it is a most safe changing table—and then having carefully placed all six plates, face downwards, in their places, I take a series of printed numbers, which I have for the purpose, ready gummed and perforated, and as I detach and moisten one after another, I stick them consecutively on the back of the plates, according to the numbers the slides bear. A little rehearsal in the dark is all that is necessary to proceed smoothly afterwards; and if you will only take time, and mind what you are about, you can work as surely as by candlelight.

PHOTOGRAPHIC RESIDUES, AND THE RECOVERY OF THE VALUABLE METAL THEREFROM.

BY F. W. HART, F.C.S.*

In selecting the subject for the lecture you did me the honour to request me to deliver before this Society this evening, I have chosen one to which I have given considerable attention for the

* Read before the London and Provincial Photographic Association.
This Treatise is Copyright.

past thirty years, so, without further preface, I enter into practical working.

FURNACES AND APPLIANCES.

When possible, it is best to construct a fire-brick furnace. This is not a difficult matter. Dig a pit about 6 by 3, and 3 feet deep; lay a foundation of brick 3 by 2 at one end; on this form the ash-pit of the fire, 12 inches wide, 14 from back to front, and four bricks high laid on their sides; this, with the fire-clay luting or cement, makes it about 11 inches high—of course, open in the front. Over the front lay a plate of iron 5½ inches wide, 21 inches long, and ⅜ thick. Lay across the pit, at back, an inch bar ⅜ thick. You will now have an opening of 12 inches between the iron edges; on these the loose fire-bars are to rest. Now build up the furnace, 12 by 14 inches, to the level of the top of the pit, putting an iron bar (5 by ⅜) across the pit at the top of the furnace, and another 2 inches above the level of the fire-bars as stays to the front. For the chimney remove some earth behind the body of the furnace, 12 inches deep from top, 14 inches wide, and 18 inches long; in this excavation, form the throat of the chimney of fire-brick 4½ inch square, the top being 4½ inch below top surface of furnace; at the end raise a chimney 9 inches square inside for two or three feet, where insert a damper plate, then contract gradually to a height of 12 or 15 feet; the upper portion of 6 feet may be a stout 4-inch flue-pipe. Next fill in the sides and back with pieces of common brick and dry earth, and with an iron cover in two parts and a grating over the pit, your furnace is complete at a cost of about £3. Other furnaces are built on the floor-level, as my own, with hood for carrying off fumes from chemical operations; then there are portable furnaces of fire-brick cased in iron; and lastly, the extreme of portability is reached in the gas furnace. These latter are very convenient for trial reductions of small quantities, but when using a No. 6 clay crucible, which is a very moderate size for reductions, the pit furnace will be found the cheapest form of all; next to that the iron-cased fire-brick; such an one also forms an excellent appliance for keeping the work-room warm; their cost is from £4 to £6, to take a No. 6 pot. For fuel use gas coke—select the dense light-coloured or grey-looking, reject all the spongy black pieces and all dust; break the hard dense pieces into such sizes as will pass readily between the pot and sides of the furnace. To prepare the furnace for use, place in the centre of the bars a fire-clay stand or piece of fire-brick about 2½ inches thick; on this, for special precaution till experience in firing is gained, place a skittle pot stand easily fitting the bottom of the crucible; this will protect the bottom against currents of air through hollow places in the fire near the grate. Now place plenty of wood all round the stand, a light sprinkling of coals, and some of the softer coke, set light, and let it burn up gradually; the skittle pot stand, crucible and cover, the meantime being placed mouth downwards over the cover of the furnace a little apart, to allow the hot gasses to gradually dry and heat up the pot and stand. By this time the fire will need attention. Put a 3-inch layer of broken coke on that. Now put the skittle pot. stand, still mouth downwards, and the crucible on the top of that; cover up the furnace. They will now advance gradually to a low red heat. Then shift the crucible to one corner of the furnace, and the stand to opposite corner. The tongs must always be heated up before touching the crucible. Clear away the ignited fuel from over the solid stand, and place the open stand on it, and into it the crucible, now mouth upwards, and place the cover on. Now consolidate the fire with the poker and fill up all round with fresh coke, ramming with the poker as you proceed till it be level with top of crucible; partially close the damper so as to only keep the fire at a bright red heat. The crucible is now ready for its charge after glazing; to do this, throw in a few lumps of borax; when this has swollen up to a spongy mass, take the iron stirrer (never use the poker) kept solely for the crucible use, and rub it all over the inside of the red-hot crucible. We will now leave this and retrace our steps, and consider the collection and preparation of chloride of silver.

CHLORIDE OF SILVER.

The precipitation and collection at the present time is mainly from the print washing waters. These are best precipitated with commercial hydrochloric acid; this in a weak solution has no solvent power over the chloride of silver, neither does it add materially to gravity. Common salt, as usually employed, is objectionable on both grounds; the precipitate does not subside so readily when it is employed, and, being a cheap substance, unthinking operators usually add ten or twenty times more than needed for the purpose, and thus increase both evils. For the receptacles of the washing waters conical jars in stoneware, with the greater diameter at the bottom, are to be preferred to all others.

After each addition of washing water and acid it is vigorously stirred and left to subside, then, on clearing, a glass developing-cup or measure is dipped in to obtain a sample, a drop of hydrochloric acid added, and if there is no opalescence produced, the clear solution can be decanted by tipping the jar or syphoning off, or an upward filter syphon employed, such as I introduced about 1863, description of which will be found in journals of the time.

This goes on till a considerable deposit is collected at the bottom. The jar should now be filled up with clean water to take up any foreign salt or excess of acid, and when clear, pour or draw off as close as possible; pour the residue on to a shallow dish, and put into an oven or other warm place to dry off.

METHODS OF REDUCTION, WET AND DRY.

The wet is as follows:—Instead of pouring the thick residue from the jar into a shallow dish, let it be placed in an open-mouthed jar, into which place a small porous pot such as is used for voltaic batteries; or, in the absence of a porous pot, procure a bladder, fill it with weak acid solution, into which is inserted a plate of zinc with a copper wire attached; to the other end of the wire attach a plate of silver (an old spoon will do), and leave it undisturbed for twenty-four hours; by this time the chloride will have been reduced to the metallic state, the zinc remaining; porous septum and plate of silver is now removed, and adhering particles of silver washed off. The silver is now transferred to a larger vessel, and repeatedly washed till a sample of the clear solution gives no precipitate or cloudiness on the addition of a solution of carbonate of soda. The liquid can now be finally drained off, and the precipitate dried for sale or use; if for sale, it had better be put into a borax-glazed clay crucible with about five per cent. of a mixture of dry carbonate of soda and nitrate of potash, melted, and poured into the ingot mould.

THE DRY OR FURNACE OPERATION ON CHLORIDE OF SILVER.

Process A.—The thoroughly dried chloride of silver is mixed with powdered resin in the proportion of two parts of the chloride to one of resin, passed through the fine sieve two or three times, and then well packed in the crucible, and submitted to a low red heat. In the decomposition of the resin, its hydrogen in immediate contact with the chloride of silver reduces the latter to the metallic state, the hydric chloride passing off quietly, leaving the silver mixed with some carbon. The whole is then turned out on to an iron plate to cool, the crucible immediately returned to the furnace, and a mixture made of two parts dry carbonate of soda, one part nitrate of potash, one part dried borax. To these add sixteen parts of the silver and carbon mixture, and pass through the 36-hole sieve to thoroughly mix. The crucible should now be of a bright red heat; ladle in, and allow each ladleful to deflagrate and partially fuse, and so continue until the whole is added. Now see that the fire is well poked down, and the coke close in all round the crucible, and the furnace filled up to the level of the top of the crucible, put on the cover, and gradually increase the heat of the furnace to the yellow-white heat. After five to ten minutes of the strong heat, remove the cover, and stir up the contents of the crucible, and on withdrawing the stirrer, gather up on its end a portion of the flux floating on the surface, and examine it. If it is speckled with small beads of metal, give it a gentle stir round, and allow it to subside a few minutes longer; then gather up a fresh portion on the end of the stirrer; this time it will most likely be practically free from beads of the metal. Check the draught of the furnace. With the hot tongs grip the crucible on the opposite side to the lip, then steadily pour out the contents into the ingot mould, which must be perfectly dry and warm, and rubbed over with chalk. Have ready to hand a light wire hook to scrape out the crucible if necessary. The pot can now be put on one side, as it is not worth risking another reduction therein.

Process B.—The chloride must be quite dry, the crucible prepared as before directed. Take three parts dry carbonate of soda, four parts dry carbonate potash, three parts carbonate of calcium, and quarter of a part of fine white sand. All these must be very dry and intimately mixed by passing through the sieve two or three times. Take an equal weight of this mixed

flux and the chloride, pass them through the sieve for thorough mixing, and then place in a bowl by the side of the furnace. The crucible should now be of a bright cherry red heat. Introduce a small ladleful into the pot, and allow all effervescence to pass off before introducing a further quantity, and so on till the crucible is about two-thirds full of a semi-fused magma. Now cover the furnace, and allow the heat to rise to the yellow, occasionally looking in the furnace to see that the fire has no open channels through it, and that the contents of the crucible is in quiet fusion. On stirring the contents, it should feel very limpid, and on withdrawing the stirrer it should have a thin coating of flux, not showing the slightest bead of metal. The contents may now be poured out as in the A process.

(To be continued.)

THE INTENSIFICATION OF GELATINO-BROMIDE NEGATIVES.

BY DR. H. W. VOGEL.

The numerous difficulties incident to the intensification of gelatine negatives are sufficiently well recognized by all workers; while collodion negatives offer no special difficulties, and several methods are available, among which may be mentioned pyrogallic acid and silver, mercuric chloride, potassium permanganate, platinum chloride, and lead ferricyanide. All these methods of intensification—and, indeed, many others—have been tried for gelatine plates, but with but little practical result, except as regards the mercuric chloride process. Even this has had its opponents, who assert that negatives intensified with mercury are not permanent. Indeed, not a few photographers have found to their disgust that such negatives, which were stored up for future order, had become damaged even in so short a time as a year. These circumstances have created a distrust with respect to intensification, and manufacturers are continually asked to supply plates which will yield sufficiently vigorous negatives in the first instance. This is all very well in a good light and under favourable conditions; but in the bad light of winter it is not always practicable to obtain vigorous negatives directly, so a satisfactory method of intensification is essential in every-day practice.

Why, then, is it that many methods which are extremely satisfactory for intensifying collodion plates, are not adapted for gelatino-bromide work? It is only of late that the question has been satisfactorily answered; it is *because in the case of a gelatine plate, the intensifying materials not only act on the true image, but also on the gelatine film; while the collodion itself is absolutely inert towards the chemicals used.* In addition to the many materials employed in intensifying are extremely difficult to work out of the gelatine film, and if any portion is left behind, mischief may set in.

Let us take a few examples. During the last few weeks Dr. Eder has published some interesting observations, to the effect that uranium salts and ferricyanide of potassium exercise a coagulating affect on gelatine, and it is obvious that a mixture of these compounds, which has no action on the basis of a collodion picture, must considerably tan or harden a gelatino-bromide film, and therefore the intensifying action cannot be freely exerted upon the image itself.

The same kind of reasoning applies also to the ordinary lead intensifying process, in which the solution consists of a mixture of lead-nitrate and potassium ferricyanide, the gelatine being hardened as in the previous case. Potassium permanganate darkens not only the image, but also the whole of the film in the case of a gelatine negative, while in the case of iodine it is not possible to break off the intensification at the right moment, owing to the difficulty with which the reagent is washed out of the film.

Another circumstance which very considerably increases the difficulty of intensifying the gelatino-bromide image, is the circumstance that it exists wholly in the substance of the film, and not mainly on the surface, as is the case with a collodion picture. The image is far more accessible to the intensifying agencies in the latter case, and hence a pyro. or iron and silver intensifier will act satisfactorily, although so extremely slow in its action on a gelatine plate.

The best intensifier is, therefore, that which exercises no action whatever upon the gelatine film, and at the same time penetrates it with the greatest facility. We may safely say that as far as our present knowledge goes, the mercurial intensifiers fulfil these conditions most completely, and various methods of mercurial intensification have been carried into practice. We have in the first place, simple treatment with mercuric chloride followed by ammonia, and also the use of a mixture of mercuric chloride with potassium iodide and hyposulphite of soda (Edwards). Then again we have a similar mixture in which cyanide of potassium takes the place of the hypo (Eder); this latter working very satisfactorily, excepting so far as the cyanide becomes decomposed by exposure to air, the carbonate of potassium so formed tending to produce frilling. Negatives intensified by the method of Edwards certainly have a tendency to become yellow, and those simply treated with bichloride and subsequently with ammonia are less liable to change; but unless the hypo has been thoroughly removed by washing them later are liable to alteration. Not less important than the thorough removal of all traces of the fixing salt, is the effectual washing away of the whole of the excess of mercuric chloride before the plate is treated with ammonia. If both washings are thoroughly performed, the method of intensification in question (mercuric chloride followed by ammonia) is very satisfactory, and intensified negatives appear to be quite permanent. The slight change of tint which takes place on exposure to light is of no importance.

HENRI BECQUEREL AND PHOSPHOROGRAMS.

BY CAPTAIN W. DE W. ABNEY, R.E., F.R.S.*

I have thought that it might not be uninteresting to give a brief account of the manner in which M. Henri Becquerel has succeeded in viewing and measuring a part of the infra-red spectrum by means of phosphorescence. He notices, first of all, that if phosphorescent substances have a preliminary exposure given them, their luminosity is increased if they be subjected to heat, but lasts a shorter time. If an excited phosphorescent body be heated in the dark, the luminosity is seen first to become exalted, and then rapidly to die away. If a spectrum is projected on the surface of a phosphorescent tablet, the infra-red and red rays exert this same influence as does heat. Thus, if a phosphorescent plate be first exposed to light, the violet part renders it more luminous, whilst the green, red, and infra-red rays render it non-luminous. If the plate be again slightly warmed, the rays which have not been extinguished shine out with a greater intensity, and we have very dark lines in the solar spectrum standing brightly out on a black background. In this manner Edmond Becquerel, in 1866, showed some of the infra-red solar lines.

By stopping off the spectrum at an early part of the proceeding, the infra-red rays appear brighter than the rest, owing to the heating effect of the spectrum lying in that region; but this brightness rapidly dies away, and leaves blackness in its place. Thus, this part of the spectrum can be viewed in either of two ways, either showing dark lines on a luminous background, or luminous lines on a dark background. Another method, first used by Edmond Becquerel, was to excite the plate with white light whilst the spectrum was allowed to fall on it; but in this case it was necessary that the extinguishing rays should preponderate in intensity over the exciting rays.

Blende (hexagonal), reduced to fine powder, dusted over a gummed card, gives a green phosphorescent surface, which is rapidly extinguished. The experiments were conducted as follows:—Solar rays were reflected by the mirror of a heliostat, and passed through two parallel slits. The rays which passed

* *Photographic Journal.*

through the first fine slit fell on a prism of 60° of bisulphide of carbon, then on a lens which formed an image on the blende screen. Through the second slit, which was wide, rays of light fell on a flint glass prism, and then on the screen without passing through the lens. Thus, the infra-red of the first spectrum could be superposed over the violet of the second, which latter excited the phosphorescence, whilst the former extinguished it.

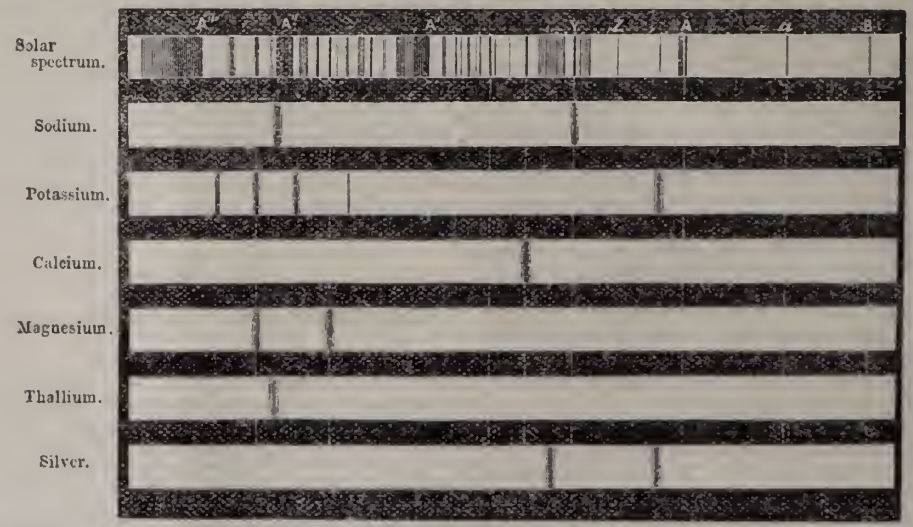
Henri Becquerel states that the blende allowed him to go further in the infra-red than other substances did, though he tried the following:—

Substance.	*Phosphorescence.*
Hexagonal blende	green.
Barium sulphide	yellow-orange.
„	green.
Strontium sulphide ...	yellow.
„	green.
Calcium sulphide	yellow.
„	green.
„	bluish-green.
„	greenish-blue } very luminous.
„	deep blue }

These bodies are all beautifully phosphorescent substances. From these experiments, he has mapped the solar spectrum, and determined some of the lines due to metal, some of which have been described before by myself. The annexed cut gives the drawing made by Becquerel. In another cut he has given the wave-lengths, which are as follows:—

The edge of A‴	12,200
Magnesium line between A‴ and A″ ...	11,310
Line to left of A″...	10,970
A″	10,820
Centre of A′	9,360
Another magnesium line	8,750
Y	8,190
Z	7,940
A	7,600

These lines are not quite in the position determined by the grating and photography, but are as near as can be expected from the method employed. The details given by photography are vastly superior to those given by phosphoreseence. Thus in the photographs, between A and Z a photograph will show 159 lines, whilst in the phosphorescent spectrum but 12 are shown. The greatest wave length shown is 14,800, a wave length which has nearly to be doubled before the limit of the solar spectrum is reached, as shown by Langley, Abney, and Colonel Festing. The lowest wave length reached by them was 28,000. With the grating 22,000 has been reached in the photographs. The region examined by Becquerel is that which it is easy to obtain by means of photography, and it seems as if below that point phos-



phorescence is incapable of giving any knowledge. The fact, however, that phosphorescence can give so much, is interesting; but great sharpness of detail can never be hoped for, since one particle of phosphorescent matter will excite a neighbouring one to a certain degree. The facts stated above as to the necessity of guarding the temperature at which the phosphorescent tablet is allowed to radiate has a practical bearing on the sensitometer now used, showing that the rate of emission may vary in summer and winter, if there be any great variation in the temperature. Mr. Warnerke has tested this matter, however, and it is probable that the interval he allows to elapse before exposing the plate to its action may have something to do with the negative results he obtained.

SHORTCOMINGS OF PHOTOGRAPHY.

BY DR. TULLOCH.*

With regard to light and shade, I consider they are not true to nature rendered by photography. Examine even the very best of photographs, and compare it with what you see in nature, and you must confess that the amount of black in it is far in excess of what you ever see in broad beautiful daylight. Cast your eye over a landscape and note that three-fourths of the whole is in half-tone, the other fourth divided between high light and deep shadow. Photograph the same landscape, and you will find a very different proportion. A tree-trunk or a large boulder innocent of black, so far as the eye could see, come out with shadows "Tarterian" in their depth. Let the light fall off so little that the eye can scarcely appreciate the shade at all, the sensitive plate will render it fourfold. The camera and the eye do not value light by the same standard at all: we judge by its luminosity, the camera by its actinic force—hence the confusion. Here we have a soft, delicate shadow, apparently only a little less intense than the high light; unfortunately, being reflected light, it has not actinic force in proportion to its apparent luminosity, and is rendered in the photograph as being many times blacker than it seems to the eye to be. But not only in individual parts does this hold good, for the whole general tone of the photograph is lowered from the very same cause. Those who practise landscape photography must have noticed how equally luminous the landscape and sky at times would appear to be. A photograph of the scene, however, represents the earth as many times blacker than the sky, and, whereas in nature the distant hills melted imperceptibly into the clouds, there was in the photograph a line of demarcation painfully plain.

To recapitulate, then, since we judge of light and shade by degrees of luminosity, and the sensitive plate by actinic value, and since shades are often luminous without being chemically active, I consider that light and shade as we see it is so far not correctly rendered in a photograph.

But photography has still another important shortcoming. I refer to the erroneous colour values which it gives us. I have already suggested, that as a mere matter of light and shade, the falling off of actinic force, even in feeble shadows, is out of all

* Continued from page 103.

proportion to the falling off of its apparent luminosity. I have now to go a step further, and remind you that in the matter of colour, of two tints, the brighter to the eye may be rendered the darker, and the darker to the eye come out the brighter. This is an entire reversal of our sensations, aud I need scarcely point out how scrious a fault this is. To be utterly false to uature is bad enough, but were we left the same range of contrasts, even if they were erroneous, our pictures might still be beautiful, as witness many charming effects in portraiture, where, although the various tints of the subject are erroneously giveu, the error is as often on the side of heightening contrast as reduciug it. In landscape work we are less fortuuate, for the prevailing colours in a landscape being various tints of yellow, brown, or green, all of about the same actinic value, we entirely lose the beautiful contrast which we see with our eyes.

Not only does the picture suffer in artistic effect from this, but should it happen that two objects of about the same actinic value lie side by side, no matter that one is orange and the other a dark olive green, they will be run together, and probably in many parts indistinguishable from each other, thus introduciug an element of great confusion. I was very much struck by this some time ago, photographing at the Gaunseley, near Breechin. To look up the water from the bridge the scene was beautiful. A few large boulders at the edge of the stream were the darkest objects, then the wet banks only a little lighter, then the dry earth above in still lighter tints of red and brown, above that, dry grass strewn with withered leaves, and last, the trees—everything from light yellow to deep sombre olive green. I was considerably disappointed, on printing from this negative, to find that to distinguish this tree from that, or to discover where rocks terminated and banks began, I had to hold the print within four inches of the eye. There were no beautiful contrasts—indeed, a few feet away it was difficult to make out even the nature of the subject; beyond that there was a sky, and something white (water perhaps), running down the centre of the picture.

Having gone over what appear to me to be some of the principal shortcomings of photography, I may, perhaps, be allowed a few words as to how these faults are to be expurgated.

In the first place, I am convinced myself that "gelatino-bromide" has done nothing for us artistically; on the contrary, I am quite sure that the various shade and colour values were more correctly given by collodion. I would not for this reason resort to collodion, but would rather hope that very soon we may be able to prepare plates exceeding gelatine in rapidity, and collodion in quality.

Certainly *the* improvement which we stand most in need of, as far as the chemical department is concerned, is the introduction of a plate giving us colours rendered correctly in black-and-white according to their visual values.

With regard to the excessive amount of detail, I would obliterate much or little of it according to circumstances, by printing upon paper with a proportionately rough surface. Small pictures to be viewed in the hand, since breadth is not of so much importance, could be printed upon a moderately smooth surface, while large photographs, intended for the decoration of walls, requiring breadth and force, and where detail to an excessive amount would be out of place, would be better printed upon rougher surfaces.

With regard to the intensely black shadows, I would obviate that by using a printing process capable of printing only to a certain depth.

I need scarcely say that this would exclude albumenized paper. A determined effort should be made to throw off the trammels of the vitiated taste brought about by albumenized paper pictures. We have been so long used to the pure high lights and deep black shadows, that a picture with less spice in it (so to speak) is apt to strike one as wanting in contrast, or to have a washed out appearance. This impression should very soon wear off, and I have no doubt but that then we would recoguize how violent an effect is produced by printing upon such a surface. With regard to the fiue contrasts which we lose from non-actinic colours in nature, I see no other way than to add them by hand.

I saw it mentioned in the photographic journals not long ago, that on the Continent, in copying works of art, correct colour values were added by skilled artists. Of course, if it is necessary to do so in copying paintings, it is just as necessary in photographing from nature. I have tried the plan of covering the back of the negative with tracing-paper, and working upon that with the pencil and stump. So far I have not been successful, the parts added being distinguishable in the print. More recently I have produced enlarged negatives from small transparencies, using "gelatino-bromide" paper. There are more successful and most effective alterations can be made either with colour or pencil. The negative, even after it is waxed, is not nearly so transpararent as glass, and the shadows do not print to such a pitchy black, giving thereby a truer effect. The very slight grain of the paper is rather an improvement than otherwise, especially in large pictures.

A FEW NOTES ON CANARY MEDIUM.

BY THOS. H. W. KNOLLES.*

Some time ago your Secretary gave me some of the canary medium, and asked me if I would try it and give him the results I arrived at.

The sketch I show you will explain the kind of room and light I have to work with. It is a small room, twelve feet by nine feet, lighted from the ceiling, which at one side slopes from near the floor. The window is two feet six inches by one foot six iuches, aud I fitted a box below it open on the top, and faced with the canary medium to give me a light directly in front when developing. This box has a shutter of brown paper stretched ou a frame to cut off as much light as is wished. The window has also a frame fitted to it, which is put up with four buttons, and it also has a brown paper shutter to regulate the light.

As my window faces east, these shutters are necessary when the sun is bright. I put on the frame three thicknesses of the canary medium; these I oiled in the same way as was usual with the ruby paper. The flood of light was very great, so much so that your Secretary, when he came iuto the room, made the remark, "What white light!"

By drawing the cord to the shutter I can make the room as dark as I please. After closing this shutter I selected two plates, one a Fry, the other a Bennett, and proceeded to make trausparencies from two negatives selected.

I then let the shutter drop right down, so that the full flood of light came upon the plate. The light at this time was so strong I could see a pin on the floor nine feet from the window. These two plates I now show you. They are *quite free from fog*. The developing dish was on the table two feet six inches below the window, and the plates were frequently lifted for examination. I then proceeded to make another transpareucy from a rather thin negative, and placed it at a distance of ten inches from the frame with the same light as before, and exposed it for five minutes, the result being a pretty fair picture. From this it was clear that, however well a plate might be developed at a distance of two feet six inches from the window, the light was far from being a safe one to trust too much to. I then removed the oiled paper and substituted two sheets of the paper unoiled, and exposed another plate for five minutes, the result being a *very faint* outline of the portrait. I then oiled one of these sheets of paper, and exposed another plate for five minutes in the same way as before, and in this case got much more detail. From this it would appear that two sheets of paper is the quantity required for a light directly in front, while one sheet oiled and one unoiled if the direct light is cut off by the shutters, as I use them, give a very pleasant and safe light to work by. I found even the two thicknesses of the canary medium gave a much more comfortable light to work by than the old ruby, which was so very trying to the eyes. I intended going over these again, giving an exposure of three minutes, but the weather being dull I had to give it up, but hope to have another opportunity before long.

* Read before the Edinburgh Photographic Society.

Notes.

Captain W. de W. Abney, R.E., F.R.S., will give the first of a course of six lectures on "Photographic Action Considered as the Work of Radiation," at the Royal Institution, on Saturday next (March 1).

A strange thing we noticed the other day when buying

some photographs of Algerian life. Some bore the name of a photographer at Algiers, and some of them emanated from Oran. But the best cartes and cabinets were mounted on plain card. Why was this? Were the negatives taken and printed by an amateur who did not desire his name to go with them, or were the pictures purchased unmounted by the shopkeeper and finished by him? We rather think the first must be the true explanation, for a shopkeeper would never let such an opportunity pass to advertise himself.

Several German photographers have distinguished themselves in African travel. It is but a little while ago that we recorded the death of Herr Remélé, who travelled with Gerhardt Rohlfs through the Libyan Desert; and it is hardly a twelvemonth since another member of the Fatherland was stabbed by Arabs while with a camera in the desert. The two photographers who are missing from Baker's force, and of whose death there can now be little doubt, were also of German nationality.

It is pleasant to find that the courtesy which has existed in many quarters among professional photographers, in permitting a visitor the use of their dark rooms for changing plates, is not fading away. A correspondent, a gentleman whose name is familiar at the Pall Mall Exhibitions, writes us that he has recently made tours in Ireland and also in Italy, and he always found that a few words of introduction on his part sufficed to secure him the hospitality he desired. In Italy, he was particularly pleased with the desire to serve him by several brethren of the craft—a disposition, he says, all the more praiseworthy, since our friend was taking photographs similar to those his hosts had on sale. In this way the *mauvais quart d'heure* of changing plates at night in an hotel bedroom was converted into half an hour's pleasant chat.

A sign of the times is very evident in one of the chief illustrated papers of Paris, *le Monde illustré*. In a recent number of the paper we counted thirteen illustrations, and of these no less than eleven were taken from photographs. But this is not the chief point; underneath each picture was its title, and in the form of a sub-heading were the words "Dessin de ——; Photographie de ——," the photographer thus receiving full honours with the draughtsman. In the edition we saw, were the names of several well-known Paris photographers, to wit: Rentlinger, Numa Blanc, Mulnier, Ladrey, &c.

We also note that the *Illustrated London News* is beginning to give due credit to those photographers to whom it is indebted, as one of Mr. Faulkner's charming studies, given as a supplement this week, bears his name in the place of honour. It is a charming study portrait of the Princess Louise, and it is printed in the red chalk colour to which Mr. Faulkner is so partial.

Some studios put up their notices about payment in advance in the reception-room; others place it upon their cards of terms; while others again either convey the announcement verbally, or hang it up in the studio. Of all these plans, we think the most effective is that of putting it up in the studio. There is always a class who object to pay in advance, and the scruples of these are often overcome when they see something has been done on the part of the photographer; while the latter, on his part, may work more conscientiously and with more spirit, if what he does in the studio will influence the payment of fees.

Moreover, the plan of notifying payment by a notice in the studio has the advantage of plainly putting the matter before your patron. There is always plenty of time for the visitor to look about him between the taking of this pose and that, and he, seeing the pains you are at to please him, must be very hard indeed to move, if he is not willing at the end of the sitting to pay your fee. Many photographers request simply a deposit—sufficient to cover the cost of the negative—and leave the rest of the payment till the prints are supplied. In Berlin, some make it a custom to require half the fee to be paid on the first visit; but, as we say, there are many things to recommend the putting up a notice in the studio itself, and taking the money after posing.

Another examination for diplomas will be instituted this spring by the French Syndicate. Last year, it may be remembered, about a dozen assistants presented themselves as candidates, and nearly all of these obtained certificates of various grades. This time there is likely to be an augmentation in the number, for some of the principal European firms have shown themselves disposed to employ these certificated assistants.

In Paris several of them have found lucrative employment; while in Madrid, the management of the first photographic atelier is under the superintendence of a Paris diplomé. We hear that St. Petersburgh and Vienna are also enquiring for these certificated assistants, and we have not the least doubt that some of our London establishments would be open to them.

Many photographers, in travelling, pack their films between sheets of paper, and if the packages are small there is not much to fear from such an arrangement. But it behoves one to be very careful as to the nature of the paper to be employed for interleaving the plates. No one is likely to employ ordinary printed paper, which almost inevitably leaves impressions behind on the sensitive film, so we need not say a word on that score. Almost as bad are harsh-fibred papers, in which the woody fibre—there is wood in nearly every paper manufactured now-a-days—is incompletely pulped, and liable, therefore, to abrade the film. Some papers there are again, which are very acid, and although the photographer is not likely to employ any other but very dry sheets, still this is a feature to be

borne in mind. A good bibulous paper is suitable, though best of all is Swedish filtering, which is the purest paper in the market.

When the German Photographic Society hold their annual meeting in Berlin this summer, a gold medal will be given for the best portrait, irrespective of the candidate's nationality. Conditions are briefly: The portrait must be taken in 1884 upon a gelatine plate, and be printed upon a whole sheet of albumenized paper; it must not be vignetted, and every candidate must send four framed portraits. Artistic retouching is desired, but rough prints must also be sent for the satisfaction of the judges, and details as to exposure and lens are to be appended. The pictures must not be forwarded anonymously, but with a motto attached, on or before the 10th of August, to Herr Karl Schwier, at Weimar.

There appears to be no other way of steadily producing gelatino-bromide plates throughout the summer than by working by night instead of by day. During the past season, several establishments commenced work at 9 p.m. instead of early morning, and these were enabled to continue their labours without a break.

Fine art on advertising hoardings was talked about a good deal when Cassell's brought out their Magazine of Art a few years ago. It will be remembered that Herkomer produced for this firm an immense art placard, which, after all, with its group of classic figures, was rather bald and uninteresting. Perhaps it was for this reason that no one followed the example of Messrs. Cassell, and engaged other members of the Royal Academy, at princely fees, to do likewise. Yet, there is no reason why we should not have plenty of art productions on our hoardings, if photography were called in to aid in the matter, and this, too, for a comparatively small outlay.

All that is necessary is to choose a little picture suitable for enlargement as a placard. Such artists as Du Maurier, Fred. Barnard, and John Proctor, whose pictures in black and white have been the admiration of the public for years past, do not demand more than fifteen or twenty guineas for the most charming productions, and there is no reason why their pictures should not be enlarged by photography to gigantic proportions. The enlarged photograph, being an absolute *fac simile*, could be inexpensively converted into a huge printing block, by a subordinate hand, and the result would be an effective poster, having, at a distance, all the charm of the original. The reason why our present wall pictures are coarse and inartistic, is simply because the hand that does them is either unskilled or unused to such big work. By having recourse to the enlarging camera, the best artists in black and white might be pressed into the service, and effective and tasteful placards would be forthcoming at small cost.

The long-talked-of Photographic Museum at South Kensington is gradually assuming an existence. Several objects of historical interest connected with the invention have already been collected, and Captain Abney, who has taken the matter under his wing, is sanguine of making the collection a very complete one.

Unfortunately, it will be difficult to make the Museum altogether complete, unless it is international, for France and America, let alone other countries, will not readily part with any relics connected with early photography they may possess. Fortunately, Nicephore Niepce, when he visited England in 1827, left behind many interesting examples of what he then termed heliographie, and some of these are now in safe keeping in this country.

In presentiug the medal of the Royal Astronomical Society to Mr. A. A. Common, for his photographs of celestial bodies, the president gave a very interesting resumé of Mr. Common's work. Mr. Common was first engaged in celestial photography in 1874, and was then working with a 5½-inch reflector. Apparatus of increased power, and designs to meet special requirements, were substituted from time to time, until a gigantic disc of three feet diameter was finally employed. The first attempt to photograph the nebula in Orion in January, 1880, was a failure, but Mr. Common, instead of abandoning the idea, made such improvements in the clock-work arrangement as enabled him afterwards, in March, 1882, to obtain the photograph which has excited so much admiration. The president laid great stress upon one fact which Mr. Common's experiments seem to have established—the necessity for long exposures in celestial photography. It appears that the longer the exposure, the better the detail; and even with an exposure of an hour and a-half, the limit of usefulness was not reached. "The success of these long exposures," remarked the president, "with this powerful instrument, has opened out a new field of research, by which the accumulating effect of the light of faint stars, too faint even for observation by the eye, have been registered upon the photographic plate." It should not, however, be forgotten that without the gelatine process Mr. Common's photographs would have been impossible.

Patent Intelligence.

Applications for Letters Patent.

3211. John Henry Johnson, of 47, Lincoln's Inn Fields, in the county of Middlesex, Gentleman, for an invention for "Improvements in the production of surfaces for printing."—A communiation to him from abroad by Auguste Tournoux, of Paris, in the republic of France.—Dated 13th February, 1884.

3510. Henry Bratt Sharp, of 5, South John Street, Liverpool, in the county of Lancaster, Optician, for an invention for "Improvements in portable legs, supports, or standards for the stands for cameras, stereoscopes, telescopes, theodolites, music, easels, surveyors' staffs, and other purposes."—Dated 18th February, 1884.

Specifications Published during the Week.

3258. Joseph Julius Sachs, of Union Court, Old Broad Street, in the City of London, for "Improvements in the production of designs upon rollers or surfaces for printing, stamping, or embossing."

The claiming clauses are: First. Producing designs upon rollers or surfaces for printing, stamping, or embossing, by first submitting the said rollers or surfaces to the action of a sand-blast, or the impact of hard particles to produce a grained ground thereon, then applying a sensitive solution to the said grained ground, or transferring or producing thereon a design in greasy ink or other resist, and subsequently treating the said rollers or surfaces so prepared substantially as and for the purpose hereinbefore described.

Second. Producing designs upon rollers or surfaces for printing, stamping, or embossing, by first submitting the said rollers or surfaces to the action of a sandblast or the impact of hard particles, so as to produce a grained ground thereon, then covering or protecting a portion or portions thereof with a stencil or resisting medium, and again treating with sand or hard particles in such a manner as to produce a ground with different grains, then applying a sensitive solution to the compound ground thus produced, or transferring or producing thereon a design in a greasy ink or other resist, and subsequently treating the said rollers or surfaces so prepared substantially as and for the purposes hereinbefore described.

Third. In the production of designs upon rollers or surfaces for printing, stamping, or embossing, effecting the etching, engraving, or biting-in of the design under a vacuum or partial vacuum or during the withdrawal of the air and gases substantially as and for the purpose hereinbefore described.

Patents Granted in America.

292,884. LEOPOLD WOLF, New York, N.Y., "Combined toilet-mirror and photographic album." Filed May 31, 1883. (No model).

Claim.—1. The combination, with an upright supporting-frame, of a centrally-pivoted and reversible panel having a mirror at one side and a photograph-album attached at the other side, the album being centrally pivoted to the back of the mirror-panel, substantially as and for the purpose set forth.

2. The combination, with an upright supporting-frame, of a centrally-pivoted and reversible panel, having a mirror at one side, and a photograph-album at the other side.

3. The combination of the upright supporting-frame, and a centrally-pivoted and reversible mirror-panel, with a locking device applied to one of the pivots, substantially as described.

4. The combination, with an upright supporting-frame, of a reversible mirror-panel, turning on centre pivots, and the upper pivot being provided with a spring-pressed locking device, while the lower pivot is provided with a torsion-spring, by which the turning of the mirror in the supporting-frame is facilitated when the locking device of the upper pivot is released, substantially as and for the purpose set forth.

Re-issue.

10,448. GEO. S. NORTH, South Norwalk, Conn., "Photographic camera." Filed Oct. 30, 1883. Original No., 276,455, dated April 24, 1883.

CHAPTERS ON LANDSCAPE AND OUT-DOOR PHOTOGRAPHY.

BY H. P. ROBINSON.

No. 7.—THE SKY.

I SHOULD like to begin this chapter with a bold proposition with which some photographers may not entirely agree. It is this: *The beauty of recent photographic landscapes depends in a very great degree on the introduction of skies from separate negatives.*

In the first edition of "Pictorial Effect," I found it necessary to enter into a serious defence of the legitimacy of skies in photographs, especially when printed from a separate negative. If I attempted to do so now I should only excite laughter, the practice of adding a sky is so universally accepted. The use of anything in photography used to be measured by the possibility of its abuse. The capabilities of any method when in skilled hands were seldom taken into consideration. The question always was: Is it possible for ignorance to go wrong with it? But if we measured every art by the mess that could be made of it by those who not only know no better, but seem to have no capacity for learning better, then no progress would be made in the world. It is pleasant to see a method I have always advocated universally adopted, but it is not so cheerful to see how the blunders that can be made with it still exist. It is pleasant to find that the practice has so far extended that even auctioneers' photographs of houses to let now have their natural skies; but it is vexing to see, as I did this morning at a railway station, a whole collection of these useful photographs with exactly the same sky used for each, and that without respect to the direction from which the light came. Photography, as I have often remarked, should be confined to the possible. Now I need not explain that it is impossible for the same clouds to exist in the same form in different parts of the earth; that no miracle in nature could produce the same sky effect exactly in separate places or on separate days. But this is not the lowest depth: I have seen in exhibitions photographs ascribed to various photographers, all of them with the same sky! There is no getting away from the fact that these photographers must have each bought their sky negatives, printed them, and unblushingly sent them to the exhibition under their own name! This is artistic immorality.

The sky is the commonest thing we have—it is always with us. It is so familiar to us that we seldom give it more than a passing thought. "It is a strange thing," says the author of "Modern Painters," "how little in general people know about the sky. It is the part of creation in which nature has done more for the sake of pleasing man, more for the sole and evident purpose of talking to him and teaching him, than in any other of her works, and it is just the part in which we least attend to her. There are not many of her other works in which some more material or essential purpose than the mere pleasing of man is not answered by every part of their organization; but every essential purpose of the sky might, as far as we know, be answered, if once in three days or thereabouts, a great, ugly, black rain-cloud were brought up over the blue, and everything well-watered, and so all left blue again till next time, with, perhaps, a film of morning or evening mist for dew. And instead of this, there is not a moment of any day of our lives when nature is not producing scene after scene, picture after picture, glory after glory, and working still upon such exquisite and constant principles of the most perfect beauty, that it is quite certain it is all done for us, and intended for our perpetual pleasure. And every man, wherever placed, however far from other sources of interest or of beauty, has this doing for him constantly."

A good deal that is suggested in the above still remains to be done. There is still room in our exhibitions for pictures in which the sky is made the principal instead of an adjunct. This I have mentioned in an earlier chapter; here it only remains for me to suggest to the student what to do, and especially what to avoid.

In many subjects, such as sea views and distant expanses of country, it would be easy to take the sky on the same plate as the landscape, and in seascapes it should always be done when fine effects can be secured; but it is seldom that the best pictorial results can be produced by this means. All skies that appear in nature are, of course, to some extent suitable to the views of which they are the background, but it does not follow that they are always the most picturesque, or conducive to pictorial effect; therefore all I have to say about obtaining the clouds on the same negative as the foreground, as some critics still maintain is the only legitimate way, is, get them if you can, and if the sky and foreground make an agreeable whole, be thankful, and exhibit the picture; but if it is not a pictorial success, then that sky must be sacrificed, and a more suitable one printed in its place. The method of obtaining sky negatives and printing them, have been so often described,* that it is not necessary to enter into any details here; but I would recommend the student to always secure a fine or useful sky whenever the chance occurs

* See "Silver Printing," by H. P. Robinson and Captain Abney.

to him. Never mind whether you see any immediate use for it: make a collection, and they will always be ready to select from. In taking your landscapes, always bear the sky in mind. If not a rule, it was at least a leading direction with the old landscape painters, that the landscape should fill up one-third or two-fifths of the picture, and the larger proportion be devoted to the sky. This will be conspicuously noticeable in the pictures of Wilson, Cuyp, Ruysdael, Hobbema, and others of the old masters; but photographers have found it best to nearly fill their pictures with their subject. The early practitioners were compelled to this, in a manner, by the difficulty of treating the sky, and they got rid of as much as they could of it; but our modern methods have changed all that, and we can represent the sky as perfectly as any other part of nature. But the practice of crowding the space with the subject by placing the horizon high up in the picture still survives. Let me recommend the student to try something different. Try a picture over a flat or slightly-undulating piece of ground, such as is to be found on almost all of our commons; if you can conveniently get a figure, or a cow, or sheep, or a cart and horse, to help to make up the picture, turn the camera towards the sun, of course shading the lens from the direct rays, and make a negative occupying about one-third of the plate. You will find that the sunlight, skimming along the upper edges of all the forms, produces a good and novel effect. Print this negative rather dark, filling the other two-thirds of the picture with a sky negative taken under the same conditions, but not necessarily at the same time, and if everything has been done well, you will find you have got a fine effect. I have recommended you in your first attempt to turn your camera to the sun, because the clouds in that position are often very beautiful in form, and strong in light and shade, and therefore more easy to photograph; but it will, of course, be understood that the sky is possible and generally beautiful in any of its phases as regards the sun, from morning to twilight. There are a few precautions that must be observed. The light must always fall on the clouds from the same direction that it falls on the landscape. Nothing could be more incongruous than a foreground lighted from the right, and the sky illuminated from the left. It is these departures from truth that bring discredit on our art. The sky should belong in character to the landscape, and should agree with and not fight against the view. If the objects in the view are important, the sky should be kept quiet: but if the subject is some very bold or striking cloud, then the landscape should be kept subordinate.

The state and character of clouds vary with the altitude at which they are formed. The visible sky consists of a graduated series of systematic forms of cloud, each of which has its own region and specific character.

Skies taken high up or looking toward the zenith should never be used near the horizon. Besides the variation in shape of clouds at different altitudes, they alter greatly according to their position in the sky; this is due to the effect of perspective; and there are some clouds, such as the cirrus, that are never seen except high in the heavens. Well defined clouds are seldom or never seen near a low horizon. Owing to the mist which always exists even on the finest days, the sky tends to plainness as it nears the horizon; this is especially noticeable over the sea.

Cloud forms are of great use in aiding and correcting composition. The great variety of lines and forms and masses of light and shade to be found in a good collection of sky negatives ought to enable the photographer to produce presentable results out of indifferent landscape materials. It sometimes occurs that the lines of composition in a scene are not what an artist would wish, and that no attention to point of view will materially improve the arrangement. A picture of this kind may be saved by a right use of a sky. Opposing lines may be introduced, and balance restored.

All this must be done with knowledge. This knowledge will come easy to the observing student, but it must be a knowledge of nature as well as of art. I hold it legitimate for the photographer to produce his effects by any means so that they are so true to nature that experts in nature shall not be able to deny their truth.

Correspondence.

TOURISTS' CAMERAS.

Sir,—Please allow me to second right heartily the sentiment of your "Cockney" contributor, that the usual tourists' cameras are good for everyone but tourists. The almost universal defect is, that the designers assume the time of the user to be of no value, and give him a multiplicity of screwings and adjustments to make and unmake over each view. I lose seven minutes in "putting up," and seven in "taking down," over each view—total loss, fourteen minutes. With three double dark slides, this means eighty-four minutes nearly—totally unnecessary waste of time over six plates, with great additional waste when the camera has to be turned on its side.

As the camera must have a case, there is no reason it should not be mounted inside that case, with the lens last used "in position," ready for employment again. Beneath the camera, inside the case, should be space for dark slides, and when the mounted camera is screwed close, the space in front of the lens can be occupied with a moveable leather rectangular receptacle, containing the extra lenses and minor necessaries.

The two ends of the case should pull out entirely, so as not to flap about when there is wind.

The front of the camera should first screw out, and the back afterwards, if necessary, to give power to use a lens of three times the length of the plate in focus.

The necessarily rigid parts of the camera can be skeleton framework, filled up with bellows work. The rigid parts of the case should be skeleton work, covered in with strong waterproof cloth.

I hope to see the day when all tourists' cameras, which are not ready for use when fixed by one screw on the top of the camera-stand, will be unsaleable.

Lucerne, February 19th. W. H. Harrison.

Proceedings of Societies.

London and Provincial Photographic Association.

A meeting of this Society was held on Thursday, the 14th inst., Mr. A. Haddon in the chair.

The Chairman said he would not detain the meeting with any introductory remarks, but call on Mr. F. W. Hart to deliver his lecturette on "Residues."

Mr. F. W. Hart, F.C.S., then read a paper (see page 115), during which he illustrated his remarks with various experiments, precipitating silver chloride from an old silver bath, dissolving an alloy in dilute nitric acid, and estimating the amount of silver therein by means of sodium chloride; also precipitating silver sulphide from hypo fixing-baths, by means of potassium sulphide (liver of sulphur). A sample of paper-ash was passed round, the lecturer preferring to store it in that form rather than allow large quantities of paper cuttings to accumulate. A small single fluid voltaic element was also shown, illustrating the gradual reduction of silver chloride to the metallic state in the immediate vicinity of the negative (silver) plate. This method was recommended for testing the value of small quantities when it is not desirable to treat the bulk; the resulting metal being weighed, dissolved in nitric acid, and estimated volumetrically. In reply to a question from Mr. W. M. Ashman, as to the strength of the chloride of sodium standard solution, the lecturer replied that it was empirical, suited only to the graduation of the instrument used. He did not think photographers were favourable to the French system of cubic

centimetres; they were far more familiar with ounces and drachms.

The CHAIRMAN: Mr. Hart has not mentioned the addition of spent developers to the fixing solution. Are they of any use to reduce the silver?

Mr. W. M. AYRES: Would not engineer's coke be better for furnace operations? It gives a more intense heat than ordinary gas coke!

Mr. F. YORK lately built a furnace to compare results obtained by sending his residues to the refiners, but had not gained much by it. For several years he had kept an account which showed that he realized fifty per cent.; a friend said he realized sixty-five per cent., and expected to get seventy; this induced him to try more accurately. He divided a batch into three equal proportions, reduced one portion himself, and sent the other portions to different refiners; the value of each was about the same in the end. His residues were collected in paraffine oil barrels. Two barrels are used; when the first one is full, it is allowed to precipitate, during the time the second is being filled. The same system is adopted with the fixing solutions. He wished to ask the lecturer why the various salts mentioned were employed in reducing; he never used any other than carbonate. What advantage was there gained by the addition of nitrate and borax? He thought the process of burning paper slow. He placed a perforated tin in the chimney, and burnt it very rapidly. Furnace coke was much better than gas coke. He also wished to know the object of adding sand to the flux?

Mr. A. COWAN: In reference to reducing ashes in small quantities, what gain is there? One refiner said it was a very great advantage to have a large proportion of salt mixed with the carbonates. Is that addition beneficial?

Mr. A. L. HENDERSON wished to know how the gold was recovered from a large quantity of residues; he sent gold and silver together to the refiners, and was allowed for each separately.

Mr. BARKER asked where the lecturer obtained his sulphide, he found, as a rule, the smell was abominable. He did not see any granules on examining the depositing arrangement. Mr. Hart's great experience would enable him to say whether the silver and chlorine are separated indiscriminately, or does one become positive and the other negative throughout the whole mass.

Mr. W. COLE: Has the method of reducing by the addition of glucose been tried by the lecturer?

The CHAIRMAN said the list of questions was sufficiently long, and called upon the lecturer to reply.

Mr. HART, in reply to the questions, said pyrogallol added to the fixing solution darkened it very much; he should hesitate adopting any process which would add obscurity to the solutions treated. He used coke of both kinds, when he got a refractory batch containing alumina. When the furnace is urged to the highest extent, he would use furnace coke always instead of the ordinary gas-coke; but in addressing photographers who are not professional refiners, he advised the kind which is easiest procured.

Mr. ADAMS: Carbon from broken retorts would be better still.

Mr. HART, continuing: It would be necessary to use a very high chimney to get such fuel to burn. Broken battery plates he mixed with ordinary coke, and burnt it. With regard to the per cent. recovered by Mr. York. Taking the value of silver as nitrate, and gold as chloride, he got, in his own operations, eighty-five per cent. Nitrate of soda is used because it is cheaper than potash. Mr. York should use soda ash. If Mr. York precipitated his chloride with hydrochloric acid, he could pour off the supernatant liquid in two hours. Borax is used when there is a suspicion of foreign metals. Boracic acid has a great affinity for the oxides of all the metals. The use of sand is to prevent burning a hole in the side of the pot. When added in a fine state, it acts on the alkaline flux instead of the pot. Salt is principally used in making assay when foreign matter is present. If only ten or fifteen grains of silver be put in, the mixture would be rendered so fluid as to be sure of getting every particle of the metal. The object in burning paper in small quantities is to lessen the bulk and the risk. Many fires have been caused by incautiously burning paper cuttings. Sulphide does not emit a disagreeable smell, if only so much is used as is actually required. Glucose is more expensive, therefore he did not think it worth while mentioning it. He kept his gold and silver residues apart, treating them separately; there was a loss otherwise. The theory of the depositing action was, that a current of electricity started at the zinc plate passed through the liquid to the silver plate, thence by the connecting wires to complete the circuit; in its passage through the liquid the molecules are decomposed, hydrogen is liberated on the negative plate, chlorine is displaced and the silver reverts to the metallic state.

Mr. BARKER: That does not answer my question.

The CHAIRMAN suggested Mr. Barker making an experiment for himself. The action would be seen to start at the positive pole, and gradually spread until all the silver is reduced.

Mr. ASHMAN: Would not a zinc plate alone be sufficient?

The CHAIRMAN: Yes.

Mr. AYRES preferred pouring the molten mass into a pail of water.

The CHAIRMAN said the best thanks of the meeting were due to Mr. Hart for the exhaustive manner in which he brought the subject before them. He moved a vote of thanks, which was seconded by Mr. Debenham, and passed unanimously.

It was announced that Mr. C. Darker would give a demonstration with the lantern on the 28th inst., illustrating the "Application of Polarized Light to Photography."

The next lecturette will be given by Mr. T. Bolas, F.C.S., on "Phototype Printing," March 13th.

GLASGOW PHOTOGRAPHIC ASSOCIATION.

A POPULAR meeting of the Association was held in the Christian Institute, 70, Bothwell Street, on Wednesday, the 6th inst., Mr. JOHN PARKER, Vice-president, in the absence of Councillor Robertson, in the chair.

The feature of the evening was a magic lantern exhibition, arranged and manipulated by Mr. Thomas Swan.

A very fine series of twenty transparencies from one negative, showing the multitude of pleasing tones which may be got in transparencies, by Mr. Alex. Cowan, of London, was very much admired.

Mr. L. DIXON, of Colne, exhibited some collodio-chloride transparencies printed by contact, most of which were very fine.

The other contributors were:—Messrs. York, Woodbury, England, Wilson, Lang, &c.

There was a very large turn-out of members and friends, and the meeting terminated with votes of thanks to the contributors of transparencies, and to Mr. Swan.

LEEDS PHOTOGRAPHIC SOCIETY.

THE usual monthly meeting was held on Thursday, February 6th, the President, Dr. THORPE, in the chair.

Mr. J. W. REFFIT introduced the subject of photographic enlarging, with a demonstration of direct enlarging upon gelatino-bromide paper. In introducing his subject, Mr. Reffit said that he thought a short outline of the various enlarging processes would be of interest to the members, especially those who had recently taken up photography. Daguerreotype or photography on a polished silver surface was introduced in the year 1839. In the same year Mr. Fox Talbot brought out his invention of making paper negatives, from which any number of positive copies could be obtained. This paper was very sensitive to light. In 1851 Scott Archer published the collodion process, by which the photographic image was produced on glass, and from this time photographers began to exercise their ingenuity in finding out the best means of enlarging photographs, in consequence of the many difficulties and drawbacks in taking large photographs direct. Having photographs on glass by the collodion process, and Fox Talbot's process of preparing very sensitive paper by means of iodide of silver, it needed but little ingenuity to adapt the well-known magic lantern to the production of enlarged photographs. [Mr. Reffit here illustrated his remarks by going through in form the various processes of taking a small ¼-plate portrait, developing and enlarging the same to life size.] One of the means employed in addition to the lantern was the solar camera or lantern, as introduced by Woodward. This was not extensively used in this country on account of the small amount of actual sunshine. Paper enlargements thus produced were very permanent. Mr. Harrison, a well-known Leeds photographer, had exhibited two such enlargements in his window, exposed to the direct rays of the sun for twenty-five years, and they showed no traces of fading. Enlargements on iodide of silver paper were largely employed for enlarged portraits to be finished in crayon, water-colour, or oil. Messrs. Winter, Bros., of Vienna, using a similar process for enlarging on calico, do a large business in enlarged portraits, for

artists using the electric light as an illuminant. Another process was to make an enlarged negative from a small albumenized paper print, or from a print by the Platinotype process. Specimens of both were exhibited, the copy from the Platinotype print showing little or no effect of grain of small paper photograph. Good results were obtained by making a transparency by carbon, dry collodion, gelatine, or gelatino-chloride by contact with negative, and the enlarging by means of the copying camera and daylight. [Mr. Reffitt then exhibited a copying camera, and described various arrangements for enlarging—such as horizontal window arrangements, vertical skylight, with table underneath to receive image, &c., &c.] An enlargement could also be made by making an enlarged transparency on glass of size required, which could be touched up to improve as much as possible, and then copied by contact on dry collodion, gelatine, or carbon. A method extensively practised amongst those who did a trade in club portraits was to clean a plate of glass, which, after dusting with talc or French chalk, was collodionized, sensitized in silver bath, exposed with small negative in copying camera, and developed to a less degree than a lantern slide. A plain sheet of paper was coated with gelatine and squeegeed upon film. After drying, the picture was stripped from the glass and mounted. Messrs. A. and G. Taylor, of Forest Hill, do a large business in this class of enlargements, employing twenty-four copying cameras, fitted with twenty-four of Dallmeyer's No. 1B lenses. Mr. Reffit mentioned that he had a letter from the late Mr. Dallmeyer, in which Mr. D. recommended the B series of lenses as the most suitable for enlarging, and he also suggested that four diameters was the extent to which enlargement should be carried. Enlargements on gelatino-bromide paper were easy to make, and its introduction by Messrs. Morgan, Hutinet, and others, would do much to make enlarging popular with amateurs. The paper being very sensitive, enlargements could easily be made with a lantern and paraffine lamp. Mr. Reffit then demonstrated the process of enlarging upon gelatino-bromide paper, using an optical lantern and four-wick lamp, and with three minutes' exposure succeeded in producing a very fine enlargement, size from a quarter plate negative to 23 by 18 inches. Mr. Reffit's paper was fully illustrated by means of diagrams, apparatus, specimens of enlarging, and enlarged negatives by all the processes mentioned.

Messrs. Teasdale, Thorpe, Holmes, and Thornton took part in the discussion that followed.

The following articles were exhibited:—Small pocket camera with attached plated box by Mr. Watson, of Hosforth; instantaneous shutter by Mr. Bradford; instantaneous shutter by Mr. Branson; adaptable carrier, for unmounted lantern slides, by Mr. Teasdale; gelatino-bromide enlargements by Mr. Rodwell; a very fine carbon enlargement by Mr. Ramsden.

The next meeting, Thursday, March 6th, will be an open lantern night. Members wishing to send slides for exhibition must send particulars of them, processes by which they were taken, &c., to the Secretary, 22, Carr Road, Leeds, not later than March 4th.

EDINBURGH PHOTOGRAPHIC SOCIETY.

THE fourth meeting of the Society was held in 5, St. Andrew Square, on Wednesday evening, February 6, Mr. WILLIAM NEILSON, President, in the chair.

The following gentlemen were elected ordinary members:—Messrs Daniel Finlayson, F.R.P.S., Andrew Forbes, Edward Debenham, Julius Peike, W. S. Anderson, and Hunter Muir.

Mr. T. D. POPE gave a demonstration of his mode of producing gelatino-bromide enlargements on paper. Two very successful enlargements were produced of good colour, which were brilliant, yet soft. In the course of the demonstration, Mr. Pope said it was imperative that every attention should be paid to cleanliness and careful washing between development and fixing, in order to avoid stains. While the paper is dry, it is very liable to receive stains from damp fingers. He particularly recommended that the developer be poured into the dish, and the exposed paper, previously soaked in water, floated thereon, face down, as the plan usually recommended, of pouring the developer on the print, in his hands, tended to produce unevenness and stains. When the image was fairly visible, then turn it face up. In practice he had a piece of white cardboard nailed on the wall of his operating room with the various sizes marked on it. The image, thrown on the desired space from a lantern, was duly focussed to the required size; the light then being turned down, a piece of dry argentic paper was tacked on the space, and the exposure proceeded with. He preferred negatives of moderate density—not too thin, but with clear shadows. The time of exposure could only be learned by experience, the quality of negative and power of light being the chief factors. The following was the formulæ employed:—

No. 1.—Oxalate of potash	... ...	6 ounces
Boiling water...	... ...	30 ,,
No. 2.—Protosulphate of iron	...	2 ounces
Water...	...	10 ,,
No. 3.—Citric acid	... ...	3 ounces
Water...	...	10 ,,
For use taken of No. 1.	... ...	8 ounces
,, No. 2.	... ...	2 ,,
,, No. 3.	... ...	½ ounce
Fixing:—Hypo	... ...	12 ounces
Water	... ...	40 ,,
Fix twenty minutes.		
Hardening bath:—Alum	... ...	2 ounces
Water	... ...	20 ,,

Mr. SAMUEL TAMKIN said his experience fully supported that of Mr. Pope's, in that greater freedom from defects resulted from floating the paper in development, and also advised that dishes only a very little larger than the paper should be employed. He handed round a large number of bromo-argentic paper prints with duplicate on ordinary albumenized paper. It was noticed that in some cases the bromide prints were the most suitable expression of the subject. In reply to question he said the difference in tone was due to modifications in the developer. The cold bluish green tone was got by the use of that generally employed, viz.:—Saturated solution of oxalate of potash, three ounces; saturated solution of proto-sulphite of iron, one ounce. He understood that an excess of iron caused yellowness; he therefore increased the proportion of oxalate, and gave a much longer exposure. By this means the prints developed as quickly as well-exposed dry plates, the colour was better, and the whites were remarkably pure. He found it of great importance to time the exposure correctly, for though a great deal is said about the latitude allowable in this as in the working of gelatine plates, in neither should the best results be looked for unless the exposure had been correctly timed. It was in this that a thorough knowledge of the proper qualities of a negative became of value, because with such knowledge an operator might produce dozens in succession without a failure. It is always advisable to immerse or float the wetted paper face down in the developing dish as mentioned by Mr. Pope. When small work is attempted, great care is necessary in the mounting and finishing, as the surface is much more liable to injury than albumenized paper. He had found prints lost brilliancy by being burnished.

Mr. M'KEAN believed a six-inch condenser ought to be employed.

Mr. TURNBULL said no advantage would be gained by a six-inch condenser for carte work; in fact, such a size would be a positive disadvantage.

A vote of thanks to Mr. Pope, proposed by Mr. Craig-Christie, was carried by acclamation.

A discussion on "Canary Medium" then took place, initiated by Mr. Knolles (see p. 119).

Mr. Bow said he had found the ruby lamp too trying, and he was endeavouring to devise a substitute. The result of his experiments he hoped to embody in a paper, which he promised to bring before the Society at an early date.

Mr. TAMKIN had tried the "Canary," and was not satisfied with it. He found three thicknesses of pale yellow tissue paper was really better—his window was not under influence of direct sunlight.

Mr. BASHFORD said that by the courtesy of Mr. Scorah, of Bradford, he had been enabled to distribute samples of canary medium to several members, and laid pieces on the table for others who might care to experiment with it. He thought that the opacity of the paper played an important part in its usefulness, as, according to Mr. Knolles, the medium was unsafe if oiled. There was no doubt, however, that the illumination was most pleasant, and with two thicknesses Mr. Knolles had shown it was quite safe, the negatives and transparencies produced being entirely free from fog. He drew the attention of experimenters to a statement by Mr. A. L. Henderson, that though the light when examined by a spectroscope might exhibit a decided green, yet it might be quite safe for the dark room. He also noticed that some experimenters had endeavoured to arrive

at a solution of the difficulty by taking negatives of surfaces covered by various pigments. These thought that the least actinic pigment ought to indicate the safest colour, and be a guide to judge of the sensitiveness of plates. He thought experiments in that direction were likely to be misleading, and believed that pigments ought not to be compared with the colours as seen in nature; their action on sensitive surfaces was entirely different. He considered it an easy matter to produce the most contradictory evidence when the pigments of the artist's colourman were employed, but the photographer generally had to go direct to nature, and it was only by experimenting with nature's colours or their equivalents that the photographer would be materially benefited.

Mr. TURNBULL exhibited a modification of Mr. M'Dougall's lantern carrier, in which the parallel sides were made of metal instead of wood, thus allowing this ingenious contrivance to be sufficiently reduced in width as to render it applicable to the sciopticon. He also exhibited Cadett's new exposure shutter.

Mr. Wardale presented the Society with a non-actinic lantern of new design for use in demonstrations.

The thanks of the Society were presented to Mr. Wardale, also to Mr. Knolles, for his carefully conducted experiments, and the meeting terminated.

NEWCASTLE-ON-TYNE AND NORTHERN COUNTIES' PHOTOGRAPHIC ASSOCIATION.

THE usual ordinary meeting of this Association was held on Tuesday evening, the 12th instant, in the College of Physical Science, Newcastle, Mr. A. L. STEAVENSON, J.P., of Tynemouth, in the chair.

Mr. E. DODDS read a paper entitled "Notes on Ruby Light." He said that he had confined his attention principally to the testing of various coloured media suggested in the photographic journals, &c., and had decided in favour of ruby glass. He, however, showed in a lantern brought for the purpose, several variously-coloured glasses and papers, some of which were highly suitable, the best of them being Mr. W. E. Debenham's cathedral green, combined with rag yellow paper, and a stained red glass combined with a saffron-coloured parchment paper.

Mr. J. P. GIBSON observed that he used cherry fabric, but always with artificial light.

Prof. HERSCHEL said that he had nothing to offer from experience regarding the relative values of the different kinds of non-actinic colours which had been exhibited to them that evening for dark-room illumination. The non-actinic property depended so much upon the nature of the chemicals used, as well as of the light tested, that it must be in great measure a subject for experiment with different sensitive plates. But the exact measurements to which Mr. Dodds had submitted them showed very clearly that for manipulations of ordinary dry plates there was a large choice of very different looking colours, of which several were almost equally harmless and inactive. Regarding the fatiguing effect of ruby-glass light upon the eyes, the complaint against it was, probably, in some degree well founded, as its low refrangibility must lengthen the visual focus distances of objects examined by it, so as to make it necessary either to hold such objects at a greater distance than usual from the eyes, or else to strain the adapted muscles of the eye to bring a distinct focus on the retina the image of such objects when they are held close at hand; and especially when they are so closely examined and inspected as we are accustomed to do by holding them very near the face, in ordinary light, for minute discrimination. Short-sighted persons have a natural advantage over those whose usual sight is either normal or long focussed in the power of minute observation; and in ruby light such persons would feel at home, or would at least be on a level of scrutinising aptitude and ability with ordinary-sighted persons in ordinary light. Normal-sighted persons, on the other hand, would feel as if the long-sighted infirmity natural to old age had overtaken them before its time, obliging them either to forego the advantages of close inspection, or to strain the focussing muscles of the eye fatiguingly to require the faculty of distinctness of sharp-focussed definition stolen from their vision by the light when attempting to enlarge the view of an object in the usual way by looking at it closely. The young generation of normal-sighted photographers will, no doubt, be led, by a prevailing use of ruby glass, to give the focussing muscles of the eye exceptional exercise in one particular direction. This will either (if over practised) tend to make them short-sighted for ordinary light, or if only exercised enough to extend and not to displace the range of muscular efficiency, will furnish easy early training in an useful means of mitigating the usual tendency to deterioration of the eye-sight; and it will prepare eyes so exercised in youth to combat more successfully than untried eyes could do the infirmity of vision natural to old age, and the defect of long-sightedness which normal eyes acquire sensibly even in the advancing years of mature life, without making it necessary to hold a page of print at arm's length, in order to see its letters clearly. A moderate use of ruby light, although somewhat fatiguing to normal eyes, must, accordingly, be rather likely to have a wholesome and invigorating than a deleterious and injurious effect upon the sight. It would be a useless light, however, for colour-blind persons; and the sense of red colour in normally-constituted eyes, it may be conjectured, would be quickened and heightened at the same time, without disadvantage, with the extended power of focus-adaptation. But a great range of other colours, not ranking nearly so low in refrangibility as ruby-red, it has been shown clearly by Mr. Dodds' illustrations and experiments, is open to selection and to adoption in a dark-room with perfect safety, by those who may be averse to suffering the feeling of inconvenience sometimes occasioned by the bright red, even if its trying effect on the eyes should be closely proved to be not only harmless, but, in reasonable limits of exposure to it, of useful service and ultimate benefit to their efficiency.

The CHAIRMAN proposed a vote of thanks to Mr. Dodds for his paper, which was carried with acclamation.

The SECRETARY exhibited and described a camera, sent for that purpose, by Mr. McKelleu, of Manchester.

Some fine transparencies were shown by Messrs. Mawson and Swan, taken on gelatino-chloride plates of their own manufacture.

Mr. DODDS proposed a vote of thanks to the Chairman, who, in reply, expressed the pleasure it had given him to be present on that occasion. He regretted that he could not come oftener to the meetings, which he said were always instructive.

THE second annual dinner of the above Association was held in the County Hotel, Neville Street, Newcastle, on Friday last, the 15th instant. Professor Herschel presided, and was supported by Mr. Way, Mr. Payne, Mr. Pike, and others. Mr. Garland occupied the vice-chair, and was supported by Mr. Ross and other members of the Association.

The CHAIRMAN proposed the usual loyal toasts, which were drunk with enthusiasm.

Mr. WAY gave the toast of "Photographic Art and Societies," and spoke of the value of an art education.

Mr. GIBSON responded.

The VICE-CHAIRMAN proposed "The Newcastle and Northern Counties' Photographic Association." He deprecated the art jealousies which seemed to exist among even our great men. He thought that there should be more generosity of disposition shown towards students by those who had made a life study of art. A different spirit prevailed among Continental artists, from whom our native painters had derived a good deal of their knowledge of art. He trusted their Association would tend to break down the spirit of exclusiveness which prevailed, and the fear, so to speak, that their ideas or knowledge of art might be acquired by anybody else. Our countrymen in the past had experienced no such narrowness or jealousy from the old masters, and Englishmen should be more willing than they were to hand down to those who aspired to follow them, all the knowledge of the art they could for the benefit of posterity.

The CHAIRMAN responded.

Mr. ROSS, in a few well-chosen remarks, proposed the toast of "The Officers and Committee of the Newcastle and Northern Counties' Photographic Association," which was responded to by Mr. Laws, Mr. Pike, and Mr. Sawyer.

Other toasts followed, and the proceedings were pleasantly interspersed with songs and pianoforte and violin solos, the instrumental music being contributed by Mr. A. de Pelsenaire and Mr. H. Sawyer.

GLASGOW AND WEST OF SCOTLAND AMATEUR PHOTOGRAPHIC ASSOCIATION.

A MEETING of this Association was held on Tuesday, February 12th, Mr. HUGH REID, President, in the chair.

After the reading of the minutes of the last meeting, the following new members were elected:—Messrs. Downie, Bischoffhousen, Chalmers, W. Millar, Garroway, and J. Barr.

The PRESIDENT proposed that the Association purchase a

quantity of trays, measures, a lamp, and other apparatus, to be used at meetings when practical demonstrations were given, and the council were directed to carry out the proposal.

Mr. T. N. ARMSTRONG then read papers on "Mounting Prints on Glass," and on "Transparency Printing." For mounting on glass, he used starch, first coating the glass, and then the damp print, and squeegeeing the two together. He found the use of the squeegee much facilitated by coating the back of the print with starch, which acted as a lubricant, preventing the prints from being torn. He had tried gelatine, but found the starch method simpler, and quite as satisfactory in result.

After Mr. Armstrong had given a successful demonstration of the process,

Mr. J. Y. MCLELLAN suggested that the addition of oxgall to the starch would make it take more kindly to the polished surface of the glass.

Mr. FALCONER enquired if a mixture of starch and gelatine had been tried?

Mr. JOHN PARKER said he had used the gelatine process for a number of years, and was quite satisfied with it, preferring it to the starch method demonstrated by Mr. Armstrong. He found no difficulty in the gelatine setting too rapidly, as, during the operation of mounting, he kept the glass over a dish of boiling water, the heat from which prevented the setting of the gelatine. He thought there was greater transparency in gelatine, and that it was less liable to decay than starch. Further, there was the advantage that, if necessary, the gelatine could be rendered insoluble by brushing the back of the print with a solution of chrome alum. He used a weak solution of gelatine, and, instead of applying it with a brush, immersed the print entirely in the solution.

Mr. ARMSTRONG said he had tried a mixture of starch and gelatine, but found no advantage over pure starch. He thought starch was less liable to decay than gelatine, especially in cases where the print might be subjected to damp.

Mr. ARMSTRONG then gave a demonstration of transparency printing by contact and through the camera, using gelatino-chloride and bromide plates.

After a hearty vote of thanks to Mr. Armstrong, the meeting adjourned.

BOLTON PHOTOGRAPHIC SOCIETY.

A MEETING of this Society was held at the Baths on the 7th inst., Mr. E. N. ASHWORTH in the chair.

The minutes of previous meeting having been read and confirmed,

Mr. MCKELLEN, of Manchester, explained the principles and details of his new camera. There can be no doubt that the inventor has overcome many of the difficulties and inconveniences of the old style of camera, and has secured lightness and compactness without sacrificing rigidity.

Mr. JOHN TAYLOR gave a very instructive explanation of the different modes of enamelling silver prints, and showed the process from the cleaning of the plates to the stripping of the finished print.

Mr. C. K. DALTON gave the paper on "Platinotype Printing" which he had promised for the previous meeting. Mr. Dalton is a very clever manipulator, and his demonstration was one of the best of the season. His method and neatness were very conspicuous, and showed at their best the beauties and simplicity of the process.

Mr. HARWOOD had promised to give a lantern exhibition, but being unavoidably detained, Mr. Thos. Parkinson very kindly officiated.

The Platinotype Company kindly lent to the meeting a number of samples of their work, which afforded another enjoyable element in a very successful meeting. It was now getting late, and the further business was postponed, and the proceedings brought to a close by a cordial vote of thanks to all who had assisted in securing one of the best attended meetings the Society ever had.

Talk in the Studio.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—The next meeting of this Society will take place on Tuesday next, February 26th, at 8 p.m., at the Gallery, 5A, Pall Mall East when the evening will be devoted to an examination of transparencies by the Society's oil lantern.

THE ALLEGED FRAUDS BY A CANVASSER.—The club agent recently charged at the Brighton Police Court with defrauding Messrs. A. and G. Taylor (see page 104) has been committed for trial at the next Borough Quarter Sessions.

BOOKS ILLUSTRATED BY SPRAGUE'S INK-PHOTO PROCESS.—We have received "Luther Miller's Ambition" and "Two Saxon Maidens" from the Wesleyan Sunday School Union, the illustrations being reproduced by Messrs. Sprague and Co. from the pen-and-ink drawings of the artist. The special advantage is the perfection with which weak or broken lines are reproduced.

MESSRS. BROWN, BARNES, AND BELL.—A proposal is made to transfer the business of this firm to a joint stock company, having a capital of £130,000, and it is now intended to issue shares to the extent of £30,000. It is evident that the promoters of the company look to the development of the photo-filigrane process and the manufacture of phototype blocks (Luxotype) as main factors in the success of the proposed Company. Together with the prospectus of the new concern, we receive a long list of general press opinions as to the value of these methods. The *City Press*, *Fife News*, two Manchester papers, five Liverpool publications, two Sunderland papers, and the *Birmingham Owl* are quoted as testifying to the value of the filigrane process; but we do not find the opinion of a single photographic authority referred to. With respect to the Luxotype the case is different, as we not only find the testimony of *The Rock*, *Bell's Life*, and one or two other metropolitan papers as to its value, but the opinions of no less than sixteen provincial papers; and in addition to these, a most flattering notice from a technical journal, *The Photographer*: still we do not quite know which publication is referred to. Can it be the Russian journal *Photographer*, or Mr. E. L. Wilson's ably conducted *Philadelphia Photographer*? Those who are interested in photo-block methods will find some details in our YEAR-BOOK, pp. 25, 78, and also several examples of photo-typographic engraving.

PHOTOGRAPHIC CLUB.—At the next meeting, on February 27th, the subject for discussion will be "On the Preparation of Lantern Slides." As this will be a lantern evening, members and visitors are invited to bring slides.

To Correspondents.

*** We cannot undertake to return rejected communications.

A. M. S.—1. It is well adapted for use with all qualities of gelatine plates, but a little judgment will be required in adjusting the proportion of No. 3 solution. 2. The time required depends mainly upon the hardness or softness of the gelatinous film, and it may, assuming the correct exposure to have been given, vary from the tenth of a second to several minutes. As a general rule, the image will appear more quickly when the developer is made up with soft water than when hard water is used. 3. If under-exposed, increase the proportion of No. 3; but if an unduly long exposure has been given, do the reverse. 4. Use the largest stop, which will give you the required definition all over the field. 5. We cannot tell, and it appears to us that there would be nothing gained by enquiring. If, however, you wish to communicate with the gentleman named, and will send a letter for him to our office, we will forward it. 6. We are sorry that we could not see our way to give you the above information by means of a private letter, as we only do this when an early answer is of special importance, or it may be undesirable to answer in this column. Your stamps have been returned. Write to us again if you require further information.

VANNIN.—Dagron, of Paris, supplies them, and we have no doubt you could obtain them to order from Messrs. Marion and Co., of Soho Square.

J. H. R. S.—Under the circumstances we will do nothing, although we had intended to make enquiries as to the reason of the delay.

G. MACKIE.—1. A weak solution is to be preferred, as it enables one to keep the reaction better under control. About ten grains to an ounce is a convenient strength. 2. If too much is added, it will completely coagulate even if warm, but only enough should be employed to produce the faintest symptoms of thickening. 3. The amount of acetic acid required will depend altogether on the quality of the gelatine. It is not desirable to use more than enough to restore the original fluidity of the mixture. 4. All can be done in daylight up to the point at which the emulsion is applied.

C. P. GIBSON.—The sensitive paper is exposed together with the printing frame containing the negative and tissue, until such a tint is impressed on the sensitive paper as experience has shown to be sufficient; the scale of tints round the circular opening affording a standard for comparison. For very long exposures, a piece of thin orange gelatine is placed over the sensitive paper. When the instrument is used for camera work, it is exposed in the direction of the proposed view, and the time required to impress a given tint is noted. The exposure given is long or short, according to the time required to give the standard tint. By enclosing stamps, you gave us the unnecessary trouble of returning them.

ALPHA.—I. You can obtain it from Mr. Cornelissen, 22, Great Queen Street, Drury Lane, London. 2. Richmond's Grammar of Lithography, published by Wyman. We believe it costs four or five shillings. 3. No, the pressure method will give a much better result. 4. The copying press will answer very well for early experiments. Cement a piece of thick plate glass to the bed, and another to the platen. 5. Fine Rives paper is used, but it requires to be coated with an alkaline solution of lac, and very carefully rolled. If you require further information, write again.

G. WILSON.—We have done as you requested.

L. S.—The address of the patentee has been forwarded to you.

W. DAVEY.—Dr. Liesegang's book is in German and costs half-a-crown. If you send a P. O. O. for 2s. 9d. to Dr. Liesegang, Dusseldorf, Germany, we have no doubt you will receive it by return of post. The title is "Photographische Schmelz-farben-bilder." See also an article which appeared on page 241 of our volume for 1882.

J. BALDWIN.—A pickle of bichromate of potash and sulphuric acid removes the films very effectually. One part of bichromate in twenty of water, with the addition of two parts of sulphuric acid, answers well.

THOS. STOKOE.—Thank you for the picture; the idea is an excellent one.

T. H. HUTCHINGS.—The Eastman machine is figured on page 564 of our volume for 1883: also on page 188 of the YEAR-BOOK.

DRY PLATE.—1. It is extremely difficult to manufacture gelatine perfectly constant as regards quality, and although both kinds mentioned will answer well, we have of late obtained better results with No. 2. 2. It makes not the slightest difference whether the water in the external vessel boils gently or violently; all excess of heat being consumed in converting the water into steam. Many have met with the same difficulty, but in every case which we have investigated, the failure has either arisen from the over-heating of the mixture, or by traces of partly decomposed gelatine from previous workings finding their way into the emulsion. When ammonia is used, extra care must be taken to guard against accidental contamination by dirty vessels. Stirring with a stick which has been previously used will often deteriorate a large batch of emulsion, merely causing thin images in one case; while in another instance, green fog may ensue. Violent agitation has, as far as we know, no mischievous action. 4. You are quite right, as after a certain point the grain becomes much coarser without a corresponding increase of sensitiveness. Try the ammonia process once more with additional care, and we are convinced you will obtain first-class results.

W. ORCHARD.—We are glad you have been so fortunate, and we can understand that you have no wish to make a change.

M. J. ADCOCK.—Registration will not do, you must take out a patent. At a cost of £4 you can obtain a patent good for four years. See article on page 754 of our volume for 1883.

ANXIETY.—1. The best way is to paint the back of the plate with a bituminous varnish, such as Brunswick black. Yes. 2. It may be useful in some cases, but we do not ordinarily employ it.

F. BARRETT.—1. The spots appear to be due to hyposulphite in the mount. Read leader on the subject in present issue, and try the experiments referred to, and if you find proper grounds for doing so, make a claim against the dealer who supplied them. 2. The developer cannot readily reach those parts which have received the fullest exposure, and it exhausts itself upon the less vigorously impressed portions. You should use very thinly-coated plates, and an emulsion containing a minimum of gelatine. 3. No, just the same exposure as if done in the usual way. 4. Replace the spring by four weaker ones—one for each corner of the plate.

SPOTS.—1. They appear to arise from the presence of hyposulphite in the mounts. See answer to F. Barrett, as your mounts appear to be of the same make as his. Probably you had better consult a solicitor. 2. It is annoying, but we do not know of any remedy. 3. In some cases we have found its use to be advantageous.

TROUBLESOME LAD.—Grind the dry colours with white of egg, and apply the mixture with a brush in the usual way. The flat portion of a glass stopper answers very well as a muller. When the work is dry, apply a few drops of alcohol to render the albumen insoluble. 2. The only way is to apply the adhesive material to the edges only; the central part being protected by a cut-out disc during its application. 3. There is none.

J. I.—1. We think that about £1,000 may be somewhere near the mark; providing, of course, that we have not misunderstood your statements. Still you must remember that we express no decided opinion. 2. Some of the pictures are very pleasing.

DAMP.—It makes but little difference whether you use the gelatine in the form of size, or whether you commence with dry gelatine. If the former, we would suggest melting four pounds of size, and stirring in three ounces of finely-powdered bichromate of potassium. The mixture should be used as soon as the bichromate is dissolved, as it is extremely liable to become insoluble. If you use solid gelatine, do not take such a low quality as common glue, but employ a cheap hard flake gelatine, which can usually be bought for about one shilling a pound. Dissolve one pound of this in three pounds of water, and stir in the above-mentioned quantity of bichromate.

A. M.—It is very difficult to form an opinion, as we do not know all the circumstances, but we are inclined to think that the mischief arises from some peculiarity in the quality of the paper used; try another sample. It is important to allow the prints to remain for a sufficient time in the fixing bath; and the solutions should be freshly made.

Employment Wanted.

Recep. Room, Mounter, &c.—M. W., 68, Parma-cres., Clapham Junction.
Printer or Gen. Assist. (young man).—Evans, 9, Church-st., Folkestone.
Reception Room, Mount, Spot, Books.—F. W., Chryssell-rd., Brixton-rd.
Printer and Toner.—Printer, 24, Crick-st., Burdett-rd., E.
Operator, Retoucher, Enlarger.—Alpha, 115, High-st., Camden-town.
Artist, well up.—P. Eckhart, 105, Hall-pl., Hall-pk., Paddington.
Retoucher and Colourist (lady).—J. J., *Photo. News* Office.
Artist, medallist.—Miss A. H., 88, Stoke Newington-rd. N.
Operator or Manager.—A. E. Walker, Eastwood, Notts.
Assist. Printer & Vignetter.—G. E. Cann, Market-st., Brighton.
Assistant Operator, or Manage Branch.—H. W., Finsbury-circus, E.C.
General Assist., good all round.—X. Y. Z., 49, Ledbury-rd., Bayswater.
Assist. Op., &c. (town only).—C. H. E., 50, London-st., Tottenham-ct.-rd.
Assist., can print, tone, paint enlarg.—Silver, 40, Gower-st., Birmingham.
Assist., enl. on Morgan's pap.—F. P., 16, Rochester-sq., Camden-rd., N.W.
Assist, retouch heads for publication.—Retoucher, *Photo. News* Office.
Reception Room, as Improver.—X. Y. Z., 5, Jesse-ter., Reading.
Assist. Operator, could manage.—F. B., 2, James-st., Iffley-rd., Oxford.
Reception Room or Shop (Lady).—A.S., 77, City-rd., N.
Operator, wet or dry.—C. O., 25, Duke-st., Bloomsbury.
Retoucher, first-class.—Artist, 15, Hastings-st., King's Cross, N.W.
Artist in Oil and Water.—J. J. Gibson, 32, Pembroke-sq., Kensington. W.
Op. & Ret., wet or dry.—F. J. M., 6, Brockham-ter., Willsbridge, nr. Bristol.
Operator and Retoucher.—Alpha, 10, Hotspur-st., Kennington-rd., S.E.
Retoucher and Min. Artist.—Miss Lea, 443, Coldharbour-la., Brixton.
Silver Printer and Toner.—F. C. M., 35, Vincent-sq., Westminster.
Gen. Assist., all round.—G. L., 49, Ledbury-rd, Bayswater, W.
Op. & Retoucher, 50/- weekly.—H. H., 146, Cheetham-hill, Manchester.
Gilder, Joiner, Fitter-up.—A. J., 31, Charles-st., Southboro', Kent.
Printer, generally useful.—F. Foy, 7, Market-st., Deal.
Finishing Enlargements at home.—L. E., Spring House, Merton, S.W.
Operator, land., portrait., monoch, crayons.—W. D., Shaw-rd., Dudley.
Reception Room, Shop, Mount, finish, &c.—B. A.. *Photo. News* Office.
Col. & Ret. (Lady).—E. McCowen, 20, Grand Parade, St. Leonard's-o-Sea.
Retoucher, Operator, Printer.—V. C. Yealett, 3, Queen-sq., Bath.
Manager, exp.—Photographer, Adelaide-rd., St. Paneras, Chichester.
Operator, Copyist, clever with children.—C. O., 25, Duke-st., Bloomsbury.
Retoucher, first-class, in London.—Artist, 15, Hastings-st., King's Cross.
Operator, can speak French.—G. P., 4, Stamford-st., Blackfriars-rd., S.E.
Retoucher, first-class.—P. Marks, 1a, Britannia-st., City-rd., E.C.
Retoucher, work at home.—J. Fisher, 7, Westmoreland-pl., City-rd,, E.C.
Shopman, town preferred.—E. D., 17, Brunswick-st., W.C.
Operator & Retoucher.—Light, 94, D Street, Queen's-pk., N.W.

Employment Offered.

Silver Printer and Toner (good).—W. Wilson, 77, De Beauvoir-rd., N.
Photo-Lithographer & Photo-Etcher.—Meek & Co., 4, Cable-st., Liverpool.
All-round hand, wet & dry.—Tune & Co., Warrington House, Tottenham.
Retoucher of first-class ability.—H. W. Winter, Alexandra Rooms, Derby.
Printer, first-class, to Manage.—Byrne & Co., Richmond, Surrey.
Printer & Toner, dry-plate.—H. Friedmann, The Grove, Stratford, E.
Assist. Landscape Printer.—Carl Norman, Graphic Villa, Tunbridge Wells
Operator for Ireland.—D. W., c/o Marion and Co., Soho-sq.
Printer, young and clever.—J. S. Catford, Art Gallery, Ilfracombe.
Assistant Operator immediately.—P. G , c/o Marion & Co., Soho-sq.
Operator, clever, for three months.—Silas Eastham, Southport.
Retoucher, three days a week.—J. S. Bayfield, 10, High-st., Notting-hill.
Retoucher, clever.—John Hawke, George-st., Plymouth.
Assist. Oper., first-class Retouch.—Disderi & Co., 4, Brook-st., Hanover-sq.
Out-door dry-plate Operator.—R. Ward & Co., 166, Piccadilly.
Sil. Print. & Ton.—Mrs. Harborne, 300, Victoria-rd., Aston, Birmingham.
English Lady for France (shop).—E. E. Y., 24, Mark-la., E.C.
Out-door Operator, Monochrome, Retouch.—A. K., *Photo. News* Office.
Operator, generally useful.—A. H., 68, Fullerton-rd., Wandsworth.
Operator, first-class, for City firm.—J. B., *Photo. News* Office.
Assist. Printer, good Vignet.—J. Ruckmann. 5, Watfield-rd., Ealing Dean.
Operator for Ireland,—D. W., c/o Marion and Co , Soho-sq.
Artist, for black-and-white.—G. N., 118, High-st., Notting Hill.
Printer and Toner, first-class.—Cobb and Son, Wellington-st., Woolwich.
Printer and Toner, to manage.—Vander Weyde, 182, Regent-st., W.
Collotype Printer, Woodburytype, &c.—X. X., 38, Poultry, E.C.
Artist, skilful, at 50/- per week.—Winter, Derby.

THE PHOTOGRAPHIC NEWS.

VOL. XXVIII. No. 1330.—*February* 29, 1884.

CONTENTS.

PHOTOGRAPHY IN EASTERN ASIA.

BARON STILLFRIED, an Austrian, who has had twenty years' experience of travel in Siam, China, Japan, and other Eastern countries, has just returned to Europe, and has brought a rich and varied collection of photographs to Vienna. In the first place, he travelled as an amateur photographer, but he ultimately made a profession of the art.

Stillfried makes very interesting observations as to the position of photography in Eastern countries, and he says that the first photographer settled in Siam about 1857. He was a missionary, and he first converted a native to Christianity, and then taught him photography. This convert is still in Siam, and is neither a good Christian nor a high class photographer; still, he turns out his work at so low a price that no European can compete with him.

The Chinese are far more industrious than the Siamese, and after the late war of England and France with China had terminated, several professional photographers settled down in the celestial empire and took native assistants; but ultimately the assistants commenced on their own account, and at the present time it is probable that there are several thousand Chinese who make a living by photography. The requirements of their customers are by no means difficult to satisfy, only the peculiar views of the Chinese as to lighting and perspective must be studied.

In a portrait the face must be as white as possible; indeed, it is usual to place the sitter in direct sunshine. All shading in the face must be removed by retouching, white lead being used for painting on the positive pictures; so that eyes, mouth, and nose are merely black dots or strokes. It is scarcely necessary to say that all resemblance to the original is lost.

Landscape photography scarcely exists in China, but the Chinese photographer is continually seeking what he can never find—an objective which will produce pictures correctly, according to the native view. He would only be contented with an instrument capable of reproducing the first house and the last house of a street view equally large. For this reason, the Chinese ordinarily take only such photographs as include but a single building.

In Japan, the conditions under which commercial photography has developed itself are somewhat different, nine-tenths of the Japanese photographers having been, at one time or another, assistants to Baron Stillfried. As soon as one of these assistants imagined himself to have learned enough to work independently, he ordinarily left, and established himself on his own account. When, however, these newly-established photographers found that they could not make good pictures, they concluded that there was some mystery in regard to the preparations used, and in several cases it has happened that when a European photographer has been working in the streets, large sums have been offered for his working appliances taken as a whole.

In conclusion, we may say a few words about the pictures which Baron Stillfried has on exhibition at the Stubering Museum. The collection is by no means confined to photographs, as there are water-colour and outline drawings, also a few miscellaneous objects. The active traveller Stillfried is, indeed, no conventional artist, but he deals clearly with things as he finds them, and his collection is thoroughly illustrative of the countries and the people, while the sacred and profane buildings or monuments are abundantly represented.

As far as the Chinese collection is concerned, we are more especially interested in a panorama of Hong-Kong. In Siam we are introduced to the governors in their state robes. We halt in the summer residence, and in the harem; while we can trace the influence of European architecture in the style of a Gothic church, and in the hotels. We also see the sacred gala-elephants, and find much to admire in the country round Bankok. Perhaps, on the whole, the Japanese scenes are the most interesting of all. Magnificent gardens, avenues of cedars, charming many-branched waterfalls, glaciers, pagodas with rich wood-carvings, quaint old symbolical doors, and sacred groves being among the striking features of the scenery.

Character studies abound, and among the female singers, dancers, and the tea-house waitresses, one finds many notable types of face; while pugilists, gladiators, and beggars all afford subjects calculated to interest the physiognomist.

STRIPPING THE FILM FROM GELATINE NEGATIVES.

WE have frequent enquiries as to the best means of removing a gelatino-bromide negative from its glass support so that it can be used either as a direct or reversed negative, and it does not appear to be very generally known that about two years ago Mr. Plener described a method which answers well under all circumstances, whether a substratum has been used or not.

If a negative is immersed in extremely dilute hydrofluoric acid contained in an ebonite dish, say half a teaspoonful to half a pint of water, the film very soon becomes loosened, and floats off the glass, this circumstance being due to the solvent action which the acid exercises upon the surface of the plate as soon as it has penetrated the film. If the floating film be now caught upon a plate which has been slightly waxed, and it is allowed to dry on this plate, it will become quite flat and free from wrinkles. To wax the plate, it should be held before the fire until it

is moderately hot, after which it is rubbed over with a lump of wax, and the excess is polished off with a piece of flannel. When the film is dry, it will leave the waxed glass immediately, if one corner is lifted by means of a penknife. The film will become somewhat enlarged during the above-described operation; but, by taking suitable precautions, this enlargement may be avoided. It is also convenient to prepare the hydrofluoric acid extemporaneously by the action of sulphuric acid on fluoride of sodium; and, in many cases, it is advisable to thicken up the film by an additional layer of gelatine.

The following directions embody these points. The negative, which must be unvarnished, is levelled, and covered with a layer of warm gelatine solution (one in eight) about as thick as a sixpence. This done, and the gelatine set, the plate is immersed in alcohol for a few minutes in order to remove the greater part of the water from the gelatinous stratum. The next step is to allow the plate to remain for five or six minutes in a cold mixture of one part of sulphuric acid with twelve parts of water, and in the meantime two parts of sodium fluoride are dissolved in one hundred parts of water, an ebonite tray being used. A volume of the dilute sulphuric acid equal to about one-fourth of the fluoride solution is next added from the first dish, and the plate is then transferred to the second dish, when the film soon becomes liberated. When this is the case it is placed once more in the dilute sulphuric acid. After a few seconds it is rinsed in water, and laid on a sheet of waxed glass, complete contact being established by means of a squeegee, and the edges are clamped down by means of strips of wood held in position by American clips or string. All excess of sulphuric acid may now be removed by soaking the plate in methylated alcohol, after which it is dried. It is as well to add a few drops of ammonia to the last quantity of alcohol used.

The plate bearing the film negative is now placed in a warm locality, under which circumstances a few hours will suffice for the complete drying of the pellicular negative, after which it may be detached with the greatest ease by lifting the edges with the point of a penknife.

TABLE OF APERTURES OF LENSES.

THE Table which we append is intended for the use of those who, not caring to have a new set of stops cut for a lens, are nevertheless desirous of knowing to what numbers of the Great Britain Society's standard the existing stops of a lens correspond.

Most of our readers are aware that the Photographic Society of Great Britain took as a unit a lens whose diameter of aperture is $\frac{1}{4}$ its focal length, or, as it is usually said, which works at f_4. A stop of half the area of this

was to be called "2"; one of $\frac{1}{3}$, "3"; of $\frac{1}{4}$, "4"; and so on. It was, at the same time, determined that the standard stops should be those to which the figures "1," "2," "4," "8," "16," &c., would attach each stop, thus necessitating double the exposure which was required by the one before it. The figure attached to a stop would thus always indicate how many times longer an exposure would be required with that stop than with a lens working at f_4.

It is not to be expected that in a lens with stops cut before the Society's standards were published, the diameters will be so adjusted as to correspond with the numbers "1," "2," "4," "8," &c., and it cannot be expected that such a set of stops will be as convenient in use as those which are cut to correspond with these figures. Nevertheless, the facility with which they may be used will be much increased if they be stamped with figures which indicate their relation to the standard unit, and as a consequence their relations to one another. The object of the Table is to facilitate such stamping.

We shall take an example of the working of the Table, and, to make the example as practical as may be, we have taken up one of our own lenses, and have measured the stops. The lens is a portrait one of 14-inch equivalent focus; the full aperture is 3 inches; the diameters of the stops respectively $2\frac{1}{4}$ inches, $1\frac{3}{4}$ inches, 1 inch, $\frac{5}{8}$ inch and $\frac{3}{8}$ inch.

We refer to the Table, and find opposite 14 inches in the first column, and under 3 inches in the top line, "1·36." This gives the ratio which the area of the lens full aperture bears to the area of a circle whose diameter is $\frac{1}{4}$ of 14 inches, or $3\frac{1}{2}$ inches. Under $2\frac{1}{4}$ inches we find "2·42"; under $1\frac{3}{4}$ inches, "4"; under 1 inch, "12·2"; under $\frac{5}{8}$ inch, "31·4;" under $\frac{3}{8}$ inch, "87·1."

These figures stamped on the diaphragms give us the relative exposures required with the different stops.

RAPID DIRECT PRINTING FROM THE WOODBURYTYPE RELIEF.

OUR readers are familiar with Ives' method of making a transfer or "mother print," by inking the Woodbury relief and taking an impression on paper which has been indented or grained, so as to leave pyramidal projections (vol. xxvii., page 498), and we have recently made an extension of the method, by which direct prints can be obtained from the Woodbury relief at the rate of over a thousand an hour on the ordinary machine. A Woodbury relief which had

been developed upon a thick slab of plate-glass was mounted like a surface block by the side of some type matter on the bed of a printing machine, and the machine was fed with paper which had been grained by pressure, just like ordinary book-binder's cloth. Under these circumstances prints were produced with a perfect gradation of half-tone, from the more or less complete crushing down of the pyramidal projections upon the paper by the inked relief; while the impression from the type itself was clear and sharp. It may be mentioned that, as an article of commerce, the grained paper should only cost a trifle more than plain paper, and it is possible to see important commercial applications of the method just described. Among these we may mention its applications to the decoration of book covers (leather or cloth), linen, calico, or even wood, it being merely necessary to impress a suitable indented grain in the first place.

A few words may also be said as to similar applications of the so-called Crayontype method, described by Mr. Ad. Eggis in our last volume (p. 789). If a few copies are required, the Woodburytype relief should be mounted on the bed of a press or machine, and each sheet of grained paper as fed in, should be faced over with a sheet of the so-called manifold tissue or carbon paper. Either the commercial crayon paper referred to by Mr. Eggis may be used, or such pyramidal paper as is referred to above; while excellent results can be obtained on grained leather, textile fabrics, or wood. It is scarcely needful to say that it is unnecessary to specially purchase the carbon paper, as any thin paper or fabric slightly inked with printer's ink will answer well; very thin silk being especially suitable. When the image is to be transferred to stone or zinc for etching, it is well to use a special transfer ink.

A form of card printing machine exists, in which a band of silk that passes between the type and the paper carries the ink supply; the impression being in reality a set-off from the inked band. By mounting a Woodburytype relief in such a machine, and printing on grained cards, photo-mechanical prints might be produced with a surprising degree of rapidity, and type matter could be printed side by side with the photograph—a business card, we will suppose, with a photographic view of the premises, or a visiting card with a portrait.

A TRIP TO THE GREAT SAHARA WITH A CAMERA.

BY A COCKNEY.*

THERE is a pleasant walk to the west of Philippeville on a green hill slope that reminds you of the North Walk at Lynton, except that there is here more foliage, also an abundance of cacti, aloes, and orange trees. After four o'clock the temperature is delightful; but the sun is hot and glaring enough about noon. On the other side of the town, again, there is an excursion worth taking to the villa of a M. Landon, whose gardens are redolent with the odours of heliotrope, hedged, in some cases, with blooming geraniums three or four feet high. The low, white villa itself is not remarkable, except for the fact that on one side thereof is a huge wooden kennel, in which repose a lion and lioness. His majesty is still a tawny youth of three years, with magnificent mane and tail; he is behind bars, of course, but the side wall of the house abuts his domain, and he can put his nose in at the scullery window, and so worry the cook, when he chooses. Let grumbling serving-maids at home think of this; they can, at any rate, peep out of their area windows without meeting with anything more formidable than a policeman.

There is a railway to Constantine; but four hours are necessary to get over the sixty miles. Constantine was the last stronghold to stand against the French, and without cannon its position is simply impregnable. Only on one side can you enter the town without a bridge, and this but by a narrow causeway. Otherwise, Constantine is perfectly isolated, perched on a lofty rock, separated by a yawning abyss from the rest of the world. In some places the rocky walls of the town rise to the giddy height of one thousand feet; and where the principal bridge spans the ravine, there the ugly cleft below, in which the rapid Rummel makes its way, is five or six hundred feet down, a far more striking picture than the far-famed Via Mala at its worst. The Eagle's Nest is the Frenchman's name for this city, and most appropriate is it for Constantine.

In the narrow streets of Constantine you are cheek by jowl with the Arabs. They sit at every doorway, stand at every corner, squat on the grass matting of every room you look into. The snow-white blanket or bournous, in which nine out of ten envelop themselves, gives the impression that you are in a city of ghosts—that is, when you have once got out of the notion that everybody has just taken a bath, and is wrapped in his white *peignoir*. In the principal streets there are still plenty of Europeans; but once penetrate into the body of the town, and the small shops and bazaars are crowded with "blankets"; while the narrow, tortuous alleys—not unlike the old part of Geneva, but much sweeter—are as thickly populated as an ant-hill.

My first plate has yet to be exposed. From the balcony of the hotel we can see the market, in front of which are gathered blanketed Arabs by the score, of every shade of colour, from the light olive of the north, to the jet black Nubian. I suggest to my friend Jones—I will call him Jones for short—we shall screw on the camera-stand and take a view then and there. He is quite agreeable. "We can then," I added, "go into the Arab quarter afterwards." Jones gives his unqualified assent. "We shall have plenty of time to do the native bazaars when we like," I say airily. "Of course we shall," says he.

The fact is, we are a couple of cowards. We would rather take a picture under shelter of the hotel, than trust ourselves among the natives. Fortunately we grow ashamed of ourselves before the picture is taken. "Come on out now; what do you say?" is presently put forward, rashly, and before we can repeat our valiant resolution, we are off down the street armed with the camera and dark slides.

C'est le premier pas qui coûte, and when we have taken our first step into one of the side streets, the task is more than half finished. The lassitude, do-nothing character of the solemn Arabs in their winding-sheets is quickened for a moment at the sight of the camera, and the white teeth of the darkies grin with pleasure. By the way, your tame Arab never seems to smile; you may look at him for half-an-hour, and he will not betray the least surprise; he is bereft of all curiosity, and does not move for minutes together. "What magnificent models for the camera!" my readers will say; for myself, I only hope that some of my clumsy efforts to secure a group of them may be successful.

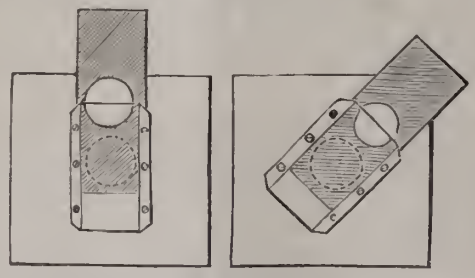
Here is a native coffee house, a "café Maure," as it is called, for Moorish seems a term adopted by Arabs who are settled in a town. Two or three "blankets" are squatting at the door, to give a *pièce de résistance* for the picture, and I hope to drop my shutter in time to get a few passers-by. I do get passers-by, but not a few. They come in troops. A friendly Arab shouts in French, a turbanned Turk roars in Turkish, a donkey-boy cries out in Arabic, and I holloa in English. The scene grows lively, but, thank goodness! everybody is delighted. A stalwart negro in blue breeches and gold-lace embroidery comes up chuckling, so I take him by the shoulders and push him beside the café door. Sambo enjoys the joke immensely, but won't stand. So the shutter has to fall on what it can. A second plate is pushed in; the crowd is beginning to enjoy my entertainment immensely, but they won't keep back. They think my juggling with the camera capital fun, and take it for a peep-show, evidently; they surround me closely. Again do I sally forth, and make a lane for

* Continued from page 115.

the lens, and a second time I let my shutter drop because I must; it is a case of a crowd or nothing.

Next, for a view of Constantine itself, perched upon the top of the cliff. I shoulder the camera, raise my hat, and move off. The crowd, fortunately, do not follow, but fall back at once to their former state of quiescence to discuss me and my apparatus at leisure. What splendid models pass on my way down! Here is a white-bournoused Saracen, mounted upon a beautiful Arab horse, with a skin of white satin and full flowing tail. Look at the man's erect carriage, clothed in white from head to foot—at his handsome trappings—at his gold-stitched harness, his chair-like saddle, and quaint shoe-like stirrups. It reminds you of the pictures of the Crusaders, and awakens in the Cockney mind those wonderful pictures of Skelt, published, I think, in Fetter Lane, a penny plain and twopence coloured. Or look at this tall young aristocrat of an Arab with cachemire toga, yellow leather stockings, and embroidered slippers, a veritable Masher Mahomedan. But they disdain even to look at me or my camera; they betray not the least knowledge of your presence, and do not give a glance in your direction.

I choose a small stop for my architectural picture, and use the cap instead of the shutter, for I mean to give an exposure of two or three seconds this time. By the way, the shutter I use is a neat little drop diaphragm of Hunter and Sands, made of ebonite, to which I have affixed in front a projecting wire for hood or shade. I have chosen it not only for its simplicity, but because, with a little care, its action may be varied considerably. A suitable weight (I employ a bunch of keys) put astride the diaphragm makes it fall very rapidly for quick exposures, while if you want to retard the fall, a plan which has several times been mentioned in these columns may be adopted on the spur of the moment. This is simply to twist the shutter apparatus round, so that instead of the diaphragm falling perpendicularly, it glides slowly down in a slanting position, say at an angle of 45°. Thus—



I do not know any other shutter at once so simple and effective for the tourist photographer.

I find my friend Jones's umbrella exceedingly useful just now to help in shading the camera, for the light is exceedingly fierce and bright, at any rate, to one who but a week ago groped about in a London fog. Two views of Constantine from the bridge are soon taken, and then there remain two other films to expose, to exhaust my slides. There is an encampment of camels outside the town, but as I expect to meet plenty of these among the palm trees of the oasis, I pass them over, and turn my steps to the Place Negrier, where there are some attractive native shops close by the Mosque. Sharp is the word, if you want to expose before a crowd gathers; and this time, with a little more experience of native character to guide me, I do pretty well. Two shopmen seated on their shopboard, talking to a lounging customer, also seated—for no one thinks of buying and selling without sitting down—are my chosen models, and within five minutes I retire with impressions of them upon a pair of plates.

Now I get used to it, I find photography a capital introduction to the good folk. Their solemnity vanishes, they grow animated, and those who know a few scraps of French chat and joke most affably. Nay, the austere turbanned Mahommedan, whom you half feared might throttle you with your own dark cloth, sympathises with you heartily, keeps the crowd from pressing against the camera-stand, and bids the gamins stand still. In fact, they are too good. If I were now asked the shortest way to make friends with them off-hand, I should say, take a camera with you and photograph away in their midst.

The second day's work is not less pleasant than the first. There is a palace here, but it is modern, and of fifth-rate order, so I do not throw a plate away upon it. I content myself again with the Arab quarter, trying a picture here and there in the slums. The Arab women, as my readers know well enough, are rarely seen out-of-doors, and when they do come out, they have their faces covered with a white visor-like mask, that has a small slit to see through. I tried once or twice to catch an Arab damsel, but cannot say yet whether I succeeded.

The Jewish quarter of Constantine is quite as picturesque as the Arab quarter. The jewesses—who commingle freely with the Arabs—adopt a custom the reverse of their Arab sisters. They are dressed out in the most gorgeous of coloured raiment, they wear bracelets, rings, and gewgaws in profusion, and their arms and necks, as well as their faces, are bare. They all incline to embonpoint, and, strange to say, while you rarely see an Arab woman in the street, so you scarcely see a Jew. I presume these latter all dress in blankets, and are, therefore, not to be distinguished from Arabs.

M. Chazal, who has a studio at Constantine, and to whom M. Leon Vidal was good enough to give me a note of introduction, permitted me the run of his premises, and allowed me to change my plates in his dark-room. This was a great convenience, and I beg to thank him here for his kindness. He was delighted to hear of my intention of going into the Sahara. "You are quite safe as far as Biskra, and may go on to Turgurth, if you like, three days further." Beyond that, it seems, travelling is rather dangerous, because you always get killed. Jones and I will, therefore, be content to visit the Biskra oasis, which, so far as I can learn, is the second or third from the north.

M. Chazal was delighted with my little camera, and praised English camera-makers to the skies; he had also a good word to say for the plates of English makers, but he pronounced them all *fort chers*. I will not translate, for fear of offending the delicate susceptibilities of my countrymen.

There are two or three things that I cannot quite make out in this photographic tour of mine. For instance, why is it that, after I have taken a couple of pictures of some native bazaar, I always come immediately afterwards upon another bazaar scene that is ten times better? Why, when I have pitched upon a good subject, it seems to lose most of its picturesque character by the time I have focussed it? Why, when I am patiently waiting to expose, there should come into the picture not an Ali Baba with his donkey, but a town-dressed Frenchwoman, with her conventional frill-capped daughter?

The reflector lantern friend Jones and I are carrying into the Desert is all right up till now. It has borne the thirteen hundred miles of travel well, and there remain but two hundred more for its journey into the interior. And for the interior we now start, after a pleasant sojourn of four days at Constantine.

I will say two words about this start ere I close. Jones and I both feel we are in for it now: but we are getting so used to blankets and their wearers, that, bless you! we wouldn't mind hustling a small one—that is, in the daytime, and if he were alone. We even walk out of an evening without being the least afraid, and go among groups of the silent, white figures, quite boldly, although they look very much like the domestic ghost or common bogey of childhood.

But the start for the interior. Well, truth to tell, it is

not very serious, after all. We buy tickets at the railway station for Batna, and get into a carriage uncommonly like one on the North London line that takes you to Broad Street. In fact, the French threaten a railway not only to the confines of the Sahara, but three hundred miles into the Desert, so that ere long there will be a dining-room car to Timbuctoo, just as there is one now-a-days to the Riviera and to Rome.

By-the-Bye.

ART AND CONCEIT.

IT has always struck us as a curious fact that in the long controversy touching photography and fine art, and the question whether or no the photographer is an artist, no one seems to have thought of applying the simplest touch-stone of all. By-issues of every kind have been raised, while the basis of all argument is ignored. Like a chemist who commits the fault of beating about the bush to tell what sort of metal there is in a body, when no metal at all exists, so the discussion seems to have missed the proper starting point. We do not mean to say that the whole question could be satisfactorily solved out-of-hand by a single question and answer, but, at any rate, photographers would thereby establish a *prima facie* case. One simple mode of reasoning would be to ask, of such or such a man—is he conceited? If he is, then, *prima facie*, he is an artist.

There are, no doubt, exceptions to this rule, as to every other, but they are very few. Again, one class of artists is more conceited than another, which is a very different thing to saying that some are less conceited than others. The actor, the painter, the poet, the sculptor, the musician, the novelist—all are endowed with conceit, and from the fact that we have met many photographers out of conceit with their works, we assert that they have gone a good way to be considered artists, although it might be too much to say that the converse is always true, and that every conceited man or woman is an artist.

And now having said so much, we will go further and say that conceit is inherent to art. Nor is there any great harm in being conceited, if only you are true to yourself and acknowledge the fact. Charles Dickens once naively admitted in a preface—we think that of Dombey and Son—that however kind his kindly critics were, and however meritorious they thought his book, none of them entertained such a high opinion of it as he himself. And so we say, that as long as you will but acknowledge your conceit, if it is only to yourself, all may be well, for you carry within you the antidote as well as the poison. How difficult it is to do this, only the successful man knows. His works are so loudly commended, his talent so highly vaunted, his praises so widely sung, that if he be young and inexperienced, no wonder he loses his wits, and half fancies himself the demi-god the critics make him out.

Conceit in artists is due to the fact that they or their works come face to face with the public, and for this reason it is that the actor has usually more of this virtue or vice, whichever he chooses to call it, in his composition. Being but a human being with his weaknesses like the rest of us, but subject more than other people to the insidious influence of loud praise, he feels the result more. Praise and flattery to tragedian or comedian are the breath of his nostrils, the sole indication of his success or failure; can it be wondered, then, that he will sacrifice most all to obtain them, and that the encomiums repeated again and again should heighten the estimate he forms of himself? So gross may his conceit become in these circumstances, that it loses all power of discrimination, and so long as praise comes, and comes in quantity, there is no question as to its quality. After a while, if successful, he is no longer satisfied with a modicum of soft-soap and frothy lather; it must needs be mixed in a bucket and poured over his head and down his back, to approach in quantity what he feels to be his due.

Scarcely less conceited are other artists, albeit the *litterateur* now and then has the advantage of receiving a lesson which, if taken to heart, occasionally, though rarely, raises the doubt in his mind whether he is so much better than his fellows. The literary man, you see, is of the same trade as his critics, and his mind is now and again balanced by brethren in the craft, who form another estimate of his worth, and tell him what that estimate is in print. In the case of other artists, there is no such wholesome corrective, for they are not their own critics. When a good criticism appears, it is acknowledged as only due; when it is a bad one, it receives no attention, since it has obviously been written by one who knows nothing of the subject he discusses.

But are photographers conceited about their work? Since they are younger brethren in the world of art, do they not relegate themselves to a humble position? We fear not. Some years since there was an animated discussion upon the subject of over-praising pictures at the Annual Exhibitions. Some half dozen gentlemen spoke very warmly on the matter; they were of opinion that it would be more conducive to art in photography if the criticisms on their pictures were more strict and severe. In a word, they would like to see the pictures at the exhibitions criticised sharply. "Tell us our faults," they said frankly, after the style of the Archbishop in Gil Blas, "and we shall be only too pleased." And yet of these gentlemen, we remember, there was one who has not exhibited since that day, and another has labelled his pictures that they were not for competition. In a word, these anxious ones desired sharp criticism—for others. Their position was so well assured, they have been praised so often and so highly, that criticism could not affect them. Yet, take them at their word and try them. Act, as did Gil Blas to his patron the Archbishop; hint to them, as gently and as lightly as you can, after the example of the Spanish hero, and see if the result is not precisely what he found it to be. The man who is so high up, who has monopolised all the praise, who has received the utmost adulation, whose position is assured, is just the one of all others who resents the least word of doubt as to the perfection of his picture. In fact, he is so accustomed to praise that he shows you picture after picture, study after study, with inviting glances and sententious grunts. He simply does so to ensure a stream of grateful homage from your lips; nothing else is possible. That is your rôle. Your friend plies you more and more; you are so sensible and so 'cute in your judgment, he implores you, if you see a fault, to mention it. And so at last you fall into the trap.

You are delighted, enraptured, in ecstacy; and then, having thus far shown your high appreciation, you think he may be tempted to accept one little word of doubting criticism. The spell is broken. He is off at once; the pictures are collected with a hasty hand, the portfolio is closed, and shortly afterwards he may be heard whispering what a fool Brown is, he having actually hinted that the foreground—that fine foreground of brake and bramble in my cottage picture, don't you know—was too striking, and interfered with the principal idea of the picture.

But surely there are plenty of photographs exhibited year by year which are quite open to criticism, and for which nobody would claim perfection! Undoubtedly, although here sometimes the proviso must be made—nobody but the author of them. At the same time, the authors of humble efforts are generally those that need criticism the least, for they are well aware of their shortcomings, and make no profession to be perfect. With them, therefore, we have nothing to do, for they do not come within this rambling dissertation. Our object, if we had any, was to simply point out, that since art and conceit go hand in

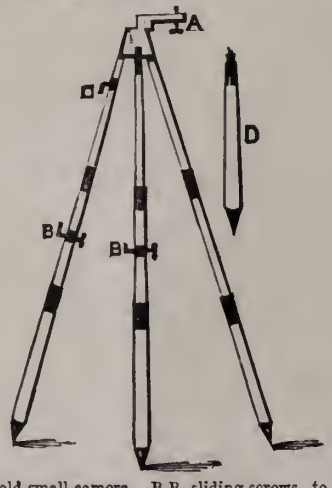
hand, it seemed to us, photographers had as good a claim as any of their prouder brethren to be considered artists. Still, the reader of these lines must not forget the old saving clause about, "present company always excepted," and bear in mind that we had no idea of instancing him particularly in introducing our theme; he is one of the exceptions that prove the rule.

COMBINED EASEL AND CAMERA-STAND.

BY T. G. WHAITE.

THIS stand is designed specially for the use of artists, and intended only for the small cameras employed by them. It is made of bamboo, and each leg being in three pieces, the two upper ones sliding, when packed, within the lower one. By placing the thicker end of the leg on the ground, very great strength and rigidity are obtained.

It is a fact that every stand hitherto made with the thicker end at the top, approaching the camera, shakes more or less with a moderate breeze.



A, bracket to hold small camera. B B, sliding screws, to receive canvas or sketch-block. C, hook, to secure canvas. D, leg as packed for travelling.

The stands I use are all made of bamboo, and the thick end on the ground. Since I have adopted this plan, I have never lost a picture by vibration of stand.

The upper portion of the leg drops within the centre one, to enable the artist to take his photograph from his "camp-stool" point of view, if desired.

PHOTOGRAPHIC RESIDUES, AND THE RECOVERY OF THE VALUABLE METAL THEREFROM.

BY F. W. HART, F.C.S.*

SENSITIVE PAPER CUTTINGS.

THE best receptacle for these is a basket; if any are put in wet or damp, they will dry. Let this not be a place to throw in all kinds of rubbish, as every pound weight of such will cost you at least half-a-crown in firing, flux, and time. It is not at all unusual to discover in the ashes sent to the smelter, burnt nails and screws, portions of scissors, parts of brass hinges, zinc, and lead. Of course this more than useless rubbish makes up a weighty parcel, but rest assured that you cannot have that separated from the silver except at a considerable cost; having collected a batch of silver paper, it is better to reduce them to ashes periodically in case of accident from fire when stored in large quantities. One pound weight of dry cuttings yields about one ounce of ashes of a light drab colour. If burnt in thick compressed portions, or with insufficient air for combustion, the ash will be more or less black; the blacker it is the more flux will have to be used, consequently, larger pots, more fuel, and expenditure of time. For small parcels of cuttings an old iron tray (or sheet of iron) may be used; place a row of bricks round on edge, lay some iron rods across to make an *extempore* grating. Select a place to burn without strong currents of air—under a wide open chimney is best, or in open air on a calm day; lay the cuttings lightly on the iron rods, and continue to supply gradually; collect the ashes to one side occasionally as they cease to show any ignited portion, then press them down tightly. I will now suppose that one pound in weight has been obtained; mix with that quantity six ounces nitrate of potash or soda, eight ounces dry carbonate of soda, and six ounces dry carbonate of potash. Grind the whole together in a mortar, which will greatly reduce the bulk of the mixture, and if it is a sample of ash free from rubbish, the proportions will give a fluid flux with a moderate yellow heat. If useless waste paper, cards, kaolin, &c., have been burnt with the cuttings proper, it may take double that amount of flux to produce a sufficiently fluid state to allow the fine particles of silver to subside; hence the necessity of keeping your residues as clean as possible. Having consolidated your mixture of ash and flux, pass it through a fine sieve. Portions of pins, nails, &c., however few, should be thrown on one side, for, bear in mind, the value of the metal recovered will be according to its freedom from alloy. The crucible prepared as before, and of a dull red heat, is now filled up to within an inch of the top; keep the fire about the same red heat until you have got in the full charge. The mixture commences to scintillate quietly, the oxygen of the nitrate combining with the carbon and traces of common metal escaping the sieve. When this sparkling has discontinued, press the now doughy mass down with the stirrer, and fill up the crucible again, not allowing the temperature of the fire to rise. Repeat the operation for the third time. The crucible contents, after the third pressing down, may be about half full; raise the heat gradually, occasionally stirring the contents of the crucible, and be very careful as it liquefies that no fuel falls into the molten flux, or it will most likely boil over. Always have an inch iron cold bar at hand to plunge into the flux, to reduce the temperature, in case of a sudden boil up; the heat is to be kept up till the contents of the pot settles down to quiet fusion, and until a sample of the flux brought out on the stirrer shows no sign of beads as large as a small pin's head. Then shut on the cover of the furnace, and get up the heat to full yellow for ten to fifteen minutes, when it will be ready to pour as before directed.

HYPO FIXINGS.

Precipitating Method.—Use a jar, as described for washings of prints and other nitrate solutions. Prepare a stock of concentrated solution of crude potassium sulphide (liver of sulphur) in a stoppered Winchester. Have a small cup of about an ounce capacity, and add one measure to (say) 3 gallons of fixing solution, stir up the solution vigorously, and the precipitate will most likely have a medium brown colour. Let it subside a few hours; then take a dip of the clear solution in the cup, and dipping a glass rod into the concentrated sulphide, let one drop fall into the cup; if a thick, dense brown precipitate falls, add another measure of sulphide to the bulk; stir again, and allow to subside. If, on again testing the clear solution, you only obtain a clear brown stain, the metal is all but thrown down; add only a drachm of sulphide, and test again after an interval for clearing; the precipitate will now exhibit a brownish-black colour, and the clear solution will be limpid like water; if yellow, it would be a proof of excess of sulphide, which is to be avoided—gold being partially soluble in such a solution. Having proceeded in this way, there will be no unpleasant smell; and if the fixing is conducted on the system I have indicated elsewhere, the quantity of sulphide can be put in at once, and only one testing needed.

The clear solution is decanted or syphoned off as in the case of the chloride, when sufficient precipitate is collected at the bottom, to make it advisable to clear out on to a shallow pan, after the washing away of soluble salts. The precipitate is then dried off in an oven, or on the top of the furnace at a strong heat, and preserved to a convenient time for reducing. There are other processes, but they are far inferior. One is to keep scraps of zinc in the fixing solution vessels; the metal is a long time going down, and is complicated with zinc. The fixing solution containing silver can also be reduced to the metallic state by electro-chemical action, but after so many years' experience, none of the many methods proposed from time to time give so little trouble, nor do they work so perfectly, as the sulphide precipitation. When properly carried out as indicated above, there is no annoyance whatever from unpleasant smells. If any sulphur have been deposited from the addition of acid to the hypo,

* Continued from page 117.

or long exposure to the air, the sulphide of silver will have in admixture free sulphur. It will then be advisable to expose such mixture on a roasting dish—a shallow fire-clay saucer—at a low red heat, the furnace top off, so that the air has access. The free sulphur will then burn off with its characteristic blue flame. Now take (say) one pound of the roasted sulphide of silver; add about seven ounces nitrate of soda, four ounces dried borax, six ounces dry carbonate of potash, and half-ounce of fine sand. Mix in the mortar, and pass through the sieve once or twice; put it into a bowl, and place near the furnace so as to be conveuient to ladle into a red hot crucible, small portion at a time, allowing deflagration to subside before adding further portions. Finally, raise the heat gradually to the yellow stage, stirring occasionally, and when calm fusion has set in, cover the furuace aud keep up a strong heat for fifteen to twenty minutes; make examination of the flux for beads, and if free from such, and the flux on breaking exhibits a glassy fracture, the contents may be poured into the ingot mould. This metal (if from gold-toned prints) contains gold, and should therefore be kept separate for parting assay, otherwise it is best to combine the separate ingots from the pot into one bar for single silver assay.

Spent Gold Toning Baths.

Collect these in conical glass vessels—precipitating jars; such vessels are obtainable holding about nine pints, or as small as assay flasks of one or two ounces. First acidify the solution with sulphuric acid, then add about half-an-ounce of hydrochloric acid to the gallon. Next prepare a saturated solution of sulphate of irou, add gradually, stirriug with a light smooth rod of wood until no further cloudiness is observed on looking through the glass. Allow the solutiou to stand at least twenty-four hours, then add a drop or two of iron solution to the now bright solution, and note if it produces any cloudiness; if so, add more sulphate of iron solution, stir up, and allow to subside again; as the precipitate is very valuable, it may stand for two or three days to collect the finer particles from this high gravity solution. When so subsided, decant very carefully, and then fill up the vessel with water rendered acid with sulphuric acid; a few hours will now be sufficient for subsidence. Decant again, and repeat three or four times, reducing the quantity of acid each time, the last being plain water. Collect the precipitate in a porcelain dish or crucible; dry off in an oven: the result is a mixture of metalic gold and chloride of silver. Melt in a small smooth crucible, called assay gold pots, with a portion of the flux recommended for the reduction of chloride in process B. Do not neglect to first glaze the pot with borax, leave the button of metal in the pot till cold, then break off the button to obtain it, clean, and weigh. Now take three times its weight of metallic silver from your other reduction, and melt together in a plumbago pot, and pour the melted metal, as soon as liquid, into a pail of water; collect the granulated metal; wash with distilled water. Then dissolve in dilute nitric acid by the aid of heat; the gold will be left as a rich brown powder, which has to be washed after decanting the acid nitrate of silver solution; then boiled with a fresh portion of nitric acid, and again well washed, testing the washiug to see if any silver is contained therein. Finally, dry for sale or use.

Gelatine Emulsion Residues.

I have used two methods for extracting the silver from gelatine solutions. In working on batches of six to ten gallons contained in chemical stoneware pans, the solution is made strongly acid with hydrochloric acid, and zinc plates placed therein. I now pass into the mixture steam at about twenty pounds' pressure to boil up rapidly, and continue the boiling for at least twenty minutes; the bromide of silver is thereby converted into metallic silver, which is allowed to subside. For small quantities I warm up the solution, dilute considerably with hot water, and add some hydrate of soda solution, then hyposulphite of soda to dissolve the bromide, and so obtain a clear solution. The silver is now precipitated with sulphide of potassium, and collected as directed under "Hypo Fixings" above described.

FRENCH CORRESPONDENCE.

Balagny Pellicle Paper—Vidal's Pocket Apparatus—Double Dark Slides—New Product for Photographic Accessories—M. Liebert on Photography in America.

Balagny Pellicle Paper.—Having previously written about M. Thiébaut's reversible pellicle paper, I have now to announce a new product of the same kind, but even better in its results. It is M. Balagny's reversible pellicle paper. As it has been patented, we do not wish to penetrate the secret of its manufacture, the most important point being that it is excellent, and does honour to the inventor, who has been two years diligently working, in order to bring it up to its present state of perfection. In describing it, the good quality of the emulsion is first observable: being developed in the ordinary way with either ferrous oxalate or pyro, it gives negatives of great intensity, and the development may be carried on at will in cases of over- or under-exposed pictures. The paper is treated exactly as an ordinary plate, without one having the least cause to fear frilling, detachment from the sensitive film, or rolliug up during the processes of fixing, washiug, &c. The paper keeping flat renders it easier of manipulation than a glass plate. Directly the image is fully developed, it is washed, dipped in a five per cent. alum bath, and in twelve per cent. of hypo in solution. It is again washed, and treated according to the different ways it is desirable to preserve the pellicle:—1. It may be a negative on glass; or—2. Reversed on the glass. 3. On a gelatine film in the state of a pellicle. 4. On gelatine between two coats of normal collodion. 5. It may be transparent (in the whites of the negative) like a glass negative. I do not say that other similar papers do not realize some of these *desiderata*, but, to my mind, none do so completely and practically. After the last washing, which may be accomplished without fear of detachment, the negative is taken out of the water, and the right side of the image pressed against a glass plate dusted over with French chalk, then coated with 1·5 per cent. normal collodion, and this again covered with a film of gelatine about $\frac{1}{3}$ of a millimetre in thickness. One can always have a certain number of the plates ready for use. The plate, with the pellicle paper upon it, is dried first between blotting-paper, and, when perfectly dry, the paper may be pulled off, and the pellicle coated with the same normal collodion. As soon as the whole is dry, the image can be detached from the glass with a penknife in the form of a pellicle thin enough to allow prints to be taken off from either side, yet sufficiently strong. To preserve the negative on glass, the pellicle has only to be firmly pressed against a clean glass to exclude air-bubbles, and left to dry. The paper may be afterwards removed. Normal collodion or any other varnish can be applied. To make it adhere to gelatine, first roughly dry between blotting-paper, and attach the pellicle paper to a piece of gummed paper, dry thoroughly, and pull off the vehicular paper. Coat a glass with gelatine, and, when set, immerse in water, and float the pellicle on to it, expressing all air-bubbles, and dry. The gummed paper is removed by damping the back. Not having come across any similar paper offering so many advantages, I have no hesitation in recommending its use, especially in my dark-slides for pellicles, as furnishing the best results with the maximum of lightness. M. Puech, 21, Place de la Madeleine, Paris, is the agent for M. Balagny's paper.

Completion of Leon Vidal's Pocket Apparatus.—The pocket photographic apparatus which I already described in a former communication is now being constructed by a Paris house. The pattern stand, lens, and shutter are finished. I have modified my dark slides so that they may be used either for glass plates or paper and pellicles. At the request of a certain number of amateurs, I have somewhat increased the dimensions without forfeiting the claim to portability. The pictures measure seven and a half centimetres, sufficiently large for projecting on a screen. The double dark slide for plate or pellicle measures four millimetres in thickness, ninety in length, and seventy in breadth; the six slides only occupying thirty millimetres altogether in thickness.

New Material for Photographic Dishes, &c.—Experiments are being made with the substance resulting from the decoction and distillation of the bark of the silver birch. With a slight addition of gutta-percha it replaces the

entire use of this last-named substance, having the advantage of being much cheaper. With caoutchouc in combination it makes a kind of ebonite, but less brittle.

M. Liebert's Book "Photography in America."—This work of M. Liebert's, published by Tignol, has reached its fourth edition. It is illustrated with numerous and interesting specimens. As to the text, I am not yet able to remark whether it contains important additions or modifications.

LEON VIDAL.

Notes.

Few awards are so well deserved as the gold medal which the Royal Astronomical Society has accorded to Mr. Ainslie Common for his astronomical photographs. Perhaps the best of all is the "Nebula of Orion," which was issued with No. 1,319 of the PHOTOGRAPHIC NEWS.

Major Chermside, the Engineer officer who aids Admiral Hewett in the defence of Suakim, is a photographer of experience, and read a paper some twelve years ago at the Photographic Society on Arctic photography.

Egyptian earthworks and defences, as well as those of the Arabs, have been made a subject of special study by Captain Clarke R.E., who has illustrated his report by numerous photographs taken in the East.

We had in hand the other day a letter, speaking of the utility of photography in warfare, and prognosticating for the art a very wide military application. The note was dated 1868, and bore the signature of an Engineer officer, who, at the taking of San Sebastian in 1812—three years before the battle of Waterloo—enjoyed the rank of Colonel, and was in chief command of the Sappers and Miners during that memorable assault. This opinion on photography was expressed, therefore, by one of the very old school, a connecting link between the last century and this, the writer being no other than the late Field-Marshal Sir John Burgoyne.

An excellent series of photographs was taken at Victoria Station before any portion of the wreck was cleared away; and one may expect that a careful study of them will bring to light many circumstances which were overlooked in the hurried examination which preceded the clearing away of the ruins.

A young French explorer, M. Foureau, is contemplating a journey through the Sahara to Timbuctoo, and, following the Niger, to come out on the west coast of Africa. He estimates his expenses at £6,000, which will include the cost of a small steamer capable of conveyance overland. His experience as a traveller in the Sahara is already very great, added to which he is a man of considerable scientific attainments. But what will interest our readers more, is to hear that M. Foureau contemplates making extensive use of photography in his journey. He is one of the most accomplished of amateurs, and already he has mapped out and photographed the principal landmarks and oases that lie in a direct line south of the principal French routes through Algeria.

M. Foureau generally travels with a hundred plates contained in fifty light slides. He is then free from the cares of complicated changing-boxes, and has no use for a dark-room until he comes back from his flying journey. On his contemplated tour to the Niger, however, he proposes to seek the aid of an assistant, although he himself will still do all the photographic work he can. Strange to say, the only difficulty that delays his start is the flag under which he will journey. Gordon Bennett will place every facility at his disposal if he will but take the American flag with him, but, being a Frenchman, he naturally has some delicacy about doing this. He himself is willing to bear some of the expense, but wants the French Government to bear a goodly share of it. In any case, M. Foureau, with natural endowments to aid his science and experience, is the beau ideal of an explorer.

Sometimes—though, fortunately, not very often—photographers are taken to task for setting up their cameras in forbidden places on the Continent. The following letter, therefore, written from the French Embassy in London, is interesting, if only to show that tourist photographers have now-a-days nothing to fear so far as French possessions go. The official note says:—Il n'existe pas en France ou en Algérie de réglement qui puisse empêcher un voyageur de prendre les vues qui peuvent lui convenir. La seule restriction, que l'on pourrait apporter à cette liberté, concerne les fortifications ou travaux de défense, et dans ce cas le Ministre de la Guerre pourrait seul donner les autorisations nécessaires."

In respect to her galleries and museums, France is even more liberal than we are. It is possible, by the mere asking, to carry a camera into the majority of the fine art galleries, and copy works of art. That is to say, the authorisation is rarely refused to any one who will sign the official regulations drawn up for the guidance of photographers, the principal rule being that only dry plates be used in the work. In these days of gelatine, this regulation will fetter no one.

Mr. H. H. Cunningham, having accepted the appointment of Stipendiary Magistrate in British Guiana, has resigned his post as Hon. Sec. to the Postal Photographic Society. Pending the selection of his successor, communications should, we are informed, be addressed to the Hon. Treasurer, Mr. W. M. Baylis, 3, Plowden Buildings, Temple.

In a paper read at the Photographic Society in 1880, the Rev. T. F. Hardwich spoke strongly of the absolute safety of the blow-through form of the oxy-hydrogen apparatus. In the discussion which followed, his views did not meet with acceptance, and Mr. Cadett, Mr. Norton, and several others gave instances of the contrary. The lamentable accident at Oldham—the actor in which, it may be men-

tioned, was a photographer—is sufficient to prove that extreme caution is needed in the manipulation of the gas bags. Whether or not the accident was due, as asserted, to the displacement of a heavy weight on the oxygen bag, and so causing a "suck back," it is pretty certain that lantern exhibitions are attended with danger.

It is needless to say anything as to the danger attending the use of the mixed gases, as all admit it; but more or less risk seems to accompany the use of oxygen in almost every case. If it is stored in an old rubber bag an explosive mixture is extremely liable to arise through the presence of a combustible dust, formed from the disintegration of the rubber, while a zinc gas-holder is not safe, as hydrogen is gradually liberated by the action of the metal upon water. The iron bottle is perhaps the most suggestive of danger, as if a spark reaches the interior the iron burns, and as the bottle becomes weakened, it bursts with a terrific explosion. In the case of the iron bottle which burst some years ago at the laboratory of the Royal Institution, the iron was kindled by the heat occasioned during the compression of the gas. We are informed that it was an ether-oxygen arrangement which occasioned the accident at Oldham, and the principal force of the explosion was exerted downward, the apparatus having been forced through the floor.

The dispute between M. Meissonnier and Mrs. Mackay touches a point on which photographers are much interested. Ought a photographer to yield to what he believes is caprice or vanity on the part of a sitter, and give the latter a re-sitting, though he feels the portrait found fault with is both truthful and artistic? Theoretically, most would hold that he ought not, but practically, the majority of photographers find themselves forced continually to make the concession. The main point, after all, is to please one's customers, and unless one happens to be a Meissonnier, and can afford to be independent, it does not pay not to be so. A good test as to the sincerity of the motive for re-sitting is to insist upon the destruction of the first negative and print. This will cause the sitter to think twice, and will prevent the disagreeable announcement by the sitter, after an immensity of trouble has been taken, "Well, I think, after all, I prefer the first portrait."

It is worthy of note that, with very few exceptions, when disputes on this point are settled in the Law Courts, the decision of the judge upholds the opinion of the photographer. Only last week a case was heard in the City of London Court, where the Stereoscopic Company brought an action to recover the price charged for photographing a stall at the Fisheries Exhibition. The defence was that the photograph was not properly taken, the particular fault being that it was too light. Mr. Commissioner Kerr, who has an awkward habit of calling a spade a spade, said this was all "rubbish," and that he had never seen a photograph taken better. It is true that the photograph in this case was not a portrait, but fanciful objections are not confined to portraits.

The official scheme for the organization of the Central Institution of the City and Guilds of London Institute has been issued. It recommends that practical laboratory instruction be given in these branches of industry in which artistic effects are produced by a combination of art with processes involving applications of science, such as photo-engraving on metals, photo-lithography, and photography.

A photographic exhibition is to take place in Northampton in December next, and applications for space should be addressed to Mr. H. Manfield, The Museum, Northampton. Northampton possesses no photographic society, but it has had for some time past a "photographic section" attached to the local "National History Club," and the members have decided to hold a Photographic Exhibition. Particulars will be found in another place.

In Italy they do not quite seem to fathom the value of photographic portraits as a means of identification by the police. A young Englishman has disappeared in Rome, and his friends are naturally anxious to find him. What better aid could the police have in their mission of search than a few photographs of the missing one? Accordingly the friend sent post haste to a photographer, requesting an immediate supply of copies from a certain negative. One hundred and fifty copies of the portrait were sent to Rome forthwith, and the friends congratulated themselves on their promptitude. But it appears that the Roman police had no idea that the pictures were to serve any useful purpose, and treated them as a gift from certain eccentric Englishmen.

A French amateur of our acquaintance has a very simple way of measuring his pyrogallic acid. He finds that the little bone spoons shaped like a spade that usually take the place of mustard spoons in France, hold as nearly as possible a gramme of pyrogallol, and therefore he calculates by spoonfuls instead of grammes. A powder like pyrogallic acid heaps itself very uniformly, and therefore the plan may be trusted with some certainty; if the little measure can be relied upon, there is no necessity to weigh your pyrogallol nine times out of ten.

Patent Intelligence.

Applications for Provisional Protection.

3722. James Sturrock, of Dundee, in the county of Forfar, North Britain, for an invention for "Improvements in apparatus for changing the sensitive plates in photographic cameras."—Dated 21st February, 1884.

3865. Thomas James, 37, Renshaw Street, Liverpool, county of Lancashire, sewing machine agent, for "Improved phototype blocks to print in the ordinary type press, to produce half-tones and gradations."—Dated 25th February, 1884.

3866. Josiah William Saunders, David Thomas Davies, and James Alexander Macdonald, trading as Saunders, Davies, and Macdonald, of Ryland Works, Upper Tower Street, Birmingham, brassfounders, for "Improvements in head-rests for perambulators, invalids' chairs, barbers' and photographers' chairs, and for other like purposes."—Dated 25th February, 1884.

Patents Filed 28th February, 1884.

4152. EUGENIO DE ZUCCATO, of Charterhouse Street, in the city of London, for an invention of "An improved method or process of producing prints or transfers of photographic pictures." —Dated 28th August, 1883.

My invention relates to an improved method or process of producing prints or transfers of photographic pictures, and is carried into practice in the following manner; that is to say, I take what is known as a "Woodburytype relief" of the picture of which it is desired to print a transfer, and I lay this relief upon a sheet of paper or analogous material, placed on a slab or plate (such as those hereinafter described), having a smooth surface, which is inked with printer's ink so as to form a grain, stipple, or series of closely-packed lines or dots; I then press the said relief, the paper, and the slab or plate together by suitable mechanical means, whereupon the printer's ink will more or less completely "set off," and be impressed on the paper or analogous material, and thus form a grained, stippled, or lined picture, or ink-photo-print corresponding to the said "Woodburytype relief." This grained, stippled, or lined image, or picture, may then be transferred to metal or lithographic stone by any method known to printers; or the grained, stippled, or lined image or picture may be photographed, and a transfer made therefrom by any method known to photo-lithographers and photo-zincographers. The term "Woodburytype relief" is understood by photographic printers, but to prevent any misapprehension I desire to state that I mean a gelatine film in which the varying tints of a photograph are represented by varying thicknesses of gelatine, or any substitute for the said "Woodburytype relief," such as a cast or mould. The materials which, for the purposes of my invention, I regard as analogous to paper, are such thin, flexible, or yielding materials as will readily take an impression in printer's ink. Among these may be mentioned tracing cloth, ribbed or grained transfer paper, tin or other foil, gold-beater's skin, silk fabric, or other suitable tissue. To explain what I mean by "a slab or plate having a smooth surface which is inked with printer's ink so as to form a grain, stipple, or series of closely-packed lines or dots," I quote the following as examples, viz.:—

1. A lithographer's stone upon which a stipple or lined ground of any kind is imprinted
2. A zinc plate upon which a stipple or lined ground of any kind is imprinted.
3. A slab of any kind upon which a tint or stipple in printer's ink has been inscribed or transferred.
4. A slab or sheet of paper, either enamelled or plain, upon which a tint or stipple in printer's ink has been impressed, inscribed, or transferred.

By the term "printer's ink" I mean any ordinary printing ink in which a pigment is incorporated with an oily vehicle; or similar fatty inks such as are especially made and sold for the purpose of transferring. When I re-photograph the ink-photo-print, I sometimes use an ink of which the vehicle is glycerine, mucilage, or a similar substance. Soft wax, fat, varnish, soap, or a mixture of these materials, may in some cases be used in place of ink when the image is to be transferred to stone or metal. Having thus fully described my said invention, and the manner of performing the same, I wish it understood that I claim—The production of a picture or transfer by pressing paper or analogous material between a "Woodburytype relief," and a slab or plate lined, grained, or stippled with ink, substantially as described.

4153. EUGENIO DE ZUCCATO, of Charterhouse Street, in the city of London, for an invention of "An improved method or process of producing prints or transfers of photographic pictures."—Dated 28th August, 1883.

My invention relates to an improved method or process of producing prints or transfers of photographic pictures, and is carried into practice in the following manner. That is to say, I saturate or ink a piece of fine network or other textile fabric either with printers' ink or with a transfer ink, such as is used by lithographers, care being taken that none of the meshes or ribs of the fabric are blocked up with ink, but that each rib or thread is well saturated. This inked fabric is placed in contact with a sheet of paper; and either upon the said paper, or upon the inked material, I place a "Woodburytype relief," and the whole is then subjected to pressure by suitable mechanical means. I can so vary the working of my invention as to ink the "Woodburytype relief" itself; but, in this case, the paper or analogous material must always be placed between the relief and the fabric. The pressure causes the ink to "set off" from the inked material on to the paper, upon which is thus formed a picture in a kind of stipple corresponding to the "Woodburytype relief." This stippled picture is then either transferred to metal or stone by any method known to printers, or it may be photographed, and a second transfer in fatty ink made by methods known to photo-lithographers and photo-zincographers. I can, if desired, so practise my invention as to obtain the grained or stippled image directly upon a plate of zinc or other metal, or upon a lithographic stone. For this purpose, I first lay the inked fabric upon the plate or stone; I then place the "Woodburytype relief" upon the said inked fabric, and apply pressure by suitable mechanical means as before. Fine wire gauze may, in some cases, be used in place of the textile fabric, and I may mention silk gauze, ribbed silk, ribbed or grained transfer paper, and bookbinder's cloth as examples of the fabrics I use—such fabrics as are thin, yielding, and flexible, being best adapted to the purposes of my invention. The term "Woodburytype relief" is understood by photographic printers; but, to prevent any misapprehension, I desire to state that I mean a gelatine film in which the varying tints of a photograph are represented by varying thicknesses of gelatine, or any substitute for the said "Woodburytype relief," such as a cast or mould. Those materials which for the purposes of my invention I regard as analogous to paper, are such thin, flexible, and yielding materials as will readily take an impression in printer's ink. Among these may be mentioned tracing cloth, tin or other foil, gold-beater's skin, a collodion pelliele, silk, fabric, or other suitable tissue. By printer's ink I mean any ordinary printing ink in which a pigment is incorporated with an oily vehicle; or similar fatty inks such as are especially made and sold for the purposes of transferring. When I re-photograph the ink-photo-print, I sometimes use an iuk of which the vehicle is glycerine, mucilage, or similar substauce. Soft wax, fat, varnish, soap, or a mixture of thesc materials may, in some cases, replace ink when the image is to be transferred to stone or metal.

Having thus described my invention, I claim—

First. The production of a picture or transfer by pressiug an inked textile fabric or the like against paper, or other suitable material, by means of a "Woodburytype relief," substantially as described.

Second. The production of a print or transfer on paper or analogous material, which is pressed between a textile fabric or the like, and an inked "Woodburytype relief," substantially as described.

4154. EUGENIO DE ZUCCATO, of Charterhouse Street, in the city of London, for an invention of "An improved method or process of producing prints or transfers of photographic pictures."—Dated 28th August, 1883.

My invention relates to an improved method or process of producing prints or transfers of photographic pictures, and is carried into practice in the following manuer. That is to say, I take what is known as a "Woodburytype relief" of the picture desired to be printed or transferred, aud I lay this relief upon a sheet of paper or analogous material, and on the other side of this paper or other material I place a roughened, grained, stippled, or lined plate, which has been inked on its roughened side with printer's iuk. The roughened side of the plate must be next the paper or analogous material. I then press the said relief, the paper, and the inky roughened plate together by suitable mechanical means, whereupon the printer's ink will "set off" or be impressed on the paper or analogous material, and thus form a grained, stippled, or lined picture or ink-photo-print corresponding to the Woodburytype relief. This grained, stippled, or lined image or picture may be transferred to metal or lithographic stone by auy method known to printers; or the grained, stippled, or liued image or picture may be photographed, and a transfer made therefrom by any methods known to photo-lithographers and photo-zincographers. The term "Woodburytype relief" is understood by photographic printers, but to prevent any misapprehension, I desire to state that I mean a gelatine film in which the varying tints of a photograph are represented by varying thicknesses of gelatine, or any substitute for the said Woodburytype relief, such as a mould or cast. Those materials which, for the purposes of my invention, I regard as analogous to paper, are such thin, flexible, or yielding materials as will readily take an impression in printer's ink. Among these may be mentioned tracing cloth, tin or other foil, gold-beaters' skins, silk fabric, or other suitable tissue. By a grained, stippled, or lined plate I mean a plate of any moderately hard material, of which at least one surface is roughened, grained, or lined. As examples, I may on the one hand mention a metal plate or block of wood which has been grooved or stippled, a cast of this plate or block in

ebonite, dry gelatine, or celluloid; and on the other hand, a sheet of emery cloth, sand-paper, or bookbinder's cloth. By printer's ink I mean any ordinary printing ink in which a pigment is incorporated with an oily vehicle; or similar fatty inks such as are especially made and sold for the purposes of transferring. When I re-photograph the ink-photo-print, I sometimes use an ink of which the vehicle is glycerine, mucilage, or a similar substance. Soft wax, fat, varnish, soap, or a mixture of these materials, may in some cases replace ink when the image is to be transferred to stone or metal. Having thus fully described my said invention, and the manner of performing the same, I wish it understood that I claim—

The production of a picture or transfer by pressing paper or other suitable material against an inked roughened plate or the like by means of a "Woodburytype relief," substantially as described.

CHAPTERS ON LANDSCAPE AND OUT-DOOR PHOTOGRAPHY.

BY H. P. ROBINSON.

No. 8.—Animals.

When Landseer asked Sydney Smith—to whom all witty sayings are attributed—to sit to him for a portrait, the Canon of St. Paul's replied: "Is thy servant a dog, that he should do this thing?" A fair suggestion that the great animal painter may not be able to render the human face divine. Will the time ever come when the several branches of photography shall have their distinct professors? Will the landscape man ever boast that he can also photograph the figure, as some landscape painters now pride themselves on their drawing of the human form, as something exceptional? Will the portrait photographer ever find himself so entranced by his portion of the art that he can never find time to do a bit of landscape or architecture? If ever any student of our art finds himself compelled to confine himself to one department, it will be the animal photographer. Just as Mark Twain says, there is more *to* a blue jay than any other bird, so there is more *to* animals, from a photographic point of view, than all the rest of creation. If you want to get the best results, you must make a more minute study of your "sitters" than is necessary even with the superior animal—man. You cannot expect to get the best expression out of a Scotch terrier at your first interview, or the amiable purr of a cat at an early acquaintance. Sir Joshua Reynolds found it of great assistance to him in getting the best and most characteristic portraits of his sitters to dine and spend the evening with them; so with what we complimentarily call the brute creation, we cannot expect to get the best results if we come upon them, camera in hand, as total strangers.

There are few animals that cannot be photographed, as Mr. York and Mr. Dixon have shown in their marvellous pictures of animals taken in the Zoological Gardens; but it is not of "wild beasts" that I have anything to say here. It is the domestic animal that is more likely to engage the attention of those for whom I write. Infinite care and patience are required to photograph animals: but some are much more difficult than others. It is seldom, for instance, that a cat will allow herself to be approached by a stranger on photographic thoughts intent; while it is imagining a vain thing to take her to the studio or other strange place for the purpose of having her portrait taken. Of all the domestic animals, the cat insists most on having an "At Home" portrait. The dog is different. He does not care where he has his portrait taken, so that it is done in the least possible time, and without much fuss. The large dogs, as a rule, take it in a lazy, contemplative manner; while the small dogs—by far the most difficult—seem to want to know all about it, and are not easily controlled or kept within range of the focus. It is difficult in writing to give any suggestions about the management of any animals "under the lens"; but you may take it as a rule that violent noises used to attract the attention of dogs will have a contrary effect to the one intended. A quiet little noise made with the mouth, scratching a paper, or gentle rapping out of sight, will almost always make a dog look up; indeed, it is scarcely too much to say that expression may be controlled by these or similar means; while everybody knows the exciting influence of the word "rats" on dogs of the terrier kind. But this should always be kept as a last resource, for no well-educated terrier can sit still for long, however obedient he might be, when he hears the word "rats" whispered in however gentle a tone. A panting dog is always a nuisance to the photographer. This difficulty may sometimes be removed by a drink; but the water should be given just before the exposure is to take place, as the effect soon wears off. It may be partly checked by keeping the dog from running about for some time before the operation. Very much more characteristic pictures of dogs ought to be got, now we can take snap shots at them, than in the olden times.

Of all animals taken to the photographer, the horse is the most frequent. Everybody who has a horse thinks it the best horse of the kind ever invented, and wants its portrait. It is fortunate that he is a good sitter. The photographer has nothing to do but to see that the position is easy—for even horses can pose—and that the expression is bright. A horse cannot smile, but he can do a good deal in the way of expression with his ears and the pose of the head. The one thing to look out for is, if possible, to get the four legs to show. It often happens that the two near legs hide the other two, and the horse looks as if he were standing on two pegs. A horse standing so is exceedingly ugly; but there is a fashion even in the way horses stand, and I lately refused to photograph a lady on a horse because her groom insisted that the horse should stand with the legs level, and stuck out at both ends of the animal in the fashionable way.

Horses are easily kept still. They will prick up their ears and listen to a noise—either the shaking of a newspaper or a whistle—for almost any length of exposure. There are some fidgety horses that nothing will keep quiet, but, fortunately, they are not numerous. Many will champ the bit unceasingly; but this can sometimes be prevented by loosening the curb. The real worry comes from the incessant whisking of the tail in hot weather, when flies are troublesome. The only way to get over this is to take the horse on a cooler and cloudy day. If a portrait of the horse is required, it is much better to do it out of the sun. The violent light and shade of sunshine is apt to spoil the likeness.

With the painter, cattle-pieces have always been favourites. The names of Cuyp, Paul Potter, Ward, and Cooper, recal triumphs in cattle-painting in generations that are past or passing, while the modern school, so different from its predecessors as to be almost a new art, has its constant admirers. But by whatever school they are produced, pictures containing cattle and sheep will always find favour with the country-loving English people. Now I do not know that photographers have yet offered to the public anything very admirable in the way of cattle-pieces. If they have been produced, they have certainly not appeared in our exhibitions. Mr. Berkeley has shown us in one little gem which he called "Noon," a perfect group of cattle in a stream; Mr. Gale has turned agricultural horses to good pictorial account, and a few sheep are found occasionally in landscapes; but the great cattle photographer has not yet arisen. Capital pictures could be obtained: the things required are opportunity, patience, and skill. The photographer who wants to succeed must make his opportunities, and he possesses the two other qualifications, or he is not in a state to gain much advantage from reading this book. A fortnight's residence at a farmhouse ought to put many fine subjects in the student's way. Milking time is always a good subject, one that comes ever fresh, however treated. "Feeding" is a theme that always supplies food for the artist. Feeding cattle—feeding pigs—feeding sheep (a splendid snow subject)—

feeding chickens—feeding pigeons, ducks, and geese; there is no end to the opportunities these operations afford.

In taking such photographs of animals as are here suggested, don't forget that your object is not so much to get a portrait of a difficult subject, as to make a picture. There are some who think that if they succeed in getting the beast still, they have done all that is proposed; but this is only a very minor detail—there is composition, light and shade, and all that goes to make a picture, to be considered. A group of sheep in a level meadow, lighted flatly from in front, would be worthless as a picture; while the same sheep viewed from the other side, with the light just edging their backs, might be very picturesque. Sheep are easily managed, and very useful in a landscape. If a group are lying in a row, or in positions that do not "compose," walking a few steps towards them will induce a few of them to rise and look about, giving the photographer the effect he wants. If they are inclined to straggle and escape, a judicious assistant, by quietly walking round them, can easily induce the group to remain, while the imitation of the bark of a dog, or a whistle, will quickly produce life and expression without frightening them away. Cows, when in the open, are rather more difficult to manage. They are given to bolting; but they are not entirely unmanageable. But whether easy to get at or difficult, refrain from exposing the plates if the "effect" is not good—the world is already flooded with indifferent photographs.

LESSONS IN OPTICS FOR PHOTOGRAPHERS.

BY CAPTAIN W. DE W. ABNEY, R.E., F.R.S.

LESSON X.

Illumination of the Field when Using a Stop.—With a single lens, whether in the rear or in front of a lens, there is not much difficulty in calculating the brightness of an image, compared to that which would be given with a full aperture. Let us take as an example the case of a lens with a stop in front, which is usually the position in single lenses.

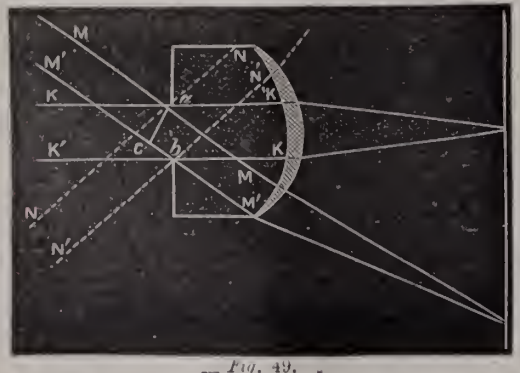


Fig. 49.

Let *a b* be the diaphragm in front of the lens shown in section, and suppose that we have a point lying in the same plane as that of the paper, and their direction in one case in the axis of the lens, and in another above the axis. These two positions are representative, since the section of the lens may be taken at any part through its axis. Let *K K*, *K*$_1$ *K*$_1$ be parallel rays coming from the point in the axis, and M M, M^1 M^1 parallel rays coming from the point above the axis. Then it is evident that in the vertical direction the available aperture in the first case is *a b*, and in the latter only *a c*, whilst the full aperture will be available in both cases in the horizontal direction. Thus the aperture which is circular as seen along the axis, is elliptical when seen along the direction M M, or in any direction other than the axis. Now, the area of a circle is to that of an ellipse as the square of the diameter of the one to the product of the least and greatest diameter of the other. In the case in point, the greatest diameter of the latter is the same as the diameter of the circle. Therefore the available aperture along the axis is to that along the direction M M, as *a b* to *a c*.

[Mathematically it may be expressed thus. Let θ be the angle which the direction of every ray makes with the axis, and *a* be the diameter of the aperture; then the available aperture for the inclined rays is cos θ times that available along the axis.

Example 1.—Rays falling at an angle of 30° with the axis from a distant point, and also along the axis, come from distant points: what is the available aperture in the two cases, supposing the area of the aperture to be unity?

$$\cos 30° = \cdot 886.$$

Therefore the image of the point away from the axis will only be ·866 times as bright as the central image, that is, about $\frac{7}{8}$ as bright.

Example 2.—In a wide-angle lens the angle embraced is 90° at times; find the ratio of available apertures as before for two points of light, one lying in the axis, and the other 45° from it.

$$\theta = 45° \text{ and } \cos\theta = \cdot 707]$$

From this cause alone, then, there would be a diminution of intensity of illumination at the margins of a plate in comparison with that at the centre; but there is still another reason why it is diminished. If the plate were spherical, so that the refracted beam always struck at the same distance from near the optical centre of the lens, this diminution of the aperture for oblique rays would be a measure of the diminution of illumination; but the rays are received on a plane, which makes an angle with them, and the image is therefore spread over a larger surface, and the distance of the image is further from the lens. If a single lens be used without a stop, there would still be a difference in illumination from the same cause as above described.

[Approximately it may be taken that the angle that the ray makes with the plate is the complement of the angle which the incident ray make with the axis of the lens, and it will be readily seen that the image is spread out to an area $\frac{1}{\cos\theta}$; when θ is the angle of incidence, the illumination of the centre of the field to that making an angle of θ with the field is as 1 to cos θ on this account; and owing to the diminution of available aperture, we have already shown it was as 1 to cos θ: therefore the comparative total illuminations due to both causes are as 1 to $\cos^2\theta$.

In the examples given above, the illumination of the field would be 1 to ·886^2, or 1 to $\frac{3}{4}$; and 1 to ·707^2, or 1 to $\frac{1}{2}$.

It will be evident, then, that as the inclination of the rays to the axis increases, so will the illumination fall off on this account alone. Thus, with a wide-angle lens embracing 90°, as in the example, if the central portion of a plate was just sufficiently exposed in five seconds, the margins would require ten seconds to give equally good exposure. In practice, this falling off of the exposure is often visible in negatives taken with a wide-angle lens.

Another point to be taken into consideration is this: the size of plate which is used should never exceed that in which the whole of the rays, going through a diaphragm, strike the lens. Thus, a point lying in the direction NN would strike part of the lens and partly the mount, hence there would be a vast falling off of illumination, of course very much greater than that calculated above.

The Effect of any Stop other than a Circular One.—It has often been proposed, but not quite so often been condemned, to use a slit or rectangular diaphragm instead of a circular one. It may be worth while for a moment to see what this leads to, as one of the principal objects of a stop is to do away with the evil effects of spherical aberration and astigmatism. If, then, a rectangular stop be used, one side of which is longer than another, it is evident that the projection of that aperture on to the lens will be rectangular. If, in the shortest dimensions, it is just capable

of giving definition in one direction, it is evident that in the direction at right angles to it there must be want of definition. Or again, if the longest dimension be capable of giving definition, then the shortest side of the rectangle must be needlessly small. It may be said that this being so, a square is the best shape to give; but it must be recollected that the diagonals are longer than the sides, and the same argument applies as before. Hence we are driven to the conclusion that a circular form is the best. Sometimes it is an advantage to give the foreground a slightly longer exposure than the sky, and it has been proposed to incline the stop at such an angle that it shall appear circular to rays coming from the foreground. In such a case, a smaller stop would have to be used, and thus a longer exposure would be necessary. The best means of securing this advantage is by a flap shutter in front of the lens, or by some other kindred contrivance. For our own part, we say, keep your stops vertical by all means, as then you can take the fullest advantage of the lens you are using.

Working Aperture of Stops in a Double Combination.—The real working size of a stop in a double lens cannot be accurately guaged by its character in relation to the full aperture. The plan to adopt is to accurately focus a distant object, then to replace the focussing screen by a sheet of cardboard in which a small hole has been punched in the axis of the lens.* On the front lens will appear a circle of light when a candle flame is held near the hole, and the diameter of this should be taken as the working aperture of the diaphragm (stop). The front lens may be removed if necessary, and a piece of translucent writing-paper substituted for it, when the measurements can very readily be made.

(To be continued.)

Review.

DIE BROMSILBER-GELATINE. Ihre Bereitung und Anwendung zu photographischen Aufnahmen. Vierte Auflage. *Von Dr. Paul E. Liesegang.*

WE have here a new edition of an excellent little manual of the gelatine-bromide method, and those of our readers who can conveniently work from a German handbook will find much that is useful. The chapter on failures is very comprehensive and well arranged, and we find full information on such subjects as the reproduction of negatives, enlarging, and the treatment of residues.

Some interesting historical notes as to the discovery of the gelatine process are to be found in the book, and it is curious to note that the earliest experiments recorded were made by Niépce de St. Victor in 1847, but these experiments seem to have relinquished been because the film dissolved too easily in water. Niépce said that gelatino-iodide plates give remarkably clear images.

We cordially recommend Dr. Liesegang's excellent little handbook.

A Dictionary of Photography.

ALBUMENIZED PAPER (Printing on).—*Continued.*

Before quitting the subject of enamelling, it will be well to give directions for removing the white and other spots caused by dust in printing and imperfections in the negative. Water colours may be used for the purpose, provided the medium cannot be easily removed by water. Such a substance we have in spike oil of lavender. For white spots, mix India ink, Indian red, and neutral tint with spike oil of lavender to the consistency of cream; test it for shade of colour by touching ont a white spot. Use a sable brush with good point. Let the brush be charged freely with colour, and then worked nearly dry on the palette; by adopting this measure, the beginner will soon be able to touch prints successfully, an achievement he would not attain if the brush were loaded with colour. In the latter case, he would take out a white spot, and put in a black one—a circumstance sometimes met with among professional spotters. If the colour is the same shade as the photograph, then proceed to remove all the white spots, levelling them carefully into the surrounding parts. Dark spots may be lightened with Chinese or zinc white and Indian red mixed with spike oil as before. All the working up that is intended to put on the print should be done after mounting, and before soaking in the vessel of cold water. Another vehicle is sometimes used for mixing the colours, viz., gelatine containing a small proportion of chhome alum to render it insoluble. There are other methods of obtaining enamelled surfaces, differing from the foregoing, inasmuch as the vehicle gelatine is dispensed with in one, and both gelatine and collodion in another. In the former case, the glass is coated with wax in one of its solvents (either benzoline spirit, or methylated ether will do), over this the plate receives a film of plain collodion in which the solvents are about equally proportioned. Thus:—

Pyroxyline (Hopkins and Williams) ...	¼ ounce
Methylated alcohol	... 10 ounces
„ ether	... 10 „
Castor oil	... 20 drops

Moisten the cotton with 2 ounces of alcohol, then add the ether. Finally add the remaining 8 ounces of alcohol in which the castor oil has been previously dissolved. When set, it should be washed in cold water until, when water is poured on, streaks and greasy lines have disappeared.

Unmounted prints previously soaked in water are to be placed wet, in contact with the plate, in the same manner described above, water being the vehicle this time instead of gelatine. Upon examining the front, no small spots should be visible, said spots being air-bubbles. Cover the back with two thicknesses of note-paper, or one of American cloth; squeeg[illegible] thoroughly, and set aside to dry. The other plan, which disp[illegible] with both collodion and gelatine, has only been recently bro[illegible] under the notice of one of the photographic societies, and therefore may be new to many besides beginners.

The glass plate is well polished with tripoli or one of the usual plate-cleaning substances. It is then dusted all over with finely-powdered French chalk, the talc being formed into a pad with flannel, which should be used to do the polishing; the plate should then be immersed in a vessel of water. A well soaked print, placed in contact with the plate as previously described, will adhere so long as moisture be present; when dry, which will happen in the course of an hour in a warm room, the print will drop off. Prints treated with collodion alone may have mounts attached to them by means of either starch, glue, or gelatine, by brushing the mountant on the mount and print, and when rubbed down in contact, put under pressure for an hour. But when neither collodion nor gelatine is used, as in the last method, the plate requires to be coated with some suitable substance on the talc, to prevent the print sticking fast to the glass. If it be desired to attach a mount, the alcoholic soap solution used for burnishing will be found to answer the purpose effectually, preventing the mountant permeating through to the glass, or, rather, holding on to it.

Spotting.—This may take place either before or after rolling, if that mode of finishing be adopted; but many persons prefer to do the spotting first, in order that, when finished, the surface shall be equal, or, in other words, the dull marks caused by the spotting-out brush will not show. The same may be said in the case of burnishing; but if the burnisher is used very hot, the touching colour will become a shade warmer than the photograph, necessitating its removal. As the print in such a case would require re-spotting on the burnished surface with a suitable colour, to match the colour of the photograph, and containing more gum, obviously the time occupied in the first work would be wasted; therefore, one or two trials may be made to indicate the shade of colour necessary to match prints of any particular tone. Moreover, it will be found easier to touch out a spot on an unrolled print, on account of the surface being more spongey. The colours employed are Indian ink, Indian red, and neutral tint, mixed with dilute gum water or albumen until the desired tint is obtained. Ivory black may be added if desired. For warm-toned photographs Indian red will predominate, whereas blue or grey-toned photographs require a larger proportion of neutral tint. The lakes, although useful for obtaining exact shades, are not sufficiently

* This may be quite closely enough to be formed by ruling to lines to the opposite angles of the card, and taking the point of intersection as the axis.

permanent, therefore do not use them; all that is necessary can be easily done by means of the above mixture. Commence by lightly stippling out a white spot in the half-tint, using only the point of a small sable pencil charged as previously described for the purpose. When finished, it should be difficult to detect where the spot existed; but if it is visible, and just a trifle lighter, it may be remedied by one or two light touches of the brush, after taking up the smallest possible quantity of colour from the palette. On the contrary, if the spot is easily discerned by being darker than the surrounding portion, remove it entirely, and start afresh. Patience is absolutely necessary if one wishes to spot prints well, for it is certainly a tedious operation; therefore, we say, persevere with the first spot until perfection has been attained, then all the others will become easier.

Next to spots, it may be necessary to subdue a too prominent light, which we will call a patch; when small, stipple in with the point of a brush slightly charged with colour; but when the patch to be worked on is large, cross hatching will be found quicker and better. Charge the brush well with colour, and make short strokes in the same manner as the down strokes of a pen, commencing at the top with three short strokes, crossing them with two in the opposite direction. Proceed in this way until the patch has been covered; when dry, stipple lightly between the short strokes by means of a fine-pointed brush containing very little colour, until the whole is perfectly levelled. Black spots may be covered with Chinese white slightly toned down with a little of the ordinary touching colour. Working up to almost any extent may be performed by persons possessing the necessary taste and skill. Shadows can be strengthened with neutral tint, or ivory black mixed with gum; lights may be worked over with Chinese white, the middle tints stippled with ordinary touching-out colour and, where needed, such as the shadows in the face, a mixture of black and white. Whether spotting is done before or after rolling or burnishing, an encaustic paste is useful to have ready, for several reasons; dull spots caused by extra touching, or by finger marks, may be easily removed, the surface becoming brighter than with burnishing alone. What is of greater importance, however, is the permanence it is said to confer. Many persons claim that when the pores of the paper are filled with wax, the photograph is protected, to a large extent, from atmospheric influences. Besides polishing photographs, it will polish the apparatus, if applied with a little friction.

Encaustic paste is essentialty bee's-wax reduced to a paste with one of its solvents, such as turpentine, and however much it may savour of furniture cleaning, it will be found quite as useful for putting a fine polish on a photograph, let it be new or old. An excellent paste is made as follows:—

White wax	1 ounce
Turpentine	5 ounces

Dissolved by gently heating over a water bath; when cold, it is ready for use. If the smell of turpentine is objectionable, one ounce of spike oil of lavender may be substituted for a similar quantity of turpentine: the result will be the same. Apply the paste to the photograph by means of a small piece of flannel, rubbing it lengthways, but all over; then work in a circular direction, using the same flannel, until the wax appears to be all rubbed into the print. Make a pad of clean flannel, and lay on the friction for a few seconds, working as before in a circular direction; if you get tired, don't make a halt on the print, or it may cause a mark; if the polish is not satisfactory, apply more wax, and repeat the operation, finishing off with a clean piece of old cambric.

Everyone has heard of Adam-Salomon, the great master in portrait photography, and who has not heard of his celebrated encaustic paste? In case there be such, we will give the formula for his benefit:—

Pure virgin wax	500 parts
Gum elemi	10 „
Benzole	200 „
Essence of lavender	300 „
Spike oil of lavender	15 „

Melt on a water bath, mixing thoroughly, and strain through muslin; or the gum elemi may be dissolved in the solvents, and ths melted wax added after filtration; to make it thinner, add a little more essence of lavender.

The silver printer should read the article RETOUCHING, as most negatives are improved by a little work. Reference should also be made to RESIDUES and SILVER SOLUTIONS.

Proceedings of Societies.

THE PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

A MEETING was held at the Gallery, 5A, Pall Mall, East, on Tuesday last, the 26th inst., Mr. SEBASTIAN DAVIS in the chair.

The CHAIRMAN said they intended to give those who were present an opportunity of judging as to the value of the simple forms of lantern in which oil light is used. For educational purposes or exhibition in a small room, the oil-lamp gives an ample light, and Mr. Davis had found that almond oil answers well as a fuel for the lamp, giving a soft and agreeable light. One disadvantage of the oil lamp in comparison with the lime-light arises from the circumstance that when the radiant is large, it is difficult to realise those optical conditions which give rise to an uniformly-lighted disc. The paraffine lamp has been much modified for lantern work, but principally by re-duplicating the burner.

Some slides were then projected on the screen, various lanterns being used. Mr. Davis' lamp, burning almond oil, did not give quite such a brilliant light as the Sciopticon Lantern belonging to the Society, but the illumination was more uniform in the case of Mr. Davis' lantern. Other paraffine lanterns were tried, but those having three or four wicks respectively did not show any corresponding advantage over the Sciopticon.

Among the slides shown were some on gelatino-bromide plates by the method of Mr. J. W. Wellington (see page 79). Those which had received a short exposure with quick development were cold and greyish in tone, while in the cases where the exposure had been increased fifty or eighty fold, and the development had been very slow, a rich red tone resulted. For the composition of the developer, see below.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

A MEETING of this Society was held on Thursday, the 21st inst., Mr. F. PIPER occupying the chair.

Mr. J. B. B. WELLINGTON exhibited several transparencies printed by contact, the tones ranging from black to red.

In reply to questions, Mr. WELLINGTON stated that he used bromide plates prepared according to the formulæ he gave at the meeting held on the 24th ult. The developer used was a modification of ferrous-oxalate, as follows (3 parts of No. 1 to 1 part of No. 2.):—

No. 1.

Oxalate of potash	2 ounces
Chloride of ammonium	20 grains
Water	20 ounces

No. 2.

Sulphate of iron	4 drachms
Citric acid...	2 „
Water	20 ounces

The difference in tone was obtained by varying the proportions of restrainer (bromide of potassium) and the time of exposure.

Mr. W. E. DEBENHAM enquired if Mr. Wellington had made any experiments of this kind on ordinary gelatino-bromide plates? It would be interesting to see if the same results could be obtained.

Mr. WELLINGTON had not experimented with ordinary plates.

Mr. DEBENHAM considered it a very decided move to be able to get such qualities.

Mr. A. L. HENDERSON said there appeared to be distinct qualities peculiar to chloride and bromide of silver, either of which for particular purposes were advantageous; possibly the two might be combined. Speaking of restrainers, he said the most powerful restrainer he knew was boracic acid.

Mr. WELLINGTON: How much stronger is it than bromide of potassium?

Mr. HENDERSON could not give the relative restraining power, but it is almost unworkable, it is so powerful. Speaking of canary medium, he had exposed two plates 7½, 15, and 22½ minutes respectively to light emitted from a gas jet placed two feet behind the canary medium; the plates being exposed six feet from the medium, an excellent light was obtained, and safe enough for all practical purposes, there being no indication of fog. Mr. Cowan developed one, and he the other. Mr. Cowan said he exposed his plate in the camera masked, before developing, there was no trace of fog. There were 200 square inches of light.

The CHAIRMAN'S experience differed from that of Messrs. Henderson and Cowan; he obtained a transparency after twenty minutes' exposure to canary medium, illuminated by a paraffin lamp; the flame was one foot from the medium, and the exposure made at eighteen inches from the light.

Mr. DEBENHAM was of opinion that yellow light is the most suitable for bromide plates. Canary medium may be good, but not so good as the lamp shown by Mr. Cowan a few weeks ago. Most samples of canary medium are faulty, owing to insufficient care in manufacture. In the lantern he found canary medium safer than two ruby glasses, or ruby and orange pot-metal.

Mr. W. COLE: Has Mr. Henderson used canary medium with daylight?

Mr. HENDERSON: Yes; but having oiled it, a wet plate can be easily fogged through it. It is a mistake to oil the paper or make it transparent.

Mr. J. M. TURNBULL (Edinburgh) said the photographers in Edinburgh had given canary medium a trial, but found orange paper answer every purpose.

The following question from the box was read:—"Does the sulphite of soda developer destroy the half-tones to an appreciable extent?"

The CHAIRMAN found it did so.

Mr. COLE said the use of citric acid to neutralize the alkalinity prevents it coming into more general use. If sulphurous acid were used to neutralize, or if the sulphite were employed without neutralizing, it would work very well. In the case of thinly-coated plates, it would be well to leave the sulphite out, as the colour might be beneficial in printing.

Mr. F. W. HART exposed two trial plates from different batches of emulsion, giving a full exposure to compensate for the large quantity of citric acid he added to neutralize an alkaline sample of sulphite of potash; both plates were over-exposed. He then exposed two more, giving each one second, $\frac{1}{10}$. One plate was correctly timed and perfect, the other slightly under-exposed; he could scarcely think citrate had a slowing action.

Mr. TURNBULL found sulphite of soda to vary considerably. Sulphurous acid was the proper acid to neutralize with, in his opinion.

Mr. F. YORK spoke favourably of sulphurous acid for the purpose named. By filtering through marble afterwards, a perfectly neutral solution could be obtained.

Mr. HENDERSON said he had been treating emulsion with dilute sulphuric acid to remove the particles of decomposed gelatine adhering to the sensitive salt. After adding more gelatine and washing, he obtained a slow emulsion, very clear in the shadows. He was now trying the addition of pepsine for the same object—viz., clearing the shadows—and found it did not slow the emulsion.

The CHAIRMAN: Has anyone tried emulsifying with castor oil instead of gelatine? He made a batch, but had not yet seen the developed results. His object in trying castor oil was to be free from decomposed gelatine.

Mr. DEBENHAM asked the Chairman how he obtained a mixture.

The CHAIRMAN replied that he dissolved the salts in distilled water, adding the bromide first and the silver afterwards.

Mr. DEBENHAM should expect to find them floating on the surface; they would not be dissolved.

Mr. W. M. ASHMAN: There it no reason why castor oil should not be employed. If an emulsion can be prepared in a mucilage like gum-arabic, why not in castor oil?

Mr. COWAN: Because one is soluble in water, and the other is not.

Mr. HART: A perfect emulsion of castor oil can be made with gum tragacanth.

Mr. HENDERSON enquired if the Chairman obtained a fine precipitate.

The CHAIRMAN said, as fine as any with gelatine; the formula is as follows:—

Castor oil	... ...	1 ounce
	A	
Silver nitrate	... ...	100 grains
Distilled water	... ...	6 drachms
	B	
Bromide of potassium	... ...	80 grains
Distilled water	... ...	1 ounce

Add B to the oil, then A, boil twenty-five minutes; then add Nelson's No. 1 gelatine, 2 drachms, set, and wash; after washing, add another 2 drachms of gelatine. Make up to 5 ounces in all.

Some doubts being expressed as to the whole of the oil being washed away, it was suggested that a final wash in alcohol would dissolve any remaining traces.

Mr. TURNBULL passed round a modified holder for lantern slides. When the slide is in position it is held by a trigger, which, being released, permits the slide to drop through, similar to the drop shutter.

Mr. HART showed a model of working parts of head-rest, combining every possible movement required.

Talk in the Studio.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.—The next meeting will be held in the Rooms of the Society of Arts, John Street, Adelphi, W.C., on Thursday, March 6th, at eight o'clock, when the adjourned discussion on "Whether pictures upon ready-sensitised paper are more or less likely to be permanent than those on ordinary paper," will be resumed, and Mr. Edward Dunmore will read a paper upon "Old Photographs." Members and friends having "old photographs" (of the method of production of which they can give particulars) will oblige by exhibiting them.

NORTHAMPTON INTERNATIONAL PHOTOGRAPHIC EXHIBITION.—This will open on December 15, 1884, and will remain open until January 10, 1885. *Conditions.*—1. There will be an entrance fee of 5s. to be paid by each exhibitor in competition whose exhibits cover less than twenty square feet, and 10s. to those whose exhibits cover more than twenty square feet. 2. All pictures for exhibition must be sent mounted and framed, with the artist's name, address, and price (if for sale) on the back; the titles of the subjects, and the process by which produced, may be neatly affixed to the front of the pictures. On no consideration will the name or address of the artist be permitted on the front, as such will appear in the catalogue. No pictures in Oxford frames will be admitted. 3. The committee undertake to unpack, re-pack, and return all exhibits remaining unsold; all carriage must be prepaid by the exhibitor. Every care will be taken of the exhibits, but at the same time the committee will not hold themselves liable for any untoward accident that may occur, with the exception of loss by fire, which is specially provided for. 4. The committee will undertake the sale of exhibited pictures (or further copies) at the usual commission of ten per cent. 5. Photographs coloured by hand will be excluded from competition. 6. The hanging committee reserve the right of rejecting any picture. 7. Each exhibitor must fill up form A, and forward it to the Hon. Secretary not later than November 1st. 8. All pictures must be sent carriage paid, to arrive not later than December 1st (form B being sent as a letter of advice), addressed—International Photographic Exhibition, The Guildhall, Northampton. *Prize List.*—Ten silver and sixteen bronze medals (from a die by Wyon) will be placed at the disposal of the jurors for the best and second best pictures in the classes mentioned. The committee will endeavour to secure the services as jurors of an artist of repute, three well-known and leading photographers, and a representative elected by the local photographic society, none of whom will be connected with the locality.

A LANTERN CATASTROPHE.—An explosion, which shook buildings for several hundred yards distant, occurred on Friday night, at Chadderton Town Hall, Oldham. A series of dissolving views were being exhibited, and whilst five hundred children were singing "Shall we gather at the river?" a loud report was heard, accompanied by the smashing of windows, the gas being at the same time extinguished. On the gas being lighted, the magic-lantern apparatus and furniture were found smashed to fragments. Children rushed down the staircase, and the police assisted numbers of them through windows and down ladders. Several were crushed. The explosion is said to have been caused by the gas-bag coming into contact with a flame, or the sudden lifting of the pressure board. The floor of the hall was ripped up, and the room beneath, where the Chadderton Local Board assemble, was wrecked. Mr. Diggle, the photographer who was exhibiting the magic-lantern, was cut about the face, and thrown down by the force of the explosion. The body of one boy who was killed was found on the staircase, he having evidently been suffocated by the pressure of the crowd. An eth-oxygen burner was employed for the lime-light (see our vol. for 1881, p. 94).

IMITATIONS OF COSTLY LEATHER BY PHOTOGRAPHY.—A genuine seal, alligator, boa, or other costly skin is photographed, then printed on sensitive gelatine, the parts not acted on by light dissolved out in water, and a cast or an electrotype plate then made in copper or type metal, as practised in the reproduction of engravings, and then the metal plate and the smooth leather of some domestic animal are passed between rollers under pressure, and the figure on the plate is permanently fixed on the leather by great pressure. These leathers may be stained, coloured, or dyed to any tint desired; but plain black or the colour left by the tannin is generally preferred.—*Scientific American.*

PHOTOGRAPHIC CLUB.—At the next meeting on March 5th, the subject for discussion will be "On the Advantages or Disadvantages of Sulphite of Soda in the Developer."

To Correspondents.

All Communications connected with Advertisements and Business to be addressed to Messrs. PIPER & CARTER, *"Photographic News" Office, 5, Castle treet, Holborn, E.C. Advertisers are requested to make all Cheques payable to* Messrs. PIPER & CARTER, *and crossed "Union Bank, Photographic News Co. Account."*

*** We cannot undertake to return rejected communications.

W. J. A.—The best preparation to use is a weak gelatinous solution: one part of a clear hard gelatine in twenty of water. 2. Immerse the glass plate and the print in the warm gelatinous solution, and establish contact by means of the squeegee.

T. P. B.—We cannot tell you what the firm in question pays, but imagine that from £3 to £4 a week, with a small commission, is the usual thing.

ALFRED KNOTT.—It is very good of you to take the trouble to send us the particulars, of which we have made use. Further information would interest us.

W. COLES.—Our impression is that the blending or graduating was done on the dry background by friction with a stiff brush, and that ordinary coloured chalks, such as can be obtained from any artists' colourman, were used.

A. G. B.—1. It acts readily on glass, and causes an immediate precipitation of salts of lime. 2. The precipitation is prevented. 3. Certainly, unless in very hot weather. 4. No, our experience does not confirm it.

L. W. B.—1. The most satisfactory cement is the elastic rubber-cement, which can be obtained at the carriers' shops. The parts must be well warmed. 2. We have not seen it; try the encaustic paste mentioned in the Formulary.

VALLETTA.—1. A squeegee is a strip of india-rubber mounted between two laths of wood, so that about a quarter of an inch of the rubber projects along the edge. It forms a kind of soft scraper. A similar instrument, but made on a larger scale, is used for clearing mud from pavements. 2. Linen or cotton fabric coated on one side with india-rubber. 3. Probably from any stock dealer. 4. We should prefer the second on your list. 5. Attend the next meeting of the South London Society; it is on Thursday evening next, at the House of the Society of Arts, John Street, Adelphi.

J. HAMPTON.—Brush it over with boiled linseed oil, and allow it to dry.

JAMES WRAYBURY.—Thank you.

C. H.—1. The action will doubtless take place much more rapidly in a damp place than in a dry locality. 2. Very likely; you had better discard it, and use slate. A coat of paint may make it worse.

LITTLE PHOTO.—You have been very successful, but perhaps you might make the contrast between the two sides of the face a trifle more pronounced. Continue to work, by all means.

IOLANTHE.—1. If you have, as you say, a thorough knowledge of the business in all its details, you will act wisely in doing as you propose, and you may reasonably expect to be successful. Business qualifications are, however, quite as important as technical skill, and from your questions we rather doubt whether you have these. 2. We would rather advise you to purchase if you can meet with a favourable opportunity. 3. From one and a-half to two.

A. BARA.—The plate you send is a very curious example of the reversal of the image. The red parts of the picture are positive, and the grey parts are negative. There is no red fog in the ordinary sense of the term. The partial reversal is doubtless due to the use of hyposulphite in the developer.

M. S.—Either your lens does not work to focus, or your plates do not register with the face of the ground-glass. Focus some fine line work accurately on a ground glass, place in the plate-carrier, and then replace this by the focussing screen. If the register is perfect, we will tell you how to test the lens.

W. M. and ENQUIRER.—Next week.

NORMAN MAY.—1. Although one-tenth of a second is a sufficiently short exposure for many street views, cases may arise in which it becomes necessary to reduce the exposure to one-fifth of this; while on the other hand it is often practicable to give a considerably longer exposure. 2. You speak of "this view," but no photograph was enclosed.

G. H. BARTHORPE.—Thank you.

The Photographic News Registry.

Employment Wanted.

Assist. Op., &c. (town only).—C. H. E., 50, London-st., Tottenham-ct.-rd.
Assist., can print, tone, paint enlarg.—Silver, 40, Gower-st., Birmingham.
Assist., cnl. on Morgan's pap.—F. P., 16, Rochester-sq., Camden-rd., N.W.
Assist, retouch heads for publication.—Retoucher, *Photo. News* Office.
Reception Room, as Improver.—X. Y. Z., 5, Jesse-ter., Reading.
Assist. Operator, could manage.—F. B., 2, James-st., Iffley-rd., Oxford.
Reception Room or Shop (Lady).—A.S., 77, City-rd., N.
Operator, wet or dry.—C. O., 25, Duke-st., Bloomsbury.
Retoucher, first-class.—Artist, 15, Hastings-st., King's Cross, N.W.
Artist in Oil and Water.—J. J. Gibson, 32, Pembroke-sq., Kensington. W.
Op. & Ret., wet or dry.—F. J. M., 6, Brockham-ter., Willsbridge, nr. Bristol.
Operator and Retoucher.—Alpha, 10, Hotspur-st., Kennington-rd., S.E.
Retoucher and Min. Artist.—Miss Lea, 443, Coldharbour-la., Brixton.
Silver Printer and Toner.—F. C. M., 35, Vincent-sq, Westminster.
Gen. Assist., all round.—G. L., 49, Ledbury-rd, Bayswater, W.
Op. & Retoucher, 50/- weekly.—H. H., 146, Cheetham-hill, Manchester.
Gilder, Joiner, Fitter-up.—A. J, 31, Charles-st., Southboro', Kent.
Printer, generally useful.—F. Foy, 7, Market-st., Deal.
Finishing Enlargements at home.—L. E., Spring House, Merton, S.W.
Operator, land., portrait., monoch, crayons.—W. D., Shaw-rd., Dudley.
Reception Room, Shop, Mount, finish, &c.—B. A.. *Photo. News* Office.
Col. & Ret. (Lady).—E. McCowen, 20, Grand Parade, St. Leonard's-o-Sea.
Retoucher, Operator, Printer.—V. C. Yealett, 3, Queen-sq., Bath.
Manager, exp.—Photographer, Adelaide-rd., St. Pancras, Chichester.
Operator, Copyist, clever with children.—C. O., 25, Duke-st., Bloomsbury.
Retoucher, first-class, in London.—Artist, 15, Hastings-st., King's Cross.
Printer, can speak French.—G. P., 45, Stamford-st., Blackfriars-rd., S.E.
Retoucher, first-class.—P. Marks, 1a, Britannia-st., City-rd., E.C.
Retoucher, work at home.—J. Fisher, 7, Westmoreland-pl., City-rd., E.C.
Shopman, town preferred.—E. D., 17, Brunswick-st., W.C.
Operator & Retoucher.—Light, 94, D Street, Queen's-pk., N.W.
Architectural or Engin. Photo.—W. S., 32½, Colebrooke-row, Islington.
Assist. Printer, good Vignetter.—G. E. C., *Photo. News* Office.
Lady in Rec. Room, or Spot.—C. R., 40, Netherwood-rd., Shepherd's Bush.
Lady as Retoucher (pupil of Arndt).—M. A., *Photo. News* Office.
Lady Spot., Mounter, Recep. Room.—E. G. C., 115, Westbourne Grove, W.
Oper., Print., Toner, Painter Water Colours.—G. L., *Photo. News* Office.
Assist. Operator and Retoucher.—F. E. Baily, 21, Gt. Oxford-st., L'pool.
Artist, well up.—P. Eckhart, 105, Hall-pl., Hall-pk., Paddington.

Employment Offered.

Printer, first-class, to Manage.—Byrne & Co., Richmond, Surrey.
Printer & Toner, dry-plate.—H. Friedmann, The Grove, Stratford, E.
Assist. Landscape Printer.—Carl Norman, Graphic Villa, Tunbridge Wells
Operator for Ireland.—D. W., c/o Marion and Co., Soho-sq.
Printer, young and clever.—J. S. Catford, Art Gallery, Ilfracombe.
Assistant Operator immediately.—P. G, c/o Marion & Co., Soho-sq.
Operator, clever, for three months.—Silas Eastham, Southport.
Retoucher, three days a week.—J. S. Bayfield, 10, High-st., Notting-hill.
Retoucher, clever.—John Hawke, George-st., Plymouth.
Assist. Oper., first-class Retouch.—Disderi & Co., 4, Brook-st., Hanover-sq.
Out-door dry-plate Operator.—R. Ward & Co., 166, Piccadilly.
Sil. Print. & Ton.—Mrs. Harborne, 300, Victoria-rd., Aston, Birmingham.
English Lady for France (shop).—E. E. Y., 24, Mark-la., E.C.
Out-door Operator, Monochrome, Retouch.—A. K., *Photo. News* Office.
Operator, generally useful.—A. H., 68, Fullerton-rd., Wandsworth.
Operator, first-class, for City firm.—J. B., *Photo. News* Office.
Assist. Printer, good Vignet.—J. Ruckmann, 5, Watfield-rd., Ealing Dean.
Operator for Ireland.—D. W., c/o Marion and Co, Soho-sq
Artist, for black-and-white.—G. N., 118, High-st., Notting Hill.
Printer and Toner, first-class.—Cobb and Son, Wellington-st., Woolwich.
Printer and Toner, to manage.—Vander Weyde, 182, Regent-st., W.
Collotype Printer, Woodburytype, &c.—X. X., 38, Poultry, E.C.
Artist, skilful, at 50/- per week.—Winter, Derby.
Printer and Vignetter.—Dickinson's, 114, New Bond-st.
Photographer on Wood.—Photo, 58, Salcott-rd., Wandsworth Common.
Printer & Toner, generally useful.—Hallier, Stafford-rd., Walsall.
Assistant Operator, first-class.—Byrne & Co., Richmond, Surrey.
Floater.—Tavistock Alb. Wks, 1, Tavistock-pl., Harrow-rd., Kensal Green.
Lady Correspondent and Shop.—West and Son, Eagle House, Gosport.
Operator for Ireland.—D. W., c/o Marion and Co., Soho-sq
Operator in Horsham.—S. Bayfield, 10, High-st, Notting-hill-gate.
Retoucher, to finish enlargements.—Whitlock, New-st., Birmingham.
Young Man, good all round.—Beta, *Western Express*, Bideford, Devon.
Printer (male or female) for Bristol.—Holden, 23, Queen-st., Plymouth.
Carbon or Lambertype Photo.—W. B. Woodbury, Manor-rd., S. Norwood.
Printer and Toner for country.—Bunyard, 36, Mildmay-st., Mildmay-pk.
Carbon Enlarger and Printer, piece work.—A. D. C., *Photo. News* Office.
Operator and Printer.—Apply, 60, Clarence-rd., Hackney.
Operator (dry plate), also Retoucher.—Lauder, Westmoreland-st., Dublin.
Under-Salesman.—Shew & Co., 132, Wardour-st., Oxford-st., W.

RETOUCHING FOR AMATEURS.

SINCE dry plates have placed in the hands of amateur photographers the possibility of turning out fairly successful portraits working in ordinary rooms, those who have taken up the practice of portraiture feel very keenly the disadvantage at which they are placed from their ignorance of the art of retouching, and feel it all the more keenly because it is almost the only point in which they find themselves really quite unable to compete with the professional.

It is unlikely that amateurs should ever actually compete with professionals in that art which, however doubtful a one it may be from an artistic point of view, is certainly a popular one with the public. Still, there is a certain amount of retouching skill which the amateur may easily acquire, and which would be just enough to greatly improve the general style of his portrait work. In fact, the amount of retouching for which the amateur is likely to gain the necessary skill is precisely that amount which will actually improve the photograph from the most severely artistic point of view. He may acquire the skill necessary to remove the blemishes which are due to the photographic plate or process itself.

The blemishes to which we refer are spots due to defects in the plate—spots which may exist on the skin of the subject, but are perceived with much less vividness by the human eye than by the photographic eye ; the increased distinctness of lines and wrinkles ; the too great heaviness of shadows.

We believe that the reason why amateurs seldom acquire the necessary skill to eliminate these defects is because they have not the smallest idea of how to commence work. We shall give a few hints on the matter.

The first attempts may be made without a retouching desk, the negative being held against a window. The position involved by this mode of procedure is by no means a comfortable one, moreover the eyes are excessively strained ; and if the practice of retouching is to be continued, a retouching desk must be used. The form of this piece of apparatus is well known. It consists of a frame for holding the negative at a convenient angle for working on, a mirror or piece of white paper being placed below it to reflect light through it. Such a desk may be purchased, or may be made by a photographer who is somewhat of a mechanician.

Before a negative is retouched, a proof should be taken of it. The next step is to get a surface on which a pencil will work or "bite." The negative should be varnished with a hard varnish. There are sold various mediums which may be applied to the part to be worked on, but we have found none of them to give a result perceptibly better than can be obtained with turpentine. A single drop of this is placed on the part to be retouched—generally the face, if the subject be a portrait—and is quickly spread over it either with the tip of the little finger or with a bit of chamois leather. It is gently rubbed with a circular motion till the part is dry. A pencil will now bite freely. It is said that the film has a "tooth."

An H pencil of good quality will be found about the best to work with. The point must be made exceedingly sharp. This should be done by first sharpening the pencil in the ordinary way with a knife, then by rubbing it to a very fine point on a piece of drawing paper.

We now refer to the print to see what portions it is desirable to modify. We will find first of all, probably, several spots which are too dark. We look for the corresponding transparent spots on the negative. The pencil is brought to bear on one of those, and by a gentle circular motion the spot is caused to disappear. So we do with all irregularities which are due either to defects in the films, or mere irregularities in the colour of the skin of the sitter.

We have now other difficulties to look at. The line which passes from the inner corner of the eye to the cheek is sure to appear more intense in the print than it did in the subject. Very likely the same will apply to lines from the corner of the nose downwards. We must reduce the transparency of these parts on the negative, and also shorten the lines by blending them with the rest of the face. We do this by gentle strokes of the pencil, being in no hurry, but by degrees working the lines partly away.

Lines of age and wrinkles are not difficult to soften : in fact, they are more easily modified than the lines which we have just referred to, but the amateur requires to use great judgment before he touches them. He must bear in mind that whereas the sloping lines just mentioned are seldom other than a disfigurement when very strongly marked, the lines of age frequently give a beauty of their own to a face. As a rule, in the case of really old people, it is inadvisable to modify these lines. It is in the case of people of an uncertain age, especially ladies, that there is necessity for retouching in this particular direction. These lines, barely visible to the eye, frequently come out with startling vividness on the photographic plate. It is only necessary to run the point of a sharp pencil along such lines, when they may be either softened or eliminated altogether, as may be thought desirable. Care must be taken not to tear through the varnish in doing this. If the lines are very strongly marked, and require to be much reduced, it is advisable to use a softer pencil than the H ; an HB, or even a B, will do.

It will generally be found that in the print from an untouched negative, especially when there has been slight under-exposure, there is a somewhat too sudden transition from high light to shadow, whereby there is a loss of roundness in the effect. To slightly improve this defect is about the limit in the way of retouching which the amateur is

likely to reach. He may increase the roundness by making the transition in the negative from opacity to transparency less sudden. This he does by working with the pencil in fine lines round the parts where the transition commences. Great care and some practice are necessary to do this with any success.

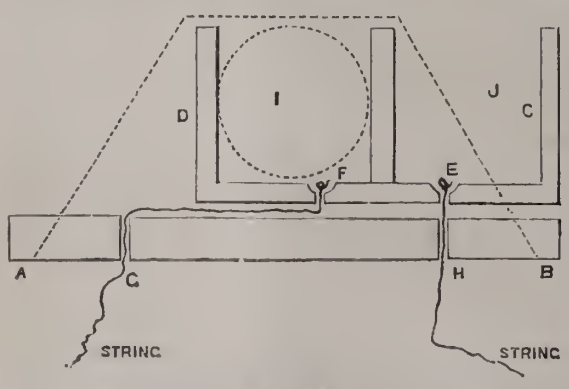
It will be noticed that the defects which are eliminated are only such as appear on the print too dark, and on the negative too transparent. Those which appear too opaque on the negative and too light on the print can only be eliminated by working on each print separately.

The first attempt at retouching may be made on a useless negative, but it is by no means absolutely necessary to use such, as it is easy to wipe out the pencil marks if they are not satisfactory. A drop of turpentine applied as at the beginning will do this.

MR. COWAN'S SLIDE-CARRIER FOR THE LANTERN.

This apparatus, which was shown at a recent meeting of the Photographic Club, enables the lanternist to bring a new slide into the field of the lantern with rapidity and exactness, the transition being almost instantaneous.

It consists of a wooden base-piece, A B, upon which there slides a kind of double frame, D C. A pair of



upright boards, shaped as indicated by the dotted lines, serve to keep the sliding frame in position. The two divisions, I and J, of the sliding double frame, are grooved so as to receive the usual lantern slide (3¼ in. square), and whichever of the divisions stands at the end of the base-piece is first charged with a slide. A steady pull at the string situated at the other extremity, G, brings the slide into position, and the other division can now be charged; after which, a pull at the second string brings the new slide into the field.

The fact of the slide which remains in the outer division of the double frame, being, in great part visible to the manipulator until the moment when it is shot into the field, is an advantage, as there is a considerable probability of any error in placing the slide being noticed before the picture is exhibited.

A TRIP TO THE GREAT SAHARA WITH A CAMERA.

BY A COCKNEY.*

There are only two trains a-day to Batna, and some six hours are necessary for a journey of seventy-five miles. Batna, so the guide-books say, means simply an encampment for the night, and I think the guide-books are quite right. No one in his senses would think of encamping more than a night if he could help it. Before you are half-way there, the country has changed for the worse, and you are in the midst of dry arid plains, with an occasional stretch of water without a blade of grass or green herb beside it. A tropical sun beats down fiercely over the black mud waste, and for miles and miles there is not the shadow of a tree or bush. It might be the great desert itself already, if it were not for the fact that we are amid the mountains, and at an elevation of some 3,000 feet.

The photographer *en voyage* does not now-a-days require to develop his plates as in the old collodion days, but boiling water is sometimes welcome to him, whether as a luxury or a necessity. I always take the means with me to obtain this, whenever there is occasion to rough it, whether the idea is to purify water by boiling, or to make an occasional cup of tea. So I will here mention how I am provided in this respect. A flat sponge spirit-lamp is in my outfit, and a tin flask of spirit. This is not methylated spirit, but pure, so that if any leaks out among your linen there is no disagreeable smell. A little saucepan, with a handle that doubles inwards, I prefer to a kettle, for it takes my tea in a tin-foil package. Moreover, I carry a dozen little cambric bags, the use of which I will explain. When I want a cup of tea, my saucepan (it holds about a pint) is filled with water and made boiling; then as much tea as is necessary is put into one of the bags and immersed in the boiling water. My tea made, I remove the bag and throw it away with the tea leaves. In this way my saucepan is always clean, and will serve immediately afterwards for any other purpose.

Another serviceable thing to carry with you is a few yards of thin waterproofing. Mine weighs but a few ounces per yard. I find this very useful for enveloping my dark slides before putting into the side-pocket ready for use. Dust is everywhere just now, and really the only way to keep it out is by an envelope of this material. Thanks to a simple covering of this, which is also as opaque as brown paper, I have so far kept my slides and plates free from dust and grit.

You are now in *la vraie Afrique*, as the landlord at the Batna auberge has it. Dilapidated tents of dirty fabric mark the encampments of Arabs here and there, very similar, indeed, to our gipsy encampments at home, except that, instead of sorry horses picketed around, there are ragged camels and plump little asses. The blankets or burnouses of these roving Arabs are much more dirty and ragged than those of their town brethren, and altogether they inspire the stranger with less confidence. Jones and I both prefer strolling about inside the Batna walls after sundown, to worrying the Arabs near their encampments.

Some very interesting remains of a Roman city are close to Batna, at a place called Lambèse. The French department of Beaux Arts have spent some seven hundred thousand francs in excavations, and with such success, that a most complete forum has been unearthed, together with a temple with several columns standing, a bath, and a portion of a theatre. There is also a large portion of the Prætorium standing, with the inscription on one of the arches, "Legio tertia Augusta," signifying pretty clearly that it was the work of the third Augustan legion. This brings us somehow within measurable distance of the founders, and Jones says that when he gets home he shall overhaul his Cæsar for an account of it.

A stately Arab in his spotless white toga served as guide, and added, perhaps, to the sentiments of the scene. Before us, stretching over the wild hills for a mile or more, were scattered the relics of a bygone race, the rugged country marked here by a graceful column, there by a pile of massive masonry. You could stand on the broad platform of the forum and harangue the soldiers of the third Augustan legion, in imagination, if not in reality. You could from this spot see in your mind's eye the populace ranged round the theatre, witnessing a drama——— "Eh! what is it?" I cry, for Jones is calling to me, as I stand alone at a solitary spot conjuring up these pleasant fancies. He has to repeat twice before I can hear. "Why, a panther half eat up a dog last night, about here, and

* Continued from page 132.

the village people are out after him to-day," roars Jones.

I am sorry to say the third Augustan legion vanished rapidly after this, and afterwards I keep close to the guide, to hear what he has to say about the Romans. For all that, the romantic fancies do not come back, though the panther does; and whenever I am rather long over focussing underneath the dark cloth my stupid companion reminds me of the panther of Lambèse.

There is a road south from Batna, along which a diligence travels as far as El Kantara, on the confines of the Sahara, but thence to Biskra, the third oasis, there is only a track. The French, however, threaten a railway not only to the Sahara, but for some 200 kilometres into it, so that a few years hence, it may be possible to penetrate the great desert within twenty-four hours of leaving the northern coast. As yet, however, the railway has still to be made, so we book places in a diligence, which is to take us the last stage of our journey, and which leaves Batna at five in the morning.

Out into the moonlight we drive, through a cool crisp air, our little party with the banquette all to ourselves—the banquette, as many of my readers know, answering to the box-seat of a stage-coach, except, as Albert Smith used to say, it is more like sitting under the awning of a bathing machine. By-the-way, Algeria is very much like old-fashioned France, so far as travelling is concerned: you have the auberge, and you have the diligence. There are no hotels worthy of the name in East Algeria; only the auberge is to be found. The cuisine is excellent, the sleeping accommodation tolerable, the conveniences vile. But then you cannot expect all the luxuries of *la vie d'asphalte*, as a Frenchman very happily expressed city life to me the other day, and to a Cockney it is worth while exchanging these occasionally for a bit of nature.

The diligence, with its seven or eight horses, harnessed three on four abreast, is also enjoyable for a time, if you are not relegated to the omnibus portion of the vehicle. Twenty or twenty-four hours is generally sufficient, however, to wear off the novelty, and then you begin to appreciate highly the thoughts of a well-ordered railway carriage.

The country is bare and sterile to a degree, your only thought being as to where the diligence will next find horses in such a wilderness. The human beings you encounter by the wayside are an occasional road-maker (generally a negro of the blackest hue), and now and then some ragged Arabs driving along groups of mangey camels, laden, apparently, with dirty bed mattrasses. The bed-ticking, however, is full of corn; and as the lumbering diligence with its clattering horses, comes rumbling along, the driver cracking his whip right and left, the timid camels, with their snake-like necks and softly-cushioned feet, hurriedly make way, and huddle together by the way-side till the noisy conveyance has gone.

The sun glows hot and red over the rocky ground; and presently a lofty granite ridge, that has hitherto barred the way, appears cleft in twain, leaving a narrow portal that is barely broad enough for the road and torrent that flows beside it. On either hand the towering walls of ruddy rock overhang, and a gorge of vast dimensions shuts in the traveller on all sides. But only for a moment. There is a turn in the road; and then, through the grand red portal, your dust-worn eyes are ravished by the sight of green palm trees and fresh verdure of the most luxuriant growth. This is El Kantara, and the golden gate of the desert—la porte d'or du desert—as it has been most appropriately termed, and these fresh, verdant palm trees, are the first oasis.

I try to retain some idea of the massive rent in the rock upon one of my sensitive plates, but it is a difficult task. I cannot see the top of the rock on the ground glass. I recede fifty paces, tilt my tripod, and use the swing-back of my camera to its utmost. In this way, I manage to get some part of the roadway in the foreground, and obtain a little margin of sky above the lofty range. Then I carry the camera into the gorge itself, picking up, on my way, a stately Arab, who is very anxious for me to look over his collection of papers, but who is not quite so satisfied when I want him to stand away at some distance to break up my foreground. He is a capital guide, he calls out to me from the spot I have put him, and he has received many testimonials from people who have employed him. In the end, I have to look them through; and I find my stately Arab friend has something besides testimonials; he has an English lady's photograph—the lady in a well-fitting Jersey and jaunty Corsair cap—with the lady's name at the back of it. Ah me! no wonder he scorned (although he took it) the half-franc I offered him for posing. The fair lady—she left her address, by-the-bye, with the stately Arab, as well as her name—must have treated him very well, to make him think a sixpence too little for doing nothing for some five minutes or so. I wonder, though, whether, when she so kindly gave her portrait to this coffee-coloured Othello, she ever dreamt he would show it to every passing stranger. And, by the way, I could give her a photograph of him now, if she would accept it.

A native mud village with its characteristic flat roofs in shelter of the oasis is so pleasing that my friend Jones and I go on our way, leaving word for the driver to pick us up as he goes. There is a street of houses all built with those black bricks of dried mud which the Israelites could not make without straw, and this we forthwith bag in the camera. Then there is a market place, with more mud houses, and this, too Joues and I pay our attentions to.

"I wish you had taken that instead," says Joues, pointing to a group of palms just as my drop-shutter has fallen. (Jones is such a fool; he always waits till I have exposed, and then says he wishes I hadn't.) I am rather sharp with him, therefore, when I say, that I don't think his palms are worth a plate. "Don't you? Well, just look how gracefully they rise against the sky line; and look, too, where the desert melts away in the distance. Why, you havn't seen such a—why, what the deuce is that moving over there?" I asked, "Where?" rather sulkily. "Why, there along the road in front of us. Yes, it is—it is the diligence." And off scuttles Jones as hard as he can run, leaving me alone in the desert.

The mud village with its uncanny Arabs are behind me, the desert in front. Despite my difference with Jones, I prefer him to the Arabs, and with one sweep I gather up camera and tripod and all. The sun does not shine, it blazes—Jones has got the umbrellas—but it is a question of must, and 'helter-skelter I go in this heavy marching order over the scorched ground. Jones set up shouting as soon as he started, and by great good fortune a man hanging at the back of the diligence sees him. The machine stops, and in five minutes' time, thank goodness, I am safe and sound once more from hungry lions, dog-eating panthers, and blood-thirsty Arabs. "Yes," says my friend, "it's a good thing I ran off when I did, or you would have been nowhere." This is only his view of affairs, I need scarcely say.

Still onwards over the black parched ground. There is still a low mountain range dividing us from the true Sahara, and before we reach this, another green oasis comes into sight. But I don't get down to take any more photographs. I prefer sitting under the awning of the banquette; it occurs to me that the glaring sunlight may be too bright for photography. At any rate, I want to finish this letter and put it into the post, and I may not be able to do this if I am left behind again.

Now we come upon patches of sand, and now again the ground is covered with white powder as if it had been dredged with flour. I consult the driver, and he says it is saltpetre, and that the French military authorities used at

one time to gather it for gunpowder making. What a pity there is not some rapid nitrate of potash developer known, and then I could get down, and collect some free, gratis, for nothing—but no, thank you, I forgot; no more getting down for me.

More sand, more droves of camels, more dust, and more heat. We have arrived at the foot of the mountain range, and are now slowly climbing the Col de Sfa, as this last pass is termed. The sun is setting, and the rocks are blood red in the ruddy glow. On toil the horses, on, on, till gradually the summit is reached, and we have but ten more kilometres now to our journey's end. The driver gets his horses once more into a trot, and then we emerge upon a terrace-like road, whence the full desert is seen at our feet.

Behold a boundless plain of golden sand, as broad and as far as the sea itself. Nay, the flat horizon is further off than at sea, for here and there are patches of green that supply a middle distance, and seem to carry the eye on, on, into the remote distance. The green patches are palms that form the oasis, but all is on one even level, that recedes to the end of vision. The tints from the setting sun stain the foreground a gorgeous purple, and there is a glitter afar off resembling that of daylight playing upon the ocean. No wonder the jaded French soldiers, as they wearily climbed the Col de Sfa for the first time and came upon this scene, cried out for very joy, "The sea! the sea!" It was like the first step home again.

Another hour's trot through the twilight, and we are under the dark shadows of the Biskra palms. Our diligence pulls up before a colonnade that faces the welcome shade, and white-robed Arabs gather round to see the arrivals. "Hotel Sahara?" calls out my friend Jones, handing down the precious reflector lantern we have safely carried some fifteen hundred miles. "A moi Monsieur," replies a swarthy "blanket," and the instrument is placed safely in his hands.

And what did you see first? Well, it was nearly dark as we walked along the covered colonnade, but on the way to the hotel I peeped through a canvas curtain that hid one of the doorways; it was a café, full of company, and there was a billiard-table and a gentleman with a cigarette in his mouth making a cannon off the red. And as I stood and watched him, there came to me the music of a military band from under the palm trees. So you see, after all, that with billiards and band, and shady palm groves, an oasis in the desert of Sahara is not such a bad place for a Cockney to come to.

THE SPECTROSCOPE AND ITS RELATION TO PHOTOGRAPHY.

BY C. RAY WOODS.

III.—The Spectrum.

We are now in a position to make ourselves acquainted with the spectrum, and to consider a few of the properties of light on which the spectroscope is able to impart information; but it is absolutely necessary, first of all, that we should make ourselves familiar with the different parts of this rainbow-coloured band, before we can properly attempt to define any of the points bearing on the familiar operations of the laboratory and dark-room. It is not needful to study the spectrum too minutely; it will be sufficient to become acquainted with certain defined landmarks by which it will be possible more or less accurately to point to any particular part of the spectrum.

We have some such index in the colours of the spectrum, but that alone is not sufficient. To say that such and such a thing takes place at the blue end, for instance, is vague, and may or may not convey an idea with scientific precision. Nor is that all. All eyes are not the same, and apart from definite colour-blindness, two persons may not gather the same mental impression from looking at a particular part of the spectrum. Again, the condition of the eye is not always the same, for by using the eye to some particular colour for a time, it is easy to produce a partial and temporary colour-blindness, to make the retina less sensitive to certain rays. The reader will see this more clearly, perhaps, by a few illustrations from actual experience with the spectroscope. Ask two observers, for instance, where the green and blue parts of the spectrum appear to blend; they will seldom mark the same place. Again, look with the spectroscope towards a dull part of the sky, then to a bright portion, and lastly to the sun itself. At each change in the intensity of the light, the colours of the spectrum will appear to have shifted their position in reference to the dark solar lines. The change in position may be small, but it will be enough to show how inefficient the sensation of colour is to define accurately any given part of the spectrum. This has been very well put by the Astronomer-Royal for Scotland, who says: "The colours, unfortunately, are not indeed so absolutely constant in spectrum place as are the Fraunhoferic lines; for they (the colours) seem to be endued with certain extents of locomotion in the spectrum according to the brightness of the light at the time, and the state of the eye. But still these ranges of locomotion never change the appearance of a colour from one side of the spectrum to the other, but only produce certain small variations of + or — on the standard colour at, and for, that place."*

The colour sensation caused by a particular ray cannot, therefore, be relied upon to furnish more than a *general* indication of its position; but as a rough guide it is sufficiently useful, and will be frequently used in these pages. To begin with, it would be almost impossible to indicate where and how the reader will recognize the principal Fraunhoferic lines without some such guide. Turn the spectroscope then to a bright portion of the sky, using a magnifier in place of the ground glass if the camera is being used. For the central parts of the spectrum this light will be quite bright enough, and will not tire the eyes; but for the rays in the dark blue and violet, and for the extreme red end, the direct light of the sun may be required. If more convenient, a small mirror or piece of looking-glass may be used to throw the light into the slit of the instrument placed horizontally instead of pointing it to the sun or sky.

The line that can be most unmistakably recognized is the line called D in the yellow. This line is seen really to consist of two when viewed under higher dispersion. Looking from D towards the red, another well-marked dark line is noticed, called C; still lower in the red, and if the instrument is

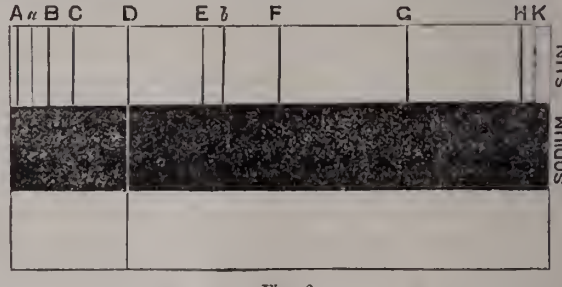


Fig. 6.

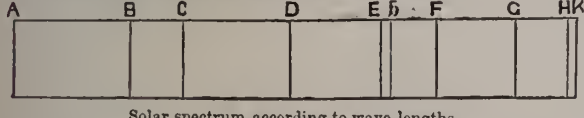
turned only towards the sky almost at the extreme part of the red end of the visible spectrum, is B. If the spectroscope be pointed to the sun, it is possible to see lower still in the spectrum, and A will come into view. Below A the spectrum is, to most people, quite invisible, and some cannot even see so far. Returning to D, and travelling from that line to more refrangible parts of the spectrum, certain definite lines will be seen about the middle of the green. These are E, and just beyond E, the *b* group, "little *b*" as it is called. In a spectroscope of small dispersion "little *b*" appears as one thin and one thick line, the thin

* Piazzi Smyth, "Madeira Spectroscopic."

line being nearest to E. With higher dispersion the thick line is resolved into two. A little beyond the green, just in the blue, is F. G is the centre of a group of dark lines in the violet-blue or indigo. At the extreme end of the violet are the two lines formerly spoken of as H_1 and H_2, but now called H and K. These lines require a strong light, that of sky scarcely being sufficient even when the eye is in a most favourable condition for seeing them. The writer can only see them with difficulty under any circumstances.

Below the red we have invisible rays that give a sensation of heat, and were consequently called *heat rays*; beyond the violet we have rays which the photographer's sensitive plate can receive, and which were called *actinic* or *chemical rays*. These terms never received a great amount of attention from spectroscopists, and need not be mentioned again, for they are now quite obsolete in scientific literature and conversation, the terms *infra-red* and *ultra-violet* having been substituted for them. To call the ultra-violet rays *the* actinic rays is quite absurd, when, as will be shown later on, the maximum reducing effect of the spectrum is with most compounds nearer to G.

The relative positions of the principal Fraunhoferic lines, as shown in an ordinary spectroscope, are not correct, however, the less refrangible end being compressed, compared with the more refrangible end. The effect is much the same as if we attempted to draw a scale on a piece of paper, and made it one inch to the foot at one end, graduating it up to two or three inches to the foot at the other end. Let us represent the lines as they are seen in the diffraction spectrum (to be treated later on), at distances apart proportionate to their wave-lengths. A comparison of the solar spectrum in fig. 6, with that of fig. 7, will show how much the prismatic spectrum is distorted.



Solar spectrum according to wave-lengths.

Fig. 7.

Hitherto we have been considering the solar spectrum; but if we examine the spectrum given by a solid body rendered luminous, such as a white-hot poker, or the particles of carbon in an ordinary gas or lamp flame, we get a spectrum perfectly continuous instead of being crossed with black lines. If we examine the spectrum of an incandescent vapour, we get a spectrum of bright lines on a dark ground. A flame containing sodium vapour, for instance, gives us a bright line in the yellow, which Fraunhofer found to be coincident with the D line of the solar spectrum (No. 2, fig. 6). If the light from a flame coloured with sodium or one of its salts be allowed to pass through sodium vapour at a lower temperature, it is found that the sodium vapour is able to absorb the very light which itself gives forth when incandescent. If the light from a gas flame be examined by the spectroscope after passing through sodium vapour, we get a continuous spectrum crossed by a dark line (No. 3, fig. 6). These facts led Professor Stokes and others to come to the conclusion that sodium existed in or surrounding the sun, and absorbed a certain amount of the light given out by the body of the sun. In 1859 this was brought more prominently forward by Kirchoff and Bunsen, the former of whom was soon able to show that many of the other lines of the solar spectrum were due to different metals. This research was rapidly followed up, and we got to know something of the constitution of not only the sun, but many of the other heavenly bodies.

The examination of the light from different sources soon proved to be a very accurate and delicate means of analysis; sodium, for instance, can be detected in the minute particles of dust floating in the atmosphere. An expert in spectroscopy can readily analyze a substance by examining its light; but in the hands of a novice the very delicacy of the method mars its practical usefulness in the laboratory, for substances can thus be detected, the presence of which cannot be shown by other means.

LESSONS IN OPTICS FOR PHOTOGRAPHERS.

BY CAPTAIN W. DE W. ABNEY, R.E., F.R.S.

Lesson X.—*continued.*

Position of the Stop.—The position of the stop in a lens is an important point to which to attend. The best position can be calculated, or can be ascertained readily by trial. Of one evil special care should be taken, viz., that a "flare spot" on the plate arising from an image of diaphragm itself should be avoided. The late Mr. J. H. Dallmeyer first brought this prominently to notice in 1867, and offered an explanation of it through the courtesy of Sir J. Herschel. The origin of the flare spot will be seen from the following diagram, and to illustrate our remarks the simplest

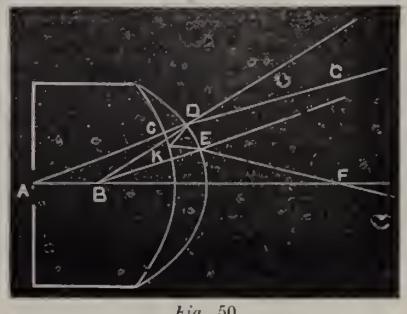


Fig. 50.

case has been taken, which is, where the centre of curvature of the anterior surface coincides with the centre of the diaphragm. Let A be the centre of curvature of the first surface and also the centre of the stop, and B that of the second surface. Then trace the course of a ray from A, such as A C. Since A C is perpendicular to the first surface, it will pass to D without refraction, whence part will be refracted along D G to form the proper image of the object, and part will be reflected back to K, where it will again be reflected to E, part being reflected again, but now of so feeble a character as to be negligible, and the greater part be refracted to F. So that at F we shall have an image of the centre of the stop with more or less distinctness. By treating the other points of the aperture at A in the same manner, it would be found that at F we had an image of A. There being no receiving screen there, the rays would pass to the plate or focussing screen on which the image of the object was received, and form a central spot of flare. The position of the stop is worse the more nearly F coincides with the focus of the image of the object, and for this reason it will be found that by moving the stop nearer to or further from the lens, the flare, though not obliterated, can be made to diffuse equally, or nearly so, over the plate. Our previous lessons will have indicated that greater flatness of field is obtainable by moving the stop further from the lens, the field being more curved as the images at the margin of the plate are formed by "oblique *contral*" rays.

Central flare is also found in double combinations, often in a much more exaggerated form, and is much more difficult to get rid of owing to centres of curvatures of the back combination lying on both sides of the axis, so that whilst by shifting the stop to get rid of one image of the aperture in the diaphragm, an image is called up from the reflections from the other surface. The best plan to get the minimum flare is by trial, shifting the stop till that is found.

Relative Illumination of the Image with Different Stops.—Let *a a* be a small stop, and let parallel rays be projected on the lens, then the brightness of the image will be dependent on the diameter Q R, which is equal to *a a*, and a measure of the illumination to form the image at F is

given by the base of the cone of rays collected at F, *i.e.*, by the area of which Q R is a section. This area may be measured by $(Q\,R)^2$. Similarly, with an aperture $b\,b$, the illumination may be measured by $(P'S)^2$. Hence it may be seen that the brightness of the image formed at F

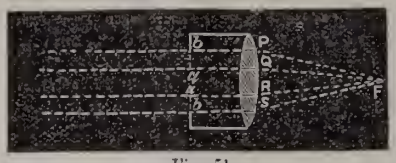

Fig. 51.

of a distant point varies as the square of the diameters of the apertures used. Thus, in one lens a stop of $\frac{1}{4}$-inch diameter will only give an image a quarter as bright as that formed by a stop of $\frac{1}{2}$-inch diameter. In general, if s be the exposure with a stop of diameter a, with a stop of diameter b the exposure will be

$$s\frac{a^2}{b_2}$$

If we wish to compare two lenses together, using different stops, we must carry the reasoning a little further.

To Calculate Exposures with Lenses of Different Focal Lengths, and Different Sizes of Diaphragms (Stops).—Let AB be the lens having a focal length (AC or BC), describe a circle with distance AC, and centre C. It is manifest that the parallel rays proceeding from a distant point to form an image of the point at C only, a small part of the

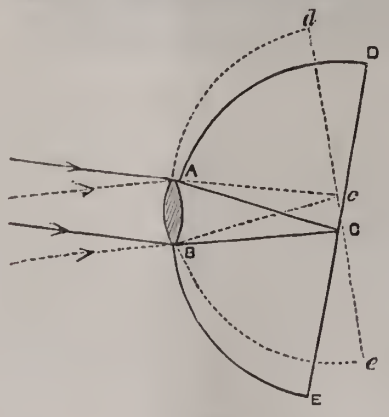

Fig. 52.

theoretically possible rays are collected, viz., those falling on a circle having a diameter AB (fig. 52). The theoretically possible rays would be collected on the surface of a hemisphere DABE. The proportion of rays collected to those theoretically possible is therefore—

$$\frac{\pi(AB)^2}{2\pi(BC)^2} \text{ or } \frac{(AB)^2}{2(BC)^2}.$$

which shows that the illumination varies directly as the square of the aperture of the lens, and inversely as the square of the focal length, or as $(\frac{f}{a})^2$, calling f the focal length, and a the aperture of the lens. If, then, we wish to compare two lenses with different apertures and focal lengths together, all that is requisite is to use the following formula:—

$$\frac{\left(\frac{f_1}{a_1}\right)^2}{\left(\frac{f}{a}\right)^2} \times s = x$$

where s is the exposure with the first lens, and f_1 and a_1 are the focal length and aperture respectively of the second lens, x is the exposure to be calculated.

As an example, suppose it is known that a lens of twelve-inch focal length, and one-quarter of an inch aperture, requires an exposure of ten seconds, what exposure must be given to the same subject with a lens of ten-inch focus, and one-eighth of an inch aperture? The above formula is—

$$\frac{\left(\frac{10}{\frac{1}{8}}\right)^2}{\left(\frac{12}{\frac{1}{4}}\right)^2} \times 10 = x = 28 \text{ seconds nearly}$$

It is manifest, then, that if we know f and a for any lens, we can readily compare it for rapidity with another lens if the same quantities are known. We have here neglected the absorptions due to varying thicknesses and qualities of the glass employed, as also the number of reflecting surfaces; but this is practically immaterial. It may roughly be taken that each reflecting surface diminishes the light by two per cent., but a dirty lens will cut off very much more. We have known as much as twenty-five per cent. to be cut off from this cause.

GENERAL NOTES.

BY COLONEL PLAYFAIR.*

We are concerned more especially with the gelatine process; and if a beginner were to turn over the pages of the journals to know what to do, or if an old hand were to refer to them trying to discover the best process, he would be rather puzzled with the amount and variety he had to deal with. Even in the present day, if the question, "What plates do you use, and how do you treat them?" were to be answered by different people, the person seeking information would have a variety of answers.

A very great deal has been written regarding the gelatine process, but, notwithstanding, what strikes me as being very peculiar, is the small variation between the make and treatment of a gelatine plate in 1873 and one in 1883. Much discussion has been owing, no doubt, to the different material with which writers and experimentalists had been working; for instance, the proportions of an emulsion had been given, and when people came to try it they commonly used their own developer, which, the chances are, was not proportioned as the one used by the person recommending the emulsion, and the same with developers being tried on different styles of plates. The one great advance has been the increase in rapidity, and this advantage chiefly caused the old processes to be laid aside.

In 1873 I dialysed with heat at about 100° for twelve hours; in the present day the heat for emulsification has, in many cases, been increased to boiling point. I have tried most of the processes in their day, the most charming being the collodio-bromide, and if anyone were to produce in the market a rapid plate, I am sure there are many who would return to that process. One which I adopted some years ago was making a collodion with silver dissolved in it. I dipped the silver film in a bromide bath, just as the iodised film is dipped in the silver bath, and, after washing off the superfluous bromide, flowed over a preservative and dried. The want of rapidity, however, stopped me; but since our knowledge of the effect of ammonia in the gelatine process, I have thought rapidity might now be produced by the addition of ammonia to the bromide bath. I have not tried it, but it is possible that something in this direction might be adopted to increase the rapidity.

For a long time the gelatine process caused much trouble and disappointment, owing to frilling, staining, green fog, and ignorance in developing; but, happily, these are things of the past, although many produce green fog by pyro. development. It can be effectually got rid of by Captain Abney's treatment with bromide of iron and ferrous oxalate.

Regarding emulsion-making and plate-coating, I will only remark that when I left off experimenting in this direction I found the "cold emulsifying" of Mr. A. L. Henderson, as well as the "depositing system" of Mr. W. K. Burton, easy, and to give good results. I now use plates from a maker, and am saved a good deal of inconvenience.

As respects development: in the year 1881—the first half especially—a great many articles were written, hardly a number of the journals being issued without an article on or some allusion to the subject. Very little alteration has taken place, however, in the nature of the developer. Formerly it was an

* Abstract of a paper read before the Bristol and West of England Amateur Photographic Association.

object to get the developer from anyone who had done good work; but the application of it to some other person's plates was a test which did not always produce the desired effect.

Experience has taught people now more about what they are using, and the object to be aimed at by altering proportions to suit their requirements, according to light, subject, exposures, &c.; in fact, this has been so generally established, that an article on development is rare in comparison, and certainly it does not call forth a discussion, as on former occasions.

There are many advocates of the ferrous-oxalate developer, and the question as to which is the best developer might be practically tested when the outdoor meetings are held by taking duplicates of a subject, and developing one by pyro., and the other by ferrous oxalate, the negatives being exhibited by the different members. This would be a matter of curiosity, and create some interest. Formerly—in fact, till lately—when a plate was cleared in the hypo. it was considered finished, and properly ought to be. But in cases of miscalculation we now have at command a subsequent treatment, and clearing it from stain, reducing and intensifying are resorted to; in fact, a gelatine negative is now so under control, as to be finished according to the standard of one's own fancy.

To say what is the *best* way of the many to make a gelatine plate and develop it, can only be looked for when it is discovered that one maker's plates are superior in every respect to another. Some approximation, however, might be obtained if medallists could be induced to mention the makers of their plates and their treatment of them—I mean specially as regards laudscapes; but I fear this high road to perfection would detract from the interest of those who take a pleasure in experimenting to overcome difficulties. Even much could be learnt among ourselves if (say) a particular subject in the vicinity were selected, and a competition for the best negative and print were to take place. The effect of different makes of plates and developers would then be apparent. A comparison of results, knowing the details of how they were manipulated, would tend to increase our interest. I think it would give a stimulus to our work, and be productive of the best results.

CAUSE OF FADING IN SILVER PRINTS.

BY ANDREW DUTHIE.*

If unable to actually solve the question, I trust at least to show some reasons for the fading of silver prints. It is usually said that insufficient washing after fixing is the cause of fading; but this I am not prepared to admit, especially when we find unmounted photographs by our best photographers are all liable to the same discolouration as mounted portraits. With those firms who deal largely in scrap photographs, the washing receives special attention. Messrs. Wilson, for example, finish the washing in nearly boiling water. This would ensure the removal of the last trace of hypo.

In 1849, Sir John Herschel recommended dabbing the back and front of the print with a soft sponge. This to be repeated three or four times. He said if the washing was properly carried out, photographers would be troubled no more by fading of prints. Of course the photographs he referred to were on plain paper, such as Whatman's drawing-paper. Nearly all of us, I think, have seen the books of Calotype photographs, exhibited by the secretary at our last conversazione. They seem to bear out Sir John Herschel's statement, for they show no signs of fading that I can see. These are also on un-albumenized paper. This, I think, brings us a point nearer a solution of the difficulty. From what I have heard about prints on plain paper, and some experiments I have been making lately, I am inclined to think fading is, to a great extent, due to the decomposition of the albumen. I mentioned this the other day to a manufacturer of albumenized paper, and was assured that they treated the paper somehow with an acid to prevent decomposition taking place. If I am not mistaken, it is citric acid that is used. This is very likely—indeed, almost sure—to be washed out by the time the print is finished. The albumen is therefore left without any preservative, and is a substance which would very likely succumb to the influence of a damp atmosphere or a hot sun. This seems probable, as we often hear of prints hanging on walls for fifteen or twenty years, and showing little signs of fading. All these years they have been pressed close to the glass of the frame, which is rendered nearly air-tight by being pasted over the back with brown paper. In the old frames, the paper was only put round over the tacks, and this, I think, was more completely air-tight than the present mode of stretching it right across the back.

I regret that the month which has elapsed since I undertook this subject has been too short to allow me to complete my experiments. I trust, however, towards the end of the year to have something to show in support of my opinion about albumen. We shall now consider another cause of fading which is not, I think, generally known. On inquiry I learn that hundreds of tons of hypo are annually used by paper manufacturers; in fact, a friend of mine was told by a member of one of the largest firms that it was impossible to do without hypo. Napoleon the First once said that there was no such thing as an impossibility; still the paper makers seem to find one here.

I mentioned at last meeting some of the results I had got with about sixteen faded cabinet portraits with which I had provided myself. I omitted to state that they were taken by the leading London photographers. They were portraits of celebrities, and had been in our windows exposed to the full blaze of the sun all the afternoon, and to the effects of gas at night. Some were in stock three or four, others twelve months. In every case I found traces of hypo, and in several free sulphuric acids present. Three mounts were analysed; the first contained in an aqueous solution hypo, sulphates, and starch. In an acid solution there were traces of iron and lime, considerable quantity of potash, and a good deal of soda. In this mount there was no excess of acid. In an aqueous solution of the second were found faint traces of hypo sulphates and chloride. In the ash were iron, lime, potash, soda, strontium, and albumina; also a considerable quantity of free sulphuric acid. The last, the only one which resisted all tests, was a black one; it was free from hypo and sulphates, although subjected to more severe tests than any of the others. This one was neutral to test paper. I might also mention that I have tested a number of sample mounts belonging to various London and local dealers; I found they all contained the same impurities, although varying in quantity.

I would like to ask some of those present for their experience of gold bevelled-edge cards. There seems to be something in the colouring matter of the chocolate which is almost fatal to silver prints. The black mounts are the same, though in a less degree. The green alone does not seem to injure the prints. In one case I had a C.D.V. photograph fade so completely that the faces were flat and pale—so much so as to be unfit for use. All this took place in about three weeks; it was mounted on a chocolate card. In conclusion, I may just mention that white and yellow cards appeared to contain most free acid, while those of darker colours were mostly neutral to test paper.

* Read before the Glasgow Photographic Association.

Notes.

The Photographic Studio of the National Library in Paris is now in complete order, and arrangements have been made by which any photographer may make use of it for reproducing the artistic and literary treasures of the institution.

M. Klary, whose name is familiar to our readers as the originator of a new style of illuminating the model, which he brought to this country some years ago, has elaborated another invention which has to do with printing in colours. We are not yet familiar with the details of the process—M. Klary has visited America with a view to its sale—but, as M. Klary is a painter, rather than a photographer, we presume the invention is not another pretension to photograph in natural colours.

The use of hyposulphite in the developer as a means of shortening the exposure has been repeatedly suggested, and several photographers have adopted the method with advantage. Audra, however, now proposes to attain the same end by immersing the gelatino-bromide plate in a

solution containing one part of sodium hyposulphite in 10,000 parts of water, the film being well rinsed before development. The fact of hyposulphite in the developer tending to cause a partial reversal of the image is an objection to its use, and it will be interesting to ascertain whether the same disadvantage attends the new method.

Mr. F. Galton's system of composite portraiture will be fresh in the memory of our readers; a number of portraits being combined so as to form a typical picture or general representation of a class of persons.

The idea of composite representation has been applied by Mr. G. M. Whipple, of Kew Observatory, to the production of average meteorological curves, so that generalisations extending over long periods may be made obvious at a glance.

Let us give an example. The wind velocity as determined at any given station during a day is recorded as a curved line, but abnormal conditions may render this curve an untrue representation of the ordinary diurnal variation of the wind. Mr. Whipple, however, employs photography to superimpose the curves obtained during a stated interval, strikes out entirely abnormal or storm curves, and draws an average curve through the remainder. A number of the average curves may be again averaged, so that a faithful representation of the general diurnal variation is realised.

In the same kind of way averages may be obtained of barograms, thermograms, electrograms, magnetograms, and rain or sunshine curves. The principle is, indeed, capable of a widespread extension to many branches of physical science.

"The terror in London" was the heading of a sensational article in the Madrid paper the other day. The reader was treated to a wonderful account of the terrible events that came to pass at the Victoria and Paddington stations. London, it said, unlike Madrid, had all its stations in the heart of the metropolis, and the consequence was that the reduction to ruins of the principal termini would carry havoc among the Londoners. But one thing we must give Madrid journalism credit for: the idea of photographing the results of the explosion, our Spanish contemporary considered a very happy one, as a ready means of bringing before experts details by which the latter can arrive at the nature of the destruction. Certainly, our authorities are now very learned in the matter of explosions, and it is said that from the photographs alone, the expert can give a very good guess as to whether the disaster has been produced by gas, gunpowder, or any of the nitro-compounds, such as guncotton, dynamite, &c.

An interesting paper was read at the last meeting of the Liverpool Astronomical Society, by Mr. Isaac Roberts, F.R.A.S., who gave an account of his experience in astral photography.

A propos of astral photography, it is noteworthy that in the thirty-eighth report of the Harvard College Observatory, just issued, the subject occupies a prominent position. Professor Pickering is a believer in the value of photography, and operations are systematically carried on. The satellites of Jupiter have occupied much attention photometrically, and by the use of a double image micrometer the time of their occultations and transits have been determined much more accurately than by the old method. Photography has also been largely made use of in the preparation of star maps.

It is not at all unlikely that the tricycle will revive an interest in photography among amateurs. The writer of an article on "The Development of Cycling" in this month's *Longman's Magazine* gives several instances of cyclists who are also photographers, and remarks, "This photographic work is a great feature in tricycling; complete apparatus can be easily carried on a modern machine, and many riders with such an outfit are to be seen gliding along the country lanes with a keen eye for "hits." He adds that a couple of well-known cyclists recently gave their club a very pleasant entertainment with the lantern, the slides being from photographs taken during a journey from London to the Land's End and back.

Photographic portrait clubs appear to offer many facilities for dishonesty. We have recently noticed an instance of this, and last week another case occurred, a canvasser of a London firm being sentenced to six weeks' imprisonment. The *modus operandi* was failing to hand over to the proprietor monies collected from members of the club.

Herr Anschütz's extensive series of military photographs, on exhibition at the Kriegsakademie in Berlin, are spoken of enthusiastically by the Prussian staff. Most of the pictures are cabinets; but excellent enlargements are shown. Men and horses were secured during the most rapid evolutions, and the sharpness of detail and perfection of the deepest shadows is said to be surprising.

We quite agree in Mr. Alfred Dawson's opinion that the most pleasing aspect of the Shakespeare bust in Stratford Church is a three-quarter face view. It is simply because draughtsmen and photographers have hitherto been in the habit of showing the effigy full-face, that so many find fault with it. Any one looking at such pictures must have been struck by the dull, pork-butcher-like aspect of the bard, whereas, seen from a three-quarter point of view, there is much more character. The new Shakespeare Society are going to have a photo-gravure prepared, and Mr. Dawson has been selected to do the photography. We are glad to find, therefore, that a mechanical full-face view is not to be selected this time.

Many people there are who hold the opinion that a photograph is never more than a photograph. They say: "Now I don't want any nonsense, but pray set up your camera in front of this object, and let me have a copy of it."

Fortunately, this class of people is easily satisfied; they know there is nothing in photography, and if you give them a bad picture, they are none the less contented, since it bears out their pet view of the soulless nature of the art. Yet, as in the instance of Mr. Dawson, so in ninety cases out of every hundred, the qualified photographer, if permitted to exercise his taste and judgment, may do a great deal; for the aspect of an object from a certain point of view, or the lighting of it from a certain quarter, let alone skilled development, often makes all the difference in the world between a good picture and a bad one. Both are photographs and represent good technical work, yet they are as different as carbonate of lime is to caseine.

A somewhat novel adaptation of the Boycotting system has been started by Messrs. Melander, photographers, of Chicago. They have discovered that the taking of portraits by amateurs has worked "positive injury" to their business, and they have therefore "decided not to buy over stock of any house dealing in these amateur outfits." A communication containing this awful threat was sent to the Chicago Amateur Photographic Club, which, we are glad to say, did not seem much disturbed by it. One of the members, however, admitted that the ladies of his family were not willing to allow him to make their portraits, and that he willingly sent them to the professional photographer. It is to be hoped this confession will bring joy to the hearts of Messrs. Melander.

The Chicago Amateur Photographic Club, by the way, has a pleasant free-and-easy method of conducting its proceedings. At a recent meeting the Secretary announced that he had not the minutes of the previous meeting with him, but, if desired, would read the report of the proceedings as published in a local newspaper. Imagine the thrill of horror which would run through the Photographic Society if the Secretary gravely proposed to put before it, as the minutes, the report published in the PHOTOGRAPHIC NEWS!

Photographers engaged in the production of studies often put the cart before the horse; that is to say, they usually choose their model first, and then think about the expression or rôle he or she is to assume afterwards. Now, in nine cases out of ten, the painter does not evolve the idea of a picture out of his own brain, but has it suggested to him by his observant eyes. Mr. Robinson told us the other day how his "Merry Tale" was suggested to him by seeing a group of ladies chatting in the drawing-room; and the same holds good with Rejlander's charming studies. The latter would see in the streets or elsewhere a model that suggested a picture to him, and, artist-like, he never rested till that model was secured.

The photographer but too frequently does the reverse. A lady of his acquaintance is elegant and good-looking, and being convenient to his hand, he sits her down before the camera, and tries what he can make out of her. Her auburn hair is let down, she has a sheaf of straw put into one hand, and a sickle in the other, and she is bade look like Ceres. But the result too often is that the hair in the picture looks as if it had been "let down" for the occasion, while the model simply appears as a lady half through her toilet. Had you met a model promiscuously, and been struck with her appearance, how her face was that of a Ceres or a Diana, or a Madonna, or what not, the chances are when she was posed and draped in accordance with your idea, she would still further please you. Better, then, let studies be suggested by the eye rather than the brain.

Specifications Published during the Week.

416. G. D. MACDOUGALD, "Improvements in apparatus for storing and conveying developing and other chemicals required for the production of photographic pictures."

This invention consists essentially in the storing of photographic chemicals in the ordinary sealed tubes of the laboratory, having the usual projecting ends, or in sealed tubes, somewhat resembling those used for chloride of gold, but having indentations for ease in breaking. The inventor also claims certain kinds of paper or other packages for the storing of chemicals, together with flexible capsules such as those used for storing medicines. We quote a few words: "These envelopes may be made with a material soluble in water, or with a material insoluble in water, and provided with a seam of gum-arabic or other soluble or adhesive substance, which opens by the action of water." Divisions in the packages enable the photographer to store several chemicals in one package. We regret that we cannot find space for the full text of the patent, as it is the first photographic patent published under the new law; but we may mention that the claims embody the use of paper boxes having lids which will open when the box is immersed in water; also the storing of chemicals in porous materials, such as the blotting-paper used in connection with the so-called magic photographs. As far as we can gather, a photographer taking a measured quantity of a dry chemical into the field in a paper box or package would not be liable to pay a royalty to Mr. Macdougald if he adopted the ordiuary plan of opening the package, and emptying the solid into his developer; but if he were to tie the box or package to the end of a stick, aud stir it about in the developer until the package gave way, he would have to pay a royalty. It also appears to us that any person tying a bulb of chloride of gold to a rod for convenience of breaking it would infringe this patent.

3362. FRANK WIRTH, of the firm of Wirth and Company, Patent Solicitors, at Frankfort-on-the-Main, in the Empire of Germany. "An improved method of producing plates by photography, to be used for printing purposes." [A communication from the firm of Benecke and Fischer, of St. Louis, United States of America, and JOHN FRANK, a person resident at Frankfort-on-the-Main, in the Empire of Germany. (*Provisional protection only*).

This invention relates to an improved method of producing photo-lithographic plates for use in printing. The object of this invention is to produce a plate from which a picture or the like can be printed, the shades of which are formed by a number of points or dots placed more or less close together, the design for the picture being engraved upon a zinc or other plate, from

which impressions may be taken by pressure. The productiou of the design is accomplished by taking by photography from a negative a small representation of the object which is to be reproduced. This representatiou is enlarged, whereby a design is produced which consists of a great number of small points or dots, and which is thus in a suitable form to be engraved upon a zinc or other plate in order to be reproduced by pressure.

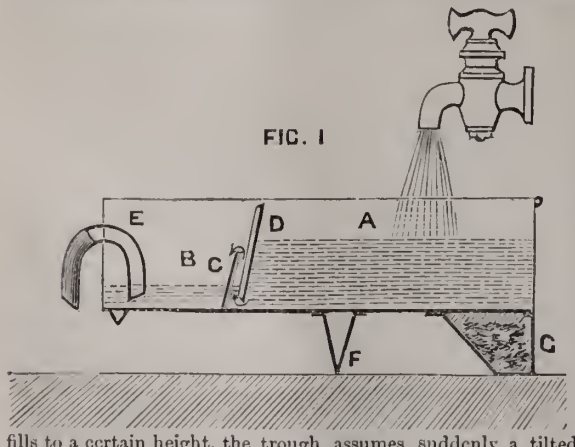
3476. Richard Brown, Robert William Barnes, and Joseph Bell, all of Liverpool, in the county of Lancaster, for "Improvements in meaus for and methods of producing designs upon paper or other fibrous or soft material, or upon metallic surfaces."

Our present invention relates more especially to improvements on inventions for which Her Majesty's Royal Letters Patent were granted to Walter Bentley Woodbury, dated July 22nd, A.D. 1878, and numbered 2912, for "Improvements in means for and methods of producing designs upon paper, cloth, or other fibrous or soft material," and dated September 19th, A.D. 1879, and numbered 3760, for "Improvements in means for and methods of producing designs upon metallic surfaces" respectively; the specifications of which Letters Patent described methods of producing designs upon the surface of paper, cloth, or other fibrous or soft material, or upon flat metallic surfaces, by means of similar designs first obtained in relief by the action of light upon sheets of gelatine or gelatinous material rendered sensitive to light in the way well understood and practised.

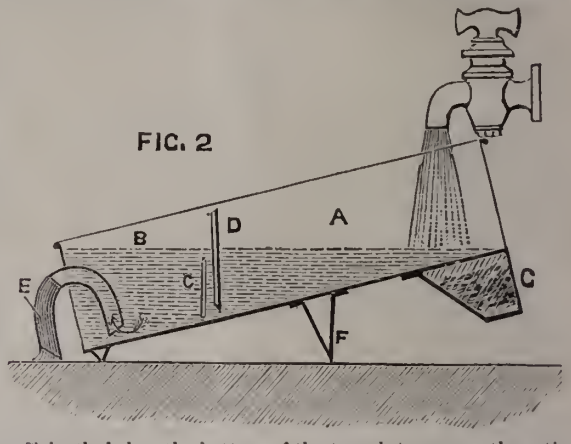
Claims.—The method of preserving from obliteration designs produced upon paper by pressure, by treating them with a waterproof solution, substantially as described. Also, the methods of producing metal relief surfaces substantially in the manner and for the purposes described (production of metal replicas of the relief). Also, the method of preparing and using metal relief surfaces for impressing designs upon sheet metal such as tinfoil, where it is desired that some parts of such metal shall be left bright, and others dead or "mat," substantially as herein described.

712. F. Hazeldine, "Improved apparatus for use in washing photogtaphic prints and other articles or materials."

The trough is divided into two compartments, of which the first or washing compartment receives a constant stream of water that flows from the one compartment to the other, whilst the second compartment is provided with an outlet syphon or valve. The trough is so balanced that when the second compartment



fills to a certain height, the trough assumes suddenly a tilted position, thereby violently agitating the water among the prints or materials being washed, separating them, and starting the syphon or opening the valve. The arrangement is such, that the outflow shall gain on the inflow, so that the water will be run off from the second compartment faster than it flows into the first, until, the second compartment having been almost emptied, the counterpoise preponderates and returns the trough to its horizontal position again, agitating the water, &c., whereupon the trough refills and the same operation is repeated. Figure 1 is a longitudinal section of the trough in its normal position, and figure 2 is a similar section showing the trough in its tilted positiou. The same letters of refercuce indicate the same parts in both the figures. A and B are the two compartments of the trough separated by a partition C, which rises from the bottom to within a certain distance of the top of the trough. The compartment A is the larger of the two, and in it are placed the prints or substances to be washed. D is another partition dipping into compartment A at a short distance from partition C, and reaching from the top of the trough to within a short distance of the bottom, so as to compel the water at the lower part holding in solution the salts washed out (and which, being of greater specific gravity, sink to the bottom of the trough) to pass out through the space between the two partitions C D iuto compartment B. E is a syphon of which the short leg dips into compartment B and reaches within a very short distance of the bottom, whilst the bend of the syphon is sufficiently below the top of the trough to ensure the syphon being started automatically when the trough assumes the inclined position figure 2. The longer leg of the syphon extends



sufficiently below the bottom of the trough to ensure the action of the syphon continuiug until the compartment B is sufficiently emptied. The trough oscillates on a transverse fulcrum formed by a downwardly projecting rib or plate F fixed or hinged to and extending across the bottom of the trough, and in its normal position (fig. 1) the trough rests partly on the fulcrum F, and partly on a downwardly projecting part G at the end opposite to the syphon, which part G is sufficiently loaded to preponderate and to bring the trough back to its horizontal position when the compartment B is nearly empty, but is overcome when the compartment B fills up to about the top of the partition C; the relative position of the partition C and of the fulcrum F being such as to enable this action to take place by the alternate preponderance of the weight G and the full chamber B. The compartment A receives a constant supply of water so regulated that the inflow is somewhat less than the outflow through the syphon E.

CHAPTERS ON LANDSCAPE AND OUT-DOOR PHOTOGRAPHY.

BY H. P. ROBINSON.

No. 9.—Old Clo'.

The student should never omit to pick up quaint and picturesque bits of costume whenever he has the opportunity of doing so. Aladdin's enemy, the African magician, offered new lamps in exchange for old; the modern magician, who evolves pictures by another kind of magic, may do worse than follow the example of his African brother. I am sometimes tempted to trade in the same, apparently, insane manner, and give a new frock in barter for a weather-stained old garment not intrinsically worth tenpence. It is curiously difficult to meet with anything that is strikingly picturesque and suitable in the way of costumes, and still more difficult to secure it. The wearers at first think you are making fun of them, and end by thinking there is something more in it than meets the eye, and that they ought to have made a better bargain. It took an artist friend of mine some hours and a long journey to buy a navvy's waistcoat. The garment is a perfect treasure to a painter, but not of so much use to a photographer, for its virtue lies in colour. It was originally a blue velveteen, but had become worn and weather-

stained into a lovely harmony in blue and green. My friend was coming on a visit to me at Tunbridge Wells, and saw the possessor of the wonderful waistcoat on the platform at Charing Cross Station. He followed him into a "third-class smoking," got into conversation, plied him with tobacco, and after a lot of diplomatic talk, offered to buy the coveted garment. The thing was not worth eighteen-pence, but my friend offered seven-and-six. The navvy thought he had met a fool or a millionaire, or perhaps both in one, and refused to sell at any price. Tunbridge Wells station was reached, and the bargain not concluded. The painter ought to have got out here, but the waistcoat was too tempting, and he went on to Hastings with the navvy, where he at last managed to arrange a deal.

An artist, who built himself a "lordly pleasure house" in the country, gave every old woman—and young one, too—in the parish a red cloak, that the spots of bright colour should add a charm to the landscape. Not knowing their origin, I once tried to buy one of these cloaks, and then I learnt the mystery that had puzzled as well as pleased me. The village was not entirely inhabited by descendants of Red Riding Hood, neither had the fashion of that particular cloak descended from generation to generation, like the tall Welsh hat, which descends as an heir-loom from mother to daughter in the Principality. It was a happy thought: but there was one defect—the cloaks were all alike in cut and colour; there was no variety. Now, what the student should aim at in the collection of a rustic wardrobe for photographic purposes is not only picturesqueness, but variety. It is more difficult than would be supposed to get what might be called prosaically a "change of clothes" for your models. And if you have collected a great variety, you have a predilection for certain dresses and effects, and they insist upon coming in like the much-quoted King Charles's head in Mr. Dick's "Memorial." I am painfully conscious that I fail in this way as much as anybody. There is a particular way of arranging one of the articles of rustic dress I so often practise that my artist-friends call it my trade-mark. I do not mean to point out what it is more particularly, for I don't want to make it more conspicuous, and I am sure I shall want to use it again.

The dresses need not be the unsophisticated bits of drapery they appear to be in the finished picture. There is no reason in the world why a white apron or handkerchief should be absolutely white in the original, when they would give nothing like so pleasing an effect, and photograph much worse than if they had been dipped in a weak solution of coffee or "Judson." In addition to dresses, cloaks, aprons, handkerchiefs, and the like, great variety of effect can be got out of hats and bonnets. There are marvellously picturesque shapes in straw to be picked up for a few pence; those introduced a few years ago, called, I think, Zulu hats, sold at about twopence each, added a new beauty to rustic life. But it is the sun-bonnet that is most characteristic of the country. This is made in every variety of shape and colour. Sometimes a light one is useful to come out as a light spot against a dark background; sometimes a bit of dark is required to contrast with a brilliant light.

In dressing your figures, let there be no mistake; your figures must be so like the real thing that only the initiated shall discover the difference. Fancy dresses won't do. Corydon and Phyllis fresh from a costume ball may be very well as china ornaments, or on the stage, but they would be out of place in an English landscape. Shepherds and shepherdesses with pet lambs and crooks, and aristocratic milkmaids, belonged to a time when art and literature were in their most debased and artificial state, and should never be revived except in burlesque. I am the more particular in insisting on this because I cannot help noticing that when attempts are made to make the kind of pictures I have been writing about, there is usually a dressed-up look about the figures. This is not the fault of the art, but of the artist.

Besides dresses, and all that belongs to dress, a collection of accessories should be got together, such as baskets, jugs, sticks, hay-rakes, and the numerous little things that are to be met with in country life likely to give a motive for a picture.

If sea-pictures are your object, it is always well to have accessories, such as shrimping-nets, lobster pots, &c., of your own; you are then independent, and it is not always possible to borrow at just the time you most want them. When people are busy they cannot always, however willing, lend the tools they are working with. If you go into a hayfield to make pictures, weather, wind, light, and all that goes to make a picture, may be right, but haymaking while the sun shines is a thing about which, proverbially, it is dangerous to have any delay, and the haymakers may be too busy to attend to you or lend you their implements; if you take your own models and everything they require, you will be able to take time over your pictures, and may expect good results.

There is another aspect of the costume question which may be referred to here. Scenes and incidents of country life seem to be better adapted to the requirements of the photographer than any other kind of subject, especially if he should intend to make a point of his figures. There are, however, subjects sometimes attempted that seem quite unsuitable to the art. We are bound to recognize ordinary facts, and should keep within the possible. An anacreonism should never be allowed. The photographer should accept the limitations to which his art confines him, and only represent those scenes and subjects which could exist in the nature of his own day. To dress a figure in the costume of past times, and to call the photograph of it by the name of some historical person, is to commit an anacreonism. In painting it is different. Although the painter uses a model, he does not give you, or pretend to give you, an exact portrait of his model. You do not think of how it is done when you look at the painting, but you can scarcely escape the feeling that a photograph is the absolute reproduction of some scene or person that has appeared before the camera. I have seen a photograph, for instance, entitled "Sir Roger de Coverley." We all know that it is not the Sir Roger of the *Spectator*, but a portrait of Mr. Blank dressed more or less like the real old country gentleman. There would have been no objection to calling this picture "Mr. Blank as Sir Roger de Coverley." In the early part of my photographic career, I was as much a sinner in this way as anybody. I didn't know better. I did not hesitate to call my little efforts by the names of people who had died a thousand years before photography was thought of, or who never had any existence at all. Ophelia, Elaine, Mariana, the Lady of Shallott—these were some of the names I profaned. I soon found out my mistake. I am not one of those who pretend not to read or take heed of criticisms, and have often felt obliged to the critics for many a hint. The following from a notice of the Exhibition, 1859, in a morning paper, is what opened my eyes on this subject. It is curious to read, after so many years, that my first success was as popular as a nigger melody—although not a dozen were sold, and it only appeared at two London Exhibitions.

"We do not say that a great many new photographs have not been collected, but simply that there are far too many old ones. Why, for instance, are we to be followed everywhere by the eternal 'Fading Away,' which is fast becoming as great a torment as a popular nigger melody, or any other fashionable street tune? If Mr. Robinson wished to give the public some specimens of his supposed skill in treating dramatic and poetic subjects, surely he could have thought of some novel scenes. We are not sure that Mr. Robinson's figure of 'Mariana' is not new, but we are quite certain that it will not suggest to anyone the 'Mariana' of Tennyson. It is simply the portrait of a young lady trying to look like 'Mariana,' and not succeeding. Cholopouin, a Russian photographer, has

sent, among other things, a figure of 'Mdlle. Orecchia as Leonora,' in the 'Trovotore,' which is satisfactory in all respects. If Mr. Robinson had been the producer of this photograph, he would, in accordance with his system, have entitled it simply 'Leonora.'"

I accepted the critic's hint at once, and have never since given any of my figures the names of historical personages. But the particular is not the general, and I see no objection to the use of well-known names, such as Clarissa or Rosalind, for a picture, so that it is not intended that the picture should represent any particular persons, such, for instance, as the Clarissa of Richardson, or the Rosalind of Shakespeare.

PHOTOGRAPHY AS THE WORK OF RADIATION.

BY CAPTAIN ABNEY, R.E., F.R.S.

The first of a series of six lectures on the above was delivered by Captain Abney, on Saturday last, March 1st, at the Royal Institution.

At the commencement of this subject, said the lecturer, it would be necessary to consider the nature of those minute portions of matter called atoms and molecules. These are too small to be seen, although there are good theoretical reasons to believe in their existence; indeed, it was absolutely necessary to assume their existence in order to account for many of the phenomena to which he would have to draw their attention.

After giving the calculations of Sir William Thompson as to their probable size, Captain Abney proceeded to explain the theory of the chemical affinity of atoms and molecules, illustrating his remarks by various experiments. Silver and antimony were thrown into chlorine gas, the former giving out only a dull red glow, and the latter combining with considerable energy, shown by the brilliant light produced. A number of small magnets were placed in a trough of water, and took up definite positions with regard to one another, unstable combinations being broken up on the application of an external force, stable combinations being then formed. This experiment, being thrown on the screen by means of the horizontal lantern, was very effective.

Applying these experiments to his subject, the lecturer then proceeded to show that in photography one had to consider the arrangement of particles produced by energy in the form first of radiation, and secondly chemical force. Chloride of silver, for instance, was blackened by sunlight, or by the radiation from the electric arc, but it was necessary for some substance to be present capable of absorbing the chlorine thrown off. Tubes of chloride and bromide of silver were shown, which would not blacken in the light, they having been made perfectly dry, and sealed up in a vacuum. Other examples were given of re-arrangement of molecules by chemical force and by radiation, in the action of chloride of copper on silver, and the combination of hydrogen with chlorine. The latter refused to take place in red light, but on the red glass being removed from before the lantern, a loud explosion ensued.

In further illustration, a number of printing processes were shown, beginning with the blackening of silver chloride paper, going on to the iron and uranium processes, and ending with platinotype and carbon printing, excellent examples being produced before the audience. In these processes the action of light—or, in other words, the work of radiation—was to re-arrange the molecules of the substances acted upon, forming new compounds, which possessed new properties, and gave rise to different chemical re-actions.

One of the difficulties met with in trying to explain the change produced by radiation on certain compounds is the great range of the spectrum that acts upon them. This the lecturer endeavoured to explain in a very ingenious manner, suggesting that the vibrations of the molecules might not be the same throughout their amplitude, showing, by way of illustration, the swing of a pendulum formed by a weight attached to a piece of elastic.

TARTARIC ACID *VERSUS* SUGAR IN THE DEVELOPER.

BY S. BOTTONE.

All who have had any experience in developing gelatino-bromide plates with the ferrous oxalate developer must have noticed with regret how quickly the solution loses its efficacy, apart from the deterioration which takes place during the development of each picture. This is owing to the avidity with which ferrous oxalate absorbs oxygen from the atmosphere, and to the fact that the resulting persalt (ferric oxalate) is not only incapable of developing a picture, but is actually a powerful restrainer. Mons. Audra's receipt, in which tartaric acid, in the proportion of about 1-30th of the ferrous salt, is added to the developer, gives certainly very surprising results. As might be expected, the acid acts as a restrainer, hence the development proceeds more slowly; but it does not prevent the evolution of the slightest detail even in the deepest shadows, so that no real loss is incurred, except in point of time.

But this is counterbalanced by several advantages. In the first place, the development is more thoroughly under control; secondly, the colour of the deposit is better, and the negative is of better printing quality; thirdly, there is little or no tendency to veil or fog. These are real and tangible advantages; but another of considerable importance follows the addition of tartaric acid—and that is, that the developer does not absorb oxygen from the atmosphere so quickly as before, and, when exposed to sunlight, recovers in great part its power of reduction. It would appear that the ferric salt which is formed during the action of the development is reduced to the ferrous state by the action of sunlight, aided by the tartaric acid. This peculiar reducing action of tartaric acid is not unknown in other cases,—*e.g.*, the formation of silver mirror by reduction of a silver salt in presence of a tartrate. Sugar also possesses this reducing power to a considerable extent, and is known to prevent the oxidation of iron salts, some of the ferrous preparation of the British Pharmacopeia, such as sgr., ferr. iod., owing their keeping qualities almost entirely to the sugar they contain. A saccharine developer for collodion pictures has been greatly extolled by Mr. Carey Lea, and I would now call the attention of my readers to the excellent qualities, both for keeping and developing, possessed by a solution made up according to the following recipe:—

A.—Ferrous sulphate	...	1 part by weight	
Distilled water ...	...	2 parts	,,
Loaf sugar ...		1-10th part	,,
B.—Potassic oxalate (neutral)		1 part	,,
Distilled water ...	...	2 parts	,,

To be mixed as required in the proportion of 1 part by measure of A, to 3 parts of B.

After having developed what pictures are required, the remainder of the mixed solution should be poured into a stock bottle, filled almost to the stopper, and kept carefully closed. Under these circumstances the mixed solution can be used again and again, until the ferrous salt is almost all exhausted. The colour of the deposit given by this solution is quite equal to that of the tartaric acid solution; being dense and creamy, the negative is never thin and poor, unless excessively over-exposed, while the gradation in detail is perfect.

Correspondence.

OPTICS FOR PHOTOGRAPHERS.

Dear Sir,—I am reluctant to trouble you again. Yet if I do not, I may be supposed quite to agree with Captain Abney's lesson in your issue of October 26th, and this I am unable to do; but I will confine myself as closely as I can to the actual issue.

"Distortion as caused by the curvature and thickness of a lens" differs more from "distortion as the effect produced by the refraction of a lens on the axis of excentrical pencils," in conception and treatment, than in reality; for refraction includes both curvature and thickness. But it appears to imply that distortion is due rather to variations in the amount of refraction (such as aberration and thickness) than to the refraction itself. Now the specially

distinctive characteristic of distortion in photographic lenses is, that the whole refraction is the whole distortion. For the desired condition is, that the relative directions of the various pencils passing through the stop should be the same as though there were no lens at all. It differs thus very materially from the ordinarily desired condition of accurate refraction; either to produce a distinct image, or correct amplification as in eye-pieces, for which the excentrical refraction of axes is necessary. Here it is unnecessary, and so we want to compensate the whole refraction, or to reduce it as much as possible. Thus negative aberration, or any effect of thickness which reduces the angle of deviation, is a clear advantage (as regards distortion) in a single lens; and is so easily corrected in an ordinary combination where the lenses are nearly or quite symmetrical, that its theory need never be considered in practice, it appearing to the workman simply as defective correction to be remedied in adjusting the stop—much as Professor Potter remarks concerning achromatic object lenses of large angular aperture, that "in practice these corrections (for thickness) would appear to the working optician as defective achromatism, and would be easily remedied by changing the curvature of one of the surfaces (Optics, vol. 2, p. 159). Fortunately, too, the most favourable conditions for reducing astigmatism, &c., in doublets or single lenses, are also the most favourable for reducing distortion. For both purposes the stop must be always on the plane or concave sides of plano-convex or meniscus lenses respectively. It is therefore with surprise that I see in Captain Abney's illustrations (figs. 36 and 37) that the stop is placed on the convex side of a plano-convex lens. A photographer who did that in practice would be sufficiently disgusted with the result. And especially when we consider how unexpectedly various errors disappear, or change in sign, with a correctly placed stop; it does not seem clear how a theoretical investigation, under these artificially false conditions, will tend to forward Captain Abney's desire to give practical instruction in "Optics" to photographers.

I venture to think it is better, and also more accurate, simply to say that a stop before a lens gives barrel-shaped distortion, because the axes of pencils, forming a pencil diverging from the stop, have this divergence reduced by the converging power of the lens; and that a stop behind the lens gives cushion-shaped distortion, because the axes of pencils, converging in direction from the various parts of an object, have such convergence increased by the same refractive power. And if we inscribe these familiar diagrams within circles, representing lenses, we see at once how the greater distortion corresponds to the greater refraction towards their margins. Variations in the amount of refraction, of course, follow from, and will be found pretty closely to agree with, the aberrations of such pencils. When the stop is properly placed, they are always small, and with meniscus lenses generally negative; though, when placed as in Captain Abney's diagrams, they are very large. Under practical circumstances, too, the thickness (t) sinks to its ordinary small and negligible value.

The special conditions of photographic distortion would appear not to have been present to Captain Abney's mind, as he apparently considers the injurious effect of thickness as equal to the difference between the course of the ray as actually refracted, and that in which it would have been refracted had the distances from the axis of the incident and emergent rays been equal; but such a condition is not required for this investigation, though convenient for calculating the correction for thickness to be applied to the curves for an achromatic and aplanatic object-lens. Thus, in fig. 38, the deviation of an oblique ray required for equal distances from the axis of the incident and emergent ray is not really a desideratum. In this figure, C K does not really measure the effect of thickness on distortion, that effect being measured by the angle contained between C D, and what C D would have been had the emergence taken place at K, and having but a very slight and quite negligible effect on the total refraction; * which total refraction is the distortion, measured by the angle contained between C D and A B produced, A B being the natural direction the ray would have had but for the lens.

I should have been glad to conclude by recognizing some of the instances in which Captain Abney has so justly called attention to, and condemned, some very prevalent errors, but space will not permit. As, however, I hinted a doubt about his explanation of "Aplanatic lenses" when incomplete, I wish to say now that I entirely agree with it.—I am, dear sir, yours truly,

W. H. Wheeler.

P.S.—Since writing the above, two more Lessons have appeared and I should like to have the pleasure of calling special attention to that explaining diffraction, as I believe it is the first popular rendering of its main theorem. Those who desire data for calculation, may be reminded that the components of a double star 1″ apart require five inches for separation, while 5″ may be seen with one inch only.

GREEN FOG.

Sir,—A very singular fact in connection with green fog in gelatine plates came under my notice a few days since, which, being quite beyond my comprehension, I will, with your permission, briefly describe in the Photographic News, as it may, perhaps, tend to throw some light on this strange phenomenon.

I was asked, on going into a professional friend's studio, to look at some negatives that he had lately taken on some plates of his own make, and developed with alkaline pyro. I at once said, "Well, there is certainly plenty of green about them." "Yes," said he, "but look at the portion about the middle, on which the plate rested on the pneumatic holder while they were being coated." And lo! *not a sign* of green fog *there*. Now, why was this the case? Will some of my more experienced brother photographers kindly explain it?—I am, yours, &c., Henry B. Hare.

TRANSPARENCIES ON GELATINO-BROMIDE PLATES.

Dear Sir,—I notice in your report of the London and Provincial Photographic Association, referring to the lantern slides shown by me, an inaccuracy in the formula for developing, which, I think, should not pass uncorrected.

The developer I used was made from a formula by Mr. B. J. Edwards, which I think has been published, and which is as follows:—

No. 1.	
Oxalate potash	4 ounces
Chloride ammonia	40 grains
Water	20 ounces
No. 2.	
Sulphate of iron	4 drachms
Citric acid	2 „
Water	20 ounces

To develop, take equal proportions of No. 1 and No. 2 for a black tone, and for a red tone I use 60 minims of bromide of potassium to each ounce of developer, 160 grains to one ounce water, and by using various quantities of restrainer, any intermediate colour can be obtained.

The above refers to bromide plates the formula for which appeared some weeks ago (p. 79). J. B. B. Wellington.

* It will be observed that the angle of emergence, either at C or at K, is so little inclined to the normal at either point, that the actual refraction would be very small, and the little difference between that at the two normals would tend to unite two rays emerging at C and at K respectively, at some point probably not far from the image. But one must not press an illustrative diagram too closely, for slips will occur between author and engraver, and the text indeed suggests this.

Proceedings of Societies.

London and Provincial Photographic Association.

A meeting of this Society was held on Thursday, the 28th ult., Mr. W. H. Prestwich in the chair.

Mr. A. Cowan showed an improved carrier for lantern slides, in which two slides may be supported in grooves on a travelling platform, and drawn past the condenser by means of strings, attached at each end below the platform.

Mr. W. E. Debenham: It meets the objection raised at the last meeting, as it permits the slides being passed either way.

Mr. Cowan had experimented further with orange paper and green glass, and found with three thicknesses of orange paper and one of green glass, or with five thicknesses of orange paper without any green, there was no effect; he therefore concluded that a red medium is not needed; the point of advantage in using green glass is to obtain a colder light.

Mr. A. L. Henderson exhibited a coating lamp, designed to keep emulsion fluid and emit sufficient light for coating; a floating oil lamp, resting on gimbals, permits the lamp being held in a convenient position for pouring. The front of the lamp was glazed with ruby glass.

The following from the question-box was read: "Why are large heads not taken direct in the camera?" The opinion of the meeting is requested thereon.

Mr. J. Traill Taylor said he should be happy to introduce the subject; but as Messrs. Darker had promised to entertain them this evening, and many visitors were present, he thought such an important question would take too long to discuss. It was ultimately arranged that Mr. Debenham should treat the subject in his coming lecturette.

The Chairman then requested Messrs. Darker to proceed.

Messrs. C. and F. Darker, who were warmly received, took up the greater part of the evening in showing the action of doubly refractive bodies in polarized light. By means of a lantern polariscope a great number of objects were projected on the screen. Commencing with the formation of crystals (benzoic acid), over a dozen different forms of crystallization were shown. Next, by means of convergent light, the rings surrounding the optic axis of crystals, both uni-axial and bi-axial systems were exhibited. These were followed by the different applications of quartz, compound wedges, &c. Next, the effect of unannealed glass was shown, and also compression and expansion of glass, colour appearing directly the molecules were disturbed. Rock sections and organic preparations were also exhibited; also three magnificent mica designs, kindly lent by Mr. Lewis Wright, the wonderful changes of colour in these being much admired.

Messrs. Darker then explained the effect of superposition and circularly-polarized light, showing some very curious effects, especially with a concave selenite plate and a mica sector superposed. But, perhaps, one of the most interesting exhibits was the transparency of salicine crystals photographed with ordinary light, and the same crystals photographed with polarized light, and specially prepared for this occasion by Mr. G. Smith. Some photographs of glass, both with and without presure, were also very instructive.

A large number of selenite designs concluded the proceedings.

Mr. Debenham was sure all felt very much indebted to Messrs. Darker for their kindness in bringing instruments of the highest class to demonstate a subject of so much scientific interest. He never remembered attending any meeting of such scientific value as this had proved, and concluded by moving a vote of thanks to Mssrs. Darker.

Mr. Haddon seconded, and it was passed *nem. con.*

Messrs. J. Cadett, C. W. Coe, and H. C. White were elected members of the Association, and Mr. W. Turnbull (Edinbargh) was elected an honarary member.

Thursday, March 13th, Mr. T. Bolas, F.C.S., will deliver a lecturette on "Phototype Printing."

Amateur Photographic Association.

A council meeting of this Society was held February 28th, at 12, York Place, Portman Square, Lieut.-Gen. the Right Hon. the Lord de Ros in the chair.

The minutes of the last meeting having been read and confirmed, the following members were elected:—Major-Gen. C. F. Arbuckle, R.A., Sir W. T. Thompson, C.B., Lieut.-Col. S. Micholl, Messrs. P. H. Emerson, B.A., M.R.C.S., H. R. Moiser, F.G.S., W. H. Sedgewick, E. G. Burls, L. F. Reichling, W. D. James, T. H. R. Salmon, H. E. White, M.A., F. C. Borckhardt, J. T. Black, R. G. Bellringer, and C. A. Gilder.

The Secretary then laid before the meeting the following prizes which had been awarded at the annual meeting:—Mr. R. Leventhorpe, the first prize, an oil painting in frame, by Carl Frisch; Mr. S. Norman, a silver goblet; Mr. W. S. Hobson, a silver goblet; Mr. R. O. Milne, a water colour drawing in frame; Mrs. Abbott, an oil painting in frame, by J. W. Waterhouse; Mr. W. Muller, a silver goblet; Mr. G. Western, a silver goblet; Mr. W. Adcock, a water colour drawing in frame; Mr. P. Gunyon, a water colour drawing in frame; Mr. T. Brownrigg, a landscape album; Mr. F. S. Schwabe, a portrait album; and Mr. G. Brook, Jun., a portrait album.

These prizes were approved, and the Secretary was directed to deliver them to the members to whom they had been accorded.

A vote of thanks to the Chairman was passed, having been proposed by Mr. Glaisher, and seconded by Captain Lewis.

Glasgow Photographic Association.

The ninth general meeting of the Association was held in the Religious Institution Rooms on Thursday, the 21st February.

Mr. John Parker (vice-president) occupied the chair.

The minutes of last meeting having been read and approved of,

The Chairman called upon Mr. Andrew Duthie to re-open the discussion on "The Cause of Fading in Silver Prints" (see page 151), which was left unfinished at the last meeting.

An interesting discussion followed, and the meeting terminated with a vote of thanks to Mr. Duthie and the Chairman.

Bristol and West of England Amateur Photographic Association.

The ordinary monthly meeting was held as usual at the Studio, Kingsdown, on Wednesday, 23rd January, Colonel Playfair in the chair.

The minutes of the previous meeting having been confirmed, the following gentlemen were elected as ordinary members of the Association:—Mr. Geo. Pearson, Mr. M. Walsh, and Mr. J. Mansell.

The weather was exceedingly unpropitious, the attendance small, and the meeting broke up at an early hour.

Another ordinary monthly meeting of this Association was held at the Studio, Portland Street, on Wednesday, the 27th ult. Colonel Playfair (vice-president) in the chair.

The minutes of the previous meeting having been read and confirmed,

The Honorary Secretary proposed Mr. Edward Walsh as an ordinary member, and he was unanimously elected.

The Chairman then read his paper "General Notes" (see page 150)

Mr. E. Brightman remarked that Mr. Bennett, in the early days of gelatine, did much to popularise the use of gelatine by the introduction of his rapid plates.

The Chairman said that although they were practically using the same plates now as in 1873, still the modification of the formulæ, the additional aids to development in the direction of reducing or increasing density, and the increased experience gained, had placed them in a vastly-advanced position, and given them a control over the results which were in the early days eagerly sought for.

Mr. Phillips inquired if it were generally considered a *sine quâ non* to use the developer recommended by the maker of the plates being used.

Mr. Daniel replied that such was undoubtedly the case, as the maker, if a reliable one, would have experimented and found what developer gave the best results with his plates. Of course, the particular mode of using the developer preferred by the operator might ultimately be adopted, the quantities suggested by the maker being brought to bear upon the operation of making up the developer.

Mr. Brightman expressed his belief in the absolute necessity for different plates being differently treated.

Mr. Daniel, in support of Mr. Brightman, remarked that for weakening his own plates he found dilute cyanide of potassium acted admirably, and was perfectly under control, and yet, when trying it with commercial plates, some were not affected at all by it, while in others the picture was most rapidly destroyed.

Mr. Phillips suggested that one would hardly follow the maker's advice so far as not using sulphite of soda, when so many found it a great assistance. One maker recommended its not being used.

Mr. Brightman stated that, although he did not mean that it *always* caused "green fog," still sulphite of soda did so undoubtedly with some makes of plates, and he was so convinced of this in the case of some plates he had used, that when developing a batch not long since, he cut plates in half before development, and dodged the other plates about, using sulphite of soda with some and not with others, and found most conclusively that in the case of those developed with that salt "green fog" was most apparent to a greater or less degree.

The Chairman recommended the treatment of the sulphite of soda as recommended by Mr. T. Furnell, and which he had found a perfect preventive of evil results.

Mr. Phillips asked if anyone present had experienced the extraordinary opalescent appearance which was seen on the surface of a negative during development sometimes, appearing like the top of a river where a freshly-tarred barge has passed along.

Mr. Daniel said he had often seen it, and found that the effect on the film was to "tan" it and to make it very horny. He had discovered it more often when a plate had had ammonia and pyro. added somewhat largely during development, and had been immersed therein for a rather long period.

After some further discussion, a vote of thanks was unanimously accorded to Colonel Playfair for his interesting paper, after which the meeting was adjourned till the 26th March.

Lochee Photographic Club.

On the 29th of February this Club held their first annual exhibition and conversatione in the Victoria Hall. The walls were hung with a very great variety of specimens of the work of the members, including portraits from the ordinary "carte" to the "life size" picture, many of them being splendid specimens of the art, both for minute accuracy of likeness and artistic pose and finish. The landscapes were a numerous and very fine collection, and attracted much attention. Photographs of public and other buildings were also pretty numerous, and were of a high standard of excellence. Altogether the exhibition, both for extent, variety, and genuine worth, was surprisingly good, and was very tangible and sufficient evidence that the members of the Lochee Club are able and painstaking enthusiasts in the art. There was a large and select company of ladies and gentlemen present. Bailie Ogilvie, the president of the Club, presided.

During the evening various of the photographs were shown by means of the magic lantern, and were much admired. A select programme of music was gone through by several accomplished amateurs, and a dramatic sketch, entitled "Photographers in a Fix," was performed by members of the Club.

Liverpool Amateur Photographic Association.

The ordinary meeting of this Association was held at the Free Library, on Thursday, the 28th ult, Dr. Kenyon, President, in the chair.

The minutes of the January meeting were read and confirmed, and Messrs. Sharp and Swinton were elected members of the Association.

The Hon. Secretary read a letter from the Hon. Secretary of the Sheffield Photographic Society, thanking the Liverpool Amateur Photographic Association for their contributions to the recent Sheffield photographic exhibition.

The Chairman read an addition to bye-law No. 5, which had been made by the Council—"That all prints for competition, or for the exhibitions of the Society, should be mounted on separate mounts, not less than 17½ by 13½ inches."

Mr. H. Rutter exhibited some of the cathedral-tinted glass recently brought to the notice of photographers by Mr. W. E. Debenham.

Mr. J. A. Forrest said that this glass, on submission to the test of the spectroscope, proved to be most unsafe for transmitting light to the developing room. If good pictures were obtained where it was in use it was the result of the merest accident.

Mr. J. H. Day passed round a beautiful transparency which had been developed in a room lit by a naked gas flame, and yet without a trace of fog.

Mr. Rutter differed from Mr. Forrest entirely, and thought that plates might be safely developed where the light passed through glass of the kind described. In practice, however, he preferred to use a sheet of orange paper in addition.

Mr. W. H. Kirkby said that, in his opinion, no glass whatever was absolutely safe for the development of exceedingly sensitive bromide-of-silver films; but he thought that the safest combination was that of light ruby glass and a sheet of orange.

The Chairman thanked Mr. Rutter for exhibiting his specimens of the glass in question, and also for introducing the subject. He (the Chairman) proceeded to say that discretion was necessary in the use of light, and when this was employed almost any mode of illumination might be used in the dark room without danger. He then called the attention of the members present to some extremely beautiful snow pictures, by Mr. Valentine, of Dundee, which he had been good enough to send for exhibition.

Mr. W. Rogers exhibited and described one of Steinheil's new lenses.

Mr. Morris showed some ferns artistically arranged on mounts for photographing.

Mr. J. H. T. Ellerbeck exhibited a number of light and portable frames, invented and constructed by himself, for the display of mounted photographs. These frames were filled with a large collection of prints by Mr. Ellerbeck, as well as with the productions of the Rev. H. J. Palmer, Messrs. Crowe, Forrest, Kirkby, and other members of the Association.

The presentation print of "Chartres," enlarged by the Woodburytype Company from a negative by the Rev. H. J. Palmer, was on view, and also a fine enlargement by Messrs. Goodall and Steven, on enamelled gelatino-bromide paper of Mr. W. H. Kirkby's picture "Tired."

An exceedingly interesting comparison of the brilliancy of the discs given by lanterns by different makers then took place. The Rev. H. J. Palmer showed Mr. Medland's pentaphane; Hughes' pamphengos was exhibited by Mr. Watts; Archer's photinus, by Mr. Phillips; and the triplexicon, by Mr. Knott. This latter is a new four-wick lantern, with a reflector of a special curvature invented by Mr. Archer.

The Rev. H. J. Palmer called attention to a feature in the pentaphane, by which enlarged negatives could be taken direct from an ordinary photographic print.

The members then adjourned to the lecture hall to enjoy a large number of views shown by Mr. Knott with the oxyhydrogen lantern. The transparencies were the work of the Revs. H. J. Palmer and Scott, and of Messrs. Beer, Day, Ellerbeck, Kirkby, Maycock, Watts, and others. Mr. Ellerbeck's series of views among the Hartz mountains and on the Rhine and Latin were much enjoyed; and his comic pictures illustrating Longfellow's poem "Excelsior," which was read by the Hon. Secretary as the pictures passed in succession over the screen, caused much amusement.

Coventry and Midland Photographic Society.

The ordinary monthly meeting was held at the Coventry Dispensary, Mr. Vice-President J. M. Danks in the chair.

After the usual business the Chairman called upon V.-P. Arthur Seymour to read his paper on "Old Dry-plate Processes."

Mr. Seymour said he began photography about the year 1858 by the successful dry-plate process of Fothergill, which was first introduced on the 18th May in that year. He then went on to speak of the troubles of a beginner, &c., and gave a description of the process. A strong neutral silver bath, an old collodion, a careful washing, and extreme cleanliness seemed to be the chief points upon which success depended. The developer he used was the pyro-acetic with the addition of a few drops of a weak solution of nitrate of silver. The exposure in a fair light was from two to three minutes, and Mr. Seymour spoke feelingly of the by-gone pleasure of seeing the image grow under the developer, a pleasure which is lost in the newer gelatine process. He also showed some negatives taken on oxymel plates, and some on Dr. Hill Norris's meta-gelatine plates, which were much admired.

A vote of thanks was unanimously passed.

The Secretary then asked the acceptance by the members of a box each of Mr. S. J. Lloyd's new mountant, whose qualities for sticking, keeping, &c., were known by several of the members to be excellent. He also handed round some German sensitized paper for trial.

After a general discussion, Mr. H. Mountsfort said he could recommend chloride of iron for reducing over-printed proofs, to be used after toning and fixing.

Talk in the Studio.

Photographic Society of Great Britain.—The next meeting of this Society will be held on Tuesday next, March 11th, at 8 p.m., at the Gallery, 5A, Pall Mall East, when a paper,

"Illumination of the Dark Room," will be read by Captain Abney, R.E., F.R.S.

THE POLYTECHNIC PHOTOGRAPHIC CLUB.—The meetings are held at the Polytechnic Institution on the second Saturday and the fourth Saturday of each month, at 7·30 p.m. About twenty members are now enrolled. President, Mr. E. Howard Farmer; Vice-president, Mr. G. E. Davies; Curator and Librarian, Mr. B. Foulkes Winks; Secretary, Mr. T. J. Ayling.

PHOTOGRAPHIC CLUB.—At the next meeting, on March 12th, the subject for discussion will be "On Dark-Room Illumination."

To Correspondents.

*** We cannot undertake to return rejected communications.

F. E.—The following is an outline of the process. An emulsion is made of—

Plain collodion	1 ounce
Nitrate of uranium	30 grains
Anhydrous bromide of calcium ...	7 grains
Nitrate of silver...	13 ,,

The nitrate uranium and the bromide calcium should be dissolved in the collodion, after which the silver should be dissolved by boiling in two drachms of alcohol, and this solution must be gradually added to the collodion, the whole being well agitated after each addition. When the material is coated with them, expose in the camera without drying, and develop with an alkaline pyro developer.

SOUTH DEVON.—You must indeed have a high estimate of our powers if you suppose that we can tell you all about the lenses without either seeing them or having some description; but the front combination of an ordinary portrait lens can be used as a view lens by mounting it in the place of the back combination, and in a reversed position—that is to say, with the convex side towards the sensitive plate.

J. P. GOSS.—1. There are many patents for colouring photographs, and there are also methods of printing colours in succession from several negatives; but no process for producing photographs in natural colours exists at the present time. A little handbook of "Photochromie," published by Liesegang, of Dusseldorf, may give you some useful ideas. 2. The artist you name has a studio in London, and we believe you are right in your conjectures.

WM. BARRETT.—Certain qualities of gelatine appear to have a special tendency to produce films with spots of the kind you refer to, but the reason is not known with certainty. A prolonged agitation of the gelatinous solution tends to lessen the evil, but you had better try another sample of gelatine.

A. B.—You should obtain Burton's "A B C of Photography," published at our office.

WILLIAM MILLER.—In most cases you would find the larger lens the better for the purpose, but much depends on the class of subjects you deal with.

W. H. S.—Thank you; we will bear it in mind.

MILO. ZNEW.—1. You would find the chloride of calcium a very mischievous companion, as it would be hardly possible to prevent traces reaching your plates. Wrap each packet of plates in several thicknesses of tin or lead foil. 2. Yes, perfectly well; but it is not desirable to use very hard water. 3. All the ordinary solutions used in dry plate work should keep well in them, excepting the ammonia; we should, however, prefer glass bottles. 4. No, but you can get some idea of the power of the light by noting how long it takes to impress a standard tint upon a piece of sensitive paper. Write again if you want further information.

W. J. W. S.—They should certainly be protected by a glass.

H. GOMALL.—It seems to us as if the plates had been exposed to light by accident. Try one out of the unopened package, and if that is wrong, communicate with the manufacturer.

C. G.—1. Remove the back combination, and replace it by the front lens, the convex side next the sensitive plate. 2. It is most likely that a notable improvement would result. Make the experiment.

J. O.—1. Use a fine-pointed pencil—not too hard. 2. Yes, only you must take care that the film is thoroughly dry before you apply it. 3. We imagine that you have been considerably over-exposing. 4. Yes. 5. It prevents the decomposition of the pyrogallic acid. 6. All you can judge by is an inspection, and it is not always easy to see clearly. 7. Abney's "Instruction." 8. Yes. 9. It is better to purchase it in the solid state.

DR. F. STOLZE.—We are much obliged to you for calling our attention to the matter, and we will allude to it next week.

ANTIPODEAN.—Such full details on the subject would fill several numbers of the NEWS, and our London subscribers would hardly approve of this.

W. M.—1. Either Nelson's X opaque or Heinrich's answers very well. 2. Any temperature between 140° and 150° will be suitable. 3. If they are acid, and you wish to make them neutral, add a minute trace of ammonia.

ENQUIRER.—See Mr. Campbell Swinton's paper on page 105 of our last volume. See also page 611 and 740.

CHAS. G. WILLIAMS.—You will find an excellent process described on page 402 of our volume for 1883.

TYRO.—No, but you will find an account of Ive's process in the YEAR-BOOK, also in the volume referred to page 498. 2. Our publishers have neither the set of numbers containing the articles, nor the complete volume, but no doubt you could obtain the volume by advertising for it. 4. Yes, but not for some months.

MORE LIGHT.—We think it is due to the mount, but should recommend you to make the experiments described in our leader of the week before last (page 113).

SHAH JEHAN.—I. The expression which you query, and that which you put forward as a correction, mean precisely the same thing, as the large figure multiplies all following it until a sign occurs. In other words, the brackets are not required. 2. In this case the end figure is superfluous. It should be 2Na Br, or 2(Na Br).

G. F. WEBBER, JR.—1. They will answer very well if you treat them as directed for the ordinary albumen prints. 2. You can make the enlargement in a whole plate camera. Compress the paper between glass plates.

The Photographic News Registry.

Employment Wanted.

Printer, generally useful.—F. Foy, 7, Market-st., Deal.
Finishing Enlargements at home.—L. E., Spring House, Merton, S.W.
Operator, land., portrait., menoch, crayons.—W. D., Shaw-rd., Dudley.
Reception Room, Shop, Mount, finish, &c.—B. A.. *Photo. News* Office.
Col. & Ret. (Lady).—E. McCowen, 20, Grand Parade, St. Leonard's-o-Sea.
Retoucher, Operator, Printer.—V. C. Yealett, 3, Queen-sq., Bath.
Manager, exp.—Photographer, Adelaide-rd., St. Pancras, Chichester.
Operator, Copyist, clever with children.—C. O., 25, Duke-st., Bloomsbury.
Retoucher, first-class, in London.—Artist, 15, Hastings-st., King's Cross.
Printer, can speak French.—G. P., 45, Stamford-st., Blackfriars-rd., S.E.
Retoucher, first-class.—P. Marks, 1A, Britannia-st., City-rd., E.C.
Retoucher, work at home.—J. Fisher, 7, Westmoreland-pl., City-rd., E.C.
Shopman, town preferred.—E. D., 17, Brunswick-st., W.C.
Operator & Retoucher.—Light, 94, D Street, Queen's-pk., N.W.
Architectural or Engin. Photo.—W. S., 32½, Colebrooke-row, Islington.
Assist. Printer, good Vignetter.—G. E. C., *Photo. News* Office.
Lady in Rec. Room, or Spot.—C. R., 40, Netherwood-rd., Shepherd's Bush.
Lady as Retoucher (pupil of Arndt).—M. A., *Photo. News* Office.
Lady Spot., Mounter, Recep. Room.—E. G. C., 115, Westbourne Grove, W.
Oper., Print., Toner, Painter Water Colours.—G. L., *Photo. News* Office.
Assist. Operator and Retoucher.—F. E. Baily, 21, Gt. Oxford-st., L'pool.
Artist, well up.—P. Eckhart, 105, Hall-pl., Hall-pk., Paddington.
Artist or Manager.—B. E. P., 91, Kingston-rd., Small Heath, Birmingham.
Silver or Managing Printer.—F. C. M., 35, Vincent-sq., S.W.
Operator and Retoucher (German).—G. Haupt, 181, Aldersgate-st., E.C.
Operator and Retoucher.—J. Brown, 29, Pond-pl., South Kensington.
Youth, as Improver.—M. A., 289, Portobello-rd., North Kensington.
Reception Room (experienced).—B. C., 72, Azenby-sq., Peckham.
Artist, oil, water, monochrome.—F. G., 3, Kenyon-ter., Clapham.
Assistant Operator (Lady).—F. S., 58, Belsize-rd., South Hampstead.
Operator and Retoucher.—Celt, 19, Kingsgate-rd., N.W.

Employment Offered.

Retoucher, clever.—John Hawke, George-st., Plymouth.
Assist. Oper., first-class Retouch.—Disderi & Co., 4, Brook-st., Hanover-sq.
Out-door dry-plate Operator.—R. Ward & Co., 166, Piccadilly.
Sil. Print. & Ton.—Mrs. Harborne, 300, Victoria-rd., Aston, Birmingham.
English Lady for France (shop).—E. E. Y., 24, Mark-la., E.C.
Out-door Operator, Monochrome, Retouch.—A. K., *Photo. News* Office.
Operator, generally useful.—A. H., 68, Fullerton-rd., Wandsworth.
Operator, first-class, for City firm.—J. B., *Photo. News* Office.
Assist. Printer, good Vignet.—J. Ruckmann, 5, Watfield-rd., Ealing Dean.
Operator for Ireland,—D. W., c/o Marion and Co, Soho-sq
Artist, for black-and-white.—G. N., 118, High-st., Notting Hill.
Printer and Toner, first-class.—Cobb and Son, Wellington-st., Woolwich.
Printer and Toner, to manage.—Vander Weyde, 182, Regent-st., W.
Collotype Printer, Woodburytype, &c.—X. X., 38, Poultry, E.C.
Artist, skilful, at 50/- per week.—Winter, Derby.
Printer and Vignetter.—Dickinson's, 114, New Bond-st.
Photographer on Wood.—Photo, 58, Salcott-rd., Wandsworth Common.
Pinter & Toner, generally useful.—Hallier, Stafford-rd., Walsall.
Assistant Operator, first-class.—Byrne & Co., Richmond, Surrey.
Floater.—Tavistock Alb. Wks, 1, Tavistock-pl., Harrow-rd., Kensal Green.
Lady Correspondent and Shop.—West and Son, Eagle House, Gosport.
Operator for Ireland.—D. W., c/o Marion and Co., Soho-sq.
Operator in Horsham.—S. Bayfield, 10, High-st., Notting-hill-gate.
Retoucher, to finish enlargements.—Whitlock, New-st., Birmingham.
Young Man, good all round.—Beta, *Western Express*, Bideford, Devon.
Printer (male or female) for Bristol.—Holden, 23, Queen-st., Plymouth.
Carbon or Lambertype Photo.—W. B. Woodbury, Manor-rd., S. Norwood.
Printer and Toner for country.—Bunyard, 36, Mildmay-st., Mildmay-pk.
Carbon Enlarger and Printer, piece work.—A. D. C., *Photo. News* Office.
Operator and Printer.—Apply, 60, Clarence-rd., Hackney.
Operator (dry plate), also Retoucher.—Lauder, Westmoreland-st., Dublin.
Under-Salesman.—Shew & Co., 132, Wardour-st., Oxford-st., W.
Silver Printer and Toner.—Turner and Kellick, 17, Upper-st., Islington, N.
Camera Makers.—Cussons & Co, 79, Bold-st., Liverpool.
Operator for Ireland, £1 4s. weekly.—D. W., c/o Marion & Co., Soho-sq.
Assistant Operator, dry plates.—Manager, 22, Bishop's-rd., W.
Operator for out-door, retouch, &c.—G., c/o F. W. Hart, 8, Kingsland-green.
Operator, quick & experienced.—H. T. Reed, 16, Tottenham-court-road.
Lady Printers, £1 weekly.—Stuart Bros., 47, Brompton-rd., S.W.
Operator & Retoucher.—Mr. Phillips, 304, Regent-st., W.
Lady for office and to spot.—Mr. Phillips, 304, Regent-st., W.
Assistant Operator for dry plates.—A. W., 62, Gt. Portland-st., W.
Operator, to take charge.—Cobb & Son, Wellington-st., Woolwich.

THE PHOTOGRAPHIC NEWS.

VOL. XXVIII. No. 1332.—*March* 14, 1884.

CONTENTS.

SMALL WORK ON OPAL GLASS, AND A NEW PRINTING FRAME FOR THE SAME.

IT is generally admitted, as a photographic axiom, that a matt surface, either on opal glass or paper designed for enlargements, affords facilities for a far more artistic effect than can be obtained when the surface is glossy; still, it is quite possible to overlook too much the value of bright opal glass properly treated for giving to miniature pictures a special charm. The fine delicate stipple in water-colour work which is out of place on a four-inch head, is the making of a little face that scarcely measures half an inch in length. So the grainless surface which gives a painfully definitive sharpness to an enlargement at the expense of softness, is by no means unsuited to a small half-length vignette when the whole picture does not measure more than two or three inches at most.

We have before us a few samples of this class of work, and propose to describe the method by which such portraits are produced; a process which has the advantage of being both simple and easy to work, and inexpensive, at the same time calculated to please a large majority of critics.

Ordinary pot opal is the base of operations, of course selected as free from flaws and scratches as possible. Slight markings may often be rendered harmless by using a substratum of gelatine dissolved in acetic acid and diluted with alcohol. This, when made with one grain of chrome alum to each dram of gelatine, answers well; can be dried off by heat in a few minutes; and should leave no trace of the smell of acetic acid, but present a smooth clean glassy surface. There is little chance of frilling when this is employed.

Ordinary gelatino-chloride might be employed for the purpose we have in view, but the pretty variety of colour obtainable by development being only visible by transmitted light, we are shut up to the two or three modifications of grey for our finished picture. We therefore prefer to print out the picture on a suitable emulsion (plain or vignetted), and tone it any colour possible with an ordinary silver print, the difference being that in this case there is no paper or other grain to mar the delicacy of detail presented by the negative. Of the permanency of these pictures we can only express opinion founded upon theory, but it is something to say there is no albumen employed in their production. The chief difficulty is, of course, the printing, no frame yet introduced being suited exactly to the purpose, especially as this glass is often exceedingly thin, and the sizes of such small work vary so much. This difficulty is entirely removed by the frame we have before us, and which we will presently describe.

To return to the emulsion employed. There are several published formulæ, but the one we prefer as most suited to our purpose is made as follows:—

For a small quantity we take eighty grains of hard gelatine, and dissolve it by gentle heat in one and a-half ounces of distilled water; into this we pour a warm solution of silver nitrate, seventy-five grains in half-an-ounce of distilled water. We have previously taken the precaution of well drying a little sodium chloride and a little potassium citrate, and of each of these salts we take twenty-one grains, and mix them in half-an-ounce of water, dissolving by heat. This mixture we pour gradually into the warm gelatine and silver, stirring all the time, and then pour out the emulsion thus made into a small dish to set.

We prefer working in yellow light at this point and onwards, though a distant gas-light is no doubt harmless in such a process. When the emulsion is set, we take a basin of water and a piece of mosquito net, and squeeze the jelly through the latter into the water, keeping the hands below the surface, because this emulsion is much more easily melted by the heat of the hands than a firm gelatine bromide. After five minutes, with an occasional stir, the water is poured off, and the basin filled up again. In another five minutes the water is again poured off, and the emulsion is thrown on to muslin stretched over some vessel, and allowed to drain for half-an-hour, when it can be melted up at a low temperature. Two drachms of alcohol must be added, in which three grains of salicylic acid are dissolved, and one grain of chrome alum dissolved in a little water by heat. Upon filtering it through some fine material, such as two folds of cambric, the emulsion is ready for coating the plates.

We have described this process at length for the sake of amateurs and others who have never made bromide or other emulsion, but in practice it really takes a very little time to prepare a batch.

When necessary, the thickness of coating can be regulated to suit the negatives, a hard negative requiring very little emulsion, and a very soft one a thicker coating. As a rule, less is required than with bromide for negative work. Upon a plain opal glass, polished with whitening, the emulsion flows as easily as collodion, but when using the before-mentioned substratum, a glass rod will be required to distribute it evenly over the plate. We have found the side of a clean little finger the most useful, and harmless, for the purpose. It is better not to pour off the plate into the coating jar, as air-bubbles are very readily formed by this mixture, and spoil the work. Either pour off into another cup, or put only just the right quantity on. Dust is a great enemy at this stage, and must be provided against by covering the top of levelling slab, and three sides. During drying also, to avoid dust, we prefer adopting the plan suggested in one of the YEAR-BOOKS,

and placing the plates at the sides of an upright box, resting them against two nails, with one corner down, and the top corner hanging over to protect the surface.

The plan we recently advised of soaking plates in methylated alcohol can be adopted, but with the sacrifice of brightness in the finished picture.

The most suitable sizes are quarter plates, one-sixth, and one-eighth, though smaller than these are used with pretty effect. Miniature gilt mounts set in velvet with oval openings of two inches by one and a-half and upwards are especially suited to the purpose, and when the prints are vignetted plain or grey they form the most charmingly delicate specimens of pure photography that we can remember seeing.

We now come to the printing, which is rather more quickly done than with albumenized paper, but as in most cases it is far better to print under ground glass or tissue paper slowly, they take about as long as the others. This frame is the unpatented invention of Mr. R. Offord, Maidenhead, and is of such simple construction that anyone possessing a modicum of mechanical ability can readily make one for himself.

The principle upon which it acts is the same as that of a pneumatic plate holder, but it really more closely resembles the apparatus employed by dentists to sustain the upper set of false teeth in their place without the use of springs. For a photographic mechanician this description would, perhaps, suffice, but for the sake of our less highly gifted brethren we will describe it more fully.

A common five by four printing frame is taken, of the sort used with or without a glass bed; in place of the wooden back, a piece of stout zinc or tin plate is fitted to lie flat where the back would be, and projects at each end nearly to edge of frame. Mark distinctly one end, and one end of frame. Two holes are made at each end of this metal back at about a quarter of an inch from the side, so that four one-inch iron wire nails carefully fitted to the holes can be driven through them into the ends of frame about midway in the width of those ends. The nails being driven perpendicularly to the frame, when the heads are cut off the back, can be lifted up and away, and the cut ends of nails smoothed round with a file. Then the back will go on and off, and keep a perfect register.

The suction plate-holder consists of a circle of soft india-rubber one-tenth of an inch thick (red preferred) one inch in diameter. This is rivetted in the centre of the back, on the under side, by means of a brass or iron nail, and a brass washer rather less than three-eighths of an inch in diameter. An inch wire nail will answer the purpose of a rivet, and the washer must be fitted tightly upon it and rounded off smoothly on the upper edge, or it will cut the rubber. It is necessary that the one side of the rubber should be perfectly smooth, and when the rivetting is done it should stand up from the back like a small saucer or shallow cup, the smooth side inside. The secret of its use lies in the application of a little glycerine, which keeps the cup moist, and ensures perfect and continuous adhesion.

Cover the under side of back with black cloth up to the holes at the ends, leaving a circular opening in the centre rather larger than the rubber cup for it to work in.

To use this frame, first fix in it securely a 5 by 4 glass. A little shellac, applied with a hot piece of iron at the corners inside, will effect this. Place the negative on this glass, and secure it by thin strips of very narrow gummed paper across the corners. Adjust the prepared opal plate in the right position, which, according to position of negative, should be near the centre. Having moistened rubber cup with a little glycerine, put the back on the four pins, and press lightly over the centre to make the cup adhere to back of opal. Fix the springs as usual with, perhaps, a strip of cardboard under them to increase pressure. Progress can be ascertained readily by turning back the springs and raising the back, to which the opal will now be firmly attached. With a faulty suction-plate, the horizontal position, either face up or down, is the safest. The frame will register perfectly when the back and plate are replaced. For larger sizes than cartes, two suction-plates are used, about two or three inches apart.

Printing should be carried on as deeply as for paper, and vignetting, which is by far the most suitable style, should be done either on a turntable, or by frequently moving the frame to different positions. The washing must be very thorough, five or six waters not being too many, nor twenty minutes in all too long. Toning we succeed best in accomplishing in a borax bath, such as is described in the Year-Book. This must be done to taste, but we prefer artificial light, and continue the process until there is only a trace of red left in the shadows when viewed by transmitted light. An alum bath for five minutes secures immunity from frilling; but it must be clean. Fixing in a twenty per cent. hypo bath for at least ten minutes completes the operation, and the usual washing as for negatives must of course be thorough.

This emulsion will not keep very well, and the plates when long coated have a tendency to discolour. They will keep better if packed in paraffin paper or tinfoil. It is better to make smaller quantities as required, and when about to coat plates, to take as much from the stock as will answer the purpose, and not warm the whole batch several times. Discolouration is avoided by this method.

THE VELVET ROLLER FOR PHOTO-LITHOGRAPHIC TRANSFERS.

By far the greater part of the photo-mechanical processes which have been introduced up to the present time depend upon the use of an inking roller, and it is in the use of the inking roller that so many fail. Although the main object of the present article is to elucidate the method of working with the velvet roller, an instrument originally introduced to the photographic fraternity in these pages, we will preface our remarks by a few observations upon inking rollers in general.

The letter-press printer ordinarily makes use of a roller consisting of a soft composition of glue and treacle, or glycerine and glue, this roller being cast round a wooden core, having a central bar of iron running through it. The roller is usually mounted in a frame, and is provided with either one handle (fig. 1), or a pair of handles as

Fig. 1.

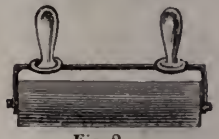


Fig. 2.

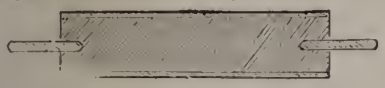
shown by fig. 2. When the surface to be inked is dry, the gelatinous roller answers very well, but it is ordinarily useless for those processes in which the surface to be inked is damp, as the moisture acts upon the surface of the roller, and so far softens it as to prevent the ink adhering. A gelatine roller, however, possesses the valuable property of being very easily cleaned with turpentine, and, moreover, such a roller can be easily made by anyone out of the chromograph composition which is sold for making copying slabs. It is merely necessary to melt the composition in a hot water bath, and to cast it in a brass tube which has been oiled inside, the core being supported in the middle of the mould.

A roller with single handle (fig. 1) is inconvenient, except in the case of an extremely small instrument, as it is difficult to control the amount of pressure given on the two ends of the roller; but when two handles are provided (fig. 2), and these are near the ends of the roller, it is easy

to keep the inking under the most perfect command. It is usual, however, when a difficult and delicate inking operation is to be performed, to make use of a roller having no frame, but simply projecting ends, as shown in the subjoined figure, these ends being furnished with sockets



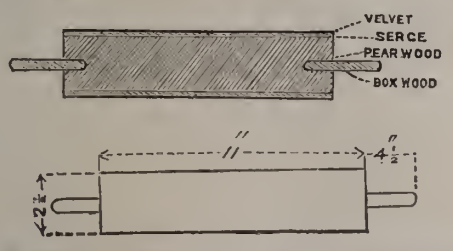
or covers of leather for convenience in working.

For lithography, collotype, and other processes in which a moist surface is inked, it is usual to employ a leather roller; but before this can be used with success it must be so thoroughly impreguated with ink that the material of the roller altogether refuses to absorb water. In order to "prepare" the roller, or give it this water-repelliug quality, it must be worked in ink or varnish at frequeut intervals during a long period. Time appears to be an essential element in the proper saturatiou of a roller with ink, and many failures have occurred through the use of rollers inadequately "prepared."

The velvet roller, of which our readers have heard much, requires to be thoroughly saturated with ink just as is the case with the leather roller, aud it sometimes happens that a little time elapses before the roller acquires the best condition for use. Probably much depends on the quality of the original velvet, and it is quite easy to conceive that the presence of a very small quantity of a gumming or mucilagious material in the dressing of the velvet would considerably hinder the free penetration of the fatty ink, and would favour the taking up of the moisture by the roller.

The substance of the following particulars has already appeared in the News, but as we have had several enquiries with respect to the use of the velvet roller, we take this opportunity of once more dealing with the subject.

The subjoined measurements specified are those to be recommended, and in the section we show the materials of



which the roller is made. After considerable experience, it is found that the *best silk velvet* is most suitable for the purpose. The body of the roller is of pear wood, a light material most favourable to the purpose, while the handles are of boxwood. Over the pear-tree block are sewn two layers of thick serge, and over the latter one thickness of velvet, the price of which is about twelve shillings a yard. A nice brisk nap is required in the velvet, and this cannot be obtained unless a good price is given.

The serge, before it is sewn on, should be scalded in hot water, so that it will not ruck afterwards, and the velvet must be fitted by a skilled seamstress. The so-called carpet stitch is best adapted to the purpose, the ends of the velvet not overlapping, but drawn together so as to meet. In this way the seam is not a ridge, but perfectly flat, and the roller does not set off at this spot. It need scarcely be said that this can only be attained with very fine stitches. The velvet is cut out exactly to size, and sewn on the block.

The roller may be put away in a linen bag as soon as done with, though perhaps it is best to clean first; the bag keeps away dust, and the grease in the ink will keep the velvet from becoming hard. Of course you can't scrape a velvet roller to get the ink off, as you do a leather one; you can only free the velvet of its ink by rolling. The roller is passed over a clean slab, and this is scraped from time to time. The slab gradually pulls the ink off, and this is then removed from the slab by scraping. If you are not able to get off all the ink in this way, pass the roller over a sheet of soft paper and apply a little turpentine. After a little practice you will soon know when the roller is free from ink.

The ink is thinned by the addition of turpentine, so that if at any time it is too thin on slab or roller, a little delay will at once mend matters to allow for the evaporation of the turpentine.

The transfer ink suitable for use with the velvet roller is made by mixing together two ounces of soft commercial transfer ink and one-fourth of an ounce of olive oil. This forms the stock ink, and, when required for use, it should be reduced to the consistency of cream with oil of turpentine. It is worked thoroughly into the velvet, and as the turpentine evaporates, the roller acquires the condition most suitable for inking up a transfer on gelatinized paper. The paper best suited for use with the velvet roller is thin bank post made sensitive by floating on—

Gelatine	3	ounces
Water	50	,,
Bichromate of potash	2	,,

The dry paper is exposed for about five or six minutes in the shade, and it is then soaked in cold water for a few minutes aud blotted off, being inked up with the velvet roller, just as if it were a lithographic stone.

It is of importance that the paper should be steadily supported under the roller; and an excellent method is to leave the sheet a little larger than the subject in one direction, and to double this extra margin under a thick slab of plate glass, after which care is taken always to roll away from the edge which is held. If the plate glass is thick and heavy, its weight will hold the transfer paper in position; but in other cases the glass may itself be held in a form of vice like the screw plate-holder, and in this case it is only necessary to turn down sufficient of the transfer to grip between the edge of the plate and one jaw of the plate-holder.

A TRIP TO THE GREAT SAHARA WITH A CAMERA.

BY A COCKNEY.*

Biskra is a green patch of palms, about two miles long and half a mile broad; but there are several other oases close by, so that agreeable excursions can be made on foot, or by car, over the desert tracks. An oasis is very much like the impression you get of it as a school-boy. The tall feather-tufted palms offer grateful shelter from burning sun and sand to the weary desert traveller, as he walks under their cool drapery beside flowing rivulets of water. For the palm trees require careful irrigation, to bring forth their date fruit, which, year by year, constitutes a rich and valuable harvest. Sometimes there is an opening among the trees, and here the well-watered land bears luxuriant crops of oats and barley, the fat green ears now within a few weeks of ripening. You stroll along in this green paradise—breast high in corn-fields, their grassy margin gay with golden brouzed marigolds and yellow star-flowers—until the palm stems gradually thin, and a wooden fence or mud wall brings you abruptly to the end of the plantation. Get over the stile, aud you are in the desert. Walk but twenty paces out of the shadow of the palm grove, and your foot is once more upon the hot arid sands.

Facing the main line of buildings, and close to the walled barracks, is a public garden with trees other than palms, and sanded walks and fountains, where the military band plays occasionally, and where is the fashionable promenade. A few streets, more or less regular, make up Biskra proper, and then, as you walk on through the plantation, there is a large opening in which a mud-walled negro village is the

* Continued from page 148.

principal object. A country road succeeds, flanked by green corn-fields, with here and there a copse of palms, and then, at the end of the oasis, is Vieux Biskra, the old Arab village, of the quaintest and most primitive construction.

We fix upon the negro village as the first field of photographic enterprise. The Arabs have not yet forgotten that the negroes were their slaves before the French came, and the two races still live apart. Each village has its chief, and each group of villages its cadi, who answer to the maire and prefêt of a French community. In these circumstances the government of the country is of the simplest. The military commandant holds the cadi responsible for the peace of his district, and if any crime is committed, he has to find the offender, and punish the latter to the satisfaction of the French governor.

In the negro village, the women do not conceal their faces. Here they are in the narrow street, laughing and grinning with delight, and dressed, not in white, like their serious neighbours, but in red and blue, and yellow and purple. What a pity the camera cannot give a trace of their picturesque garb! And the little black children! what wonderful piccaninnies they are, to be sure, and how quickly they scuttle off down a dark alley, or into their habitations, at the sight of a white face. There is a Café Maure, or native coffee-house, at the beginning of the village, where a lot of them are squatting round chattering; but I am so clumsy, and so slow with the camera, that they have all disappeared, and only their white teeth are to be seen grinning round the corner, by the time I am ready with my plate.

So I leave the apparatus and wait a while. One after another they shyly come back. But they will not venture beyond the shelter of the house; they seat themselves in front and look on. This will do nearly as well, and with a quick motion of the cap, I hope for the best. Then Jones and I move away down one of the streets. There is a bit of a square with a tree in the middle; a figure is asleep here, and further on are other negroes squatting silently before their doors. This time I am more fortunate. Despite the warning shouts of the little blackies, who keep hovering round, afraid to come to close quarters, the recumbent figure remains dormant, and the squatting habitants still squat motionless. I expose two plates and move on.

The next selection is a cross road, where two narrow streets of mud houses meet at right angles. The darkies, both old and young, have by this time acquired confidence, and when Jones puts one here and another there, distributing a few sous as he goes, the camera becomes quite popular, and the negro village begins to enjoy the joke quite as much as did the good people at Constantine.

And now a word about the reflector lantern, which, with its large square of orange glass, has been safely carried in a cardboard box some fifteen hundred miles. It is a capital illustration of what may be done with a little care and forethought, as I take the first opportunity of pointing out to Jones by way of moral. "Yes," he says, "it certainly does prove what a careful traveller may undertake. But conveying the lantern was the least I had to do, remember. How often, I should like to know, have I prevented you from sitting on it, or smashing it with your beastly luggage!" I did not think I had heard aright, and I said so. "What I mean is, that there is a precious deal more credit due to me than if I had travelled alone." I really don't know what has come to Jones, or what he means.

But whatever slight trouble was connected with the lantern journey, this was repaid a hundredfold by the kindly reception its bearers received at the hands of the owner. M. Foureau, to whom the apparatus served me by way of introduction, is not only an accomplished amateur photographer, who makes Biskra a residence for several months in the year, but he is a man of high scientific attainments, and with considerable experience as an African explorer. He exposes as many as a hundred plates sometimes on a tour, using a half-plate camera constructed by Jonte, of Paris, which weighs but two-thirds of the weight of mine, and collapses into a flat box-like form, far less liable to injury than my more solid apparatus. Whether you take a photograph with the plate upright or sideways, the front of the camera always remains in the same position. The back, however (and the bellows), is so loose that you can lift it up and twist it round bodily, whenever you want to change from a vertical to a horizontal position, the rear of the apparatus being screwed fast as soon as changed.

But M. Foureau, albeit this little camera has now served him three years in the desert, is not satisfied with it. Wood will not stand the extraordinary changes of the climate, and hence he has given the order to have a camera made of aluminium. This will be both light and rigid, while it will bear any amount of knocking about. M. Foureau, I may mention, always employs oxalate development, but as the African sun is rather powerful, he never makes use of fresh solution in his first treatment of a plate. The old solutions are invariably employed, these being carefully stored up in well-stoppered bottles (kept full); without this developer he never attempts to work.

M. Foureau tells me something about the value of an oasis and date-bearing palms. Apparently the cultivation of dates is one of the most paying of speculations, and some of my readers will be as surprised as I was to hear that you need not stop to find an oasis to grow them in; you may make one for yourself. Already many artificial oases have been created, and every year the number increases. A spot is chosen in the desert that shows some sign of herbage, or, in other words, where it is likely water may be found without difficulty. Here an artesian well is made, the soil is irrigated, and date palms are planted. After a few years they bear fruit, and in its prime, a tree will produce a hundredweight or more of dates, the value of which, weight for weight, is equal to that of corn; for dates constitute the main food of man and beast in many of the districts of the Sahara.

By the way, M. Foureau has a difficulty in getting pure water for photographic purposes, and hence makes use of a solar distilling apparatus to obtain it. His parabolic reflector of silvered metal is about the size of a large umbrella inverted, the boiler (which takes the place of the umbrella stick, and upon which the heat rays are concentrated) being large enough to distil about a litre of water during the half dozen hours it is exposed to sunshine every day. At the Biskra hospital they have a similar arrangement for distilling water, which produces some thirty litres of pure water per diem.

On our journey to Biskra I counted no less than two hundred camels during the day—or rather dromedaries, I think it is more correct to say—coming along in droves that varied in number from three to thirty. Most of us are aware that a camel will journey several days without drinking, but it is not so well known that the patient animal can go without eating almost as long. If in good condition and after eating its fill, it is stuffed by hand, as travelling Arabs are wont to do, then a camel will go a week or more without food. Near the villages, it is the custom of these caravans, whether large or small, to encamp in the open desert; but to afford them protection elsewhere, there are high walled enclosures, termed caravansaries, in which they are at any rate secure from surprise during the night. South of Biskra, the villages and oases are few and far between, and the French hold only one more military post, that at El Oued. In fact, the first covered building on the track southwards is a solitary blockhouse thirty kilometres from Biskra—you can get a glimpse from the housetops of Biskra of its roof, shining like a pebble in the plains of sand—and the nearest inhabited dwelling is fifty kilometres away. There are, however, regular postal arrangements both with El Oued and Turguth (some four days' journey south), mounted Arabs being employed to carry the letters.

In these circumstances Biskra is a favourite halting-

place for caravans, and as you emerge from the oasis in early morning, you may often count a dozen groups of recumbent camels, the women and children of the caravan usually grouped in the centre. To get a few pictures of these encampments was naturally our ambition before leaving the oasis, so one morning at sunrise, Jones and I quitted the oasis with camera and plates, with this object in view. To the south-east there was the never-ending Sahara spread before us, an eternal flatness, all the more impressive because of the clear limpid atmosphere; behind was the red ridge of the Col de Sfa, as sharply limned as if it were of painted cardboard but a hundred paces off.

There are plenty of encampments to choose from, so we are not long in getting what we want. At one point a dozen camels lie together in a picturesque group, and we approach to within twenty paces. Alas! before I have done focussing, a wretched dog has jumped out of the circle, and is baying and barking at the legs of the tripod. Some half-sitting figures rise to their feet precipitately—women almost black—and the camels stretch out their snake-like necks. A rapid exposure is made, but before I can turn the slide round to get a second one, Jones cries to me to "look out."

It is a couple of Arabs who are striding along as fast as they can without running. They have been down to the brook, and return hastily to see what it is we want with their camels and women. Fortunately, they leave the camera on one side, and make straight for the encampment; one of them speaks to the women, and stands looking defiantly at us; the other viciously kicks one of the camels, and gets it on its legs. The standing animal invests the group with a pyramidical shape; I wait no longer, but expose quickly, hoping for the best.

Neither of us is afraid, of course, but we think we had better move off, and so we do. Another group is approached, and two more plates exposed, with not less success, it is to be hoped. But the scene around is getting rather too lively to be pleasant. There are dogs barking in all directions, and in every encampment are signs of moving figures. The Arabs are getting ready for the day's march, no doubt; and as neither Jones nor I would think of delaying them for a moment, we at once withdraw with the camera. Besides, it is breakfast time, and we are both *fearfully* hungry—another good reason for hastening back as fast as we can.

THE ETHER-OXYGEN LIME-LIGHT.

BY LEWIS WRIGHT.

The Chadderton explosion has pointedly directed attention to this form of the lime-light, and it is an important question whether or not, as stated in a letter to the *Daily Chronicle*, it ought to be avoided by all public lecturers, for it has marked advantages. Its effects are, as stated by me some time ago, at least as brilliant as oxygen burnt with house-gas in a "mixed" jet, and sometimes more so, for I have successfully shown a crystal of Brookite (a most difficult one owing to its strong red colour) in the polariscope with the ether light, which on a previous occasion had baffled me with house-gas. And to be able to use the "mixed" or most brilliant form of jet in a country village where there is no gas, must be to many a great boon.

First of all, it ought not to have been stated by Mr. Etheridge in the *Daily Chronicle*, that the apparatus which exploded was the "ethoxe." That name was adopted by Mr. Broughton, who devoted much time and study to perfecting this form of light for his particular form of apparatus; and whatever merits may belong to other forms, that name ought to be left to his, and no one else has a fair right to use it. This is a case in point, for it is not the "exothe" which has exploded. Some time since another explosion took place, also *said* to be of the "exothe," but it was not; and the unfairness of pirating the name needs no further proof. Let every inventor or improver Christen his own apparatus, and stand or fall by it alone.

As far as I can ascertain, the apparatus which exploded was only a modification of the very earliest or wash-bottle form. To use such a form habitually would be in my opinion, for reasons which will appear, an effectual form of suicide, and I have seen two other forms of apparatus emanating from Birmingham which also appear to be highly dangerous. Mr. Diggle being a photographer, however, this journal has a sort of double claim upon him, and he would confer a real service on many by fully describing his apparatus, and every ascertainable detail, even the most minute, which occurred on the eventful evening. We ought to have the exact quantity of ether used, its quality and price, and where bought; the size and top area of the bag, the weight used, and anything else that can be known. Meantime, it is only possible to treat the matter generally.

Whether the ether light is "dangerous," then, "will depend." On the one hand, it has special dangers or risks above and beyond those of mixed gases; on the other hand, these admit of being certainly guarded against. But they will only be by that class of people who, fully realizing the dangerous points, are absolutely methodical and cool in the methods needed to meet them.

This is readily seen if we consider the nature of the process. From one bag of oxygen a small portion is passed through ether, and in its passage becomes saturated with ether vapour, which is burnt in place of house-gas. Another tube from the same bag feeds the oxygen to the jet as usual. Thus the same pressure is given to both, which is very handy and simple.

Now comes the element of special danger. The *saturated* mixture cannot explode, but only burn; and a small quantity of oxygen carries over a large quantity of ether vapour. But when the vapour is diluted with some thirteen times its bulk of oxygen it is violently explosive, and much less than that is probably very unsafe. Hence in the "wash-bottle" or any other "very simple" form of generator, appalling danger may arise in either of three ways:—1. The supply of ether may become so far lowered that the bubbles of oxygen do not rise through sufficient liquid to saturate them. 2. All but absolute ether contains some alcohol and a little water; and in using this over and over again, the ether may become so much diminished as to lead to the same want of saturation. 3. The ether will vaporize by the mere heat of the room sufficiently to create a small pressure in the generator. If, then, the tap connecting with the oxygen bag *should be opened first*, liquid ether will be driven back with the tube supplying oxygen to the jet, or may be even with the bag itself, thus forming an explosive compound. We may distinguish between the last and first two causes of explosion by the results. In Nos. 1 and 2 the explosive compound would be in the generator, and *that* would burst. In No. 3 the *bag* would burst. At Chadderton the bag burst; and therefore ether must have been driven back by pressure into the bag, by some mismanagement or accident with the taps and weights.

As long as the ether flame (without oxygen) is *white*, it is saturated, or nearly so. A blue flame shows the vapour is either explosive, or very near it.

Now for the conditions of safety, *not one of which can be neglected with impunity*, permanently, though it is wonderful how Providence watches over fools. First of all, good ether must be used; 730° will do, but must not be more than thrice used, and ought not to be more than *twice* used, keeping each remainder (*i.e.*, second or third) in a separate bottle. That some ether be "wasted" is then a *sine qua non*, though most people can find some other use for the waste. To fill the generator away from a flame is obvious.

Secondly, I consider that every generator *ought to have an empty chamber* to receive any suck-back or splash-back of ether which *may* occur, either from an upset or back-pressure. The want of this is the most dangerous point about all the Birmingham and some other apparatus I have seen. An

empty cell is not enough; it must be so arranged that the ether *cannot* splash direct with the oxygen supply-tube; that is, this tube must not open opposite the place where the splash, if any, must occur.

So predominant is this special danger, that in the American patent generator of Mr. Fred. E. Ives, purchased and now made by the McIntosh Company of Chicago, a fluid tank is superseded by rolls of cloth saturated with ether, through which the oxygen is passed. The desired object is attained; but such methods fail to ensure *saturating* the gas, as the supply of ether is apt to prove insufficient towards the end. The vendors of this generator, in fact, in their circular actually contemplate the blowing off the ends of the generator, and its catching fire, as an event to be by no means unexpected, and give directions for "smothering" the flame. I do not share their confidence that such accidents would always be harmless.

Thirdly, the generator must contain *ample* ether to cover all contingencies, and be so constructed that the use of the required portion *does not diminish* the quantity in action, or the path of the oxygen through the fluid. In M. Broughton's generator, ten or twelve ounces are placed in the reservoir, and about four ounces is used during two hours. The reservoir is traversed by a number of horizontal septa or partitions, which compel the gas to travel backwards and forwards in a path which is not shortened till a certain level is reached. This is the great point, with an empty or safety chamber, to be looked to in all generators; and none ought to be purchased without a diagram. I wish M. Broughton would bring his own generator fairly before the public; but in that case I consider even he ought to furnish an exact diagram of the interior, that the operator might know precisely what he was doing.

I am not sure we have the most perfect generator yet. I should be inclined, were I planning one, to construct it with a *feeding reservoir* made of glass with a cork in the top, so that the precise point of the fluid could be seen, and more put in if needed.

The best taps are needed. And as ether will dissolve all grease and make them "grind," they may be lubricated with glycerine. After use, all the ether should be *at once* emptied out, and transferred to the proper bottle as "once used" or "twice used." That "twice used" should only be used the third time with one-third of fresh ether.

Last, but not least, is *method*. There is only one; and those who cannot depend on themselves never to vary it, are in danger; for the taps must be used in a certain order and no other. Suppose all the tubes connected—oxygen-bag on to the generator, with a branch to oxygen-tap of dissolver, and vapour-tap to the hydrogen of dissolver. There will be vapour pressure in the generator; and if the bag-tap or oxygen-tap to dissolver be turned on first, ether will be driven back as already explained. The hydrogen-tap of dissolver (or jet) must be *turned on first invariably*, to give vent to all pressure, and not till that is done must the oxygen from bag be turned on; then, in a moment or two, long enough to clear the tube of air, but not enough to make explosive vapour in the lantern, light the jet, after which, when the lime is warm, turn on the oxygen and adjust as usual. At the end or when stopping, turn off the oxygen at jet *first, always*. If only a stoppage, leave the hydrogen taps on a little as usual, and *never turn them off first* in any case; but next turn off the oxygen at the bag if the exhibition is at an end, or if you must put out the light. The vapour-tap to the jet, in brief, must be *first and last vent of the generator*. And never use less than one hundredweight pressure on the bag.

I confess I cannot see how an explosion is to occur under these conditions. But it will be seen how remarkably easy it is to neglect one or other of them; and the real way to safety is to see the precise danger of each breach, which I trust will now appear. I ought, however, to add that Mr. Broughton considers he has at last discovered an absolutely secure "safety packing." It is well known that explosions have occurred through the common gauze-packing, which is a vain delusion, doing more harm than good; through Hemming's safety packing of wires wedged in a tube; and even through Gurney's water-chamber. Mr. Broughton uses pumice-stone, granulated to a certain gauge, and tells me that owing to the checked and irregular paths thus caused, an explosion cannot be made to pass through it. Rather than pack the jets with this, he prefers a separate chamber, with a fluted union-nozzle at each end for india-rubber tube; and one of these may be connected below each of the jet or dissolver nozzles. They, however, reduce the pressure and the light considerably, and heat will be needed to get the same result as with heat without them. This packing is, however, well worth experimenting with, and if really found certain will be a great boon, as such chambers with unions can be used on any lantern without the least alteration.

The danger from dust in the oxygen-bag itself is to me a very doubtful matter. But if it exists, I may, perhaps, point out that it can be absolutely guarded against by "filtering" the gas, either in the dry, wet, or adhesive manner.

It may not be amiss to point out how seldom any loss of life occurs from explosion of a bag. As a rule, there is a loud report and severe concussion, with much breakage of windows, but no more. I only really remember one case, though there are doubtless more. At Chadderton, also, there was no death directly caused—a few seem to have been stunned, and a few probably etherized; but the death occurred from crushing or suffocation on the stairs.

FRENCH CORRESPONDENCE.

Frame for Sensitive Pellicles—Photographic Jurisprudence—Laboratory of the Museum of Decorative Arts—Pocket Photographic Apparatus—Operators' Examinations.

Frame for Holding Sensitive Pellicles.—The Abbe Raboisson has shown a new kind of holder for pellicles, without having recourse to glass plates. It consists of a framework of sheet brass, the four sides of which form clippers. It is connected by two cross-bars of brass acting as springs. In use, this frame is placed at the back of the sensitive paper or pellicle, the edges of which should extend about half-an-inch beyond all round, so as to be folded over into the clips. Then place in the dark slide, when the brass springs, pressing against the side, act in stretching the pellicle. The idea, although ingenious, is subject to various inconveniences: first, these frames are tolerably heavy—a great disadvantage, overcoming the essential aim in using pellicles; secondly, they are also rather bulky, varying from one to two centimetres in thickness; thirdly, they necessitate the waste of paper or pellicle, as at least an inch all round the edges has to be sacrificed for the purpose of clamping into the frame. The question of cost need not be considered, as the price paid for any article perfectly adapted to its requirements is never money wasted. For my part, I have not found anything better than diachylon for general purposes.

Photographic Jurisprudence.—The Tribunal of Paris has just given judgment in a case of copyright of photographic works in which photo-engraving was accounted the same as any other photographic work, and that no distinction could be made between an ordinary print and one taken from a photo-gravure plate. This seems rational enough. Why should the word "photograph" only apply to a silver print? It is a very common mistake for people to say, "This is a photograph, and that a photo-engraving," as if photography did not result in an impression taken by the aid of light. The tribunal has even stipulated that the retouching, often so important on a photo-engraving plate, does not constitute a secondary operation, the photographic work being the principal part. It would be as

well not to adopt this statement; if the photograph were not impressed on the metal as the design to be followed, the engraving would result from the graver directed by the engraver's hand.

The Laboratory of the Museum of Decorative Arts.—At the Laboratory for the reproduction of objects of art, work is about to commence. It has been decided as a general rule that all negatives shall be pellicles, and capable of printing from either side, according to the nature of the print desired. As to the prints destined to be preserved as documents in the books of the Society of the Museum, they will all be in platinum, so as to ensure permanence. The platinotype seems more suitable where only a few copies are required, as carbon is too complicated.

Pocket Photographic Apparatus.—My pattern pocket apparatus is now finished, and was shown at the last meeting of the Photographic Society of France. In the course of two or three months, therefore, the most portable and lightest apparatus will be before the public; the name of M. Francais, who is the manufacturer, ought to be a sufficient guarantee for its good workmanship.

Operators' Examinations.—The examinations for photographic operators organised by the Chambre Sydicale will take place on April 7th and following days. It is probable that there will be a good number of competitors.

Leon Vidal.

PHOTOGRAPHY CONSIDERED AS THE WORK OF RADIATION.

BY CAPTAIN W. DE W. ABNEY, R.E., F.R.S.

The second lecture of this series was delivered at the Royal Institution on Saturday last.

After referring to the last lecture, and exhibiting prints showing the two states, red and blue, in which gold could be deposited, the lecturer said that hitherto they had been considering the changes produced in metallic compounds, chiefly those of silver, by radiation. He would now remind them that molecular changes produced by radiation were to be met with on every side, and photographic action must have been noticed in very early times, for the tanning of the skin was of that nature. A frame that had contained a printed notice was exhibited, the back-board of which had been darkened except where the black ink letters protected it, thus producing a negative picture. Some paper prints also were shown which were produced by the action of light on certain dyes, and would explain why sometimes the ladies' dresses faded in colour.

Turning again to the molecular changes produced by light, the lecturer asked his audience to remember that there was a certain amount of work done. In separating the particles of silver and chlorine, for instance, a very considerable amount of energy was absorbed. By a series of calculations he showed them that in blackening a square inch of silver chloride to a depth of $\frac{1}{1000}$ of an inch, the light acted on 1½ million millions of atoms, and the energy expended separating the chlorine atoms was equal to that required to raise the chlorine to a height of about 3,000 feet.

He had now to come to the question of development, to the production of photographs, in which the amount of work actually done by radiation was small, the rest being accomplished by chemical means. It was singular that development, both in the case of the Daguerrotype plate and paper processes, was discovered by a fluke; the first had come about by Daguerre leaving an under-exposed plate in a cupboard containing an unstopped bottle of mercury, and the second by the Rev. J. B. Reade, who exposed a piece of Talbotype brushed over with gallic acid as well as nitrate of silver.

To explain the theory of development he would have to draw their attention to a few experiments. Firstly, he would draw their attention to the two little magnets covered by a plate of glass, and thrown on screen by the horizontal lantern. When iron filings were shaken over them, the particles joined one another, and arranged themselves in lines round the magnets, producing what was known as Faraday's lines of force. In an upright cell in another lantern, acetate of lead was decomposed by electricity, crystals of lead rapidly growing round one pole, the particles as they were deposited being attracted by those already formed. A very beautiful specimen of lead tree was shown in a sixteen-ounce flask, the crystals being very long and well formed. Several photographs were then taken on paper and collodion to show that the particles acted on by light were first reduced, and the reducing action continuing, other particles joined those already reduced, and built up the image. In development, however, it was necessary to have some kind of restrainer, or the reduction proceeded too rapidly, and the particles of metal were deposited uniformly over the surface or film. Chloride of silver was immediately blackened by a developer, but when a physical restrainer such as gelatine, or a chemical restrainer such as bromide of potassium, was used, a clean picture could be produced. These experiments were successfully shown.

Notes.

Our Paris contemporary, *La Nature*, gives this week, by way of illustration, a balloon photograph taken by Mr. Cecil V. Shadbolt.

In the same number, the familiar name of M. Carlos Relvas occurs in connection with an invention of some importance. M. Relvas, of Gollega, Portugal, who has probably taken more medals than any other amateur photographer at various international exhibitions, has of late, it appears, given some attention to the saving of life at sea, and *La Nature* shows a picture of the new Relvas lifeboat—a narrow trough that cuts through the waves easily, flanked with broad cushions of cork to float it—which, after practical trial by the Portuguese government, has been highly approved. It is always pleasant to meet with a photographer who is something more than a photographer.

The names of the sectional officers of the ensuing meeting of the British Association, which is to be held in Montreal in August next, have just been published. The president-elect is Lord Raleigh, while the section for mathematical and physical science will be presided over by Sir William Thomson, and that of chemical science by Professor Roscoe.

The Photographic Society announce that it is now in a position, on application to the Secretary, to exhibit to apparatus makers the standard screws and gauges the Society have adopted. The standards are in steel, and have been manufactured by Sir J. Whitworth and Co., a pretty good proof of their excellence and precision. Still, we doubt much whether manufacturers will be overjoyed by the news.

Speaking of the Photographic Society, by the way, and the list of its officers just issued, it is a little difficult to guess by what plan the titles of different members have been selected for publication. Thus, Professor Donkin, the new-elected Secretary, although a Master of Arts and Fellow of the Chemical Society, is credited with neither of these distinctions. Mr. Maxwell Lyte is also a University man, if we mistake not, and it is scarcely a year since Mr. Swan had a degree conferred upon him by Durham. Again, most of our readers are aware that Mr. Ackland is a member of the Royal College of Surgeons. Yet the official list of the Society makes no mention of any of these facts.

The Committee of the Photographers' Benevolent Asso-

ciation naturally complain of the scanty support they receive from the profession generally. The receipts from ordinary members amounted last year to about thirty per cent. of the total income, certainly a small proportion. It is, however, the experience of nearly all benevolent associations that the great bulk of the funds is made up by donations from a small number of generous men, and by subscriptions from outsiders. People, even though the object be their own benefit, will not voluntarily subscribe to benevolent associations, and societies who want to show a good balance are compelled to employ energetic canvassers. Whether such a course would be advisable in regard to the Photographers' Benevolent Association it is for the Committee to consider. One fact in the report is, however, consoling. It was only found necessary during the past year to expend £6 in grants. This, at all events, shows that photographers, as a body, are independent, if all are not well-to-do.

All of us have heard of the wonderful alligator photograph, and the more wonderful story still how it was taken by a phlegmatic Englishman. There is a similar photograph exhibited in Paris, of a lioness crouching down under some olive trees, quite different to the ordinary Zoological-Garden's treatment. M. Geiser, of Algiers, told us the story of this photograph. The lioness belongs to an Arab priest, or Marabout, who has blinded and tamed the creature; it follows its master like a dog, and will obey in a most docile manner. Posed by itself under a group of trees, it makes a most effective picture, of which the photographer was not slow to avail himself.

"Two Photographs" is the title of a bright little comedietta that precedes Miss Minnie Palmer's clever performance at the Strand Theatre just now. The gist of the piece is, that two mature lovers, unable to make up their minds, advertise in a matrimonial newspaper for husband and wife respectively. Each of them receives an offer, and, in response to a request for a portrait, they send photographs taken some years ago. It is needless to add that, unbeknown, they are corresponding together and employing the aid of photography to take one another in. But it is not until they actually meet that the youthful portraits are mutually recognized, and then, like sensible people and sensible actors, they bring the drama to a happy ending.

The little play is by Mr. Arthur Clements, and in it we are told that "Devonshire air is good for photographs," while the moral—a very good one—is, that you should always exchange portraits to date. The ladies, Miss Grey and Miss Bufton, have little to do, the burden of the performance resting on Mr. Harry Proctor and Mr. Phillip Ben Greet. Mr. Greet, a young and painstaking actor, new to London, is particularly pleasing as the elderly beau, and sustains the rôle with all the ease and grace of a finished artist.

Mr. F. Hollyer has been awarded a gold medal at the Boston (U.S.A.) Exhibition, for his series of platinotypes.

That silver prints made now-a-days are less permanent than those made fifteen or twenty years ago, seems to be generally admitted, and it is instructive to note the views of Mr. Foxlee on the subject at the last South London meeting.

In the old time it was the custom to salt the paper more highly than is usual at present, to sensitize on a stronger bath, and to make use of denser negatives; all these circumstances tending towards the production of an image rich in silver, and exhibiting much body when viewed by transmitted light. The thin surface pictures of the present time are not only poorer in silver, and consequently more liable to destruction, but it is usual to make the albumen film itself thicker than formerly; and the albuman—perhaps by virtue of the sulphur which it contains—is undoubtedly a main factor in determining the fading of a print.

Mr. Foxlee exhibited an old stereoscopic picture, which had evidently been printed from a negative of which one half was much denser than the other, and the printer had shaded the weak side in order to obtain an approximate equality in the appearance of the two pictures. The image from the dense negative naturally consisted of a heavy deposit of silver, while that from the thin negative was much less rich in silver. This latter had suffered much more by time than the dense print.

In reading his paper on dark-room illumination on Tuesday night, Captain Abney contributed an interesting little fact to the history of photography. It was to the effect that Claudet was the first to suggest, in 1844, developing the latent image under the eye of the photographer. Till then, the Daguerreotypes had been evoked in the dark, and the operation of development was a purely mechanical one. M. Claudet took out a patent in the year named, for employing a red light which should be without effect upon the solarised image, while it enabled the photographer to see what he was doing during development.

Mr. Spiller's remark on the use of aurine for dark-room windows is also well worth writing down. Aurine dissolved in spirit, he had employed with considerable success, Mr. Spiller said, for dark-room illumination; while its non-actinic colour constituted it a very suitable medium, it was not a pigment, like chromate of lead, but a true stain, and hence its colouring matter did not consist of separate minute particles.

In respect to this subject of dark-room illumination, no matter how widely divergent the opinions expressed of late, there seem at any rate one or two points very clear—viz., that an orange light affords sufficient protection to the photographer under ordinary circumstances, and that the advocates of ruby light grow fewer every day. We have repeatedly said that in the matter of light in the dark-room, it is for the most part a question of "give and take." If you want to exclude all actinic rays, have recourse to a deal board or a brick wall at once; but if you want to see when

you are at work, light of some description must be admitted. And we repeat here that diffused orange light—as little of it, or as much of it, asyou please—is in our opinion theleast injurious to the film compatible with permitting you to see what you are doing.

The "stained red" glass, we may mention, of which Captain Abney speaks so highly, is not, it must be remembered, red at all, but actually orange; this with a sheet of tissue paper to diffuse the light, was in his opinion one of the best mediums for the dark-room.

By the way, we were very glad to see that Mr. Debenham took Mr. Ray Woods roundly to task for speaking of the green glass the former uses as "Cathedral green." As Mr. Debenham very strongly insisted, the name in question applies more to the make of the glass, than to its colour. Where on earth Mr. Woods got the name "Cathedral green" from, we can't think!

In respect to the proposal recently mentioned in these columns to take the electric spark as a standard light for sensitometrical purposes, it may be pointed out that an identical proposal was made about three years ago by Dr. Stolze, of Berlin, who makes use of a drying chamber in connection with the discharging apparatus. It consists of a glass tube, which encloses both the terminals; a depression in the tube serving to contain a desiccating material, such as chloride of calcium.

Although not altogether novel, this simple plan of Mr. Coolidge for producing photographic caricatures is well worth noting. We see that the idea is announced as patented in the United States, but we are not aware that

any steps have been taken to protect it in this country. Mr. Walzl, of Baltimore, announces a selection of humorous backgrounds suitable for these caricature portraits, and no doubt, if any demand for them arose in this country, they would soon be forthcoming. Indeed, with this hint before them, many professional and amateur photographers could make some suitable sketches for themselves.

Patent Intelligence.

Applications for Provisional Protection.

4404. Benjamin Pryor Stockman, of 3, Poets' Corner, Westminster, in the county of Middlesex, Civil Engineer, for "An improved method or process of colouring photographs, drawings, printed subjects, or the like."—Dated 5th March, 1884.

Notice to Proceed.

5204. Harrison Garside, of the city of Manchester, in the county of Lancaster, Photographer, for an invention of "An improved method of producing surfaces for mechanical or ink printing by means of photography."—Dated 2nd November, 1883.

4471. Richard Brown and Robert William Barnes and Joseph Bell, all of Liverpool, in the county of Lancaster, for an invention of "Improvements in means for and method of producing designs upon paper or other fibrous or soft material."—Dated 19th September, 1883.

Specification Published during the Week.

3584. J. F. Cooke, of 6, Oxford Court, Cannon Street, for "Improvements in frames for photographs and other pictures."

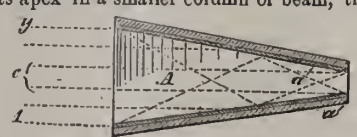
It is especially adapted to cases where the photograph or picture is seen through a piece of plate or other glass having a bevilled edge, and nothing outside such bevilled edge; but it can also be readily adapted to other styles of frames. To hold the photograph or picture against the glass, I take a flat sheet of metal or other suitable substance of the size required, and I so bend over two of the edges opposite to one another, that the said sheet of metal or other substance will slide over two of the edges of the glass, and so hold the photograph or picture securely against the back of the glass through which the photograph or picture is seen. The edges so bent over, being seen when the photograph or picture is looked at through the glass, are not necessarily left visible along the whole of those sides of the frame, but the edges so turned over may be in parts cut away, provided enough of them is left to hold well on to the edges of the glass. I also vary the shape of the metal or other substance where it is turned over in such way as to make it ornamental. The frame thus made stands by means of a projecting strut or foot attached to this back in the ordinary way in which a foot or strut is attached.—*Provisional protection only.*

Patents Granted in America, Feb. 26.

294,059. Haskell Harris McElhiney, Nebraska City, Nebr. "Photographer's retouching-point."—Filed Dec. 5, 1883. (No model). A retouching pencil attached to a spiral spring, of which the other end is connected with the vibrator of an electric contact breaker. (See description of a similar arrangement by Geruzet and Geesbergen on p. 645 of our vol. for 1883).

294,117. William Calver, Washington, D.C., "Method of and means for condensing solar rays.—Filed April 25, 1883. (No model).

Claim.—1. A condenser for solar rays, comprising a frustum of a pyramid, or its described equivalent, the length of the same and the inclination of its walls with its axis being relatively determined to advance the rays entering at its base, and to deliver them from its apex in a smaller column or beam, the whole con-



structed so as to withstand high degrees of heat, substantially as specified. 2. A solar condenser comprising a hollow frustum and a surrounding water-space provided with an inlet, an outlet, and a steam outlet, each provided with controlling-valves, substantially as specified. 3. A solar condenser comprising a frustum of a pyramid, or its described equivalent, having inner reflecting walls or surfaces, *a*, and an outer re-enforcing and protecting backing, *a'*, substantially as shown. 4. The combination of the condenser, swivel-bracket, and tripod, substantially as shown and described. 5. The combination of the condenser, jacket, steam-dome, inlet, and outlets, substantially as shown and described.

OLD PHOTOGRAPHS.

BY EDWARD DUNMORE.*

There is a ring about the words "Old Photographs," sentimental as well as scientific. I now particularly allude to landscape work, than which no occupation could be devised more conducive to health and pleasure. With portrait photographs it is somewhat different. The actors may have passed away, leaving but old memories behind, fused in the crucible of time which the magic of an "old photograph" separates.

* Abstract of a paper read before the South London Photographic Society.

The occupation of looking through a collection of old works and comparing them with recent ones is far from labour thrown away, especially if they have been one's own work. We may recal an experiment, the result of which was thought little of at the time it was made, but now, a new light being thrown on it by experience, becomes a valuable hint. The extreme importance of making notes of our experiments, if carefully performed, can scarcely be overrated. Memory is apt to play us tricks if not supported by written notes, especially if a good number of similar experiments are made, which is generally the case in working up a new process. A very little variation may mean success or failure, and it is just as well to be on the safe side by reference to methodically-kept memoranda. Since photographs we call "old" were made, photography itself has assumed a new garb and an importance in the arts and sciences that could hardly have been anticipated.

The thanks of photographers of the present day must be accorded to those persevering pioneers and experimentalists who, when the art was in its babyhood, so nearly hit on the ways and means we now adopt, and which, even after a lapse of thirty years, still form the foundations of our process. In a measure we seem to be reverting to the original plans. Paper was more successfully used in the old calotype process—one of the earliest processes discontinued—to give place to its diaphanous and brittle successor, glass. Now, again, paper is being used extensively for sky negatives and also as a support for gelatino-bromide films for landscape work on roller slides, and also in compressed blocks. Pyro-development has again come to the front in place of iron, with this difference—alkali is added instead of acid. All through the processes of negative making changes continue to be rung on similar materials, and no absolutely new departure made. With mechanical processes wonderful improvements have been effected. The working of them is, however, in comparatively few hands.

The very fact of continuing the work so much on old lines suggests the question—In what manner and degree is a modern superior to an "old photograph?" The answer is somewhat difficult to give. Is it in permanency? Surely not; for here we have prints that have proved their claim to be called "permanent" by the fact of some twenty, thirty, or more years of existence, and are still bright, good, and apparently unchanged. Is it in delicacy or quality? No; we may fairly say some photographs were produced of as good quality in the early days as at the present time, judging from the examples we have the opportunity of examining. Then what is the improvement obtained by thirty years' experience if it is not in permanence, delicacy, or quality? The superiority, where any exists, is entirely outside the chemical qualities or the actual making of the photographic print, and rests altogether in the artistic treatment and feeling imparted to the subjects, aided by skill naturally acquired through familiarity and practice.

I said "some" photographs were equal in quality to those now produced. It must be borne in mind that thousands and tens of thousands of photographs are made now to one made formerly. Manipulative skill is possessed by thousands where one was skilled in the early days. In the early days it was a rare thing to see a thoroughly good photograph—not because they could not be produced, but by reason of their limited number and there being so few to produce them. Beginners or unskilled persons generally turned out that kind of effect called "soot and whitewash." There is no doubt that the extra sensitiveness of our films will do much to alter the character of future work. This, with the unquestionable advantage of having plates ready for use at a moment's notice, instead of waiting for the completion of the many preparations necessary to be made in the old wet-plate days, must exercise considerable and favourable influence in securing negatives.

The permanency of photographs has always been a thorn in the side of the photographer, or, I should rather say, the want of permanence. With all the improvements in apparatus, uniformity in chemicals, and experience, the charge of want of permanence is quite as much and quite as fairly used as a weapon in the hands of its detractors, and even its friends, as ever it was. If anything, I believe modern silver prints are, on the whole, less permanent than old ones. The reason is understood by most who have had experience in the matter, and is, I think, fairly attributed to the more delicate negatives and less concentrated solutions used now than formerly, especially the thinness of the negatives. There seem to be a few well-ascertained causes of deterioration of silver prints, scarcely any of which are irremediable. They are—1. Very rapid printing from thin negatives. 2. Imperfect fixation, including imperfect removal of the salts formed by the process. 3. Insufficient washing or bad quality of the paper. With regard to the first reason—"quick printing from thin negatives"—the remedy is obvious. With regard to the second, which is by far the most serious fault of any, the remedy, though obvious, is not so easily applied, perfect removal of the unstable matter from the paper being somewhat troublesome to thoroughly effect. This arises in a measure from having uncertain quantities to deal with, the methods of procedure not being varied accordingly. A plan that will answer with one sample of paper at one time will at another, with a different paper, fail. The temparature, also, at which the process is worked has a considerable influence upon the results.

The following conditions, I am inclined to think, form a rough outline of causes of failure:—An exhausted or a too weak solution of hyposulphite of soda. This may be brought about by attempting to fix too many prints in one quantity of solution, or owing to the hypo. having lost some of its solvent power by being kept in solution, and exposed to light, or by the crystals being kept in a moist state; by the salt itself being impure or containing a large percentage of sulphate, or the silver salts formed by the action of the hyposulphite not being thoroughly removed from the paper by rapid and effectual washing. I have found by actual experiment that if the hypo., after having effected the solution and alteration of the salts of silver, is well washed out of the prints, fresh hyposulphite—say a twenty per cent. solution—applied to and left in the prints, and dried in the usual way, has no effect whatever on their permanence—an experiment anyone can make. This, I am aware, runs counter to the general opinion, as it includes the mounting of prints on boards containing hyposulphite, which is supposed to affect their permanence. I attribute the deleterious effects of such mounts to something else than hyposulphite—probably chlorine.

That a strong, hot solution of hyposulphite will effectually fade a silver print there is no doubt whatever, but the cases are not parallel. We might with as good reason say because strong nitric acid applied to the skin will blister it, very dilute nitric acid will do the same, only more slowly. This we know is not the case. Therefore, because under certain conditions hyposulphite of soda will be injurious, under different conditions there is no reason to look upon it as prejudicial to the degree it is generally represented. Like many other substances, the effect depends upon how it is applied. Bad quality of paper will cause a degradation of the tones, and a yellowing of the whites, but will not cause fading in the true meaning of the word.

There seems to be some amount of confusion with regard to the term "fading," which is applied indiscriminately to silver prints that have become defective from various causes, when it should rightly be confined to those prints in which the shadows have become less deep than when they were made. With numbers of photographic printers a sort of rule-of-thumb holds good—a certain quantity of hypo. in the fixing-bath, a certain time for the prints to remain therein, without any other variation, so that they are turned over occasionally, and no consideration for kind of paper used or the number of prints to be fixed. The routine is the same, winter and summer, and, like the law of the Medes and Persians, which altered not (or had not used to), the consequence is irregular results. Probably the first prints put into the bath are all right, but the subsequent additions are not so; hence some fading and some remaining good. These causes operating on different parts of degrees of substantiality, so to say—prints from strong or hard negatives, and those from delicate or weak ones—are quite sufficient to account for the different degrees of permanence. This, in fact, procured for silver printing the unenviable notoriety of being a fugitive process. In addition to these causes of failure, printing for many years was looked upon as merely an unimportant mechanical process, to perform which almost anybody was good enough.

I have as yet said nothing about toning as an influence to the preservation of silver prints. That it exercises a good effect to this end there is no doubt; but that it is absolutely necessary is doubtful. That the prints which have been toned in the old hypo. and gold bath have remained in good condition up to the present time, we have proof here to-night; but whether in some instances the toning resulted from the action of gold or sulphur, we are not so absolutely certain. Possibly, if after the toning the proofs had been subjected to a fresh hypo. bath, the result might have been much better. In our present methods of working with the alkaline gold bath we certainly do get a deposit of gold on the image, and the colour resulting therefrom is pleasant to look upon. Basing our opinion on the respective quali-

tics of the two metals (gold and silver) to resist atmospheric influences, the superior permanency must be accorded to gold. This, with the decided improvement in the appearance of the picture, will, no doubt, cause us to retain the use of the gold toning bath so long as silver printing continues to be the process in general use.

It may be asked, what is an old photograph? In my own mind I have fixed the date at any time anterior to fifteen years.

I feel quite satisfied that it is carelessness or want of the necessary chemical knowledge on the part of the photographer which has induced the idea that silver prints are not to be trusted in matters of permanence.

One conclusion we cannot fail to draw from this examination of good old photographs, and that is—they were in every way equal in manipulative qualities to very many of the modern ones; and also that old photographs have proved that silver printing, *when it is properly done*, is a permanent process, and not one of those evanescent, fugitive, unreliable methods of picture-making with which it is so unfairly credited. The older specimens of silver printing have been from negatives developed with acid pyro, or from negatives produced by the "converting process," as it used to be called; that is, a positive was taken, treated with a solution of sodium and mercury, which had the effect of increasing the density and destroying the positive appearance by reflected light it had originally possessed. The results were generally harsh and deficient in half-tone, the shadows being represented by clear glass, and consequently printed with the well-known "soot and whitewash" effect.

It was some time before the general run of photographers discovered that increase in exposure was nearly all that was required to make a sufficiently-dense image at one operation. The elaborate performance of making a negative bath that often as not ended in fog and stains deterred many from "going in" for direct negatives. Saving residues had not become generally known, and a bath that would not work satisfactorily was incontinently shot down the sink. This, with the high price of silver nitrate, acted as a considerable check to experimentalists, and the more certain, if worse, way of proceeding was for a long time the adopted process.

I have endeavoured to collect a few specimens of early work to show you to-night, and in criticising them you must forget for the time the beautiful and artistic work of the present day, and only think of them as good examples of the general work of that time. Where possible, the history of the production is written on the back; but with many of the specimens their age is their only history. In calling your attention to the transparencies by Ferrier, that I have had in my possession for more than twenty-five years, I think they compare favourably in every respect with work of the present day. The price then at Messrs. Horne and Thornwaite's was 12s. 6d. each. They have retained their brilliancy and colour unchanged, although they have been kept in both damp and dry rooms, with no other care than being placed in a grooved box. I may also mention that some of the prints shown have been for some years stored in a portfolio in a very damp room—so much so that they were quite mouldy—and with this result the mounts have suffered, but the prints themselves have not. In one case the print had been laid down on India paper or plate paper; the plate paper had become covered with mildew spots, but not one appears on the India paper, nor is the photograph at all affected. I may remark that on looking through a number of mounted photographs I did not find one instance of fading where the prints had been laid down on India paper, but when attached to ordinary white mounts some had commenced to yellow at the edges. A great number of my prints I had used to mount at home, using gum arabic, and they have stood the test of damp without showing any sign of deterioration. Others have been mounted by professional mounters, and I am unable to say what substance they used; at any rate, it has not affected the prints.

HALATION.

BY J. K. TULLOCH, M. D.*

Not being able to see in what way Mr. Geddes could reduce halation by placing a blackened card behind the sensitive plate during exposure, I nevertheless thought it only right to make a trial of the plan before coming to a conclusion in the matter. One little experiment led to another, and I will briefly state the results at which I arrived.

I have here a simple, non-achromatic lens of bi-convex form. If you catch the reflection of a bright object (such as a jet of gas) upon it you will find that there are two images to be seen—first, an erect image from the front surface of the lens; and, second, an *inverted* image from the back surface of the lens. A piece of ordinary glass would have done just as well, but the curves of the lens giving an erect image from the front and an inverted image from the back allows the back image to be at once recognized.

One quarter of the back surface I have covered with carbon tissue *in optical contact with it*. Another quarter I have covered with a backing of starch and "deep orange chrome;" the rest of the back surface is uncovered.

Now, you will find if you stand so as to catch the *inverted* image upon the uncovered part, that this back reflection is almost as powerful as the erect image thrown out by the front surface. Turn the lens in your hand so as to bring the *inverted* image upon the orange backing, and you will now find the back reflection is only half as powerful as it was. Turn the lens further and bring the *inverted* image upon the carbon tissue, and you will find that it has all but vanished. Once more bring the inverted image upon the uncovered part of the back surface, and while there place behind and in contact with the glass a blackened card. You will find this has not the slightest effect upon the back reflection.

From this demonstration I conclude that carbon tissue is a better backing than the orange chrome, and that the blackened card has no effect in reducing back reflection. Actual experiment with the camera confirmed these conclusions, the orange chrome giving slightly better results than might have been expected, but in no way equal to the backing of carbon tissue.

That halation is not entirely cured by backing the plate, even with carbon tissue, may be due either to the fact that the back reflection is not entirely obliterated by the backing, or that other causes are to be found for what is not explained by this cause.

If you examine the inverted image reflected from the surface of the lens backed by tissue you will find that it is very faint; and, since in actual practice the light is still further reduced by first having to penetrate the film, it is reasonable to suppose that any little light reflected from such a backing can be very weak indeed.

From these and one or two other experiments I conclude there are other causes at work; and, stating what appears to me to be the chief causes of halation in order of importance, I would place:—First, reflection from the back of the plate (not entirely obliterated by any backing). Second, reflection from the illuminated particles of bromide of silver acting upon adjacent particles. Third, reflection from particles of dust floating in the camera in the vicinity of the plate, as can be proved by filling the camera with dust and exposing a properly-backed plate. Fourth, a certain chemical condition of the plate—halation being often very pronounced where the physical conditions seemed to be entirely against its production.

* Read before the Dundee and East of Scotland Photographic Association.

Correspondence.

OPTICS FOR PHOTOGRAPHERS.

Dear Sir,—In reading Mr. Wheeler's able criticism on what I said about distortion, I have marked that the main point in which he differs from me is, that he takes the stop as the principal part of lens, and that the rays coming through it are controlled by the object-glass. On the other hand, I have taken all my calculations from the *fixed* point, the optical centre of the lens, and the stop used as subsidiary to the lens itself. I prefer my way of looking at the matter, as all calculations ought to be made from some immovable point. At the same time, it must be admitted that there is much to say on Mr. Wheeler's point of view. I have to thank him for the courteous way in which he has given his criticism, and for his kindly remarks on other portions of the lessons which have appeared.—Yours faithfully, W. de W. Abney.

Proceedings of Societies.

The Photographic Society of Great Britain.

The ordinary meeting of this Society was held on Tuesday, the 11th inst., at the Gallery, 5A, Pall Mall, East, Mr. Jas. Glaisher F.R.S., president, in the chair.

Mr. G. Murray was elected a member of the Society.

The Chairman read a communication from Dr. Eder, expressive of the feelings of joy and honour he felt on finding he was the recipient of the Society's "Silver Progress Medal," an award which would inspire him to further research.

Captain Abney, R.E., F.R.S., read a paper entitled "Illumination of the Dark-room, and some Optical Experiments." Capt. Abney commenced by referring to the early experiments by Daguerre, Claudet, and others, to obviate working in the dark as at first practised. Claudet, in 1854, after numerous experiments, was the first to give preference to red light. He (Capt. Abney) thought it was pretty well settled, from repeated experiments, that red light was the safest to employ, both photographically and spectroscopically. He had examined all the various media from time to time recommended, and could obtain a photograph of any of them. At a recent technical meeting, he showed the results obtained through a paper resembling canary medium, made by dipping the paper into an acetate of lead solution, and afterwards into chromate of potash; the results were not so good as with orange paper. Some plates coated with gelatine containing chromate of lead were shown, an image being obtained in two minutes. Examples of these were shown in a candle lantern, the intensities being said to be about the same. The third side of the lamp was glazed with red stained glass. Capt. Abney also made photometric tests of each light to obtain the relative intensity of illuminating power. These were repeated by Mr. C. Ray Woods and Mr. James Cadett. The results of the three observers gave a mean intensity of Canary medium, 1; orange paper, 1·86; stained red glass, 4·9. Another method was tried, viz., that of placing printed matter at a distance from each light; but less importance was attached to that method. Other experiments were detailed, in which exposures were made through orange glass covered with one thickness of orange paper, an image being obtained; whereas no image was obtained through red glass, Captain Abney saying that when he said stained red, he did not mean a stain of an orange colour. The spectra of various glass media obtained by electric and gas light was projected on the screen, and were numbered in the following order:—1, chromate of lead in gelatine; 2, orange; 3, stained red; 4, ruby; 5, green; 6 green and chromate of lead; 7, green and orange. Nos. 1 and 2 allowed a good deal of violet to pass. Nos. 5, 6, and 7 permitted the greater part of the green to pass. A series taken with candle light were also shown, comprising chromate of lead as before, stained red, orange flashed on ruby, green and ruby, cobalt and ruby. These exposures were of one minute duration through strips $\frac{1}{100}$ of an inch broad, spread out in the spectrum four inches in length. From his experiments Captain Abney concluded that green glass is not to be recommended, as it allows the green to pass, and otherwise cuts off the luminous rays of light. A sample of canary medium sent him by Mr. Scorah was very good, better than chromate of lead. Personally, he was unbiassed; but he should not care to expose a rapid plate very long to its influence. No light could be said to be absolutely safe; the point is to use that which is found to be the safest.

Mr. W. E. Debenham said Captain Abney states the point which light is the most suitable as settled. Before proceeding I shall be glad to see some of the orange paper said to give more light than the more obstructive canary medium. The results expressed in Captain Abney's paper are so contrary to my own experience, and that of several other experimenters, as to be worthy of repetition. My own experience has been that canary medium stops more photographic power than orange paper, ruby on pot metal, or cherry fabric. Canary medium is better than either of these. After repeated trials for my dark-room, yellowish-green glass and yellow paper proved the best. Supposing three media, red, orange, and yellow, to all have the same photographic power, then the one having the greatest visual power should be selected. When Mr. Cowan exhibited his lamps at another Society, and placed the green glass half down, some could not see any difference between that portion and several thicknesses of orange. He (Mr. Debenham) did not rely on spectroscopic experiments, for there was a divergence of opinion between those who made it a study.

Mr. C. Ray Woods had made comparative experiments with canary medium and orange paper; one-half the plate was covered with the former, and the other half with the latter; after exposure to daylight there appeared very little difference. The green glass employed by Captain Abney was not the cathedral green used by Mr. Debenham, but a better green for the purpose. He (Mr. Woods) had seen Mr. Debenham's lamp, and did not think the green glass was much use; the safety consisted in the yellow. Examining Mr. Cowan's lamp with the spectroscope, he found that some blue and green passed through; he can photograph the D line, but cannot get red without much longer exposure. Instead of using red, photographers adopted ruby for cheapness. He did not think the red light of the dark-room as injurious as represented.

Mr. J. Spiller recommended the use of a resinous varnish, such as aurine, which freely dissolves in alcohol. If this varnish is spread over glass it is convenient for obstructing rays which would otherwise go through; a resinous varnish being more satisfactory from a physical point of view, being a true varnish all through alike.

Mr. Cowan said the results of his experiments with canary medium were against Captain Abney. A very rapid plate exposed over twenty minutes, and afterwards in the camera, showed no trace of fog; therefore, it was safe enough to work with plates of ordinary rapidity. Regarding cathedral and orange, he thought it was a very good combination; he had prepared plates with it free from fog; but he laid no stress on the green, any further than giving a colder light.

Mr. Debenham, referring to Mr. Woods' remarks on cathedral green, said there is no green glass of that name. Mr. Woods spoke of his lamp as being unsafe; an exposure of fifteen minutes resulted in no image, whereas five minutes through ruby glass gave an image.

Mr. H. B. Berkeley said that Mr. H. Cooper, in 1877, recommended green glass for collodio-bromide work.

Mr. F. Ince agreed with Mr. Woods; the injury to eyesight was less from the red colour than going from the dark-room into the light. The use of tinted spectacles in the dark-room might be attended with advantage.

The Chairman said it was evident that a light which would affect some sights would not interfere with others. Perhaps Mr. Ackland would say a few words regarding the effect of the dark-room light on the eyesight?

Mr. W. Ackland should like the subject of colour-blindness to be examined more critically, it being a subject engaging a deal of attention now. Ruby light is decidedly and emphatically injurious to the sight, and he noticed among photographers how their sight was becoming more changed through the dim light of the dark-room. He found the comfort of changing the light in his own dark-room, and induced others to do the same.

Mr. W. S. Bird doubted, after the contradictory scientific evidence, whether the chemistry of the spectrum was as well studied as it should be. It was known that there was a prevalence of blindness among horses kept in dark stables, and he considered the transition from dark to light hurtful.

Captain Abney, replying to the discussion, said he should like Mr. Ackland to definitely state the action of red light on the ciliary muscles. Referring to Mr. Spiller's suggestion to use aurine, he found it excellent; but if not thick enough, it allowed a little blue to pass. In combination with yellow it would be safe. Replying to Mr. Bird, he said the chemical spectrum is well understood. Looking at a white object through orange, white can be distinguished; through red, it cannot. Stained red is as safe as anything possible, only it is necessary to use any light with care.

A vote of thanks to Captain Abney having been passed,

The Chairman announced that the next ordinary meeting, on April 8th, will be devoted to an exhibition of lantern slides by means of the Society's oxy-hydrogen lantern.

South London Photographic Society.

The ordinary meeting of this Society was held on Thursday, the 6th inst., at the House of the Society of Arts, John Street, Adelphi, W.C., the Rev. F. F. Statham, M.A., President, in the chair.

It was announced that a letter had been received from Mr. Macbeth, declaring Mr. Bridge's "River Scene" to be the picture selected as possessing the greatest amount of artistic merit.

The chairman further said that the committee had decided to preserve the competition pictures in a suitable album, and the artist's decision thereon. It would calculate to bring photographers' works to an ideal standard, by comparison with those pictures whose merit to the title was fully admitted. As it happened now, half-a-dozen persons taking the same view obtained different results.

On the motion of the Chairman, a vote of thanks was accorded to Mr. Macbeth.

A question from Mr. F. A. Bridge was next considered:—"What are the results obtained with the canary medium?"

The Chairman said Mr. Bridge distributed several sample sheets at the last meeting; he should like to hear from anyone who had tried it.

Mr. A. Cowan, in company with Mr. W. Cobb, had made some experiments with canary medium, about two hundred square inches of it illuminated by a batswing burner forming the source of light. Rapid plates exposed at a distance of six feet for twenty-two minutes did not produce fog, although there was sufficient light to read on the walls of the room. He considered one thickness in front of a gas jet would permit the most rapid commercial plate being exposed for thirty seconds at a distance of nine inches without any fear of fog.

Mr. E. Dunmore enquired if the batswing burner was shielded.

Mr. Cowan replied that the naked flame of a large size burner was employed.

Mr. E. Dunmore then read a paper entitled "Old Photographs" (page 169), and supplemented it with a large number of silver prints prepared within the last twenty-five years; he also showed some transparencies by Ferrier, which had been in his possession a quarter of a century. It was noticeable that some of the prints which were mounted on India-tinted boards had not faded, whereas those on white mounts had; also some mounted with gum were perfect, while others sent out to be mounted were not. A packet of old photographs sent by Mr. H. P. Robinson was handed round, the particulars of preparation being attached to each.

The Chairman said the subject under discussion was one likely to be very useful. When speaking of old photographs one is apt to forget the limited time photography has been in existence. Variety of treatment was especially desirable to study, and for this reason he brought some specimens by various processes. There were some by Mr. Johnston, his early productions in carbon; some of Mr. Rejlander's art studies, printed in silver; also specimens of wax paper prints, and some Collotype work produced by Mr. Griggs. He was informed there were several packages to be shown, therefore each exhibitor's prints would be passed round separately, and he would now ask for a vote of thanks to Mr. Dunmore for his able paper.

This having been accorded,

Mr. E. W. Foxlee said he had some prints to show, but they were not in such good preservation as Mr. Dunmore's. They were very good until a couple of years ago; since then, they had suffered somewhat through being in a damp atmosphere. One of the examples on salt paper, he believed, was prepared in 1854, and toned in the sel d'or bath. Another, in favour of the theory requiring the employment of vigorous negatives, was a stereoscopic picture, one-half of which had evidently been protected in printing, through being thinner than the other; this portion had faded, the other had not. Other specimens produced within the following four or five years, toned with hypo and gold, and mounted with gum, were in a good state of preservation. A print bearing the date of 1862 was good, although the mount was mildewed, and another (1865), waxed, had faded. It was curious that fading commenced at the edges, even in unmounted prints.

Mr. F. York showed prints bearing dates as far back as 1856; one specimen (1863), mounted over a smaller photograph, showed fading more perceptibly where the margins were in contact with the cardboard.

The Chairman said he should be glad to hear from Mr. Thos. Parkinson (Vice-president of the Bolton Society), whom they were glad to welcome.

Mr. Parkinson said his experience in silver printing dated back to 1853, and he found the prints produced in the sel d'or bath were as good as any produced by other means since.

Mr. W. M. Ayres had prints made in 1851. He also passed round some very fine unmounted prints made fifteen and twenty-two years ago respectively. He said it had been observed that prints mounted in contact with glass faded quickly. If a neutral solution of isinglass were employed, the prints would be permanent.

Mr. F. Howard had noticed fading at the edges, particularly in books kept in an apartment where there was no fire. The atmospheric influence commenced where the least protection was offered. If pictures were carefully framed and kept in a dry atmosphere, fading would not be so general.

Mr. W. M. Ashman observed that burnished prints in cut-out mounts, exposed out of doors in show-cases, lose their brilliancy in a very short time, the exposed parts being robbed of the surface; but not so the portions covered by the mounts. Many of the specimens shown were almost devoid of surface.

Mr. Foxlee attributed the loss of surface in Mr. Ashman's case to the continued action of moisture on the highly glazed surface. The prints shown (1856) were very slightly albumenized; pure albumen was rarely used in those days.

The adjourned discussion on the permanency of ready-sensitive paper was then resumed.

Mr. York could not see how it could be any less permanent than ordinary freshly sensitized paper is. Citric acid is generally used, and the citric acid is neutralized with carbonate of soda in the final wash before toning. He desired to call attention to the importance of this final wash, even with ordinary paper, as it tended to neutralize any trace of acid there might be in the paper or fixing solution, which latter was not always neutral. In reference to Mr. Dunmore's paper, many years ago he experimented with other nitrates and obtained identical prints on a 60-grain plain silver solution, and another of 30 grains with the addition of 30 grains of nitrate of soda; as the prints aged, those from the latter bath gradually bleached, therefore it shows the importance of using a silver bath strong enough to obtain permanence. Low sensitizing solutions are more liable to dissolve albumen. Mr. Dunmore says hypo deteriorates in solution. He (Mr. York) had not found it to be the case; he always kept it some time before use, to equalise the temperature.

Mr. Dunmore: If the solution is kept long, sulphate is formed, which is not a good solvent, hence prints are imperfectly fixed.

Mr. York suggested that the competition pictures should be marked whether printed on ready sensitized paper, or not; as the Society intends keeping them, it will prove a valuable record.

Mr. Ayres said citric acid for preserving paper meant more gold used in toning. With one commercial sample, he used 42 grains of chloride to tone eleven sheets of paper.

Mr. Howard was able to support Mr. York in the suggestion to soak the prints in an alkali previous to toning; he employed ammonia as a neutralizer.

Mr. Ayres: You don't get such a good surface.

Mr. Parkinson did not think the results from preserved paper could be so permanent as ordinary sensitized paper; he found, as a rule, it tones quicker, and has not such a body of silver as the other has, a fact soon discovered on reference to the residue returns.

Mr. W. K. Burton did not think the question could be easily dealt with, owing to the short time preserved papers have been in use. If prints were only washed slightly, they toned quickly, and would show signs of deterioration in a couple of years; if well washed, they tone slowly, and in his opinion will not fade so quickly.

Mr. Dunmore mentioned that several prints he had shown were on preserved paper which has been before the public about fifteen years.

Mr. A. Mackie should like the term ready-sensitized more clearly defined, as there are at least six different samples before the public. Some print red, others blue, therefore they cannot all be from the same formulæ. A secret is attached to the preparation, which made it difficult to discuss the question.

The Chairman, in closing the discussion, remarked that a certain quantity of silver was required to produce good prints; on the exact amount opinions differed. It was desirable to know the margin, because there would be little use in making prints if they are not likely to be permanent.

London and Provincial Photographic Association.

At the usual weekly meeting of this Society on Thursday, the 6th inst., Mr. J. Barker occupied the chair.

Mr. Hart exhibited a dark-room lamp which showed some novelty of construction, although the principle is not new. The outside was a glass cylinder which could be of any colour the operator might choose, having a gas-jet inserted through the bottom end, which was closed, a plain glass chimney inside

covering the gas flame. The inlet of air was through a series of holes round the top or hood of lamp, which was of Japanned tin, and made light-tight; the air entering the top of the lamp passed down between the chimney and outside glass, returning upwards through the chimney supporting the flame, and passing out at top with products of combustion. The illumination was equal to 18 candles, with a consumption of 4½ cubic feet of gas per hour. Mr. Hart also said he had constructed a lamp in which he had put an asbestos cardboard lining throughout; it was arranged with three grooves in front, in which as many sheets of glass of the same or different colours could be inserted.

A dark-room lamp was also shown by Mr. J. B. B. Wellington. It was similar to one shown by Mr. A. Cowan at a previous meeting, excepting the front, which, sliding in a groove vertically, could be readily raised for admission of white light into the room, or for the exposure of transparencies. Mr. Wellington also showed some gelatine plates which had been coated with an unwashed emulsion, from which the salts crystallising out had been entirely removed with dilute hydrochloric acid.

The Chairman was of opinion that the experiment proved that the washing of an emulsion might be dispensed with.

Mr. Henderson showed an alteration made at his suggestion in one of Messrs. [illegible]e and Hare's changing boxes. Originally the number of the plate in position for exposure was seen in front through a small piece of ruby glass; as now altered, the number was seen at the side of the box, preventing any risk to the plates from the light through the glass.

Mr. Hare explained that this was not likely to occur, as the ruby glass opening did not extend beyond the width of the plate carrier.

Mr. Henderson announced that he had designed a new coating machine, and that he intended at a subsequent meeting to demonstrate its action before the members.

Manchester Photographic Society.

The ordinary meeting of the above Society was held on February 14th, John Pollitt, President, in the chair.

Messrs. Barlow, Lomas, and Hadfield were elected members.

The President referred to the relative plates exhibited at a previous meeting by Mr. Chiltern, showing insensitive marks in pictures, and said he thought the marks were caused by the precipitation of AgBr to the edges of the plates.

Mr. Atherton said he had met with similar trouble, but had traced the defect to the emulsion being short of gelatine.

Mr. Smith brought some plates showing similar markings, which, in his opinion, were caused by imperfect tenure of the decomposition salts.

Mr. Schofield contended that this explanation could not be correct, or the marks would occur all over the plate. He further stated, in support of his belief (expressed at previous meeting), that faulty drying arrangements were the cause; that he had made an arrangement in his drying-box which permitted the plates to be inspected during drying, and was confirmed in his opinion.

A somewhat lengthy discussion ensued on the same subject, Messrs. Schofield, Atherton, Chiltern, and Smith advocating their own theories.

Mr. J. W. Leigh showed a negative developer by the light of ordinary gas light screened with canary medium, and decided to adopt the illuminary medium in his dark room. Negative perfectly clean.

Mr. Richton read a paper on "Swing Backs *versus* Rising Fronts," illustrating his remarks by means of an ingenious model of a camera in section. The paper was warmly applauded.

The President expressed his pleasure, and complimented Mr. Richton on his ingenuity in designing the model. In commenting upon the opinions held by Mr. Richton, he stated that his objection to the swing backs was, that he thought that placing the plate at too great an angle to the lens axis must have a distorting effect, and showed a photograph of a rectangular figure, using swing back and then with rising front, proving by measurement that there was some distortion arising from the use of swing backs.

Mr. McKellan advocated a swing front as doing all that could be done with swing backs without any distortion.

Mr. Schofield considered that the best way was to combine the rising front and swing backs.

Mr. Watts expressed himself much pleased with Mr. Richton's paper, and moved a vote of thanks, which, seconded by Mr. Blakely, was carried.

The President suggested that as the subject had evidently excited a good deal of interest, members should study the subject before the next meeting.

Mr. Watts was asked to read a supplementary paper.

Leeds Photographic Society.

The usual monthly meeting of this Society was held on Thursday, March 6th, in the large Lecture Hall of the Leeds Philosophical and Literary Society. The Hall was well filled by the members and their friends. In the absence of the President, Mr. J. W. Ramsdens, Vice-president, took the chair.

After the transaction of a little formal business, the meeting proceeded to the election of new members, and Messrs. Law, Whitehead, Lloyd, and Professor Rucker were declared duly elected.

The Chairman then called upon Mr. Teasdale to conduct the Lantern Exhibition.

Mr. Teasdale expressed his pleasure at seeing so many members and friends present, and also at the large number of slides which had been sent in for exhibition. Lantern work was new to most of the members, but the slides which he and the Hon. Secretary had had the opportunity of examining were very good, and quite equal to those generally seen. In selecting from such a large number, preference would be given to those produced by the members, and if time allowed, the very fine slides by professional makers would be passed through. He would first call upon Mr. Pocklington, who would exhibit a number of slides illustrating the effect of the different developers.

Mr. Pocklington exhibited a number of slides taken on gelatino-bromide plates developed with such developers as ferrous oxalate and ammonia-chloride, hydrokinone, and carbonate of soda, pyro and carbonate of soda, &c.

Mr. H. Rodwell.—Slides on gelatino-bromide plates.

Mr. J. W. Ramsden.—Slides reduced from 8 by 10 negatives, some of which were taken thirty years ago. Mr. Ramsden's slides were taken on gelatino-bromide plates (own make), mostly two of the same subject to show the effect of ferrous oxalate with tartaric acid, and of pyro with pearlash.

The Hon. Secretary.—A series of slides on gelatino-bromide and gelatino-chloride plates (own make), showing on both bromide and chloride plates the difference in tone, varying from blue-black to red, that could be obtained by variations in the exposure and development.

Mr. Ridson.—Transparencies on gelatino-bromide (Ramsden's) plates.

Mr. W. Denham.—A number of very fine transparencies on Nelson's and Cowan's plates.

Mr. Thomson.—Instantaneous view of tramway car.

Mr. W. Teasdale.—Transparencies on gelatino-bromide plates, and also on plates by Chapman, England, Cowan, &c. Mr. Teasdale also exhibited transparencies of Muybridge's animals in motion, and a very fine selection of slides by the Woodbury process.

Mr. J. W. Reffitt.—Some very fine instantaneous views of Swan's "Boy Sailing Ship," &c., and a number of Continent slides.

The lanterns, oxyhydrogen, fitted with Dallmeyer's lenses, were lent by Messrs. Reynolds and Branson, and manipulated by Mr. White, a member of the Society.

Dundee and East of Scotland Photographic Association.

The sixth regular monthly meeting of this Society was held in "Lamb's Hotel," Reform Street, on Thursday, the 6th inst. Mr. J. C. Cox occupied the chair.

The minutes having been read and approved,

Dr. Tulloch then proceeded to make some remarks on "Halation" (see page 171). A lively discussion followed, and the Doctor promised to extend his experiments, and give some more particulars at next meeting.

The adjourned discussion on Dr. Tulloch's previous paper, "Shortcomings of Photography," was then resumed, and a very animated discussion ensued.

The nomination of office-bearers for the ensuing season was then proceeded with, and it was arranged to ballot the names at next meeting.

The question-box contained the query, "Whether is collodion or varnish the better protector of gelatine plates?" The enquirer was recommended to use a coating of each, applying the collodion first, and the varnish above it.

The subject for next monthly meeting was announced as "Still Life."

It was arranged to hold a competition for lantern slides in a fortnight, each member to send only three slides for competition, although at liberty to send as many as he liked for exhibition.

Mr. Macdougald exhibited his new "Instantaneous Lantern Slide Carrier," which, by a simple but ingenious arrangement, instantly substitutes one slide for another.

A vote of thanks to the chairman brought the meeting to a close.

Bolton Photographic Society.

The usual monthly meeting of this Society was held on Tuesday last, when there was a very fair attendance.

It was decided that the third annual open meeting be held in April next, and the evening was spent in discussing the arrangements.

Owing to the unavoidable absence of Mr. R. Harwood, the usual lantern exhibition was not given.

Mr. Heaton was duly elected a member.

Sheffield Photographic Society.

The usual monthly meeting of the above Society was held in the Masonic Hall on Tuesday, the 4th inst., under the presidency of Mr. J. H. Rawson.

There was a very large attendance.

The subject of "Lantern Slide Making" was introduced by Mr. W. B. Hatfield, who exposed and developed several plates at the meeting, and succeeded in producing by contact printing, by gas and candle light, several good transparencies on Chapman's gelatino-albumen plates. He also exhibited a variety of slides made both by contact printing and through the camera.

Mr. J. Turner also exhibited some excellent slides made on ordinary gelatine plates, developed with alkaline pyro.

Mr. W. Dakin brought a brilliant transparency developed with pyro, and gave very practical arguments in support of the ordinary pyro developer being all that was necessary to produce perfect transparencies, and also suggested that the use of the alum, acid, and iron clearing and intensifying solutions was very valuable in slide making.

Mr. Ainley also gave some useful hints in the exposing of transparencies, and argued that a long exposure to weak light gave much better results than a short exposure to a strong light. Many other members also took part in the discussion.

Mr. Dickenson brought an excellent burnisher of his own make, which was highly commended for its style and also its cheapness.

Messrs. Wellington and Walker were elected members of the Society.

After further discussion and announcements relating to the monthly competition, a most interesting and practical meeting was brought to a close.

North Staffordshire Photographic Association.

The monthly meeting was held on Wednesday, March 5th, at Hanley.

The Chairman (Mr. Alfieri) exhibited an instantaneous shutter for a stereoscopic camera of his own manufacture, made to work behind the lenses; and also some home-made dark slides, each, by an ingenious contrivance, being made to hold four quarter-plates which could be exposed in succession.

On Wednesday, March 12th, at the Chairman's invitation, the members met in a large room at his residence (Northwood), where a good lantern and laboratory being kindly placed at the disposal of the members, Mr. Alfieri proceeded to give a demonstration of a method of enlarging upon the argentic bromide paper and opals manufactured by Messrs. Goodall and Steven, of Glasgow. Several enlargements were successfully made from half and quarter-plate negatives, a large three-wick burner being used. The exposures given varied from one to three minutes, the resulting positives being developed with Audra's modification of the ferrous-oxalate developer. The resulting pictures were unanimously admired, especially a viguetted enlargement on opal from a negative of a child's head, taken by Mr. Allison. Six enlargements having been made without a failure in any case, the Chairman was congratulated upon his skill, all the pictures being remarkable for the great purity preserved in the whites, and freedom from defects.

A vote of thanks having, on the proposition of Mr. F. J. Emery, seconded by Mr. Burgess, been passed to the demonstrator for his kindness, it was resolved to engage a suitable room in Hanley for the purpose of giving demonstrations, and storing apparatus, &c.

The Hon. Secretary offered the use of his studio and dark-room to the members during the summer season.

After some interesting conversation upon various technical topics, and again thanking Mr. Alfieri, the meeting separated.

Talk in the Studio.

An Interesting Mode of Making a Photographic Relief.—Mr. Francis Cobb informs us that having given a gelatino-chloride plate an insufficient exposure, and having failed to obtain an image with the citro-oxalate of iron developer, he poured hot water upon the film, and immediately a relief appeared, showing all details of the original subject. This would have been, he tells us, well suited as an original for making a printing block by moulding. The specially interesting point is the circumstance that only a very short exposure was given—insufficient, indeed, for the production of a picture by the usual method of development. Our readers will remember the experiments of Mr. Warnerke, and others, as regards the production of reliefs on gelatino-bromide films.

Universal Attraction in its Relation to the Chemical Elements.—This is the title of a small manual by Mr. W. H. Sharp, Livingstone, Edinburgh. The importance of thoroughly reviewing the Newtonian philosophy by the light of modern discoveries is insisted on, and an attempt is made to correlate all the forms of force to gravitation. The tendency of modern research is now to accurately measure force or energy, and doubtless the next great step in chemistry is to devise a system of notation by which the dynamics of a reaction can be expressed as accurately as the gravimetrical changes are indicated by the usual chemical equations. Much thought and labour must, however, be expended before this stage can be arrived at.

Pirated Photographs.—At the Guildhall Police Court, Samuel Rosenthal was summoned by Mr. Marcus Bourne Huish, the Secretary of the Fine Arts Society, Limited, for offering for sale a photographed copy of a painting called "The Return from the Battle of Inkerman," of which they were the proprietors of the copyright. He was also summoned by Mr. Benjamin Brooks, publisher, for a similar offence with regard to two pictures of which he held the copyright, one of which was called "Which do you like?" and the other "Can't you talk?" The publishers had been communicated with, and wished to press the case. The defendant did not offer them for sale in witness's presence to anyone but himself and partner, It seemed that some man had induced defendant to sell the photographs on certain conditions. Sir T. S. Owden said the defendant could be fined £10 on each summons, or go to gaol. Mr. Hnish said the Society had no wish to be hard with him, but he belonged to a class that sold those pirated copies, and they were very much on the increase. If they could be sure that the defendant would come up when required to give evidence in other cases that would come on, they would ask that he should be very leniently dealt with. In the result, Sir Thomas S. Owden fined the defendant 10s. and costs on summons, or five days' imprisonment on each, the terms each to be consecutive.

Photographic Club.—At the next meeting of this Club on March 19th, the subject for discussion will be, "On Portraiture in Ordinary Rooms.

To Correspondents.

*** We cannot undertake to return rejected communications.

F. Greaves.—Thin glue will answer, but both the parchment and the photograph should be moistened.

Constant Subscriber.—1. You should not use oxalic acid, but if you well mop the brass-work with methylated spirit, the lacquer will be softened, and you will be able to remove all dirt with a soft leather and rotten-stone. 2. Probably not much; even if genuine, it is not likely to be worth two pounds.

W. M.—1. Yes, an exceedingly good and very sensitive emulsion. 2. Two hundred and fifty grains is the right quantity to use. We should prefer the kind last mentioned. 3. It depends on the amount of acidity, but something under half-a-dozen drops should suffice in any case. 4. To each separate solution, just before boiling. Let us know how you succeed with the process.

W. M. Phillips.—Both the numbers to which you refer, and the Year-Book for 1883, are out of print. To repeat all the details you require would occupy too much space.

R. A.—You had better use four cells of bichromate battery, and a small Swan lamp (five-candle). The outfit would cost, perhaps, 25s. or 28s., and we imagine that about threepence an hour would cover the cost of working.

BETA.—1. In such a case a salary might be expected at once; but we do not think it is usual to include board and lodgings.

AMATEUR.—See the "Formulary" in this week's NEWS.

DR. R. DAWSON.—A misprint, and should simply be "gelatine."

A. H.—1. The focus of such a lens as you refer to may be determined with sufficient accuracy by adjusting it until a distant object is in focus, and then measuring the distance from the diaphragm to the ground glass. Look in the vertical column on the left-hand side of the table for the figure corresponding to the focal length, and for the figure corresponding to the diameter of each stop in the top row. In the body of the table, and at the point of intersection between the horizontal row commenced by the figure expressing the focal length, and the vertical column headed by the diameter of the stop, you will find a figure, which must be inscribed upon the stop. Each stop of the series must be marked with a figure obtained in this way, and the series of figures will represent the relative exposures required with the stops respectively. If then you know (by experience) the exposure required with one stop, you can very easily calculate that which will be wanted with the other. For example, you have stops marked f/8, 5, 10, 5, 1, and ·75, and you have found that under certain conditions the third of the series requires two seconds. The exposures will then be as follows: twenty seconds, five seconds, two seconds, one second, ·2 of a second, and ·15 of a second. 2. We shall be pleased to do so. 3. You will find the addresses of several makers in our advertising columns.

S. R. J.—1. It can be obtained from any glass merchant. 2. Thick gum with ten drops of carbolic acid to each ounce.

S. C. RILEY.—Thank you for the prints, which we think show great promise. We will write to you privately.

E. D.—Certainly.

W. E. C.—1. It will unswer perfectly well. 2. Under ordinary circumstances it should keep for several months if treated as you propose. 3. It is very good, but we prefer to use phenol or carbolic acid. Add it in the same proportion as is recommended for the salicylic acid. 4. We do not know exactly what the advantages are; indeed, we have never been able to find that any exist.

A. GRENIER.—The ammonia method, as described in Eder's "Modern Dry Plates," will give you excellent results if you follow the directions exactly. The book is published at our office.

T. S. S.—We noticed the pictures you refer to, and believe they were enlargements on a kind of Calotype (or Talbotype) paper.

SOL.—1. You will find particulars on page 246 of Pritchard's "Studios of Europe." 2. You can manage it if you give a sufficiently long exposure. Probably, more than an hour would be required.

WILLIAM TAYLOR.—1. Yes, quite practicable; but you must not expect to obtain the best possible results until you have devoted some time to working up the details of the process. 2. Certainly. 3. You must prepare them yourself. 4. Yes.

AMATEUR.—1. Your negatives are evidently far too thin. Probably you over-expose. 2. It appears to us that you have contaminated your toning bath with hypo.

A. A.—Thank you for the parsgraph, which interests us very much.

H. S.—We cannot tell you the address of the gentleman you mention, but you can obtain what you require from Dr. Liesegang, of Dusseldorf.

J. R. JONES.—You will find all you require in "Pritchard's "Photography and Photographers," and Abney's "Instruction." Both of these are published at our office.

EBBW VALE.—You can obtain it to order from Marion and Co.

The Photographic News Registry.

Employment Wanted.

Retoucher (Lady), London preferred.—M. A., *Photo. News* Office.
Assistant in Reception Room, &c.—F. S., 58, Belsize-rd., S. Hampstead.
Colourist and Retoucher (Lady).—Theta, *Photo. News* Office.
Photo-zinco. or Photo-lithog.—E. Beck, 7, Fowell-st., Lancaster-rd., W.
Assistant Operator and Retoucher.—Alpha, *Photo. News* Office.
Retoucher & Assist. Op.—H. Joyce, Sandown-villas, Fisherton, Salisbury.
Operator, wet and dry.—J. H., 38, Lansdown-rd., Dalston.
Assist. Operator & Retoucher.—T. H., 58, Campden-st., Campden-hill, W.
Retoucher (Lady).—Otto Pfenninger, St. Gall., Switzerland.

Employment Offered.

Printer and Toner.—E. W. Lavender, Tweedy Buildings, Bromley, Kent.
Photo-lithographer.—Riddle and Couchman, 22, Southwark-bridge-rd., S.E.
Operator & Retoucher. exp.—Personally to W. Phillips, 304, Regent-st., W.

"THE WHITTAKER OF THE PHOTOGRAPHER."

THE YEAR-BOOK OF PHOTOGRAPHY AND PHOTOGRAPHIC NEWS ALMANAC for 1884. Edited by H. BADEN PRITCHARD, F.C.S. Price 1s., per post 1s. 3d.—PIPER & CARTER, 5, Castle Street, Holborn, London, E.C.

THE EVERY-DAY FORMULARY.

THE GELATINO-BROMIDE PROCESS.

Emulsion.—A—Nit. silver 100 grains, dist. water 2 oz. B—Bromide potassium 85 grains, Nelson's No. 1 gelatine 20 grains, dist. water 1½ oz., a one per cent. mixture of hydrochloric acid and water 50 minims. C—Iodide potassium 8 grains, dist. water ½ oz. D—Hard gelatine 120 grains, water several oz. When the gelatine is thoroughly soaked, let all possible water be poured off D. A and B are now heated to about 120° Fahr., after which B is gradually added to A with constant agitation; C is then added. Heat in water bath for half an hour, and stir in D. After washing add ¾ oz. alcohol.

Pyro. Developer.—No. 1—Strong liq. ammonia 1½ oz., bromide potassium 240 grains, water 80 oz. No. 2—Pyro. 30 grains, water 10 oz. In case of an ordinary exposure mix equal vol.

Iron Developer.—Potassium oxalate sol. (1 and 4) 80 parts, ferrous sulphate sol. (1 and 4) 20 parts, dist. water 20 parts. To each 4 oz. of the mixed developer add from 5 to 30 drops ten per cent. sol. potassium bromide, and 30 drops sol. sodium hyposulphite (1 and 200).

Substratum or Preliminary Preparation.—Soluble silicate of soda 1 part, white of egg 5 parts, water 60 parts. Beat to froth and filter.

Fixing.—Sat. sol. of sod. hypo. 1 pint, sat. sol. of alum 2 pints, mixed.

Cowell's Clearing Solution.—Alum 1 part, citric acid 2 parts, water 10 parts. Edwards makes this sherry coloured with perchloride iron.

Eder's Method of Intensification.—The negative is whitened by soaking in sat. sol. of mercuric chloride, and after thorough rinsing immersed in potass. cyan. 10 parts, potass. iod. 5 parts, mercuric chloride 5 parts, water 2,000 parts. As film becomes dark brown, the actinic opacity is increased; but prolonged action causes brown tint to become lighter, until at last the negative is no denser than at first.

Fol's Backing Sheets.—A chromographic paste is prepared with gelatine 1 part, water 2 parts, glycerine 1 part, and a very small addition of Indian ink. Strong paper or shirting is coated, and the sheets are laid, face downward, on waxed glass to set. Press to back of glass plate.

THE WET COLLODION PROCESS.

The Nitrate Bath.—Water 14 oz., nit. silver 1 oz., nitric acid 1 drop. Before using coat a small plate, and immerse it for 20 minutes.

Cleaning Preparation for New Plates.—Alcohol 4 oz., Jeweller's rouge ½-oz., liquid ammonia ½-oz.

Film-removing Pickle for Old Plates.—Water 1 pint, sulphuric acid 4 fluid oz., bichromate potassium 4 oz.

Substratum.—Whites of 2 eggs well beaten, 6 pints of water, and 1 dr. liq. ammon.

Negative Collodion for Iron Development.—Alcohol 1 pint, pyroxyline of suitable quality 250 grains, shake well and add ether 2 pints, *Iodize this by mixing with* one-third of its volume of alcohol ½ pint, iod. ammon. 80 grains, iod. cadm. 80 grains, brom. ammon. 40 grains.

Normal Iron Developer.—Water 10 oz., proto-sulphate iron ½ oz., glacial acetic acid ½ oz., alcohol ¾ oz. The amount of proto-sulphate iron may be diminished to ¼ oz. when full contrasts are desired, or increased to 1 oz. when contrasts are unduly marked. With new bath quantity of alcohol may be reduced to ¼ oz.; but when bath is old more is wanted.

Intensifying Solution.—Water 6 oz., citric acid 75 grains, pyro. 30 grains. When used, add a few drops of the silver bath to each ounce.

Lead Intensification.—After neg. washing, immerse in dist. water 100 parts, red pruss. potash 6 parts, and nit. lead 4 parts. When it is yellowish white wash and immerse in liquid sulphide ammon. 1 part, water 4 parts.

Fixing Solution.—1. Potass. cyanide 200 grains, water 10 oz. 2. Sat. sol. of sod. hypo.

Varnish.—Shellac 2 oz., sandarac 2 oz., Canada balsam 1 dr., oil of avender 1 oz., alcohol 16 oz.

PRINTING PROCESSES.

Albumen Mixture for Paper.—White of egg 18 oz., 500 grs. ammon. chlor. in 2 oz. of water. Beat to a froth, stand, and filter.

Sensitizing Solution.—Nit. silver 50 grs., water 1 oz., sod. carb. ½ gr.

Acetate Toning Bath.—Chl. gold 1 gr., acet. soda 20 grs., water 8 oz.

Lime do.—Chl. gold 1 gr., whiting 30 grs., boiling water 8 oz., sat. sol. chl. lime 1 drop. Filter cold.

Bicarbonate do.—Chl. gold 1 gr., bicarb. soda 3 grs., water 8 oz.

Fixing Bath.—Sodium hypo. 4 oz., water 1 pint, liq. ammon. 30 drops.

Reducer for Deep Prints.—Cyan. potass. 5 grs., liq. ammon. 5 drops, water 1 pint.

Encaustic Paste.—Best white wax 1 oz., oil of turpentine 5 oz.

Sensitizing Bath for Carbon Tissue.—Bichromate potash 1½ oz., water 30 oz., ammonia 1 dr., methylated spirit 4 oz.

Enamel Collodion.—Tough pyroxyline 120 grs., methylated alcohol 10 oz., ether 10 oz., castor oil 20 drops.

Mountant.—1. Fresh solution of best white gum. 2. Fresh starch.

Collotypic Substratum.—Soluble glass 3 parts, white of egg 7 parts, water 10 parts.

Collotypic Sensitive Coating.—Bichromate potash ½ oz., gelatine 2½ oz., water 22 oz.

Collotypic Etching Fluid.—Glycerine 150 parts, ammonia 50 parts, saltpetre 5 parts, water 25 parts.

Printing on Fabric.—Remove all dressing from fabric by boiling in water containing a little potash, dry, and albumenize with ammonium chloride 2 grammes, water 250 cubic cents., and the white of 2 eggs, all being well beaten together. A 70-grain silver bath is used, and the remaining operations are as for paper.

Cyanotype Printing.—Water 1 oz., red prussiate of potash (ferricyanide) 1 dr., ammonio citrate of iron 1 dr. Prepare and preserve in the dark. Float the paper and dry. Fixation by mere soaking in water.

VARIOUS.

Luckardt's Retouching Varnish.—Alcohol 300 parts, sandarae 50 parts, camphor 5 parts, castor oil 10 parts, Venice turpentine 5 parts.

Matt Varnish.—Sandarae 13 parts, mastic 4 parts, ether 200 parts benzole 80 to 100 parts.

Encaustic Paste.—Best white wax, in shreds, 1 oz., turpentine 5 oz.; dissolve in gentle heat, and apply cold with piece of flannel.

FERROTYPES.

Collodion.—Ammonium iodide 35 grains, cadmium iodide 25 grains, cadmium bromide 20 grains, pyroxyline 70 grains, alcohol 5 oz., ether 5 oz.

Bath.—Silver nitrate 1 oz., water 10 oz., nitric acid 1 drop.

Developer.—Ferrous sulphate 1 oz., glac. acetic acid 1 oz., water 16 oz.

Fixing and Varnish.—Same as wet collodion process.

CONTENTS.

THE WOODBURYTYPE PROCESS.

(THIRD ARTICLE).

THE exposed tissue having been taken from the printing-frame, the next step is to mount it upon a rigid support, such as glass, in order that it may not altogether collapse during the operation of washing away the soluble gelatine; and india-rubber solution has been found to be the most convenient material for mounting the exposed film.

For preparing the rubber solution, it is convenient to make use of the stiff rubber paste or solution which is ordinarily sold in tins, and to thin this down with benzole until it is of such a consistency as to flow readily. A number of glass plates of suitable size are adjusted to a horizontal position upon levelling stands, and sufficient of the rubber solution is poured upon each to cover the entire surface. If a little flows off it does not matter, as it can be caught in a convenient receptacle, and returned to the stock-bottle. The plates should be allowed to remain in a horizontal position until the rubber is thoroughly set; the time required for this varying considerably according to the purity of the benzole used and the temperature, but two hours may be mentioned as an approximation to an average.

All is now ready for mounting the exposed films upon the rubber-coated plates, and the operation is a very simple one, as all that is required is to lay the film, collodion side downwards, upon the rubber surface, and to establish contact by gentle pressure. The pressure may be conveniently applied by the hand, a sheet of paper intervening; or a roller thickly coated with soft rubber may be made use of. In laying down the exposed tissue it is necessary to avoid, as far as practicable, the enclosing of air between the tissue and the plate, and for this reason it is well to first place one edge in contact with the rubber-coated glass, and then to gradually lower the remainder of the sheet. A very good method of establishing good contact between the surfaces is to pass the plates between the india-rubber rollers of an ordinary wringing machine.

The plates are now placed in warm water in order that the unaltered gelatine may dissolve away, and it is convenient to commence the development with water at 40° C. A zinc trough with vertical grooves answers very well for holding the plates, and the water should be changed from time to time. After the whole of the soluble chromium salts have been washed away, the temperature of the water may be raised occasionally, until a temperature of 65° or 70° C. is reached. It is easy to judge of the progress of the development by inspection or by feeling the degree of the relief by the application of the finger. And it may be mentioned that the development may ordinarily be regarded as finished when the bare collodion is reached in the extreme whites. The time required for development varies extremely, as, in some cases, two or three hours are sufficient, while, in other instances, as many days are required.

The development being finished, a final rinse is given with clean warm water, in order to ensure the removal of all the dissolved gelatine, and the plate is placed in a rack to drain. When all surface water has disappeared, the plate is put into a dish containing methylated spirit, in order that the greater part of the included water may be removed from the relief; a period of a quarter of an hour being ordinarily sufficient. On its removal from the alcohol, the plate should be placed in a moderately warm place, in order that it may finally dry; but care must be taken that it does not dry too rapidly, or it may become fractured from the too rapid contraction of the gelatine.

It occasionally happens that it is desirable to harden the relief by means of alum, especially when there is likely to be occasion to keep it for a long time in a somewhat damp locality, or where a very great number of impressions in lead are likely to be required. The best time for the aluming is immediately after the last washing with hot water, and a cold solution of chrome alum in twenty-five parts of water is used; the plate bearing the relief being allowed to remain in this for about five minutes. The subsequent operations are as described above.

When the relief is quite dry, it is easy to detach it from the glass plates by passing the point of a pen-knife under the edges of the collodion, and carefully lifting one of the corners. Under these circumstances, the relief is stripped off, and it brings the film of india-rubber with it. The relief is next laid, with the collodion surface upwards, upon a level surface, and the india-rubber is removed by rolling it up into balls with the finger. Care must be taken not to tear the relief during this process, and it is desirable to have a few smaller weights at hand in order to keep down any parts of the relief which may tend to curl up.

It is not desirable to make immediate use of the relief, as it continues to contract slowly for some hours after its removal from the glass plate; and until it has attained its normal condition of equilibrium, it is liable to break up under the influence of pressure.

It is often necessary to retouch the relief before moulding from it, by removing the projections which result from scratches or pinholes of the original negative. This is very easily done by scraping with the sharp edge of a fragment of glass; and backgrounds or any deeply-shaded portions may be lowered in a similar manner.

The most convenient method of storing away the reliefs is to make up books out of envelopes, the open sides of the envelopes being directed inwards towards the back of the book; this arrangement affording great facilities for indexing the subjects.

In our next article we shall treat of the making of the reverse or printing-mould in lead.

SWING-BACKS, SWING-FRONTS, AND RISING-FRONTS.

BY W. H. WHEELER.

The subject of swing-backs, swing-fronts, and rising-fronts has again been discussed, but without much result. Indeed, the questiou is rather one for systematic investigation, but would be, I venture to think, found clear enough if accurately stated. As it is evidently interesting as well as practically important, I will venture to ask a little space for an explanation which may, I hope, be acceptable to a good many of your readers.

The object of swing-backs, swing-fronts, rising-fronts, or any combination of them, is generally one and the same: it is to get on the plate an undistorted image of some object, generally architectural, with regard to which the photographer is so situated that, without modifying the usual relative positions of lens and plate, the whole of the subject cannot be adjusted on the plate as desired. The first instinct is to point the lens and camera upwards towards the middle of the object, the image of which is then probably all right on the plate, but with the important drawback that vertical lines are so represented only in the middle, those on each side being observed to converge towards one another in a manner too familiar to all of us to require further description. I am supposing that some form of "rectilinear" doublet is used, in which, as in all decent doublets, the distortion due to the lens is fully corrected. Into the complications arising when it is sought partially to correct the distortion of a single lens by combining any of these methods, I do not propose now to enter. We will consider the case in its simplist and most usual form; and I will further assume—writing to photographers—that no description of these familiar adjustments is required.

It is an interesting and convenient fact that in a strictly symmetrical and non-distorting doublet the positions of the stop and of the optical centre of the combination are identical; and the proposition will therefore be accepted as indisputable that, with such a combination, the relative directions of all pencils passing through the stop are the same as though there were no lens at all, only the stop. Their course will therefore be accurately represented by straight lines drawn from any part of the object, passing through the stop (where they intersect), and finally resting on the plate (or focussing screen) at the corresponding parts of the image. From this the result will be found inevitably to follow that the scale of the object and of its image are the same in all parts only when the planes of both are parallel to one another. Want of parallelism in the vertical plane we call distortion; for the eye is not satisfied unless vertical lines are parallel. Want of parallelism in the horizontal plane we call perspective, and are perfectly satisfied with the natural effect produced. It will be necessary to take the proposition as proved* that the vertical lines of a building will be represented as parallel when—and only when—not only they are formed by a non-distorting combination, but also on a plate or focussing-screen as truly vertical in position as is the building.

Thus when the camera has been tilted (according to our first instinct) towards the centre of the lofty building, and convergence of the vertical lines thereby produced, an adjustment of the swing-back may bring the focussing screen again to a vertical position, and the converging lines are restored to parallelism. But the picture is no longer seen to be *in focus*. If the middle be sharp, the base of the building is too near the lens, and the top too far from it. To correct either one of these faults obviously only makes the other worse. Some one suggests, therefore, "use the rising front instead." We restore the camera to its original position; finding, of course, as at first, that the upper part of our subject is below the bottom of our focussing screen. We raise the front carrying the lens, and with it the image, until (if our lens embraces a sufficiently wide angle) the whole of our subject is seen depicted on the screen. How about the focus now? The top of the building is perhaps not so sharp as we could wish, and we may find, on attempting to sharpen it by shortening the focus, that not only is the definition of other parts injured, but that by no adjustment can we bring it to a definition equalling that part of the image which is opposite the lens; or even than we obtained with the swing back when we sharpened the top at the expense of the bottom. Why is this? It is because the field of view is neither absolutely flat, nor can the definition at its extreme edge be so good as at the centre, even when adjusted to the best focus attainable there. For in raising the front we moved the lens so as to use the extreme edge of its field of view, because there alone we can see the top of our building. Thus, to compare the injurious effect on definition of a rising front with that of a swing-back, we must note that the fault of the former is the bringing into use the worst part of our lens; while the swing-back throws top and bottom out of focus to an extent depending simply on the angle at which it is inclined to its ordinary position (of perpendicularity to the optical axis), and its error is independent of the covering power of the lens. The value of the comparison must depend, therefore, entirely on the lens used. If that be a combination capable of covering a larger plate, it will probably be better to rely on the rising-front; if otherwise, it may not only be an open question which fault is the more serious, but also we may find that on rising the front we merely bring on to the plate the circular edge of the field of view, and find the desired summit of our building to be still hidden. Suppose we now try the swing-front. By using it we point the lens slightly upwards, leaving our camera still horizontal, and our focussing-screen vertical, and the desired picture is presented undistorted, but with nearly the same want of definition at the top and bottom of our picture as when we used the swing-back alone. In fact, it would be precisely the same, only that we are now using a combination of swing-front and rising-front, instead of the swing-back only. The effect, both on definition and distortion, of swing-front and swing-back are absolutely identical, provided the position of the rising-front is the same. Only there is this practical convenience, that fresh adjustments of the swing-front and of the rising-front may be made without tilting, and do not involve a re-adjustment to keep the focussing-screen vertical, a condition which, as I have shown, is essential to an undistorted image of a vertical object. On the other hand, the swing-back is sometimes an easier means of adjusting to this verticality, than to adjust the camera to an accurately horizontal position. In very difficult subjects, however, all three adjustments may be combined with advantage.

There remains one point to be noticed. It has been objected to a swing-back or front, that placing the lens at an angle other than perpendicular to the lens axis must have a distorting effect. We can all see, when adjusting the swing-back after tilting our camera, that vertical lines are *lengthened*. But the truth is, that this is a *correction* of distortion. For a want of parallelism in the vertical planes of object and image affects not only the parallelism, but also the *length* of vertical lines, which are shortened in the proportion of the cosine of the angle contained to radius, and are restored to their proper length when parallelism is restored. For this reason the method commonly recommended for correction of a distorted photograph in copying is a mistake. Instead of placing the print or transparency to be corrected at an inclination from the vertical, and making the new negative on a vertical plate, the copy should be vertical, and the sensitive plate inclined. A short-focus wide-angle lens and a swing-back to incline *from* the vertical, are the fittest for this pur-

* If we draw the straight lines as described, we shall find that with object and image in parallel planes, and only then, the triangles on each side are strictly proportional, having their common intersection at the stop. I believe the correct demonstration will be found in Euclid, vi. prop. 6.

pose. Absolute accuracy can only be insured when the focal distance bears the same proportion to the plate as in the original negative. But by the method ordinarily recommended, the corrected picture is apt to be *stunted*.

THE SPECTROSCOPE AND ITS RELATION TO PHOTOGRAPHY.

BY C. RAY WOODS.

IV.—Colour.

On emerging from the prism, a ray of light is, as we have seen, spread out into a band, which produces a series of sensations on the retina of the eye, known as "colour." The question of colour is of far too much importance to be lightly passed over; it is not to be left out of the photographer's calculations, and is continually coming to the fore in all branches of his practice. That different colours—or, more correctly speaking, objects the light from which give rise to different colour sensations—produce vastly different effects on a sensitive plate, is too well known to need repetition here, and this fact is frequently bewailed. It must not be forgotten, however, that this has its advantages as well as its disadvantages; in illustration of which it is simply necessary to mention the question of dark-room illumination. It would be very awkward indeed if we had to work now as some of the early workers in photography did—in darkness. This is one of the main advantages in the inequality of the reducing action of different parts of the spectrum. One of its main disadvantages is, that the comparative luminosities are not fairly represented in the photograph; but nature herself steps in to our aid here, in never giving us purity of colour.

The question of colour sensation has always presented difficulties—difficulties that were more readily mastered in by-gone days with very imperfect knowledge, than they can be at the present time with less imperfect knowledge. The subject is a fascinating one that has occupied the attention of many masters of science. Books have been written on the subject; and it is obvious, therefore, that only a few of the most important points can be touched upon here.

It had been known as long, probably, as the art of painting had existed, that the artist could produce from three pigments any of the other colours. The three colours which could not be imitated by mixture of other pigments were red, yellow, and blue, and these were called the primary colours. Newton's experiment seemed to add confirmation to this view, for the other tints of the spectrum were easily explained by Sir David Brewster on the supposition that they were produced by the overlapping of its three primary colours. More modern experimenters, notably Helmholtz and Maxwell, by experiments on the mixing of lights of various refrangibility (or, to use more popular terms, mixtures of coloured lights as distinguished from pigments), came to the conclusion, first mooted by Young at the beginning of the present century, that red, green, and blue or blue-violet, came nearer to being the three primary colours than red, yellow, and blue. There are three colours in the spectrum which, it is said, cannot be imitated by mixtures, that is mixtures of coloured lights; and because they cannot be imitated they are sometimes regarded as the primaries; these are the extreme red and violet, and a deep olive green.

Clerk Maxwell, however, considered the primary colours to be:—1. A red resembling the pigment vermilion, situated about one-third the distance between C and D from C; 2. Green resembling emerald green, situated about one-fourth the distance between E and F from E; 3. A violet-blue, situated midway between F and G, and capable of being fairly represented by artificial ultramarine.

It is not easy, however, to satisfy the spectroscopist that the eye is capable of receiving only three independent sensations of colour. From red to violet the spectrum is one beautiful gradation of colours melting imperceptibly into one another; the greater the dispersion the more noticeable does this become. True, the eye is not delicate enough to distinguish between the tints of two lines lying very close together, and yet it has been estimated that about a thousand different tints can be counted. Each of these tints would be regarded as a primary colour, were the wave length producing it the only factor brought in to decide what is a primary colour, and what is not. The difficulty of arriving at a true explanation of the sensation of colour is due to our lack of knowledge of what takes place after the waves of light reach the retina. It is known that there are certain structures there called rods and cones, which have something to do with carrying the sensation of sight to the brain, but that is all. The three-colour sensation theory has to rest on an assumption that each terminal of the optic nerve ends in three organs, which are capable of responding to certain portions of the spectrum, and each wave of light (unless it is capable of causing one of the three primary colour sensations) produces two distinct sensations. Anatomy has no knowledge at present of any such structure, and the theory at present rests on evidence derived from experiments with coloured lights, and on deductions from the study of colour blindness. The subject is in a somewhat unsatisfactory condition, and, as already mentioned, authorities hold different opinions as to what reds, greens, and violets are primary, after all.

But be the explanation of colour sensation what it may, the artist will take the old view of the question. Colour and pigment are to him such interchangeable terms, that to him there always will be three primary colours, but *his* primary colours will be red, yellow, and blue, as of old. The three-primary-colour theory has been to him, and is likely always to be, a valuable working hypothesis, and, providing that *pigments* are understood, there can be little objection to its retention.

The writer must ask the reader's pardon for this little digression. The interest attaching to this still debateable subject is common to all, especially to photographers who are not indifferent to the subject of colour, although their results are produced in black-and-white, and this interest must be my apology. It is only a digression in this sense: that the explanations of colour-phenomena that the photographer meets with are comparatively simple, and do not require the aid of any such theory. The retina of the camera, if such an expression may be used, is well understood. The sensitive plate is a ground capable of being influenced by certain portions of the spectrum. It may be said to possess, in a transcendant degree, that colour sense which to us is weakest, namely, the blue. As will be shown in the next chapter, we may say in a general sense, that it is the *most* refrangible portion of the visible spectrum which produces the *most* effect on a plate. We have, therefore to consider the nature of the light received from terrestrial objects, paying most attention to the blue. A brief consideration of what takes place in reference to coloured glasses and pigments is all that is required to properly understand the matter.

If a piece of yellow glass be placed before the slit of the spectroscope it will be seen to cut off a lot of the violet and some of the blue, letting most of the green, yellow, orange, and red pass through. The yellow colour is given to the glass by the combination of tints that pass through it. If a piece of cobalt blue glass be examined, it will be seen that it derives its colour from the violet and blue rays chiefly, as well as to parts of the green, yellow, and red. Its absorption takes places by two bands in the red, and a smaller general absorption along the red, yellow, and green. If these two glasses be placed in contact, it will be found that they appear green, the spectroscope showing that it is the green and green-yellow rays which find their way through. But if these two glasses be placed in separate optical lanterns, and the lights be projected on the same screen, it

will be found that white light is produced tinged with yellow or blue according to the colour that is strongest. In the first case we have the difference, in the second case the sum, of the rays which they transmit.

A mixture of pigments resembles more the first than the second of these two cases; the light sent to the eye is chiefly that which neither of them absorbs. Hence it has been said that "every mixture on the artist's palette is a step towards blackness." What we meet with in nature is analogous to the effect produced on white light by a pigment, and just as we seldom find pigments that reflect light from a limited portion of the spectrum only, so do we seldom or never meet with pure colours in nature. They may be pure in the artist's sense of the word—that is, they may be clear and bright—but never pure in the sense that the spectroscopist uses the word.

In addition to this lack of purity in colours, all objects reflect more or less white light from their surfaces as well. A striking instance of this, for example, may be observed by looking at grass or foliage in bright sunshine through cobalt blue glass (as pointed out by Mr. Woodbury*), or through permanganate of potash; it is suprising how red they appear, that colour appearing to predominate over the rest. But for this reflected white light it would be almost impossible to get detail of objects otherwise lacking in rays of high refrangibility without very considerable over-exposure in others.

A TRIP TO THE GREAT SAHARA WITH A CAMERA.

BY A COCKNEY.†

This afternoon we had a sensation. Two English ladies who are with us here went to a harem, or in other words paid an "at home" visit to the native schoolmaster of Vieux Biskra. What a chance for Mr. Bolas' detective-camera, I thought, if only in the form of a muff or reticule; our lady friends could then have secured some "interiors" of fabulous value. But all the wishing in the world would not convert my tourist apparatus into the desired form, so Jones and I had perforce to wait patiently for a picture of the harem in words.

"What did you see? what did you see?" was our rather rude enquiry the instant the ladies came back. Well! they would tell us all about it. In the first place they had some coffee—some delicious coffee. "Some what?" I ask, for at times my hearing is a little defective. "Coarfy, if you don't understaud!" roars Jones in a vulgar tone (I am sure I am no worse a Cockney than he is, and I would tell him so, only I don't want to interrupt just now). Well, they had some delicious coffee, and down stairs they saw three plain and untidy women at work weaving. And then——well, then, after they had drunk the coffee, most delicious coffee, they shook hands with the three women, and then——

"Yes, yes, and what else did you see?" we say, eagerly. Well, it seems, they drank the coffee, the delicious coffee, and then they shook hands with the untidy women—very plain and untidy—and then——

Well, then, the story ended very much like one I have heard our excellent comedian, Toole, tell, of his once going to an hotel, and making his way to the wrong room; if I remember right, his number was 6, but that on No. 9 door happened to be loose, and had swung round looking like No. 6. He opened the door, only for a moment, and then he saw——well, well, he couldn't bring himself to say, he was so startled. "But what was it?" the comedian is asked. "What was it? Why, I simply opened the door a few inches—of course I thought it was my own room—and then——but 'pon my word I couldn't tell it." "Not tell it! then write it down," he is implored. "Write it down! never. You know I thought it was my own room at the time, and when I opened the door—well, there—no, I really couldn't do it." And so it was with the harem visit; we only heard of delicious coffee, and of three untidy women.

Biskra is getting a little warm for us now when we make an appearance with the camera. Youthful Arabs start up from every corner at the sight of the apparatus, and mob us right and left. It is not so much a question of sous—although these are in brisk demand—so much as the honour of being photographed, that interests them. They have discussed among themselves the nature of the apparatus, and begin thoroughly to understand its capabilities. I want to get a picture of our auberge—the Grand Hotel de Sahara, as it calls itself—but when I set up the camera and begin to focus, there are nothing but big black heads bobbing all over the ground glass. Jones tries his best to get them back, but no sooner is the front row disposed of, than a second and third show up. They want to be photographed, as their comrades were the other day, and they don't mean to budge till they see the instrument at work.

In these circumstances I have recourse to a little artifice, well known to most photographers. Jones groups the young ragamuffins very seriously, gruffly bids them be quiet, while I let the drop-shutter fall two or three times. In this way we please them all round, and in a few minutes everybody is taken to his satisfaction, and willing to retire. The hotel colonnade, with a graceful palm stem in the background, should make a capital picture, and serve as a pleasant reminiscence of Biskra, so I am anxious to get a successful result. Unfortunately, just at the last moment, the landlady, who is standing at the gateway, in her anxiety to please us, orders off a group of Arabs who are quietly squatting on the curb, and thus robs the scene of much of its character. However, I have it over again, pressing a few young *Indigenes* into the service this time, and hope to get something better.

This is not the first time I have had to do "hocus-pocus" with the camera, as a means of quickly satisfying importunate appeals. I was worried by an Arab guide, who knew everything, to photograph a small cascade near El Kantara. However wonderful it might have been to him, it presented nothing to a European, but as the quickest way out of the dilemma, I turned the camera round and fired point blank at the falling water, without troubling, of course, to put in a dark-slide.

In selecting objects for the camera, I go on an old plan I have adopted on previous tours. It is to prefer character to natural beauties; that is to say, rather than photograph a waterfall, mountain, or lake, I choose objects that unmistakably show the character of the inhabitants. I do not mean to deprecate landscape photography, and should, indeed, only be too happy to be able to retain *souvenirs* both of the geography, as well as of the people of a land I visit; but since, under the circumstances I travel, my plates are few, I must perforce incline to one class of picture or the other. You see, a waterfall, or cascade, however grand it may be, never furnishes such a "speaking likeness" hereafter to the traveller, as does a corner of a street, an old church, or perhaps a market place. The cascade may be in the Tyrol, or Norway, or Switzerland; but if you secure a picture of your hostelry with perhaps a figure or two, or of a bridge, or a turnpike, or a bazaar, or mosque, or anything else that has distinctive character, then I hold you fulfil your purpose as a tourist photographer in the best way you can.

There is another reason, too, why pure landscape is not a good investment to the tourist. He has not experience enough to treat it as it should be treated, and as often as not, his camera dwarfs the grandeur of the scene. I once heard a critic say of a photograph: "Oh yes, I recognise the place well enough; but the photograph hasn't any of that grandeur with which the scene inspires you at first sight; it is the impression that you get after you

* Tyndall on Light.

† Continued from page 165.

have been looking at the place for half an hour." He was quite right; the photograph was a true representation of the scene with five-and-twenty per cent. discount off. The photographer had forgotten to raise his lens, and so the horizon was depressed throughout.

I must not forget to mention the Jardin Landon, which is one of the attractions of Biskra, a tropical garden laid out with exquisite taste, replete with sanded paths, cool brooks, shady bowers, and trimly-kept flower beds. It is the property of a benevolent gentleman—that villa at Philippeville with the lions, I have mentioned, belonging to him—who has made tropical vegetation a study, and who shows the visitor well nigh every variety of shrub that will grow hereabouts. Here is the cocoa-nut palm, the bamboo, the eucaliptus, the sago-palm, the banana, &c., &c., while in conjunction with these there are grassy lawns that would be the envy of a British squire, and aloes and cacti such as the curator of Kew Gardens can only dream about. Moreover, the owner of this green paradise is a thorough-going disciple of the no-fee system; at the entrance gate is a large board bearing in bold characters two notices: one an invitation to the visitor to enter and remain as long as it so pleases him, and the other an urgent request to pay nothing to the Arab attendants.

M. Foureau—whose stand and dark cloth, by the way, I take the precaution to borrow during my photographic excursions here, since they are far superior to what I carry—complains a good deal of the bright yellowness of the light in the desert. He has an idea of trying a disk of blue glass in front of his lens this next summer to modify the glare, a suggestion, it may be remembered, made many years ago by M. Gaudin. The plan, I believe, has never been found of very practical value, for both glare and intensity of light can be modified by other and more simple methods. Another theory M. Foureau has is, that exposed plates should not be left too long before development. He never likes to allow his films to remain more than a month or six weeks between exposure and development, otherwise their treatment in the developing solution gives, as a rule, some trouble.

But our week at Biskra is at an end, and it is time to return on our way to Batna. So tedious is travelling hereabouts, that I may mention it will take longer for our little party to get hence to the town of Algiers, than it took us to travel from London to Constantine. The diligence bears us once more to Batna, and thence we take rail to Sétif, the distance as the crow flies being about eighty miles, yet involving eight hours' confinement in a railway carriage.

The Arab market at Sétif is one of the largest in Algeria, and one little feature of it I must, as a Cockney, here record. As we came to the end of a broad thoroughfare, there sat a small group of Arabs, in noisy excitement, squatting round a bit of carpet. Naturally, we stopped and looked on. It was the pea and thimble trick of Epsom race-course in full swing, the operator, however, manipulating with three walnut-shells and a pebble. He was a very stupid operator, for every now and then he left the pebble quite visible under the shell; still, he was not so stupid as the Arab who was betting, and who, let the pebble be ever so visible, would go on staking his money on the other shells, and losing countless coin. And as we watched and waited—the gambling Arabs, of course, quite oblivious of our presence—a friendly native, who spoke French, kindly volunteered to tell us all about the game, and expressed his perfect willingness to act as interpreter, in case we liked to take a hand in it. Strange to say, the dear simple children of the desert lost all interest in their game as we departed.

I started in my first letter with a few remarks on keeping down the quantity of luggage, if you valued your peace of mind as a traveller. Here, perhaps more than anywhere else, "baggage is the bane" of travelling More than ever am I pleased to think my photographic outfit does not weigh one ounce heavier; more than ever do I regret my camera is four and a-half pounds of dead weight. The tourist camera—light and non-complicated—is still to be created, and the manufacturer who solves the problem happily, will earn the gratitude of thousands. Our little party, thanks to rigid rule, is capable, at a pinch, of conveying its own luggage from steamer to land, or from station to hotel; but as it is, the frightful examples we meet with of luggage-devouring-Arabs, and baggage-tortured travellers, make one shudder for the horrors we have escaped so narrowly.

PHOTOGRAPHY CONSIDERED AS THE WORK OF RADIATION.

BY CAPTAIN ABNEY, R.E., F.R.S.

The third lecture of this series was delivered at the Royal Institution on Saturday last.

Referring to the previous lecture, Captain Abney said there was one experiment which failed on that occasion on account of the wrong coloured medium being used, but he hoped to show it successfully on this occasion. A wet plate was then exposed and put into a cell in the lantern, the development gradually taking place, and the image appearing on the screen. The lecturer said his audience would remember the experiments of the magnets and the filings, and of the growth of the lead tree illustrating the subject of crystallization; some such action took place in the development of photographic images, the particles as they were deposited attaching themselves to those already in the film. In order that they should be deposited in this manner, it was necessary that the development should not take place too rapidly, or the particles were deposited over the entire film, producing what was technically known as "fog." He showed them in test-tubes that when nitrate of silver is added to pyrogallic acid by itself, an immediate precipitation of silver takes place, but if some restrainer was present, such as glycerine or acetic acid, the silver was deposited much more slowly. As the particles of the subsalt produced by the action of the light in a film were reduced by the developer, the molecules of silver in their nascent state combined with molecules of the haloid salt in their vicinity, forming further molecules of the subsalt ready to be acted on by the developer. That this really appeared to be the case he showed by projecting on the screen a slide which was produced by preparing a dry plate in the bath, exposing it to light beneath a negative, and then pouring collodion emulsion over one half of it; the part treated with collodion was of good density, the other part being thin, showing conclusively that the action of the developer had extended to particles of silver bromide which had had no exposure to light whatever. By means of a piece of bromide paper smeared over in parts with sulphite of soda, the lecturer then showed the action of a sensitizer in reducing the exposure by taking up the bromide as soon as it was separated from the silver by radiation.

It was not only radiation, however, but other forms of energy also were able to produce changes in compounds capable of being rendered visible by a suitable developer. Shearing stress, for instance, was capable of separating the atoms of silver and bromine. A piece of gelatino-bromide paper was taken, and written on with a pointed glass rod, the writing appearing to the audience on the application of oxalate developer. The lecturer said that this experiment had been objected to on the ground that the film was probably disrupted by the glass rod. That this would not account for the phenomenon he was able to show by projecting on the screen two slides. The first was produced by writing on a gelatine plate and developing it; the second by writing on a plate, wetting it, and then melting it to restore the smooth surface of the film; in the second case the writing was still legible, but somewhat blurred, as might be expected.

There was another thing connected with the action of radiation to which the lecturer said he would like to draw their attention. Taking two sensitive plates, one of them was exposed beneath a negative to the light from a Bunsen burner for thirty seconds; the other was exposed beneath a rotating disc to the light emitted by an electric spark, which they were aware only lasted for the two-hundred-and-fifty-thousandth part of a second. Both plates were developed, shown round, and subsequently fixed and shown in the lantern. In the one case the exposure was seven million five hundred thousand times as long as in the other, but taking

the relative sizes of the two lights into consideratiou, the exposures were in the ratio of 7,500,000,000 to 1. Now he could hardly ask his audience to believe that the relative intensities of the two lights were in that ratio, and the explanatiou therefore must be that a greater proportionate effect was produced on the sensitive substance by a sharp hard knock, as it were, than by a slow soft one containing the same amount of energy.

He had yet another action of radiation to show them. There were certain subjects, such as bichromate of potash, which were capable of undoing the work of radiation (this was shown on a piece of bromide paper). But radiatiou assisted this reversing action. Taking a plate from the bath, the lecturer exposed it to the light from a piece of magnesium wire, washed it, treated it with bichromate, and exposed it to light behind a negative consisting of a white cross cut out of black paper. On being placed iu the developer in a cell in the lantern, the white cross on the black ground slowly developed till it reached a good density, thus concluding a very successful lecture.

ON THE PERMANENCY OF SILVER PRINTS.

BY R. STANLEY FREEMAN.*

From the discussious now taking place at the various photographic societies, and in the journals devoted to photography, aucnt the fading of silver prints, I infer that the subject has come so promineutly forward agaiu by photographers finding a great dispositiou in modern prints to fade thau was the case formerly. The cause of this rapid fading must be rather far to seek, or some satisfactory elucidation would ere this have been put forward.

Must we, then, be content to receive as an axiom the saying, that "silver prints *will* fade?" Well; yes. They will, and so will engravings and every other production with paper for its base. But the difficulty is the short space of time photographs too often take to reach this stage. Many of us have photographs by us of twenty years' stauding as good as wheu first produced, and examples of which I will show you, while others but a few months old are passing rapidly away. How are we to reconcile this discrepancy? To what influence does the one owe its preservation and the other its decay, yet both equally, carefully, or carelessly kept? I would like I could tell you. I can only offer a few remarks on the subject.

From the discussion and opinions promulgated by the earliest workers in photography one is led to infer that the permanency of silver prints was more favoured by the old sel d'or, or mixed hypo aud gold bath, than by the present alkaline toning method. But is it so? As an old worker, both in the printing and albumenizing, I trust I may veuture to add my mite of iuformation to that already laid before us through the medium of the photographic publications.

I am of opinion that the permaneucy of silver prints is only in favour of the sel d'or method of touing and fixing at one operation when certaiu conditions are observed, and those conditions exercise an influcnce upon the permanency of silver prints by any of the methods of toning. I have known prints to fade quite as rapidly when toned by the sel d'or bath as by any method subsequently introduced. The first of the couditions essential to permanency I consider to be the use of perfectly fresh albumen, with nothing added thereto but the necessary chloride, whether of sodium, ammonium, or barium, or a mixture of these according to the required time of the prints. There is no question that the use of fresh albumen in the preparation of paper entails more labour in beating up, and greater care is necessary in coating the paper; the glass, too, may not be so smooth and high as that produced by stale albumen. These considerations, perhaps, may account for many manufacturers of albumenized paper using albumen in a state of fermentation, or, as we may judge at times by the perfume of the paper, in an advanced stage of decomposition.

Looking at the constituents of albumen, does it not stand to reason that if in the very first stage of our printing operations we use a material in a state of decay, we introduce the elements of that decay into our photographs? I think this point may be satisfactorily proved us:—Take two sheets of paper—one prepared with fresh albumen and the other with albumen that is in a state of decomposition, sufficiently so as to be unpleasant to a person with a delicate sense of smell. Sensitize those sheets on the same silver solution. What is the result? The paper prepared with the fresh albumen will retain its purity for some time. I have known it to keep a week in cold weather, while that prepared with the stale, according to the extent of the decay, turned yellow before it was dry, or very shortly afterwards. Take prints from these papers, toned by any method you please, and I will venture to say that the prints on the latter or decomposed albumen will soon be in the "sear and yellow leaf."

The next consideration is the toning bath. There are two drawbacks to the use of the mixed hypo and gold bath. The first is its apparent extravagance, and the next, the difficulty of knowing when you have left off toning with gold and begun toning with sulphur. Thus, it often happened that, when a larger batch of prints was toned iu the same bath than the capacity of that bath could possibly tone with gold, part of that bateh would be in a condition to fade on the least provocation, and often without it. But you must remember that the votaries of the art in those days had not the means of information at their fingers' ends the present generation has. Photographic chemistry was at a very low ebb, consequently errors were committed that we should not be guilty of now. Yet, with it all, work was produced by a few able hands that would bear favourable comparison with the work of the present day, as my recollection of the first exhibitiou of the Parent Society enables me to say.

To return, however, to my subject. As to the extravagance of the sel d'or bath, that is more apparent than real, as by a very simple method all the gold not taken up by the prints can be recovered. The process is an interesting one, and made pleasurable at the finish by the large percentage of metal recovered. The whole process of recovery has lately been treated in a very exhaustive and able manner by Mr. F. W. Hart, so that I need say nothing on that head.

Of the alkaline methods of toning I certainly give preference to the carbonate of soda bath, as, although not, perhaps, giving the richness of tone the acetate bath does, I am inclined to think, by comparison, that the prints are more permanent. This bath you must make up freshly each day—presuming you tone every day, or, if not, a few hours before use, and that I take to be in its favour, as I consider a bath that has been used over and over again must necessarily carry some impurities with it. As the undeposited gold can be precipitated with sulphate of iron, there is little gain in pushing a bath to the utmost of its powers.

The next consideration is the ready-sensitized paper, and whether its introduction is in any way answerable for the fading of silver prints. I have been led to the conclusion that it is. The accusation is sweeping, I admit; but as it is founded upon practical experience, and not theoretical reasoning—theory and practice not always agreeing, especially in photography—I shall stand by my statement until refuted by the comparative experiments of others. It has been our custom—rather an apathetic one—so long as a paper would "keep well, print quickly, tone easily, and yield prints of good quality," to be content, giving no thought to the morrow of such prints.

The method of toning the mounting medium and the quality of the mounts have been from time to time put forward as the delinquents in bringing about fading, and albumen more than once has been pointed out as the culprit; but a bill of indictment has never, to my knowledge, been preferred against durable sensitized paper. Well, it is done now, and, therefore, the sooner you constitute yourselves a grand jury to inquire into its merits the better, and if you are unable to return a true bill, my experience will not be verified.

We must bear in mind, when making comparisons between the permanency of prints of the present day and those of the past, that in the earlier days of photography absolutely fresh albumen was considered imperative in the preparation of paper—so much so, that each egg was broken singly into a cup in order that its freshness might be assured before being added to the bulk.

What is the moral of the little I have had the privilege of saying? Firstly, that if you wish to secure the greatest amount of permanency in your prints, use paper that has been prepared with absolutely fresh albumen, with nothing added but the salting medium. Secondly, whether you tone by the sel d'or or one of the many alkaline methods, do not overwork your bath. Thirdly, watch the behaviour of your ready-sensitized paper. Lastly—and this is only a hint—finish washing in several changes of warm water.

Bear these items in mind, and I think there will be less cause to complain of the fading of silver prints.

* Read before the Newcastle-on-Tyne and Northern Counties' Photographic Association.

RECREATION IN ART.

BY JOHN SIMPSON.*

To a Society such as this, with its several hundred members, the vast majority of whom are amateurs studying photography for the pleasure it brings, it may not be amiss to turn aside for an evening from the dry bones of technique and manipulation, to consider in what way photography stands related to other arts as a source of recreation and enjoyment.

To the professional, who has to attend upon the wants of a somewhat captious and exacting public, the practice of photography may be some *few* degrees removed from the domain of pure pleasure; indeed, if we are to believe the facetious "notes" and "incidents" recorded in the journals from time to time, it would appear that few occupations are more irksome, worrying, and wearying than the photographic portraitist's. So that even to them the following remarks may not be without their interest. They are, however, more particularly addressed to the younger amateurs of the Society—to those who, while delighting in the skill of a handicraft, exercising both brain and hand to the utmost, yet look upon the pursuit as a pleasant, a rational, and artistic pastime.

It is not necessary at this time of day to urge the necessity of recreation. Every one recognises the need for it; it is one of the prime necessities of civilised life. The more complex society becomes, and anxiety and worry ramify life in its various relations, commercial and otherwise, the greater is the need of sources of relaxation which shall give rest and change to those faculties and powers that have been perhaps overtaxed, or at least kept too long in a state of tension.

My special plea is for the higher forms of recreation, in that sphere where not only can our higher faculties be brought into active exercise, but where the light of genius sheds its rays upon our path, revealing the beauty, the grandeur, and sublimity of nature; that sphere is the sphere of art, and its seers, its prophets, its missionaries, are the true artists, under whatever name they may be known, and with whatsoever implements or tools they may wield their power. There is no recreation so beneficial, so much in unison with our constitution, as that which ministers to the imagination.

Photography, of all the arts, is one of the most *practicable* as a source of recreation in the largest and widest sense. It gives opportunity for the employment of every faculty. Brain and hand, muscle and nerve, must equally come into play. But not only these, which are but the generalities of our possession; there must come into full occupation, taste, judgment, observation, a quick sense of harmony, of space and time, of cause and effect, and, above all, a deep knowledge and love of nature. To him who possesses these qualities, not only will photography be an *available* art, but one in which he will find endless and ever widening recreation.

It may be safely affirmed that there are possibilities of art-culture latent in every one, be his daily calling what it may, and no better instruments exist for calling these possibilities into play than the camera and the sensitive plate.

With these a man may discover a whole continent in himself, of powers and capacities that were known neither to himself nor his friends. Many in this Society, I have no doubt, could verify that assertion in their own experience. By the use of the camera they have come to realise what beauty and grandeur are in nature, and their great ambition as well as delight is to be able to secure transcripts of these as mementoes of things their souls now love. Before they knew it, form had no poetry, no enchantment for them. Outlines and space were but elements of objects that were so common, and of "the nature of things," as to be unworthy of observation. Now, the camera has shown to them that all things, the commonest and the meanest, have a beauty, a charm, a character that is not only worthy of passing observation, but of transcription and preservation. Need I refer in illustration of this to the last popular entertainment of this Society? On that occasion (as well as on many former ones) there were representations of objects, the charms of which lay entirely in the delineation of form. This was particularly the case in groups of cattle and of birds. Few people but would confess to a liking of either horses or swans from their boyhood up, that liking resting, however, chiefly, if not entirely, on the intelligence and gentleness of the creatures, rather than their æsthetic qualities. Those, on the other hand, who "took" those groups I have referred to, took them because they had come to appreciate and love form. I say nothing about the sentiment that may exist in a picture of cattle listlessly standing knee-deep in a stream, or of sheep browsing on a quiet hill-side. Their forms are not the least of the aspects that strike the mental excitation. But when you find an amateur "catching" horses standing heads and tails in a stubble field, with no picturesque accessories to enhance or even to form a picture, be sure he has had his mind bent on securing those graceful lines, those facinating contours that have ever made the horse a favourite with artists and lovers of nature. He has caught the infection of beauty, and is on the way to understand its principles without the tedious drudgery of studying definition, explanations, and all the paraphernalia of science and literature.

Already he has mastered perhaps more than Hogarth could impart to him in his interesting "Essay on Beauty," with his investigations into the secrets of the ancient masters, and his laborious conclusion that it consisted after all in the use of the curved or spiral line—the line of beauty and of grace. But besides *form*, which is the *chief* object of the camera to secure, there is the indication of air, space, and distance, tone, colour, and definition to be obtained, and these must first be seen and appreciated before they will find their proper representation in the finished picture. This also, it is gratifying to say, was well illustrated in the collection shown at last meeting. Some sea pieces, with yachts in full sail and steamers *en route*, showed considerable feeling of tone and air effect, both sky and sea being, in many cases, harmonised remarkably; so soft and at the same time so firm were the relative tone-values that no difficulty was experienced in distinguishing degrees of distance and local effects. Those who set themselves to take "pictures from Nature" by the camera are thus bringing themselves into contact with the very spirit of Nature, from which contact, with its deeper knowledge and keener insight, there arise love and admiration, a desire ever to be with it, to share its bounties, and *this* is of the essence of real æsthetic recreation.

* Abstract of a communication to the Edinburgh Photographic Society.

Notes.

The Year-Book of Photography and Photographic News Almanack for 1884 is out of print.

We make this announcement with no little gratification, since it is the best proof that can be adduced of the appreciation of our little annual. Though the edition this year was considerably greater than on any previous occasion, this is the first time it has run out of print within three months of publication.

A new departure in photo-ceramics is announced. Last Friday, at the Russian Polytechnic Society, Lieutenant Pavloffski demonstrated a new process of producing photographic enamels, which—we have Mr. Warnerke's word for it—will revolutionize altogether our present plan of preparing photographs on porcelain. Not only this, but Lieutenant Pavloffski's process adapts itself to producing photographs on wood and canvas for engravers and painters. Let us hope, therefore, that Mr. Warnerke's opinion of the process, the details of which we shall publish next week, will be fully borne out in practice.

We much regret to announce, by the way, that a sad mishap has befallen Mr. Warnerke. While visiting the theatre at St. Petersburg a few days back, his pocket-book, containing some two thousand roubles, was stolen from him.

Mr. Robinson's new book announced as in the press by Messrs. Piper and Carter, is likely to prove the most popu-

lar work of the season. The chapters on art photography recently appearing in these columns from Mr. Robinson's pen will be incorporated in the volume, which will be profusely illustrated, and form a complete manual of picture-making by photography.

Mr. Moncure D. Conway made a happy use of the word photograph in his lecture last Sunday on the "Poetry and Prose of London." He spoke of the London Press, with its rapidity and minuteness of detail, as photographing the action of the world from day to day. It is impossible now, the lecturer said, to hamper or check "the free speech of this free city. The sun never shines through a day, but it prints here that day's photograph of the world. The eyes of our press go to and fro in the earth, and drag into the light every wrong and crime." A better compliment surely could not be paid, than to compare in this way the detail of the London Press with the detail of a photograph.

Next week Dr. J. M. Eder will contribute an important paper in connection with the past history of photography.

News of the awards made at the Calcutta Exhibition reached us by the last mail, and we are glad to find several well-known names in the list of honour. Thus, Mr. Frederick York secures a first-class certificate and a silver medal for a collection of lantern transparencies; Mr. H. Manfield, of Northampton, receives also a first-class certificate and silver medal for his "interiors," a series that has repeatedly won him honours in this country. Mr. G. Renwick, of Northampton, gets likewise a silver medal and first-class certificate for an exhibit of snow scenes, of which we have several times spoken highly in these columns.

The Autotype Company has not been overlooked at Calcutta, for their name is set down for a silver medal and first-class certificate in recognition of the excellent examples of photo-mechanical printing they forwarded to India; while equal honours fall to Messrs. A. and W. Dawson, whose names are connected with some exceedingly fine typographic etchings and photo-engravings.

Writing on the subject of the photographic section of the Calcutta Exhibition, our friend Major Waterhouse says: "Some of the finest pictures in the Exhibition are by Mr. J. W. Lindt, of Melbourne, who takes a gold medal, while a similar high award falls to the lot of Messrs. Bourne and Sheppard, of Calcutta, who also make a very fine show."

The Exhibition closed on the 8th of this month. The Military Geographical Institute of Vienna, the Military Topographical Institute of Florence, and the Military Photographic Institute of Brussels, all take silver medals for their photo-mechanical work.

Sorry tidings if it come to pass. The jury on the Chadderton accident are of opinion "that no person should be permitted to *give exhibitions of explosive gas* without a licence for such purpose first obtained.

The notice of Dr. Eder's book, "The Chemical Effect of the Spectrum," in last week's *Athenæum*, bears somewhat on the doubts which were expressed on the subject at the last meeting of the Photographic Society. One or two of the speakers, it will be remembered, were more inclined to place faith on actual everyday experience in the dark room as a test for actinic light, than on photographs of the spectrum, alleging that sufficient was not yet known—even by those who had investigated the subject—to make spectrum tests reliable. Still, the reviewer of Dr. Eder's book is rather difficult to please. In the first place, he says that the title is a misnomer, since it treats "in a very general way of the chemical agents which are susceptible of change under the influence of the sun's rays," while it contains "very little information as to the extent to which chemical changes are produced by the several rays of the prismatic spectrum, whether isolated or combined in action." The reviewer also alludes to what he takes to be a contradiction, in the following terms: "The author and his translator refer all the changes with which this volume deals, to the chemical action of the luminous rays," yet in the last chapter, which is devoted to the general effect of the spectrum, we are told that "there is a point in the spectrum where the chemical action of light is *nil*, this point being where the luminous influence is the most powerful." Well, if we had no critics, we should have no controversies.

Mr. Greenwood Pim has recently been advocating before the Royal Society of Edinburgh the use of eosine-treated bromide plates where colours have to be photographed. The plates he found so beneficial are prepared, he tells us, with eosine in the presence of an alkali, usually ammonia, and they appear to owe their property, he says, more to the chemical action than to the physical character of the red colour; for a screen of eosined collodion interposed between a band of coloured ribbons and a sensitive plate had but little effect, except so far as it exerted a general slowing action.

The French Government is about to make a wise move, which our authorities at Greenwich would do well to follow. Some time ago Admiral Mouchez addressed the Minister of Public Instruction on the subject of removing the Astronomical Observatory at Paris to a distance from the metropolis, where the murky atmosphere, no less than the noise and vibration, interfered with scientific work. Admiral Mouchez' suggestion was submitted to various authorities, with the result that his view has now been universally adopted, and the old observatory is to be abandoned. If the light and atmosphere of Paris are bad, how much worse are the thick vapours of the Isle of Dogs that frequently envelop the Royal Observatory at Greenwich!

Some of the continental photographers are very much alive to the value of keeping their names before the public. The other day, in a sleeping-car between Madrid and Paris, we noticed on the walls photographs of several places of resort and hotels of note, one of the best being an interior of the dining-room at a Naples hostelry. The picture was a very good one, showing the decorated

panels and tables neatly laid for dinner, and it served two purposes: first, as an advertisement of the hotel, and secondly as an advertisement to the photographer, Signor Brogi, of Naples. This idea of double advertisements our photographers might occasionally make use of with advantage.

Dr. Eder promises shortly a little work on "Instantaneous Photography," illustrated with forty wood-cuts and one collotype. It is issued under the auspices of the Viennese Society for Diffusion of Natural Science.

A funny thing happened at the last South London meeting. Mr. Robinson sent a copy of his charming composition "Fading Away"—a sick girl reclining on a couch—one of the most touching pictures Mr. Robinson has ever attempted. But some chemists got hold of the print and examined it crucially; they regarded it as an example of imperfect washing, and anxiously searched its surface for first symptoms of "Fading Away."

At a Conversazione of members of the London Tricycle Club, held last week at the Cannon Street Hotel, a tricycle specially arranged for the conveyance of photographic apparatus was exhibited. The arrangement is the invention of a Mr. Pillin.

The portrait club system has been introduced into America. The *Danbury News Letter* announces that a Mr. Hendricks, of Stamford, Connecticut, "is building a photographic studio which will be very convenient, as the skylight is on a level with the street, and especially adapted for the instantaneous cabinet photographs which he proposes making at club rates." These rates are two dollars and a-half for a club of twelve, and paying thirty dollars for twelve tickets, the thirteenth ticket being free.

A society which is doing such good work as the Society for Photographing Relics of Old London ought to be more widely known than it is. Is it not possible to let the public see some of its results? There is a wide-spread interest in old London now so rapidly disappearing, and photographs having an historical or antiquarian association might well be deposited in some place where they could be open to inspection—say the South Kensington Museum or the Guildhall Library. Only a fortnight ago, some one, unaware of the existence of the Society, wrote to the *Athenæum* suggesting that the old houses in Wych Street, now in course of demolition, should be photographed. As it happened, these houses had been photographed by the Society in 1876; but who knew of it besides the members ?

There is plenty of light for taking portraits in Algiers; still the photographers of the fashionable Brighton of Africa ask their customers to come in light-coloured clothing. "Les toilettes claires sont preferables," is the advice given at one of the leading studios.

A correspondent, who confesses that his acquaintance with astronomy is very limited, writes to enquire whether any photographs of Venus were taken "during the recent occultation!" We fear not. A photograph of the "occultation of Venus" would only be paralleled by the definition of darkness which says it is like "a negro in a coal cellar looking for a black cat."

Patent Intelligence.

Applications for Letters Patent.

4759. Theodor Schmidt, 122, Oranien Street, Berlin, Manufacturer, for "Improvements in photograph holders."—Dated 12th March, 1884.

4906. Arthur Fullerton Howman, George Street, Oxford, Oxfordshire, Photographer, for "Dark-slide for photographic cameras."—Dated 14th March, 1884.

4989. James Sturrock, Cashier, Dundee Advertiser Office, Dundee, for "Changing sensitized plates in photographic cameras.' —Dated 17th March, 1884.

Specifications Published during the Week.

3709. Francesco Antonio Marra, of No. 69, New Bond Street, in the County of Middlesex, Artist, "Improvements in the manufacture or production of backgrounds for photographic and other pictures."

My invention has for object the manufacture or production in an economical manner of a brilliant, strong, and durable background that will show up and prevent fading of photographs, and which is applicable also to Indian ink and other drawings or paintings. To produce such a background according to my invention, I employ metal in a pulverized or flocculent state, which I cause to adhere to the paper or material that contains the picture by means of adhesive material such as size. In practice, I find it advantageous to coat or cover the paper or material containing the picture with size of the kind used by gilders, taking care to exactly follow the outlines of the picture; then I sprinkle or flock the metallic powder, or powders, or flakes, on to the layer of size, applying pressure so far as needful to obtain an uniform coating, after which the whole is slowly dried, producing a strong background of paper or other fabric and metal so combined as to resemble a sheet of metal with a sparkling roughened surface, and practically imperishable. Various kinds of metals, such as gold, silver, bronze, aluminium, and others may be employed according to the result desired to be produced, and by the use of two or more different metals polychromatic effects can be obtained.—*Provisional Protection only.*

3,800. Alberta Mary Frances Caspar, of 200 and 223, Regent Street, in the County of Middlesex, Artist, "A new process for preparing and painting photographs, prints, or drawings so as to resemble oil paintings on canvas."

The photograph, print, or drawing selected should be quite dry, and fastened face downwards to a drawing-board or table with four drawing pins. It should then be rubbed with glass or sand paper until it becomes quite thin. The surface of this reverse side must then be spread with an adhesive gum, or paste, or glue, and if a photograph, must be previously soaked with water. The photograph, print, or drawing so prepared is then covered by coarse canvas, and this is pressed and rolled until the fibre of the canvas penetrates and shows through the photograph, print, or drawing. The photograph, print, or drawing and canvas is then allowed to dry, while still fastened flatly to the board or table. When dry, the canvas is stretched on a stretcher. After the canvas is so stretched, the picture is clearly shown thereon, and must be painted with transparent albumen colours mixed with water or a water medium, coarse touches of body colour being freely used to add to the illusion. When the picture so painted is dry, a coat of varnish can be applied to the whole surface of the picture, which will then be ready for framing. The novelty consists in—

1. The preparation of the surface of the photograph, print, or drawing so as to admit of the canvas showing through it.

2. The pressing or rolling of the canvas upon the prepared photograph, print, or picture, so that the canvas shall be seen through the same.

3. The painting in transparent albuminous colours in water which produce upon the canvas so prepared as aforesaid, the resemblance of oil paintings.—*Provisional Protection only.*

Patent Granted in America.

294,485. H. Mandel, Astoria, N.Y., "Process of making copies of tracings." Filed June 26, 1883 (No specimens).
Reproduction by the dusting-on process is claimed.

WAX MATCHES FOR PRINTING TRANSPARENCIES.

BY H. H. CUNNINGHAM, B.A.

In my early attempts at making transparencies by artificial light on gelatino-bromide plates, I found more or less difficulty in determining the amount of exposure necessary; and this difficulty became greater when using different sources of light.

For example, a time exposure to a candle is fairly accurate when the same candle is used throughout, and the same distance from the source of light is observed. But even in the case of candles, there is a considerable variation in the light, according to the condition of the *wick*, both in quantity and quality, considered actinically—*e.g.*, a long wick gives a large flame but a yellow one; and though the total of light is greater, the amount of actinic light is probably much less; at any rate, it is very difficult to estimate.

Again, gas varies very much in the quantity and quality of the light being emitted, according as the quality and pressure of the gas varies; and the light from paraffin lamps is also of a very variable character, and hardly to be trusted for uniformity. It therefore struck me that a fairly uniform, simple, and at the same time easily obtainable source of light, would simplify the production of transparencies, and I found what I sought in the simple wax vesta match. These vary very little in length and thickness among those of the same make, and they can easily be picked out of a size, and, if necessary, cut to an equal length with a pair of scissors; and since the same weight of wax burned in the same-sized wick (temperature and barometrical pressure being unnecessary to consider here) will give as near as possible exactly the same total of light, it will be evident that a very accurate measure of light is obtained by burning a given number of similar wax vestas.

My practical method of proceeding is this. At a distance of 12, 18, and 24 inches from where the printing-frame is placed, I have marks on a board, and I bring the wax vesta in position by sticking it on a pin, raised on a block of wood to bring it central with the printing-frame. Then, all being ready, I strike another match, touch the one on the pin, which of course instantly flames up, and which I allow to burn for half or whole of its length, according to the density of the negative. Of course the first match is blown out as soon as the standard is ignited, and the head of the standard is pulled off as soon as its presence dulls the flame. As an example, an ordinarily dense negative at 18 or 24 inches distance will require about half of one of Bryant and May's wax vestas, burnt in the manner indicated. Dense negatives require two or more such vestas to be burnt, and they may be burnt either together or consecutively, it makes no difference, as we count the total of light as depending not upon the time of exposure, but upon the weight of wax burnt.

HISTORY OF PHOTOGRAPHY IN GLASGOW.

BY ANDREW MACTEAR.

After some preliminary remarks on the general history of photography, the author said: I will now, so far as certain data and my memory serve me, trace out "The History of Photography in Glasgow," and I hope that I may be corrected by any member present wherein I may be wrong.

One of our members, Mr. Samuel B. Brown, being in Paris in 1839, received from M. Daguerre one of his pictures, which on his arrival in Glasgow he exhibited in Royal Exchange Square, and which I recollect seeing. Dr. Paterson (to whom the photographers in Glasgow are largely indebted) as usual with him in anything new and worthy, set to work at it at once. Mr. Brown himself and another member, Mr. Hugh Wilson, were also engaged in it, but who has the precedence I cannot determine; perhaps they will be able to do so.

In June, 1842, I got over one of the American apparatus—I think the very first in Glasgow, and which I have still. The lenses are about four inches diameter. It has a very short focus, and works only a one-sixth plate, and can be worked in a room at a common window. It was so powerful that I worked with it by the north light, and I exhibited two portraits in the exhibition of paintings as having been done by a northern exposure.

In 1841 the first professional photographer who came to Glasgow was Mr. Edwards, who opened in Buchanan Street (opposite the Arcade), and who in dull weather used to secure the loan of my camera. The glass of his place was entirely blue, as was then the custom. In the same year Mr. Treffray also began at the corner of Union and Argyle Streets. Then came Mr. Pickering, and in 1846 Mr. Bernard commenced; then the art made a rapid advance—in fact, his pictures were splendid. Messrs. Borthwick and Stanley next came, and in 1849 Mr. Hughes succeeded Mr. Bernard. Then Mr. Gardner, Mr. Young (1850), and Mr. White successively came forward, the Daguerreotype process alone being worked by all the above.

In June, 1851, Archer's collodion process was published in the *Art Union Journal*, and within five months afterwards Dr. Paterson not only made the collodion, but produced excellent pictures by that process. He communicated the new mode to his friend Mr. King, Mr. Duncan Brown, myself, and many others, and he may fairly be said to be the father of the collodion process here, as he most willingly communicated any knowledge he acquired to all inquirers.

Professor Taylor has also been the means (through his interesting lectures) of producing many excellent photographers, both amateur and professional. I have met with many of them, and they speak highly of the Professor's ability and knowledge of the art.

Our President, Mr. Kibble, must now rank and be awarded the first place amongst our amateurs (which are legion since the collodion process), not only for his great attempts, but for their quality, and his indefatigable exertions in perfecting an instantaneous process in which he has been so successful, and specimens of which I am sure all of you have seen.

I hope I will be excused when I make no attempt at enumerating the names and abilities of such a multitude of amateurs and others who are working the art in all its various styles, as it would be both invidious and injudicious at this meeting.

Within two years (from the simplicity and cheapness of this new process) we had establishments for it alone opened by Messrs. Dessurne (March, 1852), Urie, Taylor, and McNab (May, 1852). When the Daguerreotypists had to follow in the wake, and now the collodion process has become general. I do not know if a Daguerreotype could or would be taken in Glasgow. I think we cannot omit mentioning one name which for coloured positives stands almost unrivalled—I mean that of Mr. Douglas, one of your Council.

The month of June, 1856, ushered in a new feature in the art here, when Mr. McNab exhibited his coloured specimens at the foot of Buchanan Street and elsewhere. I have seen crowds looking on admiringly at these pictures, and I am glad that Mr. McNab has not only reaped golden opinions, but golden rewards for his bold attempt.

Mr. Werge, Mr. Urie, and Mr. Stuart (who commenced in 1855), Mr. Peebles (an excellent calotypist), Mr. W. Young, Mr. Bowman, and Mr. Cramb have all followed in this new channel, and Glasgow can now feel proud of her high position in the photographic world.

I have, therefore, given you the brief outline, which to have been filled up with all the details that might have been given would have occupied too much of your valuable time, and I would take it kind that any errors which may have crept in may be corrected by those who can do so.

[Abstract of paper written in 1864, and re-read before the Glasgow Photographic Association on March 6, 1884].

ON BICHROMATED GELATINE FILMS AND THE STANNOTYPE PROCESS.

BY W. LANG, JUN.*

The action of light on the bichromates in presence of organic matter has been known for a very considerable period. Mungo

* Read before the Glasgow and West of Scotland Amateur Photographic Association.

Ponton, in 1839, was the first to base a process on this reaction. He applied a solution of potassium bichromate to paper, dried it in the dark, and on exposing to light he found that it darkened very considerably. The chromic acid in the salt was reduced to chromic oxide. Placing paper prepared in this manner behind a copper plate engraving and exposing to light, a negative copy of the engraving was obtained. To fix such a picture, all that was necessary was to wash in water, so as to dissolve away the unaltered bichromate. Here is a print obtained in a similar manner from a copper plate engraving, and which you see is a negative reproduction which is capable of producing in its turn a picture having the lights and shades as in the original. Becquerel (1840) demonstrated that the reduction of the bichromate was due to the presence of the size in the paper, and he devised a process which consisted in mixing the bichromate with starch-paste and applying it to paper. On exposing to light under a copper-plate engraving, and afterwards immersing in an alcoholic solution of iodine, a blue reproduction of the engraving was obtained; the rationale of this change being due to the fact that in those parts where the light had not penetrated (the dark parts of the engraving) the starch remained unaltered, and was able to form the blue iodide of starch. This iodide of starch is, however, a very unstable substance, and although the picture appears strong enough when wet, it loses a good deal of its character in drying, changing from blue to a pale violet. Here is one of Becquerel's pictures.

Hunt worked also with the bichromates, and to the various processes he brought forward, he gave the generic name of chromotype. They consist essentially in forming a chromate of copper in the paper, and after exposure behind the engraving, developing the picture by means of gold, silver, or mercury salts. Some of these early light pictures I have here reproduced.

While it was sufficiently apparent that light had wrought a change in the bichromate employed in these examples, it was further discovered that the organic matter was itself altered in its physical character; in fact, Becquerel's method of producing a picture with the lights and shades the same as the original shows clearly that the starch had been on where the light had access in such a way as to lose its characteristic property of forming a blue compound with iodine. Mixed with a bichromate and exposed to light, gelatine, gum, starch, albumen, &c., were all found to be rendered insoluble. Now what is the cause of this insolubility?

Two theories have been put forward to account for it.

First.—That the organic matter is oxidised at the expense of the chromate, which is reduced to chromic oxide, and the insoluble body is virtually oxidized organic matter.

Second.—That the organic matter forms a true compound with the chromic oxide reduced by light. This view was first propounded by Mr. Swan, of Newcastle, in a paper read before the Photographic Society of Great Britain on May 10, 1870, and it is the one which has the most evidence in its favour. There is, however, much complexity involved in the chemistry of the matter. Mr. Spiller has been making some experiments with the various chromates and bichromates with a view to unravel some of these reactions, and those interested will find a short article by the gentleman in question in the Photographic News Almanac of the current year, giving some details of what he has done and intends doing. In addition to the prints already shown, where bichromate of potash has been employed as the sensitizing agent, I have one or two here prepared with ammonium bichromate and the normal chromate of ammonium. In the case of normal chromate or yellow chromate of potash, light has no great reducing action. In the case of the normal chromate ammonium it is a very sensitive body indeed.

A very curious fact in connection with these changes was demonstrated by Captain Abney. Taking a piece of paper coated with gelatine rendered insoluble by alum, and duly sensitized with a bichromate, and exposing under a negative, he placed it in contact with a piece of carbon also impregnated with a bichromate, and the two surfaces were kept in the dark and under pressure for some ten or twelve hours. The paper that had received the impress of light communicates the action that the light had started to the pigmented tissue, the result being that a picture is obtainable on the film which has never been exposed to light.

The great experimenter in this field of work was undoubtedly the French chemist Poitevin; it is to his researches more than to any other that the whole superstructure of carbon printing, autotype printing, the powder processes, the various collotype or printing with lithographic ink processes, has been raised. As far back as 1848 we find Poitevin devoting himself to the production of photographic relief pictures. He named his process helioplastic, and his *modus operandi* was as follows:—A bichromated gelatine film was exposed to light under a positive or negative according to the nature of the relief picture wanted. It was developed by being allowed to swell in cold water, whereby those parts acted on by light refused to swell, while those that had been protected swelled. This relief picture was hardened in a solution of sulphate of iron, and, after draining, a plaster cast was taken of it. From this again, by means of a fusible composition, another casting was taken, to utilize which, he coated with copper by means of a galvanic current.

Poitevin, however, does not seem to have carried his researches sufficiently far to have made his process a truly practical one. In reading the record of these early experiments, Poitevin seems always to have worked with gelatine in the moist state. It is to Woodbury that we are indebted for a rational process of relief printing, and the reaction by which he obtains his reliefs is the solubility in warm water of those parts of a bichromated film which have been protected from the light. Woodbury's patent for the production of those pictures, known under the name of autotype or Woodburytype, was taken out in 1866. We are all more or less familiar with these productions, and their beauty, apart from the fact of their absolute permanence, attests the value of this very perfect photo-mechanical process.

It may be interesting to note that all those pictures of actors and actresses which appear in the magazine *The Theatre* are done by Woodburytype. In France, the process does not bear the name of its inventor, but is known under the name of photoglyptic. The Woodbury process, while giving such excellent results, is by no means one that amateurs could avail themselves of, as it necessitates the employment of a hydraulic press, whereby the hard gelatine relief is pressed into a bed of lead or other soft metal, which forms the printing mould. However, Woodbury within these last two years has brought forward a process which meets, I think, the requirements of amateurs. To this he has given the name of stannotype, inasmuch as the relief picture is covered with tin foil. Tin-type might have expressed the same idea more graphically, but I think you will admit it lacks dignity. In Woodbury type the start is made with a negative, in stannotype with a positive or transparency. And Woodbury recommends that this be produced by means of the carbon process. The negative from which this is produced will require to be masked, so as to give clear glass all round the finished transparency; the reason of this will be obvious as we go on. The timing of the exposure of the tissue under the negative must be regulated by a photometer, and Woodbury's form of this instrument you have here. After the exposure has been completed, development of the tissue is to be made on a collodionised glass plate well washed to free it from the ether and alcohol. The tissue, having been allowed to soften in water for a short period, is squeegeed on to the glass plate, and, after remaining some little time in contact, the plate with the tissue is plunged into water about 95° F., when the development of the picture takes place so soon as the original paper of the tissue comes away. You thus have a positive picture reversed as regards right and left, and outside of the picture you have clear glass. The reversal of the picture at this stage is necessary, otherwise your mould would throw off reversed prints. Then carbon transparencies require, as a rule, strengthening, and for this purpose a solution of permanganate of potash is made use of—a quarter of an ounce permanganate to one pint water. This gives a non-actinic colour to the picture, the character of which you can judge of from the example I now put forward. You will see that this picture has been masked in such a way as to leave a margin of about one-eighth of an inch clear glass all round the picture. For my own convenience I have made the transparency on a whole plate, but of course the half plate would have been the correct size to have produced the transparency on.

(To be continued.)

Correspondence.

HALATION.

Dear Sir,—You will perhaps think me rather presumptuous, but on reading the able article of Dr. Tulloch in this week's News on Halation—I myself having tried a

number of different things to prevent it—have found the very best thing is a vegetable black, a piece of which I enclose. Scraped with a pen-knife it is used with a little table beer, applied to the back of the plate with a flat camel's hair brush. I send you also by this post a photograph of an interior, the windows opposite the lens being blue and white glass, in which there is scarcely any perceptible halation. I might mention that the black comes off immediately on being wetted.—I am dear sir, yours obediently, F. W. Broadhead.

[The photograph which Mr. Broadhead sends quite bears out his statement.—Ed. P.N.]

THE ETHER LIME-LIGHT.

Sir,—Will you allow me to correct two *errata* in the article on the above? In the sixth and ninth paragraphs, for liquid ether being (in three places) spoken of as driven "with" the oxygen supply-tube or oxygen-bag, it should read "into," as, no doubt, most have discovered. And in the last paragraph but two, referring to safety chambers, instead of "heat" being required, it should read: "They, however, reduce the pressure and the light considerably, and two cwt. will be needed to get the same result as with one cwt. without them." Lewis Wright.

A CAUTION.

Sir,—I write as soon as I can to ask you to insert a caution in your next issue. A stout elderly man, with a plausible manner, is going about amongst photographers with apparent introductions from other photographers who do not do the special kind of work he comes about. He represents that some important work is immediately wanted by some well-known firm, makes an appointment for the photographer to wait on said firm, subject to their reply to the memorandum he asks for, and of course obtains, to use against some other probable victim. When he goes he suggests drinking your health over the important introduction. He looks so respectable and genuine that I dare say he sometimes succeeds better than he did with me—I gave him a few pence. When he had gone I telegraphed to the firm he professed to come from for fuller instructions, and got a letter to-day saying they had half-a-dozen letters and telegrams about the same thing. They do not want any photographing done, and would like to bring the man to justice, and say that he has been going by the name of "Herbert."—Yours truly, H. D.

Proceedings of Societies.

London and Provincial Photographic Association.

A meeting of this Society was held on Thursday, the 13th inst., Mr. A. Cowan in the chair.

The usual routine business having been disposed of, the Chairman invited Mr. T. Bolas, F.C.S., to deliver his promised lecturette on "Photo-Block Printing."

Mr. Bolas commenced by saying that it is a matter of the greatest interest to every photographer that his prints should be permanent. The future of photography will not be very promising if the silver print holds its own against permanent printing. He remembered asking Mr. Edwards some eight or nine years ago what he considered was likely to be the printing process of the future. Mr. Edwards at once replied, block printing. The results recently obtained indicated that he was right.

Electrotype and other block processes are between twenty and thirty years old; but it is only recently there has been a revival of these block processes. To give a list of all the photo-block processes actually at work, and treat each separately, would occupy a dozen lecturettes, therefore only the most practical will be dealt with, touching on points here and there.

Nearly thirty years ago Paul Pretsch came from Vienna, and, with the perseverance worthy of a great man, attempted to introduce his method of printing in half tone by means of the reticulation bichromated gelatine undergoes when soaked in water, after being acted upon by light, this serving as the basis for producing an electrotype.

If bichromated gelatine is poured over a plate, dried, and exposed to light under the negative, then soaked in water, it will be noticed that the smoothness is on the portions which have been most exposed; these constitute the blacks.

The Pretsch process was not worked much commercially. A block illustrating the method will be passed round—this block having been used in printing an illustration of the process in the Photographic News, and in the current Year-Book, page 80.

The company formed to work the process came to grief, but Mr. Dallas, who was with them, makes blocks of a similar character. A Dallas block and print will now be passed round. Mr. Debenham, who made the negative, sent it to Mr. Dallas, and here is a print. The lights and shades are worthy of notice. The Pretsch block, and probably the Dallas blocks, are moulded, as already stated, from the reticulated gelatine original.

Perhaps it is scarcely worth while to lecture on lithography or zincography. Suffice it to say that a fatty image is taken which adheres to the stone, the stone being next moistened with gum-water. An inky roller is then passed over; the damp parts refuse to take the ink. The image on zinc or stone may be converted into a typographic block by treatment with dilute nitric acid, which dissolves away the bare stone or metal to a certain depth. Some care is necessary to prevent the acid working underneath or under a cutting, and thus destroying the fine lines; by dusting with fine resin-powder and warming the plate, this is in a measure prevented. Much work of this kind is carried on daily in many houses in London.

Examples of zinc blocks and fatty images on stone having been passed round, the lecturer went on to say, that the production of a transfer in fatty ink is equivalent to a block. A great many processes might be mentioned, but enough would be said to indicate the method of obtaining an inky transfer.

Translating a Woodbury relief into line or stipple was next dealt with, in their application to photographic images, showing the relation of tone. A gelatine relief on glass having been passed round, the lecturer said it would be understood from that what the nature of a relief is. The thin portions represent the lights, and the thick portions the dark.

Mr. Ives, of Philadelphia, inks a Woodbury relief with ordinary printer's ink. An ordinary printing roller inked, and sufficiently soft to penetrate the depth of the relief, is passed over. If a sheet of ordinary white paper is laid on and pressure applied, we should get an intense black and white image; if grained paper be used, we shall obtain an image with half tones. If we were to examine this grained paper under a microscope, we should see a number of pyramids. A relief was inked and placed in a small press with thicknesses of grained paper to illustrate Ives' method of converting Woodbury reliefs into half-tone.

An Ives' block and print from the same were passed round, the print being made in an ordinary machine, throwing off twelve hundred impressions per hour, and in which no particular care was taken. Comparing the rapidity of silver printing, it sometimes in dull weather requires two days to get a single print against twelve hundred per hour; and taking into consideration that silver prints fade, and block prints do not, a good deal of advantage rests on the block method.

Other methods have been devised, and exceedingly fine work has been done. Here is an example of the Meisenbach process, in which there is a good deal of quality. Block-printing by photographic means is in its infancy. When the manipulations have been studied out as much as silver printing, we may obtain results quite equal. At all events, in the example now shown there is a very good attempt of quality. Three methods of converting Woodbury reliefs into stipple have recently been patented by Zuccato. The first consists in planing metal into a series of pyramids or ridges; this is inked, a sheet of paper is laid on it, over this the relief, when a transfer is obtained by means of pressure. In the second case, fine gauze is introduced; while in the third case the relief is pressed against a stippled or grained impression on a zinc plate or lithographic stone. This causes a spreading out of the lines, which, uniting, forms the blacks of the picture. Mr. Bolas concluded by referring to Mr. Woodbury's method of backing up the negative with fine or coarse net, and from this making a grained relief, promising on some future occasion, when the competition is keener against silver printing, to renew the subject.

The Chairman, in moving a vote of thanks to Mr. Bolas, said they had all listened to his lecture with the greatest interest. He, the Chairman, well remembered assisting Paul Pretsch to make electro-type blocks twenty-nine years ago.

A hearty vote of thanks having been accorded, the Chairman invited a discussion or questions to the lecturer.

Mr. W. M. Ayres, having spoken very highly of the work produced by Paul Pretsch, and his acquaintance with that gentleman, contended that silver prints properly produced are permanent.

Mr. J. Barker wished to know how a gelatine relief is made? which roller is the most suitable to employ? and may common sixpenny ink be used?

Mr. Bolas replied that a strong gelatine solution is made (such as Nelson's No. 2 being used) in which sugar and bi-chromate of potash is dissolved, paper is coated with the melted mixture to the depth of 2 m.m., dried, exposed under a suitable negative, rendering the gelatine insoluble in the exposed parts. The paper is then soaked in water, and mounted on a glass plate; as the gelatine softens, the paper can be stripped off. With regard to the other questions. The ordinary lithographic roller made of sheepskin is suitable; the composition roller, made of glue and treacle, is not suited for stone work, on account of the moisture present; it may be used for anything not in itself damp. Very good prints can be obtained with sixpenny ink if it is a good sample; but as so little is required, a more expensive ink is preferable, as it will go farther, and is of better colour.

Mr. A. L. Henderson enquired if the amount of relief was in any way due to the thickness of the gelatine coating?

Mr. Bolas.—No. Provided the coating is thick enough, the depth of relief is determined by the action of light.

Mr. Henderson desired to know what effect would be gained by the addition of a hard cutting substance to the ink.

Mr. Bolas instanced the photo-gravure process designed by Mr. Woodbury, examples of these being shown at the recent lectures before the Society of Arts.

Mr. A. J. Brown suggested crushed hard bottle glass as being suitable.

Mr. Barker suggested glass-paper, which could be easily procured of suitable grain.

Mr. Bolas said crushed glass suitably prepared is an article of commerce.

Mr. Henderson did not think Sprague's ink-photo process answered the requirements of photographers.

Mr. J. H. Hare.—Is Sprague's process worked like any shown this evening?

Mr. Bolas said the general impression is, a fatty image is put on a litho stone, the stipple being either a Pretsch grain or mechanical. Very good results are obtained by the process, and in judging the capabilities of a process, only the best, not the worst examples, should be taken. Probably Mr. Henderson would agree with him, that there are good and bad collodion negatives as well as many bad silver prints.

Mr. J. Traill Taylor.—Is Mr. Bolas acquainted with a process suggested some years ago by Winstanley, and which he (Mr. Taylor) thought was the first application of the Woodbury process to block-printing? Mr. Taylor then went on to describe the manner of arranging a quantity of suitably-shaped needles so as to permit their falling by gravity on the film; in this state the needles are clamped, raised, and the series of points have a flat stone passed over them. This leaves them either sharp or blunt, depending on the irregularity of the gelatine surface, the impression being a counterpart of the negative, the small dot forming the lights, and the larger dot the blacks.

Mr. Bolas said a client consulted him a few years ago on the subject, and he went into the matter. There were mechanical difficulties not easy to overcome, which, added to the cost of getting square needles manufactured perfectly true, led him to consider the method impracticable.

Mr. Henderson said Mr. Bullock (Leamington) introduced a process some years ago similar to Messrs. Sprague's.

Mr. Bolas replied that in 1866 the Photographic News gave illustrations of the process.

The Chairman having thanked the lecturer for replying to the questions, announced the presentation of two books for the Society's library, for which votes of thanks were accorded.

Photographers' Benevolent Association.

A special Board meeting was held on the 5th inst., at 181, Aldersgate Street.

The minutes of the previous meeting having been read and confirmed,

Messrs. Muller and Collius were elected members of the Association.

The list of members requiring situations and correspondence was then submitted.

The following alteration of Rule 4, clause 1, was then proposed by Mr. Ashman, and seconded by Mr. Ganly—"That subscriptions shall be 10s. per annum, payable quarterly, half-yearly, or yearly, which shall entitle the subscriber to one vote at general and special general meetings; also at each election of pensioners. Rule 4, line 9, word benefit, be struck out."

Mr. Ashman, speaking in support of his proposition, said the existing rule did not allow an honorary subscriber to receive assistance should misfortune overtake him. That he considered a mistake, and to his knowledge deterred some of the profession from supporting the Association. He had no fear that by removing the distinction between the classes, that those gentlemen who had hitherto ranked as honorary members would withdraw their support; the proposition gave them the option of being donors, or donors and members. He would like to see them enrolled as members, and the balance of their usual subscription considered as a donation. At the same time, it would enable those whose position was not fully assured, to feel that in case of need they would be entitled to the support which the Society could render. Again, the reduction of the subscription would enable the assistants who could not afford to subscribe the yearly subscription in once, to do so by two payments of 5s., or four of 2s. 6d., as circumstances would permit. This he believed would considerably augment the strength of the Society, and that most desirable object having been attained, the success of the Society was certain.

Messrs. Ganly, Hall, Thorne, and others spoke in favour of the proposition, which was put to the meeting, and carried unanimously.

Mr. Collins, the son of the late Mr. C. G. Collins, was elected as a member of the Board of Management, and the meeting concluded.

Newcastle-on-Tyne and Northern Counties' Photographic Association.

The ordinary meeting of this Association was held in the College of Physical Science, on Tuesday, the 11th inst., Mr. J. B. Payne in the chair.

The minutes of the last meeting having been read and passed Mr. Andrew Ross, Mr. John Russell, Mr. J. H. Inness, and Mr. F. W. Morgan were nominated for membership.

Mr. R. S. Freeman read a paper "On the Permanency of Silver Prints" (see page 182).

The Chairman remarked that the subject was of a very interesting character, and that no one was better qualified to speak and write on such a subject than Mr. Freeman. Personally, his own experience of silver printing had been considerable, and he detailed an experiment he had conducted some time ago. A sheet of paper was sensitized, divided in two, and these halves were printed together to the same depth as nearly as possible under a mask, and vignetted. One-half was toned, and the other not toned. They were fixed together, washed together, mounted together on the same mount, and exposed together to sunlight. The *toned* print began to fade in the vignetted portion, and in three months had faded altogether. He (the Chairman) remarked that this had never been satisfactorily explained.

Mr. J. P. Gibson was opposed to the use of the sel d'or bath, and did not agree with Mr. Freeman's remarks on the use of ready-sensitized papers, especially those prepared with albumen in a state of decomposition. He (Mr. Gibson) had used ready-sensitized paper for many years, had always found it equal in quality to the paper he had sensitized himself, and far less trouble. He used a toning bath composed of chloride of gold and washing soda, being careful not to use too much of the latter, and he always took care to have his fixing-bath alkaline. Carbonate of ammonia, in the proportion of about two ounces to the gallon of hypo. solution, was used. He thought that damp was chiefly to blame in cases of fading, and some mountants were totally unsuitable. He preferred himself, for mounting purposes, a solution of gelatine with a large proportion of alcohol added.

Mr. E. Sawyer advocated the use of warm water for washing prints.

The Chairman reminded members that the late Professor

Marreco, in a paper read at one of the early meetings of the Association, proved, from experiments, that the copious washing of silver prints so much recommended in photographic text-books was quite unnecessary, and that with care the hypo could be easily. perfectly, and quickly eliminated.

Mr. P. M. Laws deprecated the practice some photographers had of overworking their baths. He always made fresh baths, using as much gold as was necessary, and then discarding the bath. He considered that gold was one of the cheapest chemicals they used.

Mr. Proctor said he had no prints by him. He had, in conjunction with Mr. Swan and Mr. Pattinson, produced many years ago the first prints ever done in Newcastle. They were on plain paper, salted, and sensitized; but they faded very quickly. That was before the introduction of albumen. He (Mr. Proctor) thought very little was known then of the cause of fading, and that they knew very little even now of the matter. The metals forming the tones of the print would be probably in the form of sulphide, and this might eventually turn to sulphate; but, whatever they were, damp and sunlight would favour such chemical changes.

Mr. Freeman narrated his first experience with ready-sensitized paper, and the failure (by fading) which resulted. He would not condemn *all* ready-sensitised papers, as he had found some to be excellent in all respects. He (Mr. Freeman) showed, at the close of his paper, a large number of prints of various ages. Some mounted cartes of the Exhibition of 1862 were excellent. They were toned in the sel d'or bath, and mounted, he stated, with a freshly-prepared solution of gum-arabic.

On the proposition of the Chairman, a hearty vote of thanks was accorded Mr. Freeman.

Glasgow and West of Scotland Amateur Photographic Association.

The usual monthly meeting was held in the Religious Institution Rooms, Glasgow, on Tuesday, the 11th of March, Mr. Hugh Reid, President, in the chair.

Messrs. F. C. Buchanan, James Harvey, A. W. Hogg, and John Sheriff, were elected members.

On the recommendation of the Committee, it was agreed to take a lease of premises for the sole use of the Association, the rooms to be used for meetings, demonstrations, &c.; members also having a right to use them for any of their operations connected with photography.

Mr. Lang, Junr., then read his lecture "On Bichromated Gelatine Films and the Stannotype Process" (see page 186), and gave a demoustration of the whole process of Staunotype printing, and threw off a number of prints at the meeting from moulds made by himself. The interest of Mr. Lang's lecture was much enhanced by a number of very fine specimens of the various biehromated processes, and some exquisite Stannotype prints, all very kindly lent by Mr. Woodbury for the occasion.

The meeting awarded a very hearty vote of thanks to Mr. Woodbury for his kindness in sending the specimens; and the same compliment was paid Mr. Lang for his interesting paper, and for the immense amount of trouble he had taken in getting up his demonstration.

The President then read a letter of resignation from Mr. Smithells, the Secretary, who is leaving Glasgow, and the meeting passed an unanimous vote of thanks to Mr. Smithells for all his work on behalf of the Society.

Mr. George Murray, 31, St. Vincent Place, Glasgow, was appointed new secretary.

Glasgow Photographic Association.

The tenth general meeting of the session was held in the Religious Institution Rooms, on Thursday, the 6th iust., Councillor Robertson in the chair.

The minute of the last meeting was read, and after an addition—viz., the exhibition of a patented camera by Mr. S. D. McKellen, of Manchester, and the thanks of the Society to Mr. McKellen—approved of.

The question-box was then opened, and one of the questions found in it raised a slight discussion which was not satisfactorily settled, viz., "Does the luminous paint used with Warnerke's Sensitometer lose its power through time?"

Mr. Parker then read a paper on a sky-shade invented by Mr Henderson, of Moutreal. As a special article will be published soon on this shade, it is not necessary to comment upon it now.

Mr. McGhie then exhibited several new pieces of apparatus. Addenbrook's instantaneous shutter, giving an exposure as desired from $\frac{1}{4}$th of a second to 3 seconds, and Cadett's latest studio shutter, the principle of which is a sliding front raised and lowered by the usual air-pressure arrangement, both worked very well, and were much appreciated by the meeting. He also exhibited Samuel's uew patent camera, the novelty of which is the dark-slide, which may be made to hold any number of plates. It is simply a box twice the size of the plates to be used, with a division in the centre and a shutter in front of one of the divisions. The sensitive plates, in blackened tin holders, are put into the division behiud the shutter. When it is withdrawn, a strong spring pushes the plates forward, the front plate taking the place of the shutter. It is now in position for exposure. When the shutter is pushed back again, it pushes the plate before it into the other division of the dark-slide, which projects beyond the side of the camera. This operation is repeated until all the plates are exposed.

Mr. Dodd then exhibited a combined apparatus for varnishing negatives and distilling water which he has used constantly with great satisfaction for the last twelve years. It is a flat copper case about thirty inches square and two iuches thick, tinned iu the inside, and standing at an angle of about 80°. There are hooks at intervals on each side to which are fastened movable wooden supports for different sizes of negatives. It is heated by steam conveyed by a tube from a small tinned copper boiler heated by gas. A tube in one of the corners draws off the condensed steam, which, if the apparatus be kept free from dust, is chemically pure distilled water.

The Chairman then called upon Mr. Andrew Mactear to reread a paper which he prepared for the Association twenty years ago, on "The History of Photography in Glasgow" (see page 186).

The meeting closed with the customary votes of thanks.

Edinburgh Photographic Society.

The fifth meeting of the current session was held in 5, St. Andrew Square, on the evening of Wednesday, 5th March, Mr. W. Nielson presiding.

After business of a private character, which occupied more than an hour,

Mr. J. H. Simpson read a paper entitled "Recreation in Art," in which, after referring to the great branches of art, and suggestions for recreation iu them, he referred more particularly to photography (see page 183).

The set of transparencies in gelatino-chloride by Mr. Cowan were then exhibited.

The Secretary intimated that Mr. A. L. Henderson, on his recent visit to Edinburgh, had promised that he would endeavour to get members an opportunity of examining these beautiful productions, and Mr. Cowan had most courteously sent them. The transparencies were examined with great interest.

Mr. A. Pringle stated that he had had an extended experience with the gelatino-chloride plates, having experimented with them from their first introduction. Their manipulation was so easy, and the results so certain, that he fancied if he had had failures he could perhaps have given better information as to the working of these plates. He used the dullest diffused day-light to impress the plates, and he could pretty correctly hit any colour he desired—the larger the quantity of citric acid employed in the developer, the larger must the exposure be. He found a ten per cent. solution of common salt a splendid restrainer—keeping the bright lines beautifully clear. From extended experiments he, however, had come to the conclusion that as yet no gelatine film was capable of yielding such clear and brilliant transparencies as collodion. He thought, however, for printing on opal, the gelatino-chloride was unapproached for beauty. He preferred to develop a red image, and then tone to the desired colour—the result being one of the prettiest things it is possible to see.

Mr. Alexander Matheson had come to the same conclusion, and he found that when transparencies were thrown on the screen, people with a knowledge of the requirements constituting a good transparency invariably selected those in collodion from any kind of gelatine transparency, as being in some sense more acceptable.

Mr. Forgan had only tried two of Mr. Cowan's plates, and he submitted these. They were both successful.

Mr. Frasier had tried several dozens, chiefly for microscopic work, and found them much superior to bromide plates; and so

simple were the operations and requirements, that he was invariably successful.

Mr. J. M. Turnbull thought those who required a perfect lantern slide ought to fall back on the old collodion-bromide. In every particular the development was exceedingly simple, and as certain as simple, while any desired result could be obtained with ease, every detail being under most thorough control.

Mr. Pringle entirely agreed with these remarks of Mr. Turnbull's.

Hearty votes of thanks to Mr. Simpson and Mr. Cowan were accorded by acclamation.

Mr. J. M. Turnbull exhibited a new slide-carrier which he had picked up in his recent wanderings in the south. He did not know its author, but it was admitted by all present as probably the simplest and most generally acceptable form of carrier for a single lantern that could be found.

Mr. G. Mitchell exhibited a splendid series of views and animal studies, by Mr. Reid, of Wishaw. They were examined with great interest, and greatly admired.

The Secretary submitted what he had found to be a very useful adhesive material, obtainable at a very low price, under the name of "Gloy." He was afraid to recommend it for mounting silver prints, as he had only met with it during the last six weeks, but a silver print coated on both sides with the material had not undergone any change during that time; but for every other purpose he thought it greatly superior to the adhesive materials commonly met with. It dried slowly with a minimum of "cockling," and free from unevenness of body. It was very cleanly in use, practically transparent, and dried with a slight gloss. By the addition of water it could be reduced in consistency, and still retain great tenacity, and it seemed well suited for many purposes where ordinary glue, gum, or starches did not always answer satisfactorily. By the courtesy of Messrs. Fraser and Co. he was able to distribute samples to all who desired to test the material. Several questions were asked as to the constitution of "Gloy," but the only thing definitely announced was that it was a waste product.

Mr. Fraser said that when potato-starch was boiled in a *bain-marie* for several hours, a somewhat similar material resulted.

The Secretary next exhibited a new American camera, which possessed several novel features. The 10 by 8 camera with three double slides only weighed about 7½ lbs.; it was, nevertheless, very strong and rigid. By a beautifully-finished rack arrangement, exceptional length for focussing was available. The bellows were of india-rubber, and all the metal work was nickelled. By an ingenious arrangement the slides could be used vertically or horizontally without altering the position of the camera, and by the simplest of devices the unwitting exposure of the same plate twice was prevented. In reply to a number of questions, the Secretary intimated that Mr. Atkinson, of Liverpool, would answer queries as to other sizes of these cameras.

Cambridge University Photographic Society.

A meeting of this Society was held in Mr. Scott's Rooms, Trinity College, on Monday last; Mr. Scott, President, being in the chair.

The minutes of the preceding meeting having been read and confirmed, Messrs. Turner and Wild were elected members of the Society, and Mr. Pritchard was elected a member of the committee.

The Treasurer then read a statement of accounts, which appeared to be in a satisfactory condition.

The President then called upon Mr. Laurie to read a paper on "Scieneific Photography in 1840."

Mr. Laurie dwelt chiefly on the theory of development, and quoted several experiments by Talbot, Hunt, and others.

A short discussion followed, in which Messrs. Scott, Harrison, and Pritchard took part, and the meeting then adjourned.

Bury Photographic and Arts Club.

The first conversazione since the formation of this Club took place on Tuesday evening, March 11th, at the Temperance Hall, when a very agreeable evening was spent by about 240 ladies and gentlemen. Around the room were placed tables on which were arranged photographs of notable places and choice bits of local scenery, the work of the members, and much of it of the most commendable character. These included views taken in the Fylde district by Mr. C. H. Openshaw, one of the junior members of the Club. Mr. William Booth, Heywood, exhibited views of the Isle of Man, &c., while a large number of photographs of local and other scenery, including an excellent view of the interior of a farmhouse where John Wesley preached, were the work of Mr. J. Nelson. Mr. W. Palmer contributed an oil painting of the old White Lion Inn, Bolton Street, before it was pulled down, and Mr. J. H. Rishton, a number of views on the Wharf. Views of the district through which the river Wyre flows were shown by Mr. R. Grundy, junior. Mr. H. M. Dearden had no less than 30 photographs of bits of local and other scenery, including the interior of the Bury Grammar School. Mr. F. W. Livsey (secretary) contributed 29 views, amongst which were some capital sea pieces produced by the instantaneous process. Mr. W. S. Barlow had several, and Mr. E Eccles a fine case of portraits. The Rev. J. C Horderu sent two excellent water-colour drawings, "April on the Yare, Norfolk," and "Quarry Tramway, Penmaenmawr;" Mr. Shaw also exhibited a figure of Hamlet, the gift of his friend Mr. Henry Irving, and some portraits of Miss Terry, having written upon the back by that lady an expression of thanks for many kindnesses received.

A number of microscopes were lent by Mr. J. Taylor, Mr. E. W. Mellor, Mr. J. Walmsley, and Mr. J. Nelson. Mr. E. W. Mellor lent some beautiful views of the Bermudas and Eastern scenery, and a pencil drawing of Mrs. Langtry by Mr. E. W[illegible], of Sale.

The President opened the proceedings by briefly giving those present a hearty welcome. He remarked that clubs of that kind were doing a useful work. Young people after leaving school, in order to keep out of mischief, should have some hobby, whatever it might be, for their leisure. It was therefore only natural that that those having similar tastes should join together and form clubs such as that was. The bulk of the members of the Club had taken to photography as their hobby, but they did not wish to confine the Club to that; they wished to have their taste improved, and desired those to join the society who devoted their spare time to the brush and pencil in order that they might be told where they had gone wrong, so that their photographic views might be as artistic as possible. He thanked especially the president and members of the Manchester Society for attending.

During the evening songs, glees, &c., were given by a number of the members assisted by several lady friends; and a number of views taken by the members of the Club were shown on a screen by Mr. Walmsley by means of the oxy-hydrogen lantern.

Imperial Russian Polytechnic Society.

The monthly meeting was held on Friday, March 14th.

Lieut. V. Pavloffski explained and practically demonstrated his simplified methods for producing vitrifiable enamels on china, porcelain, opal, &c., and for making photographs on wood, canvas, &c., for engravers and painters.

Mr. Warnerke, in seconding the vote of thanks to Lieut. Pavloffski, said, that what he had seen and heard he was sure would make quite a revolution in photo-ceramics, as such an efficient process must tend to vulgarise both photography in enamel colours as well as upon wood, two branches of the art which are as yet trade secrets, and known only to a few.

Talk in the Studio.

Photographic Society of Great Britain.—The next mid-monthly meeting will be held on Tuesday next, March 25th, at the Gallery, 5A, Pall Mall East, at 8 p.m., and it is expected that Mr. R. Meldola will show a series of slides from his photographs of the Nicobar Islands.

Chromo-Photo-Lithography.—We are glad to receive practical evidence of Mr. W. Griggs having thoroughly reorganized his photo-lithographic establishment after the disastrous fire which we reported some time ago. The two numbers of *The Journal of Indian Art* which Mr. Griggs sends us are certainly magnificent examples of photo-lithographic work Most of the reproductions are, as might be supposed, from hand drawings, but the prints are in some instances in five or six colours. Plate XIV., representing a silver pen-case and ink-stand, is exquisitely rendered in two degrees of silver bronze and black, while it is difficult to speak too highly of the multi-coloured reproductions of enamel and inlaid ivory work.

Professor Rowland.—Professor Rowland, who has recently been presented with the Rumford medal by the American Academy of Arts and Sciences, in recognition of his services in producing the concave refraction grating for spectrum work, now so well-known, tells us something of his adaptation of the grating to the camera. He says:—"Having made the concave grating, I invented a simple arrangement for mounting it, so that a photographic camera should move along the arc of a circle at one end of a diameter, upon the other end of which the grating was placed, and always remain in focus. With this apparatus, one can do in an hour what formerly took days. Moreover, the spectra obtained are always normal spectra, and every inch on a photograph represents a certain number of wave-lengths. After finishing my apparatus, I found it necessary to study photography; and I therefore devoted much time to this subject, and made a special study of all known emulsions. I discovered that an emulsion containing eocene enabled me to photograph from the violet down to the D line; and other emulsions were used for the red rays. I have also been engaged in enlarging my negatives and in printing from these negatives. On these enlarged photographs lines are doubled, which have always been supposed to be single. The E line is easily doubled. My map of wave-lengths is based upon Prof. Charles S. Peirce's measurements of the wave-lengths of a line in the green portion of the spectrum."

Explosions with the Ethoxygen Light.—At the inquest on the Chadderton accident, held on Monday, evidence was brought forward which seems to conclusively prove that the explosion arose from some of the ether being drawn back into the oxygen-bag, and the following is the finding of the jury. "William Heywood was accidentally suffocated owing to the pressure on the stairs caused by a panic owing to an explosion of a mixture of oxygen gas and other vapour in the Town Hall on the 22nd February. They append to their verdict the following recommendations:—1st, The jury are of opinion that the use of eth-oxo. gas should be prohibited at public entertainments. 2nd, That a recommendation be forwarded to the Home Secretary that no persons should be permitted to give exhibitions of explosive gas without a licence for such purpose first obtained." It may be mentioned that a second explosion has just occurred with the ether-oxygen light. It took place at Farnworth, near Bolton, on the 17th instant, but fortunately no serious damage was done.

The Development of Over-Exposed Plates.—It is said that Mr. Sautter, of Geneva, having given some gelatino-bromide plates about 180 times the correct exposure, found that they might be made to yield satisfactory pictures if they were treated with bromide of potassium before development. A ten per cent. solution of the bromide was used, and the plates were allowed to remain in it for one to two minutes. After having been drained for a few seconds, they were developed in the usual oxalate developer, to which a little citric acid had been added.

An innovation, says the *Daily News*, was introduced in parliamentary debate yesterday. Mr. Broadhurst illustrated his speech on moving the second reading of the Leaseholders' Bill by distributing photographs of a tumbledown house. It was labelled, "The Fruits of Life Leases at Malvern."

Photographic Club.—At the next meeting, on March 26, the subject for discussion will be, "The Preparation of Lantern Slides." This being a lantern night, members and visitors are invited to bring slides for exhibition.

To Correspondents.

*** We cannot undertake to return rejected communications.

A. Van Gogly.—1. *Monteur de la Photographie*, published at 13, Quai Voltaire, Paris. 2. The amount is not likely to be less.

E. B. S.—Three articles appeared in our volume for 1882, and they will be found upon pages 166, 246, and 370 respectively.

E. B. D.—1. Many have wished to obtain it, but no method is known at present; indeed, the colour changes if the impression is kept in a dark place for an hour. 2. The best way of working when a particular tint is desired is to adopt the (so-called) carbon process, as the tissue can be made up with a suitable mixture of pigments.

C. C. Lyon.—The most convenient method is the process of double printing to which you refer.

W. Dawson—Either all the negatives must be upon glass of approximately the same thickness, or those on thin glass must be adjusted by placing a few thicknesses of stout paper behind the sensitive tissue.

A. H.—We are glad to have made the matter clear to you, and hope you will communicate with us in case of any further difficulty.

R. Evans.—Details will be found upon page 498 of the last volume of the News, and in the current Year-Book. If any difficulty presents itself in working, do not fail to communicate with us.

Henry Crutchley.—Judging from what you say, we think it likely that the plates recently supplied have been made with a harder gelatine. If this is so, you will have to prolong the development in order to allow the solution to sufficiently penetrate the film.

H. J. D.—Thank you; we will make use of it if we can.

Thos. Widdop.—Thank you very much for the papers.

Ebbw Vale.—The next is that of the Photographic Society of Great Britain. It will open towards the end of September.

Argent Nit.—1. The value of this by itself would probably be nothing, as to extract the silver from such a small quantity of residues would cost more than the worth of the metal. If the whole of the silver originally present in the plates were recovered, it might be worth between one shilling and three shillings. 2. We would advise you to be cautious in making a claim, and to act under competent advice.

W. M. G.—The additions to which you refer are not likely to interfere with the original copyright; but if you wish to secure the additions, a second registration will be necessary.

C. B.—It cannot be accurately described as a new invention, as an instrument almost identical was figured in the fourteenth volume of the Photographic News.

Constant Reader.—2. Traces of soluble chlorides are invariably present, hence the turbidity which arises on adding nitrate of silver. 2. The tissue should have been used soon after it was sensitised, as by long keeping the gelatinous film becomes totally insoluble in water. 3. The single lens will answer admirably; indeed, you could not have a lens better suited for the work.

William Foster.—Nitric acid will dissolve it at once, and the acid need not be very strong. Try a mixture of one part of commercial acid and six parts of water. 2. The portrait is fairly good, but lighted too much from the top.

Beginner.—1. We would not advise you to purchase such an expensive outfit as No. 3 at present, as No. 4 will serve your purpose very well until you have made considerable progress. 2. If we could have but one, we should select the third on your list.

Ruben. J——.—It is the presence of iron oxide which gives it a colour, but beyond this there is no objection to its use.

J. C. M.—It is insoluble in ether, so there is evidently some mistake.

C. Morris.—1. Try very much shorter exposures. 2. Imperfectly cleaned glass. 3. Send us further particulars.

The Photographic News Registry.

Employment Wanted.

Retoucher (Lady), London preferred.—M. A., *Photo. News* Office.
Assistant in Reception Room, &c.—F. S., 58, Belsize-rd., S. Hampstead.
Colourist and Retoucher (Lady).—Theta, *Photo. News* Office.
Photo-ziaco. or Photo-lithog.—E. Beck, 7, Fowell-st., Lancaster-rd., W.
Assistant Operator and Retoucher.—Alpha, *Photo. News* Office.
Retoucher & Assist. Op.—H. Joyce, Saudown-villas, Fisherton, Salisbury.
Operator, wet and dry.—J. H., 38, Lansdown-rd., Dalston.
Assist. Operator & Retoucher.—T. H., 58, Campden-st., Campden-hill, W.
Retoucher (Lady).—Otto Pfenninger, St. Gall., Switzerland.
General Assistant, good all-round.—M. R. C., 49, Ledbury-rd., Bayswater.
Retoucher & Operator.—H. F., 120, Alexandra-rd., Dereham-rd., Norwich.
General Assistant (Lady).—C. F., 35, Lamb's Conduit-st., W.C.
Operator & Retoucher.—J. B., *Photo. News* Office.
Vigaette Printer and Toner.—P. T. F., 4, Wellington-st., Belfast.
Recep.-room, young Lady, experienced.—A. B., 72, Azenby-sq., Peckham.
Assist. Operator (photo's. son).—Z., c/o Mr. Gregory, High-st., Marlboro'.
Oper., Retoucher, &c.—Manager, Taunt & Co., High Wycombe, Bucks.
Recep.-room, Lady, in prov.—Alpha, 10, Kempshed-rd., Albany-rd., S.E.
Gen. Assist., can repair apparatus.—T. Edmunds, 2, Haven-ter., Ealing, W.

Recep.-room, Spotting, &c. (Lady), first-class.—A. B., *Photo. News* Office.
Printer & Toner, first-class.—Photo. 8, Stile-gr., Gunnersbury, Chiswick.
Assist. Operator, good printer & toner.—E. W., 31, Sutherland-st., Pimlico.
General Assistant, 21/-.—C. S., 7, Jeffries-st., Kentish Town Road.
Recep. Room Lady, exp.—H. Beale, 39, De Beauvoir-rd., Kensington.
Retouch., in or near London.—Retouch., 2, Hanover-pl., Regent's-pk.
Operator or Manager, home or abroad.—A. E. Walker, Eastwood, Notts.

Employment Offered.

Printer and Toner.—E. W. Lavender, Tweedy Buildings, Bromley, Kent.
Photo-lithographer.—Riddle and Couchman, 22, Southwark-bridge-rd., S.E.
Operator & Retoucher. exp.—Personally to W. Phillips, 304, Regent-st., W.
Operator, good all-round, single.—Cuckney & Co., Rochester.
Recep.-Room, Lady, and manage Branch.—J. K., 14, Mildmay-grove, N.
Youth, to be generally useful.—103, Newgate-st., E.C.
Retoucher (Lady).—Universal Printing Company, 280, High Holborn.
Positive work, single man.—R. W. Pitt, Devil's Dyke, Sussex.
Chromo. Printer, lady or gentleman.—Chromotype, *Photo. News* Office.
Junior Clerk.—Letter only to Boning & Small, 22, Baker-st., W.
Printer, Develop Dry Plates, & Operate.—9, Widdicombe-ter., Barking-rd.
Operator & Printer, Landscape work, &c.—Taunt & Co., Oxford.

THE PHOTOGRAPHIC NEWS.

VOL. XXVIII. No. 1334.—*March* 28, 1884.

CONTENTS.

PHOTO-TRANSFERS FOR ENAMELS AND WOOD BLOCKS.

LAST week we announced that Lieutenant V. Pavloffski had communicated to the Imperial Russian Polytechnic Society of St. Petersburg a new and important method of producing photo-enamels, and what, perhaps, is more valuable still, an easy plan of applying photo-transfers to wood blocks. We have now the pleasure of giving our readers the practical details of the process—a most simple one, as they will perceive—and by way of preface we may add, that in support of his process, Lieutenant Pavloffski produced before the members of the Russian Society some excellent transfers of various subjects. The method, therefore, is shown to be a thoroughly practical one, while in further proof, if such were needed of its excellence, we may adduce the opinion of our friend Mr. Warnerke, who was among the audience, and who prognosticates that M. Pavloffski's process is likely to bring about a revolution in the art of photo-enamelling and photo-wood-engraving.

Be this as it may, photographers have, one and all, to thank M. Pavloffski for so generously communicating the working details of his process, and placing at the disposal of his fellow-workers in every land the valuable results of his labours. To produce an effective photograph on wood has been a stumbling block for years past, for although engravers have called photography to their aid repeatedly, the transfer of the photographic film to boxwood is still a matter beset with much difficulty. Let us hope, therefore, that the method now proposed will solve the problem.

We will come at once to the details. The first thing is to prepare the sensitive film. The sensitive compound is thus made up:—

Twenty-five parts of the best picked gum-arabic are soaked for two or three days in 100 parts of distilled water, or in water previously boiled to dispel as much of the air as possible. When dissolved, the gum water is strained through a linen cloth into an evaporating dish. Now take from 16 to 20 parts of vitrifiable pigment, if for transfers to be burnt in, or of calcined lamp black if for transfer to wood, canvas, &c., or for other similar purposes. The pigment or lamp-black must be very carefully ground upon a marble slab or a sheet of ground glass with a few drops of the gum solution; then there is added by degrees 7 parts of crystallized honey. The latter is then stirred into the gum water, and when thoroughly incorporated, 6 parts of bichromate of potash are added, previously dissolved in a little hot water. This mixture, now sensitive to light, is well stirred with a glass rod, and filtered three times through flannel, and finally through dry cotton wool. This solution can be preserved for nearly a week in a dark place.

Patent plate glass, which has previously been cleaned with a weak solution of soluble glass, or received a preliminary treatment with lump-sugar-water, is coated as may be required with the above solution heated to about 190° F. to dispel any air-bubbles it may contain; but these prepared plates do not keep more than two days.

Lieutenant Pavloffski does not regulate the thickness of the film by measuring the quantity of solution, but merely pours a pool of it on the centre of the plate, and allows it to flow all over like collodion; drains the superfluous mixture off at one corner, and as soon as he perceives that the upper end of the plate can be seen through, he places the glass in an horizontal position to dry.

A marble slab heated with hot water, or a drying cupboard, will answer the purpose of preparation, provided that the temperature at which the plates are dried is between 100° and 120° F. Half-an-hour suffices for their complete desiccation. While yet warm, the plates are exposed, the negative being also slightly warmed, and as an extra precaution, the latter should be dusted over with French chalk to prevent it adhering to the sensitive surface. If the negative is not quite flat, thin sheets of mica will be found preferable to plate glass as a support for the sensitive compound.

About one-fifth of the time necessary for a silver print is ample exposure—better more than less, as the development can always be forced in case of over-exposure; but hard pictures are inevitable if the film is under-exposed.

After removing the impressed film from the printing-frame, coat it with a two per cent. normal collodion, and when this is thoroughly set, pour a stream of cold water gently over it. In a few moments the collodion commences to blister; when this happens, take a piece of paper the same size as the plate (but not highly sized nor very thick), and place it, after soaking in water, on the collodion. Then with a needle or the point of a penknife detach the film from two edges of the plate, and raise the corner very carefully. The collodion, carrying the partly developed picture, will adhere to the paper, and can be stripped off and laid film upwards on a clean glass plate, when it is gently sluiced with cold water until it is nearly free from the soluble or unexposed mixture. This particular moment must be carefully watched, and the development retarded by pouring over the impression very dilute spirit (20 parts alcohol to 100 of water); afterwards flood with equal parts of spirit and water, and finally pour on a small quantity of absolute alcohol,* which will completely arrest further development, and the picture is ready for transferring.

Next comes the transfer. To do this, take the enamel tablet or wooden block as the case may be, and lay the picture face upwards on the reverse side of it. Having

* These solutions should be kept ready in three stoppered bottles.

chosen the position the picture is to occupy, cut round with a pair of scissors close to the edges; then wipe the surface of the tablet or block, and coat it with a mixture of 1 part of thick gum mucilage to 3 parts of weak spirit. Pour a little of the same mixture on to the picture, and with an adroit movement, reverse the picture so as to bring it on the surface it is intended to occupy, slightly pressing it with a linen cloth or towel. If the transfer is made to an enamelled tablet, or plate or glass, then the drying can be accelerated by heat; if to wood, ivory, or canvas, then it must be allowed to dry spontaneously. In the latter case, however, the paper support may be removed as soon as transferred.

To wash off the collodion, equal parts of alcohol and ether are used at first, and afterwards ether alone; this dries immediately without having imparted the least humidity to the boxwood block. This last point, it must be remembered, is of very considerable importance, as experienced engravers very well know, for blocks treated with ordinary liquids, although whole and sound enough apparently when put into the engravers' hands, not unfrequently split and spoil during the operation of cutting.

As soon as the ether has evaporated, the picture is ready for the engraver, without any varnish or protective coating being necessary; its hygroscopic character will prevent the film from peeling off or splitting during the operation of cutting, neither does the film, such as it is, offer any resistance to the graver, as his breath alone is sufficient to keep it in a supple condition.

Revenons à nos—transfers. If for enamelling, the collodion can very well remain on them, for Lieut. Pavloffski assures us that the fire consumes it without in the least affecting the resulting picture.

Previous to firing, he applies the glaze in the following manner:—A pad, or dabber of wool, is made, covered with a layer of silk; with this pad you gently apply a very thin and even coating of varnish, prepared with oil of lavender, thickened essence of turpeutine, and an easily fusible glaze, the whole being about the consistency of cream.

The firing is best given over to an experienced person if the photographer is unacquainted with the process; those who undertake to burn in hand-painted tiles, plaques, &c., would have no difficulty in treating photographs, and would scarcely charge exorbitant prices.

As regards the pigments to be used, Lieut. Pavloffsky recommends oxide of copper and gold purple for warm tones, and the oxides of copper and cobalt for cold tones; no admixture of flux or glaze is needed with them.

Another way of applying the glaze is to dab the picture over with the varnish, and dust the glaze over the tacky surface, either from a wide-mouthed bottle with three folds of muslin tied over it, or by using a box like that for strewing powdered resin over copper plates to make aquatinted grounds for etching purposes.

THE PROPRIETORSHIP OF THE NEGATIVE.

Gradually and surely we are getting the law on the side of the photographers. Every case that comes before our tribunals on the subject of the proprietorship of the negative deserves to be carefully noted, and we must beg our correspondents, as much for their own sakes as for our own, to make known to us any decisions of this nature that come under their observation. Lawyers, as everybody knows, go as much by precedent as by equity, and hence it is of the highest importance to place on record every decision pronounced in favour of photographers.

Although we are now in a position to cite some half dozen cases in which the proprietorship of the negative has been decided in favour of the photographer, these decisions have for the most part been given abroad. It is the rarest occurrence to find the matter in dispute in an English court; still we do not remember a single instance in which a photographer—who has not previously bargained to take a *negative* for his client—has been compelled to give up the negative, as part and parcel of a contract entered into to supply photographs. The case decided last week by Mr. B. T. Williams, Q.C., the judge at the Swansea County Court, is not so strong as one in which the negative of an ordinary portrait is involved, but still the dictum of the learned judge is clear enough on the subject, and it is one which our professional readers should bear in mind.

The opposing counsel's contention that the case was on all fours with that of an engineer who charges a customer with a steam engine at £500, and for patterns in making it, £250, and where the customer would have a claim to the patterns, since he paid for them, can in no way be compared to the case of the photographer. Had the latter charged for a foreground for taking the pictures, no doubt the customer might have claimed it; but negatives, as the learned judge remarked, are rather in the category of tools, and a workman does not usually part with these when he sends home his work.

However, for the present, it will suffice to quote the case as it stands in the *Cambria Daily Leader* of March 21:—

Mr. Andrews, photographer, Wind Street, sued Mr. Robert Capper, superintendent of the Swansea Harbour, for £5 8s. 6d. Mr. Monger appeared for plaintiff, and Mr. Glascodine represented the defendant. The claim arose in connection with certain photographs of H.M.S. *Dwarf*, which was in Swansea in September last. Defendant commissioned the plaintiff to execute views of the vessel on her arrival in and departure from the port, together with groups of officers and men on board—an order which the plaintiff duly carried out. He delivered several copies to Mr. Capper, and supplied copies to others. The amount charged was £10 11s. 6d., £5 8s. 6d. of which was for "photographing" the vessel and groups, and £5 3s. for the copies supplied. Mr. Capper paid for the copies supplied, and offered to pay the £5 8s. 6d. if Mr. Andrews handed over the negatives, but the plaintiff claimed that the negatives continued his property. For the defence, it was urged by Mr. Glascodine, that as the plaintiff claimed to charge for executing the negatives, they belonged to the defendant, who gave the order, and charged for making them. The Judge: If you order a photograph, unless you make special terms for the purchase of a negative, the photographer is not entitled to give it up. Mr. Glascodine said if he asked a man to make something for him, and he afterwards asked for copies and paid for them, they were his. If a photographer charged him for taking a negative, did it not belong to him?—The Judge: No! it is part of the instruments used in the business. It is what a photographer uses in his business to make photographs. Why should he part with the instruments of his trade? A negative may be a secret in his trade, and he does not part with it unless there is a contract to that effect.—Mr. Glascodine: Suppose I ask a man to make me an engine for £500, and suppose he charges £250 for the patterns. Do the patterns belong to me or do they not? If he charges me for them, they are mine. If he does not charge me for them, then of course they are not mine.—The Judge: But here he does not charge for the negative. He charges for his work and for copies, and he makes an estimate accordingly. You want photographs for your friends. It does not matter to you how he makes or produces them. There might be other means to produce what you want; therefore what has this to do with you? He charges you for the expense in producing what you want. As I said before, he estimates the cost of producing, but does not sell the material used in production. He wants it for other purposes. If you like, I will give you leave to appeal.—Mr. Glascodine: If so, that will be sufficient. Perhaps you will be good enough to note what I said about the making of an engine and the patterns. —His Honour: Quite so; I find as a fact that the photographer never sold the negatives to the defendant, and I give judgment for the amount claimed with costs and advocates' fees. I give Mr. Glascodine leave to appeal. I think, however, it will be useless to appeal.

PHOTOGRAPHY OF YELLOW AND BLUE IN TRUE PROPORTION OF THEIR INTENSITY.

BY DR. H. W. VOGEL.

It is now more than ten years since that I published an observation of considerable interest—viz., the process of "actinising non-actinic rays," as the late Wharton Simpson called it; or a means to sensitize bromide and chloride of silver for yellow, green, and red rays, by mixing them with certain bodies which absorb the coloured rays mentioned. I made my first experiments with the spectrum of the sun, and succeeded in photographing the red and yellow part of it. My observations and views met, in the first place, with some opposition. My late friend, Monckhoven, doubted them at first altogether. Carey Lea tried to prove that I was mistaken. The first who confirmed my results was Becquerel, the second Major Waterhouse of Calcutta. These gentlemen confirmed the principle pronounced by me in 1873:—*That certain dyes, which have a powerful absorbing action for coloured rays, make bromide of silver sensitive to those rays.*

I proved by further experiments that this action of absorbing agents on bromide of silver is met with only under certain favourable conditions; that is to say, an ordinary chemical sensitizer, which combines easily with bromine, or chlorine, or iodine, and therefore accelerates the action of light on the haloid salts of silver, must be present. For instance, bromide of silver precipitated with an excess of nitrate, well washed, and dyed with fuchsine, is sensisive for yellow and green rays; but if it is precipitated with an excess of soluble bromide, the fuchsine has no action at all. Morphine, pyrogallic acid, and even gelatine, act like a trace of nitrate of silver, and in their presence fuchsine is a sensitizer for yellow rays.

But all these researches were, at first, of merely scientific value for spectrum analysis. Already, in 1873, I tried to take pictures of coloured subjects by stained bromide plates; but I soon observed that bromide plates made sensitive for the yellow rays of the spectrum showed only a trace of sensitiveness for the yellow colour of our pigments. The reason of this was, that the yellow rays of the spectrum are many thousand times more intense than the yellow rays of the most brillant yellow pigment. But I observed (also 1873) that it was possible to get a picture of a dark violet ribbon on a light yellow ground in their true proportion of intensity by the interposition of a yellow glass, which diminished the intensity of the blue rays.

Years past, and yet no useful application came of these observations. Ducos du Hauron and Albert did something in 1877. But they aimed too high; they wanted not to reproduce colours by photographic tones, but by colours again, a task that naturally led them into a sea of difficulty. Albert and Ducos employed for their purpose coloured collodion and coloured glass, using the latter to sift out such colours as they did not want. Cros, in Paris, worked somewhat after the same fashion.

Of late years, an effort has been made to make use of the principle in gelatine photography. Some five years ago I published researches on the subject, showing that gelatine plates could be made sensitive to certain colours. Eosine was found to be the most favourable absorbing medium, a body that had been employed in collodion by all experienced in this branch of photography, having been first proposed for the purpose by Waterhouse. Eosined gelatine plates are already a commercial article, and have been manufactured for some time past by Messrs. Clayton and Tailfer, of Paris. Eosine, I found, materially improves the sensitiveness of the yellow, and lessens the sensitiveness of the plates for blue. This, by the way, is to be observed in other bodies, as, for instance, in fuchsine, and it is precisely this quality, viz.—the increase of sensitiveness for yellow, and decrease for blue—that is of the utmost importance, for without it, in photographing colours, the blue would act as powerfully as the yellow, or, in other words, appear as bright as the latter.

I examined with the spectroscope the commercial eosine plates, and found that for yellow rays they were about double as sensitive as for the blue; their sensitiveness for red, on the other hand, is not greater than in ordinary plates. Still the sensitiveness to yellow was not sufficient to permit the reproduction in their true proportion of intensity of yellow and blue colours together; and for this reason I tried if it were not possible to increase the sensitiveness of yellow still more, as well as to increase also the sensitiveness of red. In both these objects, I am happy to say, I have succeeded, but it is with collodion, and not with gelatine. I am able to produce wet collodion plates which are at least ten times more sensitive for yellow than for blue. With such plates I am enabled, in fact, to reproduce yellow objects in a light tint, and blue ones in a dark tint. All colours, in fact, have an action upon the plates so long as these colours contain yellow and green rays. A photograph taken of the colour-table that appears in my manual gave a most surprising result; the light green came out lightest, yellow was very light indeed, while the blue gave quite a dark photographic tint. I forward you a print from the negative.

A TRIP TO THE GREAT SAHARA WITH A CAMERA.

BY A COCKNEY.*

The railway already goes beyond Sétif on its way to Algiers, but it will probably be two or three years before the line is completed. At present you leave the train at a small town rejoicing in the name of Bordj-bou-Arreredj, where very simple accommodation awaits the traveller, and then take diligence to Ménérville, another station on the line some thirty miles this side of Algiers. You begin coaching at six in the morning from Bordj—I found out you may call it familiarly Bordj for short, if you like, after the manner of Lucretia of that name, though nobody knows this but the townspeople—and you continue your journey through the day and night until six next morning. But it is pleasant travelling, even in the night-time, for the air is never very cold; moreover, there are some magnificent views—the Porte de Fer, for instance, the Gorge de Palaestro, and the snow-tipped Atlas range—sufficient to keep up a keen interest the whole while.

It is something, too, to travel once more in old-fashioned style, in a diligence, after the manner of our fathers, when they did the "grand tour" through Europe fifty years ago, or, to make a more familiar comparison, after the fashion of Mr. Ledbury when he made his first trip to Paris. The bigger diligences here have coupé, banquette, intérieur, and rotonde all complete as in the good old times, and on long journies I should think they are quite as painful and inconvenient as of yore. Still, diligence travel has its advantages. If you are active of limb, you may every now and then get a pleasant walk for a mile or two, while the halts on the road are sufficiently long and frequent to permit of breakfasting and dining in comfort.

As I said before, I think the tourist who carries a camera should be always on the look-out for character rather than nature, and it was for this reason I determined to photograph our diligence at the first opportunity. This occurred at breakfast time, when the two drivers—driving a seven-horse diligence all day long is no joke, so the two men relieved each other every stage—sat down sociably with us and shared the meal. As I wanted to take the machine at the moment of starting, with the driver on the box, ribbons in hand, and the passengers in their places, it was necessary get the driver's good will first of all. Now, many men in this world are nice unassuming

* Continued from page 181.

fellows enough until you ask them a small favour, and then the unexpected position of exercising patronage suddenly changes their nature. Our driver was one of this class, and he suddenly became very official in his demeanour, as soon as I preferred my request. He hummed and ha'ad and really did not know whether he could sanction such a thing. "It won't take two minutes," I urged, as he looked so serious over it all. No doubt he meant to comply from the first, but it would not do to accord permission out of hand. So, after due deliberation, he said: "Pas plus que deux minutes? Eh, bien, soit."

But I had not got the length of my petition. I asked him and his comrade to take their places and have everything ready for the start, that the picture might have some "go" in it. And to facilitate arrangements I mentioned that if he gave me his name, I would send on a copy of the photograph.

But again I failed to evoke any show of enthusiasm. He almost seemed offended, and I thought he might not have understood; therefore, in a smiling mood, I produced a pencil from my pocket to write down his name and address. He took no notice, but gravely drawing a pocket-book from his pouch, handed me a card——

ARCHINARD FILS

Bordj-Bouïra (Algérie)

I bowed and took it, and after this we understood each other much better. The camera was already focused, so that as soon as my friend had taken his seat on the box, I let fall the drop-shutter, reversed the dark-slide, and impressed a second film well within the two minutes for which I had bargained. But had I wished for half an-hour I could have got it, now that the proper relation of passenger to driver was set fast and acknowledged.

This new acquaintance of ours could be sarcastic enough when he chose. He had a difference with the ostlers as to the way they harnessed the horses, and spoke of them as "Messieurs les garçons;" while a native passenger who disputed the fare and handed up a few centimes less than it should be, was asked, what he took him (the driver) for, and whether he thought that he (the driver) had come over to Algeria by the last boat. Still, he was a capital companion to have up in the banquette, and, so long as he was treated with due deference, would answer a question in a most affable manner. For his sake I hope one of those diligence photographs will turn out all right when I come to develop them.

Coming from El Kantara, the mountain fastnesses on the road do not make such an impression on the traveller as would be the case if he were on his way to the interior from the town of Algiers. Still, as I have said, the road presents many interesting features. At Bordj-Bouira (the word Bordj is our burgh or German Burg), where dinner is served about seven, we change vehicles, and thence we see little of the way until Ménérville is reached on the railway.

There was a picture I much longed to take, for it was one that photography could have done justice to; unfortunately, there were more serious objections to its being undertaken than the mere technical one. In the omnibus portion of the vehicle we carried three white-robed Arabs of stately mien and spotless exterior. At day-break, and again at sunset, taking the opportunity of a short halt to refresh the horses, our native passengers got down, and proceeding some twenty paces to the right of the vehicle, they disrobed and engaged in prayer. As they turned towards the declining sun with arms stretched forth and heads lowered to the earth, its glinting rays lit up every fold of their white raiment, and bathed the kneeling worshippers in a flood of lurid light. A truly eastern picture, it was powerful alike in its devout and its artistic character; and somehow it called to mind that group of wandering shepherds who watched from afar the Star of Bethlehem nineteen hundred years ago.

The railway to Algiers furnishes a succession of pleasing panoramas. The deep blue Mediterranean comes into view once more, while the country in many parts is fertile to a degree with its green corn fields, leafy trees, and fresh succulent herbage. Again, as you near the city, bright villas of white stone are seen upon the green hills, with gaily-decked gardens and trellissed vines and orange shrubs with golden fruit still hanging to the stem, while feathery clematis and purple flowering creepers cling to porch and portico. Green cacti hedges and clumps of spear-pointed aloes line the roadways too, and recal the generous tropical climate.

Algiers is never seen to better advantage than when you first sight its white-terraced houses, tier above tier, bordering the sunny bay, the blue water flecked here and there with snowy sails. The Grand Mosque, with its huge white dome, is a wonderful landmark, while the magnificent stone quays—all seen at their best as you come round the bend of the railway—and the fine old-fashioned harbour, compose a superb picture. I don't know why, but the ancient landing-places and arches and quaint water-side steps reminded me directly of the Red Rover and Dick Fid, they were so strange, and yet so familiar. Then, again, the colonnades made up of hotels and cafés, and faced by a broad promenade the whole front of the sea, are a marvellous sight, and the handsome stone buildings, topped here and there by a grim fort, all denote a prosperous and flourishing city. In a word, Algiers is an African Brighton—the very name of the principal restaurateur is Moutton—and serves as an attractive place of resort every year to thousands of Europeans.

From our windows at the Hotel de la Regence there is such a lovely view of the harbour over the top of a group of palms, that my last two plates are devoted to it. It is strange to think, as you look down on the fashionables sauntering to and fro on the polished asphalte, and gaze at the yachts and sleek steamers at rest on the smooth water, that scarce fifty years ago Algiers was the headquarters of piracy, and that slaves—European as well as African—were hard at work, where now monsieur sips his absinthe, and madame and bébé promenade with their white chip bonnets and dainty parasols. Why, even in Captain Marryat's day, a merchantman in difficulties off the Algerian shore was certain to be attacked by pirates, their swift boats lying *perdus* behind the headlands you can see yonder. The Dey of Algiers and his myrmidons seem to have treated all Europeans very impartially; they made no difficulty about sacking and burning any ship they could capture, and selling the crew into slavery. The new order of things only dates from 1836.

Yes, all my films are exposed and my camera work is done. In most cases I have duplicated, for I found, as a rule, so much time involved in selecting a point of view, and arranging the picture, that it would have been unwise not to make as sure as you could by repeating the exposure. It is true I only get half the number of views I might have secured, but still a roving photographer may consider himself pretty fortunate if every other plate gives him a tolerable picture.

At the same time, as I read over the descriptions in my pocket-book, the photographs I have taken seem few indeed. "Ah! but that's not the worst of it," says Jones, to whom I appeal for sympathy. "What's not the worst of it?" is my rather curt reply. I don't want to have a row with Jones; I have kept my temper pretty well, so far, I

fancy, and I shouldn't like just at the end of the trip to come to loggerheads. What I most dislike is that Jones always speaks with a quiet dictatorial manner as if he must be right, he can't help it, and this makes him all the more aggravating. What he now says is, as it were, more in sorrow than in anger.

"What's the worst of it?" I repeat.

"I mean," he continues, "that even the photographs you have taken are not the best bits. It is a pity you didn't go in more for some of the women's costumes we saw at Constantine. And the palm trees at Biskra—you know you didn't take one of those picturesque trees in Landon's garden."

"Go on," I said, keeping myself quite quiet.

"Well, then the Ali Babas you talked about. You haven't a single photograph of a woodcutter with his donkey, nor of a mounted Saracen, nor one of those Aladdin shops with the lanterns hanging up, nor the inside of a harem, nor the hall of a mosque, nor a funeral procession—we saw lots of them—nor a marabout's grave, nor a . . . .

"Go on."

"Well, but now didn't I tell you time after time not to waste a plate, but look out for something better?"

"Yes, after waiting till I had exposed."

"Not always."

"You did."

"I didn't."

"You did."

* * * * * * * * * *

I print no more of this, but simply beg the reader to observe that I had the last word, at any rate.

Algiers with its clubs and cafés and theatres and busy shops, and better still its green lanes, wooded hills, and bright, blue sea, is a delightful residence, and the four days we spent here, after our rougher journey South, were exceedingly pleasant. Altogether it is a much more charming spot than the town of Oran—about twelve hours by rail—to which we next repair on our way homewards. Oran is more Spanish than French, although still in Algeria, and in its architecture and in its inhabitants, you can everywhere trace the Spaniard.

A steamer transports you in nine hours to Carthagena, whence Madrid may be reached in eighteen hours more. I pass over my Spanish experiences, except to say that our small amount of luggage containing sundry parcels of dry plates, got safely past the Custom officers, who on the other hand devoted themselves manfully to a thorough examination of the heavy trunks and bulky luggage with which many of our shipmates were encumbered. I pass over, too, Jones' crushing defeat by the Spanish language, albeit he had given me to understand that a dialogue book he carried would help us through, all standing. For myself, I was never more deceived in my life; he simply knew nothing at all, and his book was always telling what we didn't want to know. For instance, if I asked the Castilian for brandy-and-water—merely out of curiosity to see if he knew it—he would, after five minutes' close study, regret it was not in the book, but that if "my mother has married again" was of any use to me, he would gladly spell it over in Spanish.

In Madrid, Jones was even more unfortunate, for he engaged the services of what is sometimes called an "interrupter," who, though his knowledge of Spanish was vast and profound, had never learned anything beyond his mother tongue.

Madrid—Bordeaux—Paris. In these days of sleeping-cars and express trains, travelling is not only bereft of much of its fatigue, but of much of its tediousness as well, and four days after leaving Oran, I am facing a Customs officer at Charing Cross Station, with my Gladstone bag between us, explaining to him, in the vernacular he and I understood so well, that my camera is not an infernal machine, nor the packets of dry plates, dynamite cartridges.

PHOTOGRAPHY CONSIDERED AS THE WORK OF RADIATION.

BY CAPTAIN ABNEY, R.E., F.R.S.

The fourth lecture of this series was delivered at the Royal Institution on Saturday last.

Referring to the bichromate experiments shown at the last lecture, the Lecturer said they had seen how radiation assisted the destruction of the image by assisting in the combination of oxygen with the reduced silver salt. He would now show them that the visible as well as the invisible image could be destroyed by causing it to combine with oxygen. A piece of blackened chloride of silver paper was then acted upon by peroxide of hydrogen, or hydroxyl.

The image could be destroyed readily by acids, such as nitric, sulphuric, and hydrochloric, as he could show them on bromide paper. In these cases, the sub-haloid salt was split up into the usual haloid compound and silver, the latter combining with the acid. There were other substances as well, that when aided by radiation would destroy the image, such as bromide and iodide of potassium. Plates were then prepared in the bath, washed, and treated with weak solutions of these salts, and then exposed beneath a black and white negative. On being developed in the lantern and projected on the screen, the direct positive pictures came up successfully in both cases. This reaction only took place when oxygen was present, but the action was not altogether unlike that produced by radiation on silver salts, the metal and the halogen of the alkaline bromide or iodide ing separated. He had warned photographers, therefore, of the danger of leaving a soluble bromide in their films.

Radiation alone, continued the Lecturer, was capable of destroying the image, but he could best illustrate this by some experiments of another nature. He had in his hand some tubes containing sulphides of calcium, &c., and after exposure to the electric light, they would see that these tubes emitted light. The rays which produced this phosphorescence he could show by projecting the spectrum on the screen, and holding up a piece of cardboard covered with sulphate of quinine, and still better by the use of paper soaked in a very cheap substance, common lubricating oil. The large phosphorescent tablet which he held in his hand was affected by rays which the eye could not see; the molecules of the phosphorescent compound were set in motion, and emitted light of a somewhat lower refrangibility, which could affect the eye. They would also affect a piece of bromide paper exposed beneath a negative, and he would develop this on the screen before them. Now if he showed the image of a cross or a wide slit upon such a tablet, they could see—or at least those in the front could see plainly—that a bright image was produced. But now, by exciting the table all over first, and then projecting upon it an image produced by red light only, they would see that a black mark was produced, or in other words, the luminosity was destroyed where the red light acted. A series of coloured glasses placed upon a tablet were then exposed to the light, and the glasses were afterwards passed in front of the spectrum to show what kind of light passed through them. The audience could see that the greatest amount of luminosity was produced by the glasses which let through the greatest amount of violet light, and that the tendency of red light was to destroy what luminosity was there originally. Repeating an experiment shown in a previous lecture, Captain Abney demonstrated, by means of repeated puffs of wind on a pendulum, that when these puffs coincided with the rate of vibration of the pendulum, the greater was the pendulum's swing; but if the puffs were otherwise timed, the pendulum was stopped. This represented what took place with the tablet. Throwing the spectrum on a phosphorescent tablet, the decrease of luminosity was shown in the red part, except where the vibrations were the octave of those in the violet. Heat, by increasing the swing of the atoms, made the luminosity greater at first, but the application of ice, on the other hand, slowed down the vibrations for a time. In phosphorescence there was then a visible demonstration of vibration stopped by badly-timed swings.

As he would have to say a great deal about the action of the spectrum, the Lecturer said he would conclude by showing them another way of producing a spectrum than by prisms; this was by means of the grating, the latest and best form being the beautiful grating produced by Professor Rowland, of America. The poles of an arc lamp were charged with lithium, sodium, and thallium, and a brilliant series of spectra, numbering twenty at least, were projected by one grating on to a transparent screen.

A SUMMER HOLIDAY.

BY JOSEPH R. GREATREX.*

On a Friday night in July, two summers ago, I was deliberating on the wisdom or otherwise of going alone to Switzerland on a tour which I had planned out. I had packed most of my requirements, and, although anxious to go, still I did not relish the idea of solitude, when fortune favoured me in the person of a friend who consented to accompany me on twenty-four hours' notice.

My apparatus consisted of a Rouch's whole-plate camera, three double backs; Ross's rapid symmetrical lens, eleven-inch focus; Dallmeyer's rapid rectilinear, eight and a-quarter-inch focus; Dallmeyer's 7¼ by 4½ W. A. P. landscape lens; a Rouch's folding stand, a good supply of Swan's plates, and our esteemed President's collodio-albumen plates. I may here say that during the whole of my travels I have never had the least difficulty with regard to passing the Customs with my photographic kit. The moment I get to the examination room I immediately open my kit and portmanteau, courteously explain that it is a photographic apparatus, that I photograph for pleasure, offer to show ho contents, and never, in the course of my experience, have It had any further prying, but have passed on at once. The Custom officers have a very disagreeable duty to perform, and they can make that duty a very unpleasant one for any shortcomings of courtesy.

We started on the Saturday night with light hearts by the 11 p.m. train for London, and were soon quickly speeding away through the semi-darkness of a summer night. We arrived in the metropolis too early—aye, and had to leave too early—for any chauce of a breakfast; so, having two hours to spare, we whiled away the time by taking a walk along the Thames Embankment, where many a shocking sight presented itself of the wretchedness of men, women, and children asleep on the seats as we strolled along that beautiful summer morn. Unfortunately, I had left my camera at the station, or I should certainly have been tempted to depict this sad state of human existence.

We left about ten o'clock for Dover, and on the steamer we did get something to eat, having fasted nearly sixteen hours. A short, smooth passage, and we were at Calais. There was no time to spare; we started again, through the flat and dreary landscapes of France. A little more patience, and we were at Paris. *Anglais!* The magic word sent us through the Customs without trouble. We stayed in Paris until next day, as we thought it better to break the journey there, our next stopping place being Geneva, the richest and most populous town in Switzerland, and abounding with lovely views, both lake and architecture. The banks of the Rhone are flanked with broad quays and substantial buildings; but the streets, with few exceptions, are narrow, steep, and crooked. Between the Pont du Mont Blanc and the Pont des Bergues is Rousseau's Island. In the centre stands the bronze statue of the wild, self-torturing sophist himself. The national monument also is good, and the Duke gorgeous. They are both well worth a plate or two being exposed on them.

Next morning saw us loading a *voiture* (the driver of which looked like a brigand's apprentice, but turned out a very jolly fellow) with our baggage and selves for Chamounix, *viâ* Bonneville Cluses, St. Martin, and Sallanches. The road traverses the new village of Chêne. A few miles further on the scenery becomes more picturesque. Near Bonneville, on the right bank of the Arve, stands a monument to the natives of the department who fell in the campaign of 1870-71; and on the left, 100 feet high, another to the memory of King Charles Felix of Sardinia. Cluses, the next small town, is chiefly inhabited by watchmakers.

The hills here begin to assume the stupendous height and size which so thoroughly defy the traveller to judge distances in this part of the world. At the village of St. Martin we suddenly obtained a magnificent view of Mont Blanc. A collodio-albumen plate was exposed here from the bridge, which turned out a very fair negative. Passing onwards through Sallanches we came to the small but popular watering-place of St. Gervais-le-Bains, situated in the wooded ravine of Montjoie. The building is something after the Chinese pagoda style, and I exposed a plate on it with success. As we drove along, the glaciers were now visible; but, owing to the vastness of the mountains in which they are framed, it is impossible at first to realize their extent.

At last we arrived at Chamounix, where the hospitable and attentive landlord of the Hotel de Londres received us as brothers, and immediately had us ushered up to our bedroom, a metal plate on the door of which bore an inscription to the effect that it had been occupied by Albert Smith, whose famous caricatures of the "Ascent of Mont Blanc" are so famous. Of course this was too good a chance to be missed, so I photographed Mont Blanc from the window.

Next morning saw us off on mules to Montanvert for the Mer-de-Glace. From this point a magnificent sight presents itself, and finds plenty of work for the camera. The Mer-de-Glace, or Sea of Ice, is a most imposing sight. I exposed several plates on the glacier, also on two pretty waterfalls, and bye-and-by came to the Mauvais Pas. It is a winding foot-path round a precipice, with nothing to hold but some loose iron railings, here and there plugged into the rock with wedges of wood, and perhaps 1,000 feet straight down. I got safely across, and wanted my friend to stand in the middle of the pass while I exposed a plate, but he declined. However, I made one exposure on it when another party was coming over.

We left next morning for Martigny by *voiture*. On our way we made a *detour* to the Cascade-de-Bérard—a picturesque waterfall, in a wild district. I made two exposures here successfully. A "shot" was also made on a pretty village with a rustic bridge in the foreground, which was shortly afterwards passed. Beyond Poyaz the road leads through a valley containing the church of Valorcine, which is protected from avalanches by a barrier of masonry. Pursuing our way we soon afterwards reached the famous rocks of the Tête-Noire. The scenery at this point is indescribably grand and beautiful, and two or three plates may be profitably employed. Proceeding on our journey by a good road we at length arrived at Martigny—a pretty village in the valley of the Rhone.

The next day was spent in visiting and photographing the Gorges-du-Durnant. It is a gorge through which the Durnant is precipitated in a succession of four cascades. The Gorge-de-Trient was another trip. The view is imposing—the rocks, 420 feet high, almost close in over-head, looking like a large cavern. I did not expose any plates here, as it would have required a long exposure, and we had not the time to spare; but I often regretted that I came away without doing so, even had I been compelled to stay another day.

The huge, perpendicular wall of the Gemmi presents the appearance of inaccessibility. When we had climbed two or three thousand feet, and looked for a last view of the place we had left, there was presented the charming view of the bright green level, with a pretty town in its midst, and a silvery stream winding amongst the meadows, the background of gigantic precipices clothed with pines, and above all the snowy domes and peaks of the Monte Rosa region.

On our downward track, which now began, the path lay through a wild and uninteresting country, enlivened only by the pretty alpine flowers, which seem to grow at any height, until we reached the level of vegetation again. Now beauty after beauty began to be unfolded to our view in the most marvellous manner; and oh! for one half-hour without those fleecy clouds now below, then above, and again all round, dancing and drifting in most fantastic beauty, but never leaving us long enough to permit us to have a "shot." The only view I did get was in one minute afterwards, enveloped in cloud and thoroughly hid. However, all things end, and, after eight hours' walking, we reached Kandersteg, where we stayed for the night.

I had some misgivings about the carriage of the baggage on our mule, and felt very anxious about the safety of our plates, which were stored in my portmanteau. As soon as I could, I took the opportunity of examining them, when a deplorable sight presented itself. There were no fewer than fourteen exposed ones broken into fragments. It was very disheartening, and has ever afterwards proved a lesson to me in packing plates. I now invariably cut a quantity of thin card-board angles, and gum one to each corner on the back of the plate. In packing thus they form one solid mass, and I have never had a broken plate since I adopted this method.

From Kandersteg we left next morning, and soon reached the square tower of the ruined Felsenberg, passing the road which diverges to the Blaue See or Blue Sea, picturesquely embosomed in wood, and remarkable for its brilliant effects of colour. The road was now very level, and passing Fellenburg (now a prison), we were soon at Fruitigen—one of the cleanest and prettiest villages I ever saw, situated in a very fertile valley. I took a view of the principal part of the village on a collodio-albumen plate with good success.

* Abstract of a communication to the Manchester Photographic Society.

Interlaken attracts numerous visitors, and is noted for its mild, equable climate. For want of opportunity I only exposed one plate here; it was a view of the English chapel, where nearly every sect alternately hold services.

We were off in good time next morning for Lauterbrunnen, and had not proceeded far when the Jungfrau, with her dazzling shroud of eternal snow, appeared in all her majesty. Close by here is the celebrated Staubbach Fall, which descends in an unbroken fall of 980 feet. I unfortunately could not get a "shot" here, as I had not a lens short enough in focus. Passing along we ascended through a wood to a bridge over the Staubbach; then we crossed two small streams and quitted the wood. Here is suddenly disclosed a magnificent view of an amphitheatre of mountains and glaciers, where we were photographed in a group, after instructing the guide how to uncap the lens and cap it again.

Next morning our journey was Grindelwald and the Eismeer. Grindelwald owes much of its reputation to its two glaciers, which descend far into the valley and are easy of access. To obtain a survey of the glacier a visit should be paid to the Eismeer. A narrow but well-kept path ascends the slope to the left, whence a steep flight of steps descends to the glacier. Two groups were taken here, which turned out very successful. Returning, we diverted to the left to view the ice tunnels, which are very wonderful. A plate was exposed here; and, although it was blowing half a gale, a successful picture was obtained, without blurring, on a collodion-albumen plate. I here wish to remind young amateurs of a very good plan of steadying the camera in strong wind. It is simply to get a large stone, tie a cord round it, and suspend inside the tripod to the screw. There is then no fear of vibration, or of the camera being blown over and damaged.

Next day we turned towards home, taking train for Darlingen, and embarked on the steamboat for Thun. There I got a very good negative of its principal street, on collodio-albumen, although the street was continually alive with people passing to and fro.

ON BICHROMATED GELATINE FILMS AND THE STANNOTYPE PROCESS.

BY W. LANG, JUN.*

Before going on to consider the process by which the mould is obtained, a word or two regarding the special form of tissue that is required may be necessary. To those who may work the process, prepared tissue can be had from Mr. Woodbury. It has very little colouring matter in it. The colouring matter here, as far as the mould is concerned, is superfluous, but it was found necessary to have a little, so as to judge of the developing of the mould. The tissue can be prepared by the amateur should he be so minded, and the formula for preparing the same is:—

Gelatine...	4 ounces
Glycerine	½ ounce
Sugar	180 grains
Water	16 ounces
Colouring as required	

The sugar and glycerine are dissolved in the water, and the gelatine allowed to swell therein. The gelatine must be of an easily soluble kind—Nelson's is recommended. After all is dissolved by heat, the colouring matter—liquid indian ink does very well—is added. The mixture, after filtering, is ready to be poured on to glass plates accurately levelled and previously coated over with ox-gall. The plates can be made into shallow trays by surrounding with pieces of wood, which can be removed so soon as the gelatine has set. The glass plates are then dried in an apartment or drying-cupboard at a temperature of about 70°. The gelatine takes about two days to dry. Sheets of paper cut to the required size are then wetted, and applied to the film by means of a squeegee, and after two hours' further drying, paper will be found adhesive. The tissue can be kept on these glass plates till actually required.

We come now to the sensitizing of the tissue. A six per cent. solution of bichromate is required, and the time of immersion five to six minutes. After sensitizing and allowing to drain, the tissue has to be dried, and as drying by heat is objectionable, as the tissue might be thereby rendered insoluble, a special mode of drying has to be adopted. For this a drying-box with chloride of calcium is necessary. By sensitizing overnight and leaving the box in a somewhat warm room, the tissue should be ready for use in the morning. It is necessary that the chloride of calcium be fresh to give satisfactory results The exposure of the sensitized tissue behind the prepared transparency must be regulated by the photometer; it should be stated, however, that behind the tissue in the printing-frame, a piece of india-rubber cloth or oil-skin paper, such as used in copying letters, should be placed. As to the necessary exposure, experience will be found to be the *sine qua non*. The exposure over the tissue is developed on patent plate-glass collodionized, as in the case of preparing the transparency. After the tissue is squeegeed on to the plate, the glass should be covered with blotting paper, a sheet of glass laid over it, and the whole subjected to some heavy weight. A quarter of an hour or so thereafter, development may be proceeded with. This is a somewhat prolonged process, occupying from about three to five hours. It is evidently a matter of considerable judgment to determine when a mould has been sufficiently washed. The water to be used in the development must be at a temperature of about 110° F. When the mould is sufficiently developed, it is rinsed with hot water, and then in cold. After draining, it is removed to a dish containing fresh methylated spirits, and allowed to remain for several hours. The gelatine is thereby deprived of its water, and on the mould being removed it very quickly dries. Black spots on the mould, due to defects in the transparency, can at this stage be removed, and for this purpose a strip of glass with a clean fracture across will be found most serviceable. The mould is now ready to receive its coating of tin-foil, only before doing so, a solution of india-rubber in benzole is poured over the mould, as in coating a glass-plate with collodion. A thicker solution of india-rubber is passed round the edges of the glass by means of a brush. Having cut a piece of tin-foil to the size of the glass free from holes, the tin-foil and the glass are put together through the rollers of a domestic wringing machine, one with india-rubber rollers. The rollers have to be separated sufficiently far apart in the first instance to allow the glass and foil to enter freely, and when the centre of the glass is between the two rollers pressure is applied, and the glass worked gradually backwards and forwards, extending motion till both edges of the glass be reached. It is necessary to start in the centre of the glass to avoid any bubbles getting between the mould and the tin-foil.

The press claims our next attention, and here it will be seen that Woodbury's mechanical ingenuity comes into play. The mode of using it is as follows:—Having cut a piece of stout blotting-board to the size of the glass, and having steeped it in water and allowed it to drain, it is placed thereon, and all the screws having been loosened, the top part of the press is allowed to lie freely of its own weight on the mould; the press is then closed by pushing the handle forwards, and the screw under the arch of the press screwed up as tightly as possible; thereafter the top screw; and lastly the screw which fixes the ball-and-socket joint. On releasing the handle the top part of the press lifts as a whole, and will always fall back again to the same position. The mould is now greased with a mixture of salad oil and paraffin oil by means of a piece of flannel, and we are ready to draw proofs.

A word as to the ink employed: it is simply gelatine dissolved in water—one ounce gelatine to six to seven parts water, and with colouring matter added to suit particular requirements of each mould.

The photographic tint which we are all so much accustomed to is arrived at by means of a mixture of carmine and indian ink, or alizarine and indian ink. A deep mould requires less colouring matter than a shallow one. The temperature at which the ink should be kept is somewhere about 120° to 130° F. At this stage it may be as well to close this paper, and proceed to throw off a print or two from the mould, which at present is lying in the bed of the press. The mould is not quite such a perfect one as I could have wished, but as I was afraid, on account of the defective light we have lately been having, that I was going to be short-shipped altogether, I was only too glad to get one at all to show at this meeting. Since taking to Stannotype, I have only prepared two moulds altogether, so that I bring forward the process to your notice under somewhat imperfect conditions. Had the light been better than what we have been having lately, I feel justified in saying that more perfect results would have been obtainable. Mr. Woodbury, knowing that I was to communicate something regarding his process to our Society, has very kindly sent down some of his printing moulds; he has also sent down some magnificent examples of Stannotype prints. I think for this attention he should receive our most cordial thanks; I think also you will admit that the work produced is magnificent,

* Continued from page 687.

and that there is a great future for Stannotype there cannot be a doubt. Mr. Woodbnry deserves all success in the process which he has devised, and I am sure the members of the Glasgow and West of Scotland Amateur Photographic Association will join me in wishing him that that success may be of a kind that will benefit himself in no stinted degree.

Notes.

"A Trip to the Sahara," with a few practical details added as to time occupied in travelling and cost of the journey, will he issued next week by Messrs. Piper and Cartel in the the form of a sixpenny pamphlet.

M. Chapiro, the eminent photographer of St. Petersburg, recently hrought to the attention of the Polytechnic Society of that metropolis a novel retouching and preservative varnish, suitahle alike for gelatine plates, as also for making outlines on lantern slides, since it permits of pencilling with the greatest facility. It is composed of 20 parts by measure of a saturated solution of ruhher in benzine, added to 100 parts of ordinary chloroform or amber varnish; it is ready for use as soon as filtered, and is applied without heat. It it said to have a tooth like ground glass.

A modification in the production of glazed photographs —*cartes emaillées*—was hrought forward at the same time by M. Degoe. Instead of collodionising a plain glass surface for imparting the glaze, M. Degoe has hit upon the happy idea of using glass plates etched with a border or frame, or wreath, or other suitable design, which naturally comes out matt in the finished picture. In vignettes, the effect is particularly pleasing, we are told, while, in some cases, the name of the firm had heen impressed. Something analogous to this was attempted a few years ago in the printing of carbon pictures, and should any of our readers desire to make experiments in this direction, glass plates with etched designs of this kind could be obtained very cheaply in this country.

Our colleague, Dr. Vogel, reserves to himself, for the present, the details of the process by which he renders collodion plates more sensitive to the yellow rays than to the blue, but that he has succeeded in solving the difficult problem appears evident enough from a photograph of a colour table which accompanies the communication we have printed in another column. For the reproduction of paintings by photography the process should he singularly useful.

There are no limits to the uses of photography. The latest novelty is the introduction of photographs to give force to arguments in a parliamentary debate. The credit of the idea is due to Mr. Broadhurst, who, as we mentioned last week, on moving the second reading of the Leaseholders' Bill, illustrated his speech by the distribution of photographs of a tumble-down house. It was labelled "The Fruits of Life Leases at Malvern."

It may not he generally known that photographs have been found extremely valuable in the cause of charity. Miss Rye, whose hobby is the exportation of homeless and friendless girls to Canada, has a large album filled with some hundreds of photographs, showing the portraits of *protégées* who have, under her auspices, gone on and prospered. Dr. Bernardo goes a little further. He photographs the street Arab immediately after his capture, and photographs him again after six months' experience or so in the Home. Charitable people, to use a slang expression, are at once "knocked" when they are told to "look on this picture and on that."

Herr L. Giese writes in the *Archiv* on the subject of taking portraits in dining-room and drawing-room. The difficulty, as most of our readers know, is to get sufficient reflection on the shadow side of the model, and for this purpose, it is usual to approach a white screen as nearly as possible to the figure. Herr Giese says that a far more effective reflector is the ordinary dining-room mirror, and he has no difficulty in producing harmonious pictures by means of a five-foot looking-glass. The distance at which the mirror is placed, as also its angle, permits the operator a wide range of lighting, and altogether the dull lustreless effect seen in most "at home" portraits falls away altogether in these circumstances.

A correspondent of a contemporary contemplates something very ambitious in the way of instantaneous photography, hut at present he does not know how to set about it. He says: "I sometimes pass, as I travel hy rail, a picturesque ruin and some pleasing pastoral scenery. I am tempted to ask my photographic friends if I can get satisfactory negatives of those places from the carriage window as I travel along at twenty-five miles per hour? I fancy I can sight the object over the body of my camera as I do a rifle, having an instantaneous shutter flash off the picture." At present photographs of trains in motion have all been taken "end on," and no one has succeeded in photographing one travelling at twenty-five miles an hour "broadside." It matters not whether the camera or the object to be photographed is moving at this rate, and the result would be much about the same—somewhat mixed. But why does not our friend try the experiment for himself? There are no lack either of instantaneous shutters or rapid plates in the market.

Mr. W. Broughton, the inventor of the ethoxo apparatus for lantern exhibitions, writes to the *English Mechanic apropos* of the lamentable accident at Chadderton. His opinion is that the apparatus on that occasion was not one on his principle, as had been asserted, but was one made on the old principle of the wash-bottle, which he had long discarded as being liable to cause an explosion. His opinion is that the explosive compound was not formed in the generator, but in the bag, and not on the evening when the explosion occurred, but on the last time the bag was used. His theory is, that upon the pressure being removed after its last use, the ether entered the tubes and thence the bag; this, on being refilled with oxygen,

formed the explosive compound, and this, together with insufficient weight on the bag, would tend to produce an explosion; for, if the explosive velocity of the gas be greater than the issuing velocity, the flame will travel along the tube.

Turpentine saturated with camphor is, according to the *Scientific American*, a wonderful aid in filing glass. The file should be well tempered, and then, if it is kept wet with this liquid, glass may be filed, it is said, almost as easily as brass; the glass may even, in these circumstances, be fitted into a lathe and worked by the tool.

Next week we shall resume our series of "By-the-Bye" and "At Home" articles.

An important defect in a sunshine recorder now being brought before the public, says a contemporary, appears to have escaped the attention of its makers. It will not record sunshine before 6 a.m., nor after 6 p.m., so that during summer time, several hours' sunshine are often disregarded by the instrument. The reason of the defect is, that though the card-holder has adjustment for any latitude, it does not allow the sunshine to focus through the glass sphere for more than six hours on each side of the meridian. The sunshine recorder, however, is but a rough instrument at the best, and its results are never regarded as scientifically accurate.

The trade in photographic paper has been greater last year than on any previous occasion, if we may trust some of the German returns. The united manufacturers of photographic paper at Dresden, for instance, albumenized no less than 16,100 reams of paper, and sold during that same period 16,545 reams. The nett profit made by this company was 271,251 marks (say £13,500), which is 18,929 marks (£945) more than last year. Another firm of photographic manufacturers, that of P. Berg, acknowledges a nett profit for the past year of 42,160 marks, (£2,108).

"Golden fabric" for the dark-room window is a new material introduced, at the suggestion of Mr. J. W. Zaehnsdorf, by Messrs. Law and Co., the manufacturers of "cherry fabric." Mr. Zaehnsdorf speaks enthusiastically of it, as it allows a flood of clear yellow light to pass without endangering the plate. It is said to be coloured with tri-nitro. naphtol or Martius' yellow. Mr. Zaehnsdorf gave a demonstration with it at the meeting of the Photographic Club on Wednesday exening.

In the New York *Deutschen Apotheker Versammlung*, Mr. S. T. Bendiner recently called attention to a new sensitive compound—namely, a mixture of iodoform and calomel, in the proportion of two parts of the latter to one of the former. Mr. Bendiner exposed five samples to light for six hours—No. 1 under colourless glass, No. 2 under amber yellow, No. 3 under cobalt-blue, No. 4 under black glass, while No. 5 sample was upon white paper, and uncovered. After the lapse of time mentioned, No. 1 specimen became brick red, Nos. 2 and 3 exhibited here and there spots of a dirty red colour. No. 4 was unchanged, and No. 5 assumed an intense dirty yellow tint. Further exposure for three hours brought about no change in No. 4, but Nos 1 and 5 grew more red. The reaction, which probably rests upon the production of iodo-chloroform, goes on more rapidly by heating. We have here, then, another interesting body sensitive to light, with which photographers will no doubt make experiment.

When nearly everybody looks upon being photographed as a mild form of torture, it is refreshing to hear from so eminent an authority as the late Cetewayo that there is a lower depth still. Mr. Whiteley, the "universal provider," has been discoursing concerning his relations with the Zulu monarch. Mr. Whiteley—who, it seems, was commissioned by the Government to "provide" for his majesty during his stay in London—tells us that the most miserable day Cetewayo spent while in the metroplis was that on which he had to sit for his portrait to the Queen's portrait painter. Not knowing what awaited him, the King had gaily consented; "but he had imagined," observes Mr. Whiteley, "that it was a process of photography, and great, indeed, was his disappointment and weariness when hour after hour went by, and still the man with the brush went on with his work." It is to be hoped that the incident here recorded will have the widest publicity, so that sitters may be encouraged when they are asked to remain perfectly still for a few seconds.

Now that the electric light has become familiar in every-day life, it is well to glance back to see how far English philosophers have helped to usher it into being. The first arc-light publicly displayed was that shown by Sir Humphry Davy at the Royal Institution in 1813, when he employed a battery power no less than 2,000 pairs of plates, representing a surface equal to 128,000 square feet. The plates were excited by a solution of alum acidified with sulphuric acid. Faraday it was who, later, at the same institution, showed how magnetism could be converted into electricity, and thus discovered the principle upon which all the powerful dynamo machines of the present day are founded. Finally, the first incandescent lamp, commercially successful, was also that of an Englishman, our friend Mr. Swan, whose invention still holds its own in the front rank. So that, while we do not wish to ignore the many important improvements in electric lighting made on the Continent and in America, British philosophers, it will seem, have at any rate contributed a full share to the invention.

A correspondent who has had a photographic business to dispose of relates his experience. Out of about thirty answers, some eight or nine were written on dirty half sheets of paper and in villainous handwritings. About one-fourth came from residents in London, and the remainder from all parts of the country, showing that the metropolis is still looked upon as the goal of the provincial photographer. On one point, singular to say, all the

writers agree—each one was a superlative operator, and his work absolutely first-class. "I do not fear any competition," writes one, "because I know no one can turn out better pictures." "The quality of my work is the very best, and only a first-rate business would suit me," says another. "I am most particular over every picture I send out, and am certain few can beat me," and so on. If these gentlemen do not overrate their abilities, the fact that out of thirty photographers taken at random, not one is an inferior manipulator, is a most cheering one. But we fear the news is too good to be true.

Patent Intelligence.

Applications for Provisional Protection.

5134. Louis de Roux, residing at Begles, near Bordeaux, Gironde, France, for "Engraving by photography without retouch on my system of metal, which he names 'Cœlator.'"—Dated 19th March, 1884.

5164. Walter Bentley Woodbury, 35, Southampton Buildings, Middlesex, Photographer, for "An improved device for testing the presence of moisture in linen and other articles."—Dated 19th March, 1884.

5353. Heinrich Kayser, Doctor of Philosophy and Lecturer at the University in Berlin, 16a, Neue Wilhelm Strasse, Berlin, Germany, for "Improvements in photographic exchange boxes with sleeve for preventing the penetration of light to the plates."—(Complete Specification.)—Dated 24th March, 1884.

Notice to Proceed.

5464. Albert Kepler, of Peckham, in the county of Surrey, Archille Morin de Bremion, and Alfred Pigeau, of Lombard Street, in the city of London, for an invention of "Improvements in the manner, method, or mode of preparing and producing coloured photographs, and in the arrangements and apparatus employed therefor."—Dated 20th November, 1883.

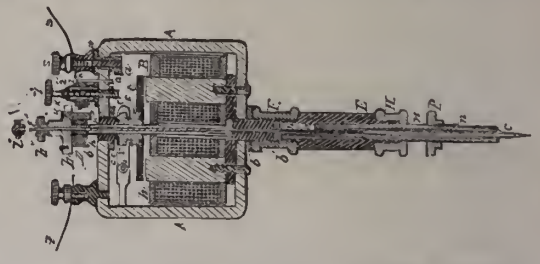
Specification Published during the Week.

3948. Joseph Julius Sachs, of 8, Union Court, Old Broad Street, in the City of London, "Improvements in the manufacture of pliable plates and surfaces as a substitute for Glass for Photographic and other purposes," a communication to me from Messieurs Fickeisson and Becker, resident at Villingen, Baden, Germany.

This invention relates to the manufacture of pliable plates and surfaces for various purposes. These plates or surfaces can be prepared from paper, cloth, or other suitable fabrics or materials, but, by preference, of white paper, which contains very little size, and does not possess much grain. This paper is first extended on a frame, or other arrangement, according to the size of the plate or surface which is desired. After it is dry, the surface is covered in any convenient manner with a fine varnish or composition, such as copal varnish, for the purpose of rendering the fabric transparent. It is then dried, and after it is quite dry, the surface is rendered smooth by the application of powdered pumice stone or other suitable material, or it may be smoothed by suitable machinery. This process of smoothing may be repeated, if necessary, two or three times, until the surface or plate is smooth or transparent. The surface so prepared is then covered on one or both sides with a solution of gelatine or isinglass, or other substance possessing similar properties, and allowed to dry. The surface so prepared may, if desired, be further treated with a preparation of ox-gall, from which the fatty matter has been extracted by acetate of alumina or similarly acting agents, which will precipitate the fat of the gall, the resulting preparation being then passed through a filter, whereby a clear solution will be obtained, with which the plate or surface may be covered, so as to secure the safe reception of the emulsion for photographic or other use. Instead of ox-gall, any similarly acting substance or material may be used. The plates or sheets prepared as above may be used with great advantage in reproducing photographs from nature, in lines or stipples, for calico and other printing, as the stipples or lines can be printed first on the material before it is made transparent. Any photographic design or drawing can be put on the transparent surface in the usual way; and by using the said film as a negative or positive in photographing from nature or from drawing, half-tones will be reproduced in lines and stipples available for any kind of printing. As these plates or sheets are waterproof, they can also be used as surfaces upon which can be printed or produced all kinds of ornamental and useful work. Having now described and particularly ascertained the nature of my said invention, and the manner in which the same is or may be used or carried into effect, I would observe, in conclusion, that what I consider novel and original, and therefore claim as the invention secured to me by the hereinbefore in part recited letters patent is, the manufactnre of pliable plates or surfaces by treating paper or other fabric in the manner hereinbefore described.

Patent Granted in America

294,817. Charles H. Shaffer, Rockford, Ill., assignor of one-half to Jones, Woodruff, and Co., same place. "Retouching-machine." Filed August 11, 1883. (No model).



Claim.—1. The combination, with the tubular shaft, with an armature mounted thereon, and capable of a rotary movement, of a centre shaft supported in the axial centre of the tubular shaft, and capable of an endwise reciprocating movement therein, substantially as and for the purpose set forth.

2. The combination, with the tubular shaft, with an armature mounted thereon and capable of a rotary movement, and with the centre shaft supported in its axial centre, of a clutching mechanism to connect the centre shaft with the tubular shaft, or disconnect it therefrom, substantially as and for the purpose set forth.

3. The combination, with the centre shaft supported in the axial centre of the tubular shaft, and capable of a rotary motion therewith, of a spring within the tubular shaft, and a cam to engage an anti-friction wheel to impart an endwise reciprocating movement to the shaft in its rotary movement, substantially as and for the purpose set forth.

4. The combination, with the spring within the tubular shaft, and a cam mounted upon the central shaft, of an anti-friction wheel having an adjustable support to vary the throw of the shaft in its endwise reciprocating movements, substantially as and for the purpose set forth.

5. The combination, with the anti-friction wheel having an adjustable support, of a spring within the adjustable tubular support, substantially as and for the purpose set forth.

6. The combination, with the adjustable tubular support of the anti-friction wheel, having its base grooved, of a guide-bar to engage the groove in the base of the support, substantially as and for the purpose set forth.

7. The combination, with the cam mounted upon the centre shaft and clutch-head, of a pivoted lever-latch capable of radial position, substantially as and for the purpose set forth.

8. The combination, with the cam and with the clutching-latch pivoted therein, of a spring to hold the latch in its clutching or radial positions, substantially as and for the purpose set forth.

9. The combination, with the cam mounted upon the centre shaft and disengaged from the clutching-head, of an anti-friction wheel supported in the clutch-head to impart an endwise reciprocating movement to the centre shaft, substantially as and for the purpose set forth.

10. The combination, with the centre shaft and with the hand-piece, of a pencil-receiving tube having its projecting end provided with a pencil-holder, said tube suitably connected with the centre shaft and supported in the axial centre of the hand-piece, and capable of a rotary and reciprocating movement therein, substantially as and for the purpose set forth.

A TABULAR STATEMENT OF THE MOST IMPORTANT DISCOVERIES ON THE CHEMICAL ACTION OF LIGHT, AS BEARING ON PHOTOGRAPHY.

BY DR. J. M. EDER.

Although I published in the year 1881 certain fragments of the byegone history of photography in the *Photographische Correspondenz*, there still appear, unfortunately, from time to time, incorrect and imperfect statements concerning many well-known landmarks in our art. I should still have been silent on this subject had not Mr. Robert Hunt, in the Year-Book for 1882, in an article on "Photographic Researches" before Daguerre, repeated some of these data which, according to my experience, are quite untenable, and had there not appeared in the *Photographic Journal* for February (page 81) a "Table showing discoveries regarding action of light, drawn up by R. Hunt, F.R.S., for the British Association in 1850," which on many points runs counter to the information I have myself gained on the subject.

I place the result of my own researches side by side with those of Hunt, so that the fallacy of the latter may be more readily perceived.

Hunt's Table (1850).

Silver.		
Nitrate of	Ritter	1801
— (photographically (employed)	Wedgwood and Davy	1802
— with organic matter	J. F. Herschel	1839
— with salts of lead	J. F. Herschel	1839
Coloride of	C. W. Scheelcs	1777
— (photographically employed)	Wedgwood	1802
	Talbot	1839
— darkened, and hydriodic salts	Fyfe Lassaigne	1839
Iodide of (photographically used)	Herschel	1840
	Ryan	1840
— with ferrocyanide of potash	Hunt	1841
— with gallic acid (calotype)	Talbot	1841
— with protosulphate of iron (ferrotype)	Hunt	1844
— with iodide of iron (catalysotype)	Woods	1844
Bromide of	Bayard	1840
Fluoride of	Channing	1842
Fluorotype	Hunt	1844
Oxide of	Davy	1803
— with ammonia	Uncertain.	
Tartrate, urate, oxalate, borate, &c.	Herschel	1840
Benzoates of	Hunt	1844
Formiates of	Hunt	1844
Fulminates of	Hunt	1844
Silver Plate.		
With vapour of iodine (Daguerreotype)	Daguerre	1839
With vapour of bromide	Goddard	1840
With chlorine and iodine	Claudet	1840
With vapour of sulphur	Niepce	1820
With vapour of phosphorous	Niepce	1820
Glass Plate.		
Precipitates of silver	Herschel	1839
Albumen	Niepce de St. Victor	1848
Collodion	Archer and Fry	1850
Gold.		
Chloride of	Rumford	1798
	Herschel	1840

My tabular statement, it will be seen, contains several fresh contributions to the history of photo-chemistry, not previously known. Still, it does not profess, in any way, to be complete. In fact, it includes only the older discoveries, and there is not a doubt that hereafter it will be rendered fuller. The quotations and their sources I have myself personally verified, and I shall be happy, in case any of my readers desire it, to indicate how the same may be substantiated. It is only because I do not wish to take up too much space that I have not included the quotations here. In my "History of Photo-chemistry," they are all published at length.

Correspondence.

THE PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

SIR,—Allow me, as a member of the Photographic Society of Great Britain, to call your attention to the inexact way in which notices of many of our meetings are given in the PHOTOGRAPHIC NEWS; and, indeed, as I shall presently point out, the reports which you insert are themselves by no means all that the members of this Society have a right to expect.

You will remember that some years ago the Photographic Society of Great Britain instituted "Technical

Meetings," these being held between the ordinary monthly gatherings; and quite recently the title has been changed to "Monthly Technical Meeting" (I am told that this addition to the name has been made at the suggestion of a Provincial or Suburban Photographic Society, it having been alleged that they held meetings under the original title).

Now what I complain of is this. In speaking of the new intermediate meetings, you frequently allude to them as "social gatherings," "pleasant assemblies," "mid-monthly meetings," &c., &c., while you very seldom use the correct designation. In addition to this, your reports of the Technical meetings are absurdly incomplete, and the mere fact that there are seldom more than fifteen or eighteen persons present, indicates the need of full reports, in order that all those members of the Society who see the Photographic News may be promptly posted up in what goes on.—Yours, &c., Councillor.

March 26, 1884.

OLD LONDON.

Dear Sir,—In your last issue you express regret that so little is known of the publications of the Society for Photographing Relics of Old London, and that there ought to be some public place where these could be seen. Specially you name the South Kensington Museum and the Guildhall Library. You will be pleased to learn that both those institutions, as well as the Library of the Royal Academy, Burlington House, subscribe for them; and a full set, which, including one dozen just about to be issued, amounts to ninety-six, can no doubt be seen at either place. Also a set is always on view at 112, Albany Street, N.W.—Yours truly, Henry Dixon.

PHOTOGRAPHY AND ENGRAVING.

Dear Sir,—Here is a twin picture to the Fine Arts Co.'s complaints. Last year, the Society for Reproductive Arts held an exhibition in Vienna, to which were welcomed not only engravings on metal and wood, but helio-engravings, photo-mechanical prints, &c.—in fact, all that was applicable to book illustration, with the exception of ordinary silver prints. Notwithstanding this special invitation, it appears from the final report of the Exhibition commissioners, just published, that the jury, composed chiefly of painters and engravers, unanimously excluded from participation in the prize awards all methods of reproduction in which photography played a rôle.

Now, photo-mechanical reproductions materially assisted in making the Exhibition a success, yet, although the vice-president of the central commission called the jury together again after its dissolution, to reconsider the matter, they stoutly refused to alter their decision. The reason surmised is, that engravers did not like to openly countenance the photo-engraving methods, since they are such formidable usurpers. Mr. Comyns Carr, in his lectures last year, speaking of Mons. Rousellon's process, said that, in some cases, it surpassed some of the older methods of engraving!

On dit, that some engravers like the process, as one firm I wot of, employ four skilled engravers at high salaries merely to retouch photo-engraved plates.—Faithfully yours, C. Chesterman.

Proceedings of Societies.

The Photographic Society of Great Britain.

A meeting was held at the Gallery, 5a, Pall Mall East, on Tuesday, the 25th inst., Mr. John Spiller, Vice-president, in the chair.

Two queries were found in the question-box. The first referred to Mr. Spiller's method of reducing gelatine negatives with a solution made up of alum, sulphate of copper, and common salt (see the Year-Book p. 68). The questioner wished to know if the solution could be advantageously returned to the stock bottle after having been used.

The Chairman said he thought that, considering the extreme cheapness of the solution, it would be better to throw it away after the first time of using, than to run the risk of any diminished vigour in its action.

The second question had reference to some prints which had been sent to Mr. Ashman. The albumen face had disintegrated, and partly come away during the washing.

Mr. Sebastian Davis thought that the fault might result from the use of a weak sensitizing bath, and the consequent imperfect coagulation of the albumen.

Mr. England suggested that perhaps the paper had been too strongly sized, and that the disintegration was the result of numerous small blisters

Mr. Ashman, however, attributed it to sensitizing in a very cold place, and thought that the solution either partially froze or crystallized, and in doing so broke up the albumen.

Mr. Best showed examples of the distortion which results from the unequal shrinkage of albumenized paper, and it was pointed out that the dry mounting method (Photographic News, 1883, p. 516) affords a satisfactory remedy for the mischief. Two cabinets, one to illustrate equatorial contraction, and the other to show longitudinal contraction, were handed round, and Professor Donkin found that the difference in their length was as 152 to 145.

Mr. Ashman exhibited Mr. Offord's registering frame, which was described on p. 162 of our present volume, and he said it had been very much admired at the last meeting of the London and Provincial Photographic Association.

Mr. W. E. Debenham exhibited a folding lantern in which green oil silk was used in conjunction with yellow paper, the result being satisfactory.

The Chairman read an extract from Dr. Halleur's *brochure* on photography, published in 1854; it referred to Poitevin's gelatino iodide process (published in 1850), and to the undesirability of using common glue. Working details of this process will be found on page 206 of the first volume of the Photographic Society's Journal.

Mr. Meldola's slides of the Nicobar Islands were not shown, but it is intended that they shall be exhibited at the next meeting (April 8).

London and Provincial Photographic Association.

A meeting of this Society was held on Thursday, the 20th inst., Mr. J. Traill Taylor in the chair.

Mr. W. M. Ashman exhibited a printing-frame for securing perfect registration, made on the principle designed by Mr. R. Offord, and described on page 162 of the present volume of the Photographic News. Mr. Ashman remarked that, no matter how many times the opal picture be examined during the process of printing, no loss of sharpness need result.

Mr. A. L. Henderson said the old form, in which springs and a screw are employed for securing the plates, was a perfect nuisance; if the plates are fixed well down in a corner of an ordinary printing-frame, perfect registration would result.

M. A. Cowan understood the advantages gained to be the facility by which small pieces of opal may be printed from any portion of a negative; in the case of large size opals, the pneumatic arrangement would require to be distributed.

Mr. Ashman replied that, when larger sizes than quarter-plates are used, two suction-plates are recommended.

Mr. W. E. Debenham considered the idea very good; but should prefer registering at two points instead of four.

The Chairman was much pleased with Mr. Offord's new departure, which he considered very clever. To be able to print small portions of opal or even transparencies from large negatives is a great advantage, no special size being used; there are many ways in which the principle underlying its construction might be useful to photographers, and he thanked Mr. Ashman for bringing it before their notice.

Mr. Cowan passed round a negative handed to him by Mr. Henderson to test. It received only one-third the exposure required for an ordinary commercial plate; he believed there was a new departure in making the emulsion.

In response to the chairman, Mr. Henderson said his experiments were not ripe for publication; he would complete his experiments, and give the formulæ on another occasion. Replying to further questions, he said the sensitive salt was

obtained by double decomposition, no gelatine, castor oil, gum, or colloid body being present; the gelatine is added after the salt is formed, the temperature being 120° F; the emulsion is then set, and washed thoroughly. By his new plan, bromide of silver is formed in a spongy condition, the solutions used being highly concentrated.

Mr. Cowan said he had only one fault to find with the plates, and that was the thinness of the coating; it was necessary to intensify the plates shown to get a satisfactory print. He used Monckhoven's formula.

Mr. Henderson attributed the thinness to over-exposure.

Mr. Cowan replied that he tried a plate with less exposure, and it was worse; he found in using Monckhoven's intensifier it was necessary that the negative should appear too dense. The best results were obtained in this way.

A conversation then took place on the suitability of *papier mineral* and like substances, to receive a coating of gelatine emulsion either for stripping to obtain pellicle, or as a base for paper negatives. Paper varnished with ordinary spirit varnish, also benzole varnish, and tracing cloth, being advocated.

The Chairman enquired if any present would give their experience with negatives on paper faced with gelatine emulsion—not Talbotypes. With regard to the latter process, he possessed some exceedingly fine negatives taken from inscriptions in the books of a library; one by Fox Talbot being very perfect, showing that granularity sometimes complained of does not operate against the value of the process.

Mr. A. Haddon expected better results to be obtained on gelatino-bromide paper negatives, than with the old Talbotype process, because in the latter case the image is entirely on the surface.

Mr. W. Cole recently saw prints of the same subject from glass and paper negatives; it was necessary to look very closely to say which was the paper negative.

Mr. Ashman said so closely can they be made to resemble each other, that nine persons out of ten select the wrong print when they are placed side by side.

Mr. Moule had no difficulty in making negatives with ordinary bromide paper made transparent with castor oil.

Mr. Briginshaw, in showing a lantern slide in which two very thin glasses occupied less space than some single plates do, dwelt on the advantage of portability which would accrue if thinner plates were in more general use.

A discussion then took place on the quantity of silver extracted from the sensitizing bath with various makes of papers, and long or short floating, Messrs. Ayres, Debenham, Henderson, and the Chairman taking part.

Messrs. R. Chipperfield and F. G. Nicholls were elected members of the Association.

Lochee Photographic Club.

There has just been erected in Marshall Street a new studio for this Club. The studio is an exceedingly neat and commodious structure, and is fitted with all the most recent appliances for the efficient prosecution of the art. On Tuesday evening the formal opening took place, when there was a large attendance of members. Bailie Ogilvie, the President of the Club, occupied the chair, and, in the course of a brief opening address, congratulated the members upon the realisation of their great desideratum—a studio. He referred to the success which had attended the Club since its commencement in April last, the membership at present being thirty. The ample facilities they now possessed for carrying on their photographic studies and experiments would, he had no doubt, be taken advantage of, and the Club in this way would have its efficiency and influence largely extended. They would be all most willing to afford every information and help in their power to beginners who might connect themselves with the Club.

After consideration, certain rules for the guidance of members in using the studio were agreed to by the meeting. Seven gentlemen were also proposed for membership.

Mr. Robert Keir, in proposing a vote of thanks to the Chairman, referred to the great interest he had taken in the development of the Club and in the erection of the studio. But for the Bailie's enthusiastic encouragement of the venture, the Club would not have prospered so remarkably.

Dundee and East of Scotland Photographic Association.

This Society had a special lantern evening on Thursday, 20th inst., at which there was a very large attendance of members and their friends. Mr. J. C. Cox presided.

The principal feature of the exhibition was a lantern slide competition open to members, the number of slides being limited to three each. Voting papers were distributed amongst the members present, and 300 marks were allowed to each voter for each set of three slides.

The following was the result of the voting:—John Mathewson, 4,111; D. Ireland, 3,980; D. Ireland, jun., 3,961; J. Y. Rogers, 2,595; A. Simpson, 2,532; J. R. Wilson, 2,355; W. M. Martin, 2,002.

Many of the slides were on Chapman's gelatine albumen plates, and several on Cowan's chloride plates, the whole, with one or two exceptions, reflecting great credit on the exhibitors.

A lantern exhibition then followed, to which Messrs. Valentine, Mathewson, Ireland, Wilson, Martin, Rogers, Ritchie, and others contributed.

A frame of transparencies kindly sent by Mr. Cowan was shown and very much admired, and several members expressed their determination to make a trial of these plates, which, as yet, are not in general use here.

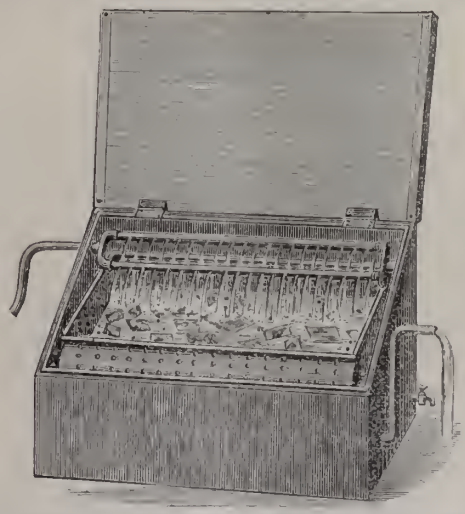
Mr. John Whawdon exhibited and explained a new American camera, embodying a number of ingenious movements.

The usual votes of thanks brought an exceedingly enjoyable evening to a close.

Talk in the Studio.

South London Photographic Society.—At the next meeting to be held at the Rooms of the Society of Arts, John Street, Adelphi, on April 3rd, at eight o'clock, Messrs. C. and F. Darker will exhibit some objects in the lantern polariscope, and the following (from the question-box) will be discussed: "Does the burnishing of prints produce any chemical change in them?"

Marion and Co's New Registered Washing Apparatus.—Messrs. Marion and Co. have recently introduced a new apparatus for washing prints, of which we append a sketch. The great



feature of the apparatus, Messrs. Marion inform us, consists in the rotatory movement of the prints, caused by the system of inflow and outflow of the water. The prints are in constant motion with the water; they circulate continuously in the trough from top to bottom, and never curl together. An hour-and-a-half is said to be sufficient to thoroughly wash them.

A Machine for Wiping Emulsion from the Backs of Plates.—Plate makers have experienced much annoyance from the presence of traces of emulsion on the backs of the plates, this causing adhesion to the levelling slab. Mr. Cowan has recently constructed an ingenious machine, which wipes each plate as it leaves the hands of the coater. The plate is laid over the jaws of a kind of wooden vice, these jaws being clothed with flannel, and as the jaws open, the back of the glass is effectually wiped, after which the plate drops through on the bars of a levelling arrangement. In order that fresh flannel may be used for each

wiping, the covering of the jaws is made to shift onwards about three-sixteenths of an inch after every action of the machine; a ratchet or roller arrangement being used. When the whole of the flannel has been used, it is replaced by fresh, and the old material is washed. The machine is actuated by a pedal which is pressed each time a plate is deposited upon the impress.

PIRATING PHOTOGRAPHS.—William Smith, a wholesale photographer dealer in Vine Street, Minories, was summoned on Friday last, at the Mansion House, for an infringement of the Copyright Act in selling pirated copies of a photograph of Miss Mary Anderson. There were nine more summonses in respect of other photographs. Mr. Foote was counsel for the prosecution, Mr. Tickell for the defence. Evidence was given that the copyright of the photograph in question of Miss Anderson was vested in Mr. Henry Van der Weyde, of 182, Regent Street, and it was alleged that the pirated copies had been sold by the defendant to hawkers at the rate of six shillings per gross. Among other places at which they were sold was the recent World's Fair at the Agricultural Hall, and it was asserted that the defendant when selling them advised that they should not be publicly exposed. Mr. Tickell submitted that the defendant had no guilty knowledge that the photograph was a piracy, and stated that he had sold none since his attention had been drawn to the matter. The Lord Mayor said the defendant had been before the court previously under discreditable circumstances connected with the sale of photographs, and he thought the case was proved. The defendant then pleaded guilty on the other nine charges, the circumstances said to be the same. The Lord Mayor fined the defendant £10 in each of two cases, and £3 3s. costs in each, and respited judgment in the remainder of the charges. The defendant paid the fine. Messrs. Neish and Howell, of Watling Street, write to say that their client, Mr. Henry Van der Weyde, was not, as would appear, the only prosecutor. They wish it to be stated that the defendant was also summoned for pirating copyrights the property of their other clients, Messrs. Poulton and Son, of Lee, Kent, and that he pleaded guilty to three.—*Daily Chronicle.*

PHOTOGRAPHIC CLUB.—At the meeting on April 2nd, the subject for discussion will be "On the best lenses for large portraits on geletine plates."

To Correspondents.

*** We cannot undertake to return rejected communications.

*** ERRATUM.—We mentioned last week that Mr. George Renwick received a silver medal at the Calcutta Exhibition, but we gave his address as Northampton; it should be Burton-on-Trent.

A CONSTANT READER.—We cannot even form a conjecture as to the cause, as we do not know what process you adopted, or anything about your method of working.

X. Y.—1. All depends on the condition of the closet, and the number of plates you put into it. If the closet is thoroughly dry, less time than that you mention will suffice. 2. Yes.

G. BEARD.—Thank you for suggestion, but, as you intimate, the advantages would not compensate for the loss of light and the extreme narrowing of the angle of view which would result from such an arrangement.

DAMP.—1. Your description interests us, and we should like to see a sample. 2. By keeping the moisture in.

H. P. T.—1. Yes, very good indeed; and for ordinary work a simply-constructed piece of apparatus, such as that to which you refer, is very much to be preferred to more complex contrivances. Although there are theoretical reasons for using the shutter in the position of the diaphragm, it is more convenient and more usual to use it in front. We advise you to follow the usual course. 2. If you tell us what lens you intend to use, we may be able to give you some idea. 3. It appears to us that the plate has been generally light fogged. Do you think that your dark-room lamp is safe? 4. Yes, very good.

A. MORRISON.—1. They are printed direct on the glass; it is easier than to make prints on paper. 2. It makes no difference. 3. Our publishers will secure the registration if a print if sent together with a fee of 1s. 6d. 4. Under favourable circumstances it may remain good for a day or two. 5. A sample with a more pronounced grain would be better.

P. S.—It appears to us that the mischief is due to the presence of hyposulphite in the mounts; but see our answer to F. Barrett in the issue of 22nd Feb. last, and read the leader which appears in the same number. If you find the mischief is due to the mounts, you should claim damages against the firm from which you procured them. Let us know the result of your enquiries.

J. S.—1. Yes, quite sufficiently simple for one knowing nothing of the subject. 2. Moderately full directions: remember, it is only a small book. 3. One shilling. 4. Anything from £5 upwards.

A. G. B.—1. You are quite right as to precipitation not taking place under the circumstances you mention. 2. We prefer Eder's for regular work. 3. We think not, but imagine that any plate maker would be willing to enter into such an arrangement.

ASPIRANT.—Mr. A. L. Henderson, of London Bridge, is noted for work of this class. You had better write to him.

J. P.—The main point is to select flat glass. Let us, however, know the exact nature of your difficulty.

PIN.—1. We should suggest that of Asser. 2. It is to be found in the YEAR-BOOK. 3. The details have not been published. 4. No.

J. ADAMS (Liverpool).—1. A photographic portrait of Mr. W. B. Woodbury (taken from the same negative as the picture which you enclose) appeared on page 464 of our volume for 1882, and also in the YEAR-BOOK for 1883 (page 129). 2. We have already given photographic portraits of all the distinguished men to whom you allude, and we have no intention of re-issuing them just at present. 3. The paragraph is interesting, but as we treated of the subject in a leader rather more than a year ago (vol. xxvii., p. 2), we do not care to occupy valuable space with a repetition. It is more convenient to use a solution of hyposulsulphito to which a little sulphuric acid has been added, than to employ a simple solution of sulphurous acid in water. Those who practise the bichromato processes of photography have found our suggestion to be a valuable one, as the stains are removed immediately. 4. There must be some mistake, as the series does not begin with the first volume, but the sixth or seventh; but the complete set of the PHOTOGRAPHIC NEWS (twenty-seven complete volumes) may be referred to at our office. 5. The PHOTOGRAPHIC NEWS is the only weekly Photographic Journal printed and published in London.

A. H.—The apertures are such that if one unit of exposure is required with the largest diaphragm, the following exposures will be required with the remaining stops—No. 1 stop 1 unit, No. 2 stop 1½ units, No. 3 stop 2⅔ units, No. 4 stop 8 units, No. 5 stop 16 units. With a plate of average sensitiveness, and using the largest stop, a second might be required for an out-door group in the shade. Still, the absolute exposure for one stop must be determined experimentally.

HARDWICH'S MANUAL.—In the advertisement of this book in our columns by Messrs. Churchill, the name of the author was printed Hardwick in error; it should, of course, have been Hardwich.

Employment Wanted.

Operator & Retoucher.—J. B., *Photo. News* Office.
Vignetto Printer and Toner.—P. T. F., 4, Wellington-st., Belfast.
Recep.-room, young Lady, experienced.—A. B., 72, Azenby-sq., Peckham.
Assist. Operator (photo's. son).—Z., c/o Mr. Gregory, High-st., Marlboro'.
Oper., Retoucher, &c.—Manager, Taunt & Co., High Wycombe, Bucks.
Recep.-room, Lady, in prov.—Alpha, 10, Kempshed-rd., Albany-rd., S.E.
Gen. Assist., can repair apparatus.—T. Edmunds, 2, Haven-ter., Ealing, W.
Lady, in studio, can tint.—A. H., 15, Arlington-rd., N.
Recep.-room, Spotting, &c. (Lady), first-class.—A. B., *Photo. News* Office.
Printer & Toner, first-class.—Photo. 8, Stile-gr, Gunnersbury, Chiswick.
Assist. Operator, good printer & toner.—E. W., 31, Sutherland-st., Pimlico.
General Assistant, 21/-.—C. S., 7, Jeffries-st., Kentish Town Road.
Recep. Room Lady, exp.—H. Beale, 39, De Beauvoir-rd., Kensington.
Retouch., in or near London.—Retouch., 2, Hanover-pl., Regent's-pk.
Operator or Manager, home or abroad.—A. E. Walker, Eastwood, Notts.
Printer & Assist. Operator.—A. S., 47, New York-st., Manchester.
Mounter, Cutter, Spotter (lady).—H. H., 12, Croysland-rd., Chalk Farm.
Printer, Toner, General Assist.—Photo., 3, Alma Cottages, Barking-rd., E.
Retoucher and Operator, first-class.—H. S. Healey, 32, Stall-st., Bath.
Retoucher, Mounter, Finisher (lady).—B. C., 10, Patrick-st., Cork.
Op., &c. (Italian, speaks Fnch. & Eng).—L. S., 35, Grove-lane, Camberwell.
Printer, Retoucher, assist generally.—Argent, *Photo. News* Office.
Retoucher and Assistant Operator.—W. Leuchars, 51a, Perth-rd., Dundee.
Colourist & Ret. (lady).—E. McCowen, 20, Grand Parade, St. Leonards-o-S.
Printer, generally useful.—C. R. M., Station-rd., Sleaford, Lincoln.
Operator and Retoucher, speaks French.—Franco, *Photo. News* Office.
Operator and Retoucher, wet or dry.—X. Y. Z., P. O., Bitton, nr. Bristol.
Retoucher and Assist. Op.—W. H. T., 11, Kirkwood-rd., Haverstock-hill.

Employment Offered.

Positive work, single man.—R. W. Pitt, Devil's Dyke, Sussex.
Chromo. Printer, lady or gentleman.—Chromotype, *Photo. News* Office.
Junior Clerk.—Letter only to Boning & Small, 22, Baker-st., W.
Printer, Develop Dry Plates, & Operate.—9, Widdicombe-ter., Barking-rd.
Operator & Printer, Landscape work, &c.—Taunt & Co., Oxford.
Operator, indoor or out.—C. Gillman, 107, St. Aldate's, Oxford.
Assistant, first-class.—C. Gillman, 107, St. Aldate's, Oxford
Neg. Retoucher (lady), first-class.—W. H. Mason, 89, George-st., Croydon.
Operator, clever at lighting and posing.—Artist, 22, Red Lion Square.
Operator and Retoucher, to manage.—West and Son, Eagle House, Gosport.
Printer and Assistant immediately.—S., 38, Queen's-sq., Bristol.
Neg. Ret., &c.—T. Williams, Talbot-pl., Darlington-st. Wolverhampton.
Operator, skilful & clever Ret.—S. W. Barns, 100, High-st., Ashford, Kent.
Retoucher (lady)), quick, 30/- weekly.—Stuart, 47, Brompton-rd., S.W.
Retoucher, good.—Barraud, 263, Oxford-st., W.
Assistant in Stock-dealer's Warehouse.—Ruby, *Photo. News* Office.

THE PHOTOGRAPHIC NEWS.

VOL. XXVIII. No. 1335.—*April* 4, 1884.

CONTENTS.

GELATINE AS A BROMINE ABSORBENT.

MANY theories have been advanced to explain the difference of sensitiveness which exists between a collodio-bromide and a gelatine emulsion. It has been held that the bromide of silver which is suspended in a collodion emulsion is in a totally different molecular condition from that which is suspended in a gelatine emulsion. The difference in sensitiveness is said by those who hold this theory to be due entirely to this different molecular condition, and to be entirely independent of the suspending emulsion, except in as much as this may tend to bring about the particular condition.

Again, it is pointed out that the restraining property of gelatine is such, that a developer which, without the action of light, would reduce silver bromide either alone or in a collodion film, will not so reduce it in the film of a gelatino-bromide plate. This enables a much stronger developer to be used with a gelatine plate than with a collodio-bromide one.

Another explanation of the superior sensitiveness of a gelatine plate is, that the gelatine acts as a bromine absorbent. This theory is a very plausible one. The action which is imagined is somewhat as follows. It is supposed that the effect of light on a molecule of silver bromide tends to set free one atom of bromine. The amount of light requisite actually to do this varies according to circumstances; and amongst others, according to whether or not there is in proximity to the molecule of silver bromide any substance which will readily absorb the bromine—so to speak, sponge it up. A substance which will do this—or at least, which has an action supposed to depend on its property of doing it—is called a sensitizer, and it is supposed that gelatine is a sensitizer in this sense.

When we come to consider molecular action such as the above, it is very difficult to either prove or disprove a certain theory, and, therefore it is with anything but positiveness that we bring forward certain facts which appear to point out that gelatine does not act as a sensitizer in the manner described, or does so only in a very slight degree.

We have recently been experimenting on the use of free bromine in gelatine emulsions, with a view to the elimination of fog. These experiments we shall not describe in detail at present. The idea of using free bromine to counteract the influence of light is very old—we believe almost as old as the Daguerreotype itself. It was the custom of Claudet, the famous Daguerreotypist, when he noticed that a sitter had moved during exposure, to place the sensitive plate for a few moments in the fumes of bromine, when the effects of the light which had acted upon it were entirely eliminated.

We may say that we have found bromine capable of eliminating light-fog, and also certain varieties of chemical fog from gelatine plates. It is not upon this that we intend to dwell just now, however, but upon the bearing which the use of it has on the theory which is explained above.

Bromine can be had in the form of a heavy fluid of a dark colour, which is very volatile. It is not convenient for use in this form, and a word of warning may not be out of place to those who think of experimenting with it. If it comes in contact with any part of the skin, a very painful sore will result. A drop of this liquid running down the back of the hand will cause a long burn, which will pain for many days.

The fluid bromine is soluble in water, and the solution or mixture generally known as bromine water is the most convenient for practical use. The amount of bromine which will remain in solution varies slightly with the temperature. It is a little less at a high than at a low temperature, on account of the volatile properties of the substance. The difference, however, is not great, and we may take it roughly that a saturated solution contains a little over three per cent. of bromine, or about one part in thirty.

The bromine water may be added to the emulsion during experiment, or the plates may be fumed over some of the water placed in a flat dish. In adding the bromine to an emulsion it is neceseary to bear in mind that it has a powerful action on the gelatine, rendering it insoluble in hot water when present in any considerable quantity. In one experiment which we made, an addition of four minims of bromine water to each ounce of an emulsion totally spoiled it. A much smaller quantity is, however, sufficient to cause the elimination of such fog as is eliminable by its means.

When we commenced our experiments, we concluded that whatever bromine was added to an emulsion must be so completely eliminated, either by washing or otherwise, that there would be no smell of it left. Our argument was, that so long as a plate smelled of bromine, this was proof that there was in the film more bromine than the gelatine could absorb, and that, as a consequence, this latter must have lost such sensitizing action as was due to its power of absorbing bromine.

To our surprise, we found that on adding sufficient bromine water to an emulsion to cause the plates coated with it to smell quite perceptibly of bromine whilst wet, we got no reduction of sensitiveness, or scarcely any. The plates were tested wet, and we supplemented our experiment by impregnating the films of dried plates with bromine by means of the vapour. The result was the same as before. The films which smelled quite perceptibly of bromine were as rapid as those that did not. It is, however, difficult to perfectly distinguish between the smell of free bromine and the odour of certain compounds which may be formed by its action on organic bodies.

It is certainly quite possible to add to an emulsion sufficient bromine (short of coagulating the gelatine) to reduce the sensitiveness of the plates whilst wet. It is found, however, that in such a case, the plates, even when they have been dried, and when by the drying process all the bromine has been eliminated by volatilization, the sensitiveness remains reduced. This seems to point to the fact that the reduction of sensitiveness arises from an action on the gelatine itself, this having been hardened or rendered less absorbent by the developer.

In experimenting with free bromine on emulsions it is necessary to bear in mind that there must be no iodide of silver present. If there is, the only effect of the addition of the bromine is to decompose some of the iodide of silver, forming bromide of silver, and setting free iodine; the effect of the free iodine appears, however, to be very similar to that of free bromine.

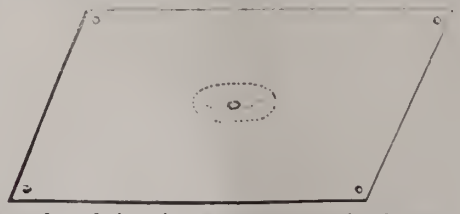
MR. R. OFFORD'S REGISTERING FRAME.

A few weeks ago we described an ingeniously-devised registering frame for printing on opal plates, the invention of Mr. R. Offord (p. 161); and as we have had several enquiries concerning it, we now give two diagrams illustrative of its construction.

The india-rubber sucker, which consists merely of a disc of soft red rubber an inch in diameter, rivetted to the sheet of zinc which takes the place of the back of the frame, is represented below, but the rivet should not project too much inside the sucker. When the face of the

sucker is well anointed with glycerine, a very little pressure serves to make the opal plate adhere firmly; but if the plate is large, it is desirable to have several suckers.

The method of mounting the zinc back in the printing frame is very simple, there being merely four small pins driven into the wood so as to correspond with the four holes in the sucker plate. A printing-frame of the portable



type is used, and the pins are consequently driven in the low part of the framework, just beyond the seating of the back. Mr. Ashman tells us that he has removed an opal plate from the frame no less than six times during an exposure, and no trace of false register was noticable.

THE WOODBURYTYPE PROCESS.

(Fourth Article).

To make a counter mould of the gelatine relief in lead, requires an amount of pressure which is, at first sight, surprising, and we may estimate the pressure required as about fifty tons for a quarter plate picture ($3\frac{1}{4} \times 4\frac{1}{4}$ inch), or two hundred tons for a whole plate ($8\frac{1}{2} \times 6\frac{1}{2}$ inch). In some instances, however, it is desirable to give even more pressure than this.

It is not necessary for us to say much as to the hydraulic press, excepting to say that, if expressly made for the Woodburytype process, a very small rise will suffice, and the bed or platten of the press need be scarcely larger than the top of the ram.

A press suitable for whole plates may be estimated to cost about £50, but a little more will have to be allowed to cover the cost of the steel plate upon which the relief is laid. Suitable presses are made by Tangye Brothers, of Queen Victoria Street, London.

A few words must be said as to the steel plate. It should be fully half-an-inch thick, and must be of the best cast steel or tool steel. After it has been carefully softened by being heated to bright redness, and being allowed to cool very slowly, it is planed all over with as much care as possible; but it is scarcely necessary to say that the photographer will, in most cases, have to send the metal to an engineer to be planed, as a planing machine is not often to be found among the appliances of the photographer's workshop. All round the edge of the plate, and at a distance of about an inch and a quarter apart, are fixed a number of screwed studs, and these should project about an inch. These studs may be three-eighths of an inch in diameter, and well-fitting nuts should be provided for them.

These studs and nuts serve to hold four steel bars in position around the plate, these bars being mitred at the angles so as to form a frame, and they should project about three-eighths of an inch above the face of the plate. A thickness of half-an-inch is ordinarily sufficient for the side strips. The object of these strips is to prevent a lateral extension of the lead on the face next the relief, as any such extension would result in the immediate destruction of the relief. It is well to chamfer off the strips at the top, so that they may penetrate more readily into the sheet of lead than would be the case if they were left square; and in ordinary cases it suffices to bevil them off so as to form an angle of 95 degrees with the outside vertical edge. The planing on the steel plate will not, even if carefully performed, give a sufficiently accurate surface, so it becomes necessary to grind the upper surface of the plate with fine emery and water until the planing marks are removed, and no trace of inequality can be detected when the surface is tested with a surface plate or an accurate straight edge. The emery should be number 150, that is to say, it should have been passed through a sieve having 150 meshes to the linear inch; and the best grinding surface is a thick slab of plate glass, upon the face of which a few grooves about a quarter of an inch wide, and half as deep, have been cut. These grooves hold the mixture of emery and water, and consequently prevent the rubbing surfaces running dry. Care must be taken to shift the steel plate about sufficiently during the grinding, and also to work as much on the edges of the plate glass as on the middle. When the grinding is finished, the plate should be slightly oiled, and the side strips bolted in position. Some pieces of sheet lead, half an inch thick, and about half an inch longer and broader than the steel plate, are now carefully cleaned on the best side by means of a stiff brush, and all is now ready for making the mould.

The relief is laid on the surface of the steel plate, the edge strips being bolted on so as to virtually convert the plate into a tray, a sheet of the cleaned lead is laid over the strips, and this sheet of lead will, if its dimensions are in accordance with our directions, overlap the inner edges of the strips to the extent of a quarter-of-an-inch all round. A piece of stout millboard is now laid over the lead, and the steel plate, with its charge, is brought into a central position on the platten of the hydraulic press, after which the pressure is applied. The side strips easily shear through the lead, thus cutting out a piece which exactly fits the tray, and as the face of the lead next the relief is effectually prevented from stretching by the edge strips, the relief is very seldom damaged by the pressure; no difficulty is experienced in separating the relief from the lead mould.

If the original negative was an ordinary or direct negative, and the relief was laid with the collodion side downwards, a mould will result, which will yield a reversed print. So in ordinary cases a reversed negative must be used, or else the relief must be moulded with the collodion film next the lead.

his latter course results in a very slight loss of sharpness, t so slight as to he unimportant in most cases. This loss sharpness hecomes less when the relief has heen several mes moulded from, as the gelatine side hecomes perma-ently flattened, and the finer details of the relief gradually equire prominence on the collodion side.

Before speaking of the mounting of the block and the inting operation, it is necessary to describe the method of reparing the paper upon which the impressions are to be ade.

CARBON PRINTING.

Lesson I.

Carbon printing is the art of making photographs in pig-ented gelatine, for which purpose the gelatine, after heing ixed with the chosen pigments, is spread upon a somewhat oarse paper, which acts as a support to the gelatine film uring the operations necessary for the production of the rint.

Paper coated with pigmented gelatine is called carbon ssue, and is sold in rolls (or bands, as they are usually alled) containing about twenty or thirty square feet.

To render carbon tissue sensitive to light, it is immersed i a solution of bichromate of potash, and dried; it is then xposed to light under a negative, the duration of such ex-osures heing timed by means of an actinometer, hecause he progress of the action of the light cannot be watched.

The exposure heing effected, the tissue is immersed in cold vater, and then hy means of an india-rubber squeegee is ounted upon a suitable support, either rigid or flexible, and ien, after soaking in hot water, the paper hacking is stripped ff, when the unaltered pigmented gelatine is, hy the action f the hot water, dissolved away, leaving the image upon he support, so much of the pigmented gelatine requisite or the formation of the image having hy the action of light een rendered insoluble in the hot water.

The carbon image, being developed from the hack of the issue at this stage when made from an ordinary negative, vill he found to be reversed in position as regards right and eft, and to get it into its right position it will require ransferring to another support so that the image may he n its proper position, this heing called the double transfer rocess.

But if a special or reversed negative be used, then the rint is at once developed upon its final support, as in the ingle transfer process.

From the above it will be seen that the following are the arious stages through which a carbon print has to go—viz., ensitizing and drying the carbon tissue, printing under a egative, and timing the exposure hy means of an actino-neter, mounting the exposed tissue upon the temporary upport, developing the exposed tissue in the hot water, and hen transferring the developed image from the temporary o the final support; and as each of these several stages re-quires to he thoroughly understood and properly carried out, t will be hest, before proceeding to the actual process of making prints, to deal in detail with each stage. The most mportant stage in the production of a carbon print is dry-ng the carbon tissue after sensitizing, and unless this be effected in a proper manner, all subsequent work is thrown away.

The conditions of success are drying at a moderately low emperature in a room or closet free from all gaseous exhala-ions, and through which can pass a constant stream of pure dry air, and from which all actinic light is excluded.

In dry weather the tissue will dry spontaneously, but in damp, close weather, a slight accession of artificial heat will be requisite; if the drying-room he provided with an ordinary fire stove, a fire for an hour or two will he generally sufficient for such a contingency; but on no account must an ordinary gas stove he used, as the products of combustion are fatal to the solubility of sensitized carbon tissue.

For small batches of tissue no better place for drying can he had than the domestic kitchen after the duties of the day, provided no gas is burnt during the drying, and that white light can he excluded. The time occupied in drying the tissue has a marked influence upon its quality and sensitive-ness; if dried too quickly, besides running the risk of melting the gelatinous coating, it will he comparatively insensitive and very brittle; the prints will also he hard and deficient in half-tone. On the other hand, if dried too slowly, the tissue will he too sensitive, sometimes so much so as to he unmanageable; it will also he tinted or fogged, in which case it may he thrown away, as, with tinted tissue, it is im-possible to get pure whites.

Tissue ought to dry in from six to ten hours; but that dried the quickest will print the slowest, but will keep good longer—*i.e.*, will keep from spontaneous insolubility longer. Sensitive tissue, when dried, ought to he kept in a tin tube so as to protect it from the action of damp, which will soon set up spontaneous insolubility. To dry the wet tissue it is best hung over a clean broomstick, which, in turn, is sus-pended on a couple of cords running the length of the drying room (fig. 1). *a a a a*, two cords stretched across the

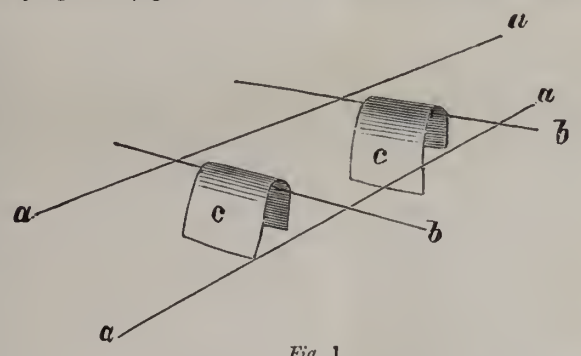


Fig. 1.

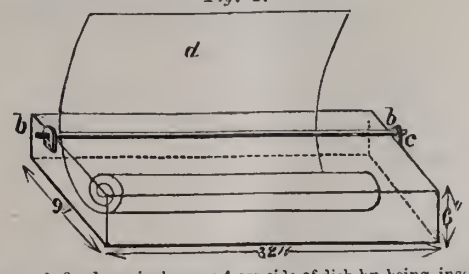
room, *b b*, broomsticks carrying lengths of sensitive tissue.

To sensitize tissue we require a tin dish sixteen inches long hy nine inches wide and six inches deep; close to top and near one edge are two holes through which are thrust a glass rod (fig. 2); cut the roll of tissue in two with a saw, and then divide the two resulting rolls into six feet lengths. Place the dish upon the floor, and half fill it with a solution of bichromate of potash, composed of bichromate of potash two ounces, water eighty ounces, liquor ammonia half a dram; dissolve, and filter. Now take one of the rolls of tissue six feet hy fifteen inches, and immerse in the solution,

Fig. 2.



c, glass rod, fixed one inch away from side of dish by being inserted in lugs; *b b*, soldered upon ends of dish; *d*, tissue being lifted out of bi-chromate solution, the face in contact with the roll.

at once commencing to re-roll from the loose end, unrolling from the other, keeping the tissue well under the solution; when the roll has been unwound and re-rolled, repeat the operation again and again for two minutes, or until the tissue gets rather limp; then, with the face next the body of the operator, place in contact with glass rod, taking hold of the end of roll, gradually lift from the solution, dragging the face of tissue in close contact with the glass rod, then place over

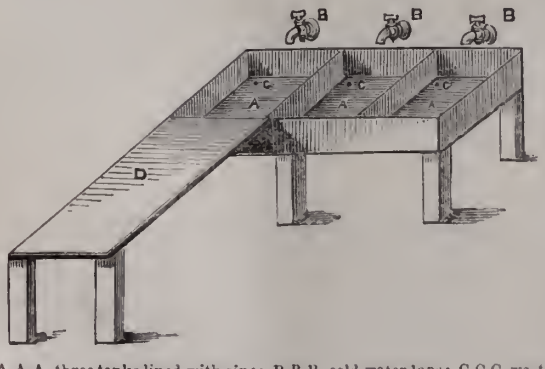
a broomstick, which may be conveniently placed upon two chairs back to back about two feet apart, and remove to drying place (see fig. 2). In hot weather the temperature of the bichromate solution must be kept below 50° F., or else the coating of pigmented gelatine will he dissolved preparing the negative for printing.

Before putting a negative into print, it is necessary to provide a mark or safe edge, arranged in such a manner that without interfering with the subject matter required to show in the print will shield the extreme edges of the tissue from the action of light, so as to provide a safe edge to the tissue, that will be quite soluble in hot water, and absorbent in cold, so that, when mounted upon the development support, the atmospheric pressure will cause the tissue to adhere to the support, and prevent the hot water penetrating between the two surfaces, which it would be sure to do if the edges of the tissue had been made non-absorbent and insoluble by the action of light. Of course, if the print has to be a vignette, no other safe edge is required than the operation of vignetting.

Timing the exposure is done best by means of Johnson's cube actinometer, and the best way of acquiring a knowledge of how to use the instrument is to select a negative of good average density, and place in a printing-frame with a piece of sensitive albumenized paper in contact, and expose to light simultaneously with an actinometer. Now watch the sensitive paper under the slit in lid of actinometer, and shortly it will assume the colour of the pigment painted upon the lid; when this is done, one tint or period is registered; now pull forward the strip of sensitive paper until a fresh surface of sensitive paper is again under the clear slit in lid, and again watch, and when of the same depth as the first, another tint is counted, and so on, until the silver print under the negative has acquired sufficient depth, when the number of tints registered by the actinometer represent the time necessary to secure a fully exposed print from that negative on silver paper; but as carbon is a little quicker, one-fourth less may be safely marked upon the negative, which may be kept as a standard to judge the value of other negatives by.

Mounting the exposed tissue does not require any further comments than those that will come in at the proper time. For the development of the exposed tissue, a good supply of hot water will be required, also a set of sinks or of tin dishes of a suitable size. For those who can spare a room, one fitted like figure 3 will be found very convenient, the

Fig. 3.



A A A, three tanks lined with zinc; B B B, cold water taps; C C C, waste plugs; D, bench for squeegeeing upon.

hot water being supplied either from an ordinary copper or a water heater; but for amateur operations, three tin dishes about 24 by 18 may be substituted for the tanks, and for hot water the kitchen boiler may be requisitioned, especially if it is provided with a self-filling arrangement; whilst, for laying the support and tissue upon for mounting and transferring, a board covered with American cloth will be all that is desired.

By-the-Bye.

ABOUT GRAMMES AND CUBIC CENTIMETRES.

Many of our good old-fashioned notions about the French are disappearing. One by one, they leave us—cherished relics of a byegone age—and before long there will not be a single trait remaining to remind us of the vast superiority of England and all things English. The good old times have gone, indeed, and no wonder we hear on all sides of our decline and fall off. Our fathers despised the French as frog-eaters; to-day, a Paris *chef* receives double the pay of an English professed cook. It used to be a maxim that my Englishman could beat three Frenchmen, as he had done repeatedly at Waterloo, Agincourt, and Fontenoy. Or was it the other way at Fontenoy? No matter, the principle was so evident that illustrations were unnecessary. Yet we find to-day discussions going on at home in military circles in which the British soldier is valued at no more than an ordinary German or Frenchman.

The same levelling spirit is attacking our weights and measures. The metrical system and the decimal system have carried all before them on the Continent; and the Englishman's house, which is proverbially his castle, is in danger of assault. Our insular position has saved us to some extent; but when we find Germany—the natural foe, as she has been termed, of France—quietly and steadily adopting French measures and even French milestones, the end, if slow in coming, is none the less sure. The metrical and decimal systems are certain of adoption by Great Britain, since they have been adopted by all the enlightened nations of Europe. Nay, science, the forerunner of all, has already recognized the innovation in this country, and British chemists and physicists, as everybody knows, no longer calculate by ounce and grain. Science, all the world over, has but one way of expressing figures, and it is evident, therefore, that if photographers desire to be numbered in the world of science, they have no option but to adopt the universal language also.

The first essential of any system of measurement is an unvarying standard. This is obvious. Now the unsatisfactory nature of such variable standards as barleycorns, hands, cubits, and feet, was ofttimes subject for discussion in byegone times, and many were the suggestions of philosophers to select a standard rule. At last, a very sound suggestion came from the French geometricians. "Let us take the earth itself as a standard," they said, and the idea met with almost unanimous approval. One ten-millionth part of the distance from the equator to the pole, measured over the curved surface of the earth, and not in a direct line, like the string of a bow, was selected as the basis, and this was termed a metre. A metre is thirty-nine inches and a-third (39·37), and it was subdivided by the French philosophers into one thousand millimetres, one hundred centimetres, and ten decimetres.

The hundredth of a metre, which is called a centimetre interests us, more especially since it is the immediate parent of the gramme. The weight of a measure of water, exactly one centimetre high, and one centimetre broad, and one centimetre wide—or, in other words, the weight of water that fills a cubical measure of exactly one cubic centimetre—was taken as the new unit of weight. This unit of weight is called a gramme, and hence a gramme and cubic centimetre are one and the same thing when water is concerned. They are to each other as the ounce avoirdupois is to the fluid ounce. To be particular, we ought to mention, perhaps, that the gramme standard was arrived at on the supposition that water is taken at its point of maximum density (4° C).

Since the standard metre and gramme were fixed, there has been some discussion upon the original correctness of the measurements of the earth, and there is very little doubt that the data assumed by the French geometricians are incorrect, and therefore the measure they adopted is

also proportionately incorrect. But this matters little, since no one cares whence a standard is derived, so long as all are agreed to acknowledge that standard. And, as we have said, throughout the whole world of science there is now unanimity on this score. They acknowledge only one measure—the metre; and only one weight—the gramme. Or put it more correctly, perhaps, the universal standards are the gramme and the cubic centimetre.

The old-fashioned photographer, like the old-fashioned chemist, has still a lingering fondness for the old-fashioned British weights and measures; but the belief in them must go as surely as the tradition that one Englishman is equal to three Frenchmen. The simple, universal language of grammes and centimetres is so explicit and so intelligible to all who will bring an unprejudiced mind to bear upon the subject, that it is only wonderful we have stuck so long to ounces, drams, and grains in English manuals. Mr. Arnold Spiller's lessons in elementary photographic chemistry, which we published last year in these columns,* has been translated into several languages, no less because the quantities and measurements are given in grammes and centimetres, than on account of its intrinsic value, great as this may be. A Portuguese rendering of Mr. Spiller's work was in our hands the other day; and in a criticism of the French edition, we read these words:—"En terminant, nous ferons remarquer que M. Spiller, dans ses calculs, se sert des notations du système métrique; il engage vivement ses collégues anglais à renoncer à leur once et à leur grain. Nous ne pouvons qu'applaudir à cette excellente idée, et souhaiter qu'elle se réalise promptement, afin de faciliter l'échange des communications et des formules entre les deux pays."

The International Geodetic Congress, which has recently closed its sittings, and which has come to the conclusion that it would be well if all nations adopted the same longitude calculations, recommending, moreover, that the longitude of Greenwich be adopted by all the world, added a rider to the effect that if this concession were made to Great Britain, then we should no longer stand out of the ring in respect to metrical measurements. In being the only one among the big nations which has not adopted the metrical system, the United Kingdom adopts a stand-still policy ridiculous in the eyes of all intelligent beings. For, as we have said, our advance-guard in the persons of British scientific men have long since seen the advantage of an universal system of measurement, and have not been slow to avail themselves of it.

Still, all changes must be gradual, and the photographer, we must admit, is placed in an unfortunate position. The apothecaries' weights and measures he has by him serve his purpose very well, and as he employs them daily, it is not surprising that when he recommends the use of a new developer or toning solution, he should express the quantities by the measurements he uses every day. Still, there is no reason why, when he is fitting up his laboratory, he should not buy a few gramme weights and purchase a cubic centimetre measure. These are as cheap, if not cheaper, than appurtenances only fitted for use in this country, for a demand for them exists all over the world, and no apparatus maker or dealer can afford to be without them. We repeat, the whole matter is but a question of time and nothing more. All scientific experimentalists among photographers must be conversant with grammes and cubic centimetres, and those who practise much with foreign formulæ require gramme weights and glass measures divided into cubic centimetres. Indeed, the simplest of all methods, as we have before mentioned, for converting fluid ounces into cubic centimetres, or *vice versa*, is simply to pour the liquid from the ounce measure into the metrical measure, and as the latter costs but a couple of shillings, the plan, beyond being a cheap and trustworthy one, obviates many troublesome calculations. In the same way, if you are in possession of a few gramme weights, you can, by weighing them against your British weights, compare them without trouble. But the time will come, and that very shortly, when no such comparison will hinder the photographer's work, and when he, like his senior brother the chemist, will adopt but on measure and one weight in his laboratory.

The "At Home" next week will be "Senor Otero at Madrid."

THE SPECTROSCOPE AND ITS RELATION TO PHOTOGRAPHY.

BY C. RAY WOODS.

V.—The Reducing Action of the Spectrum on the Haloid Salts of Silver, Applied to the Making and Working of Sensitive Films.

Having acquainted ourselves to some extent with the different parts of the spectrum, and glanced briefly at the phenomenon of colour, we are now in a position to examine in detail the action of the spectrum on the principal compounds which the photographer uses. It has already been stated that it is the *most* refrangible portion of the visible spectrum which has the *most* reducing action on sensitive plates; this is only, of course, to be taken in a general sense, for it is found that all compounds, even all silver compounds, are differently sensitive, but the alliterative use of the word "most" may be a useful aid to the memory of the beginner if he is not above accepting artificial aids to his mental powers. Referring once more to the three primary colour sensation theory, and speaking, again, in a general sense, we may regard the sensitive plate as possessing in a transcendent degree only the blue sensation. A once very popular impression, and one that even now exists, to some extent, was that the greatest effect was produced by the rays beyond the violet. How far this is the case we shall soon see; but in the mean time, it may be mentioned, that it certainly appears to be the case so far as the chloride of silver is concerned, the substance whose sensitiveness to light was first noted.

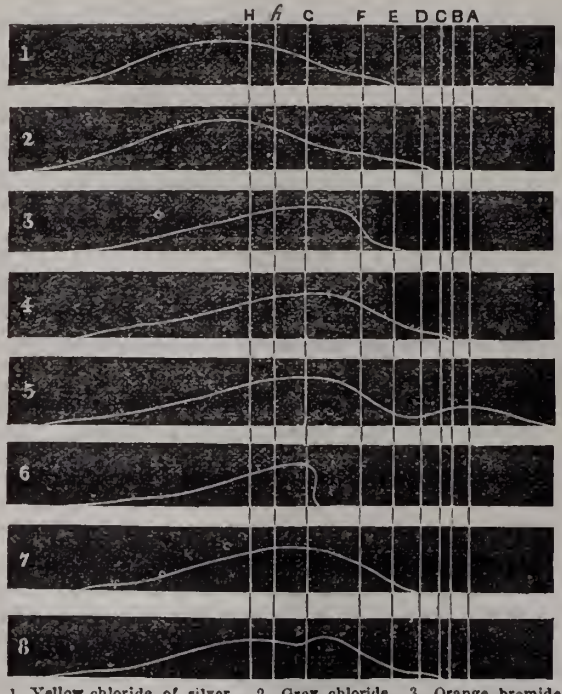
One of the first things that the scientific investigator—aye, and the scientific student, too—has to learn, is to follow the rule that nothing is to be taken for granted. Adopting this principle in the present discussion, and verifying each statement by personal experiment, will not be found a difficult task, when the necessary amount of care and patience is exercised. The mode of procedure, though simple, is worth a brief statement.

The source of light is the first consideration, for it is obvious that the result will vary with the method of illumination. As the light we meet with in nature is emitted by the sun, we need go no further for a source of illumination that shall enable us to make an examination that may go fairly in hand with our ordinary photographic experience. Directing a beam of sunlight on to the slit of the spectroscope by means of a mirror, and condensing the rays on to the slit by means of a lens, in order to shorten exposures, a plate is placed in the dark slide of the camera, and exposed and developed. Assuming that the plate has had sufficient exposure to receive all that it can receive, what do we notice? Leaving out of consideration the Fraunhoferic lines—or rather, using them as an index only—it will be noticed that the image possesses different shades, a gradation of density falling away on both sides of some particular region. This gradation of density gives us a rough idea of the relative sensitiveness of the medium to different parts of the spectrum. To get a more accurate notion, a few more exposures are necessary. A very rapid exposure will show what part of the spectrum produces the greatest effect, for that part will be the first to be impressed. A little longer exposure will show what part is next easily impressed, and so on. By this means we are able to get a very correct notion of the action of different parts of the spectrum on the particular kind of plate that

is being used, and by combining these photographs, representing the action of each part of the spectrum by a line proportionate to its intensity, and drawing a curve upon them, we get a very graphic representation.

The investigation of the action of the spectrum on substances sensitive to light has been followed up from the earliest days of photography. It may be said to have begun before the days of photography or spectroscopy, for when, in 1777, Scheele stated that the violet rays had the greatest blackening action on silver chloride, he had only the impure spectrum as given by Newton's experiment to work with, and, as the reader knows, it was not for many years after that date that the first delineation of an object was produced by the action of light. To give an account of all that has been done since then has formed the subject of a book only receutly,* and those who appreciate that book most, must regret its brevity. In these articles only a few of the best known compounds and combinations can be spoken of, and only the most recent researches. Not long since, a careful examination of the haloid salts of silver was made by Captain Abney,† and the effect of the spectrum was graphically, as well as verbally, delineated by him. The accompanying diagram

Fig. 8.



1. Yellow chloride of silver. 2. Grey chloride. 3. Orange bromide. 4. Grey bromide. 5. Green bromide. 6. Pure iodide. 7. Iodide, bromide with nitrate of silver. 8. Iodide and bromide in gelatine.

gives the result of an examination of those compounds in which the general worker will be most interested. Captain Abney's results do not differ very materially from the work of others in this direction, and the reader cau readily test them for himself.

Chloride of silver, in its yellow state, it will be noticed, has its maximum near H, which is about the extreme limit of the visible spectrum. It is sensitive far up into the ultra-violet, and in the lower part of the spectrum it comes down to about F, its sensitiveness thus stopping short at about the commencement of the green. The grey form of chloride—that is to say, a chloride emulsion which has been boiled—is most sensitive at the same place as the unboiled, but it is sensitive to a greater range of the spectrum, the boiling of the emulsion having made it sensitive as far as D. Bromide of silver is most sensitive midway between G and F, well into the dark blue. The orange or unboiled emulsion, whilst its maximum is in the same place as that of the grey form produced by boiling or by the ammonia process, only goes down as far as E, about the middle of the green, whereas the grey extends as far as B in the red. Pure iodide of silver is most sensitive at about G, and the curve ends very sharply. The addition of bromide makes it extend much lower, and when further reinforced by the presence of free nitrate of silver, as in the wet plate process, we get a considerable range of sensitiveness. With a mixture of bromide and iodide in gelatine we get two maxima, the most sensitive point, as might be anticipated, coinciding with that of pure bromide. At the point where the maximum of the iodide should be, we get a depression in the curve, the mixture of the two salts being less sensitive there. In this curve, however, we have the result produced when a considerable quantity of iodide is present; in the emulsions contaiuing iodide, which the photographer usually works with, the loss of sensitiveness at G is comparatively small and scarcely appreciable, so far as his work is concerned.

Now several questions arise in looking at the different effects produced on different salts. First of all, there is the consideration of what kind of plate will be the best for photographing a particular part of the spectrum, supposing we are making spectroscopic researches in which we are calling in photography to help us. This, so far as the substances already considered are concerned, is a simple matter, and need not be dwelt upon. It is obvious that chloride, if we succeed in getting it in its most sensitive state, whilst we can also develop it free from fog, is the best for work in the violet and ultra-violet portion of the spectrum. For rays below G, and for all-round work, the bromide is the best. Again, if we are using the wet collodion process, it is plain that a mixture of bromide and iodide will give us far better results than iodide alone. Secondly, we have to consider what salt is best for ordinary photographic work, and in what ways may the different salts be utilized in order to work to the greatest advantage. In connection with this it is necessary to consider the question of atmospheric absorption so far as it effects the light that impresses the image. Lastly, there is the action of heat upon a sensitive salt in the preparation of plates, and the application of spectroscopic research in settling doubtful points. These last two questions, however, must be left over for the next article.

† Proceedings Royal Society.

PHOTOGRAPHY CONSIDERED AS THE WORK OF RADIATION.

BY CAPTAIN ABNEY, R.E., F.R.S.

The fifth lecture of this series was delivered at the Royal Institution on Saturday last, March 29th.

Having in the last lecture shown how the application of heat increased the amplitude of vibration in the case of the phosphorescent tablet, the Lecturer said he would now proceed to show that an exactly similar effect could be, and in the ordinary course of photographic practice was, often produced on a gelatine plate. Taking a dry gelatino-bromide plate, he placed a hot iron on the back of it for a short time, and while the plate was still warm where the iron had been, a very brief exposure was given with a match. On being developed, the plate showed a black smudge where the hot iron had been, the remainder of the plate being under-exposed. This meant that gelatino-bromide plates were more sensitive in hot than in cold weather, and in summer than in winter.

The Lecturer then proceeded to demonstrate the effect of radiation of different wave-lengths by exposing various sensitive substances to the action of the spectrum. Chloride, bromide, and iodide of silver papers were placed in the spectroscopic camera, and developed before the audience, the chloride going most into the ultra-violet, and the iodide giving the shortest range of chemical action by the spectrum. Films of chloride, bromide, and iodide were then placed in front of the slit in a lantern, projecting the spectrum on a screen, to show what parts

of the spectrum they cut off. In all cases, said the Lecturer, they would notice that work was done where absorption took place. To this rule he knew of no exception. It was just the same with other compounds. Ferric chloride, uranium chloride, and bichromate of potash all showed, as they could see on the screen, an absorption in the regions of the spectrum which affected them.

A series of coloured media were then placed before the slit, to show on the screen the absorption that took place. Different forms of bromide were then placed in the ordinary projecting lantern to show their colour, which had a marked connection with the part of the spectrum that acted upon them. One form, which was distinctly green, was used, said the Lecturer, for photographing the red and ultra-red portions of the spectrum.

Referring, then, to an experiment in the second lecture which had failed, the Lecturer said that this failure had rankled in his mind, and he would like to make amends by explaining how it happened. On being placed in the cell containing the developer, the strong light of the lantern completely fogged the plate, they would recollect. He now had in his hand the piece of yellow glass which was used on that occasion, and he would take a photograph in the spectroscope of the light which passed through it. As they would see, he got a considerable quantity of blue light through, and it was little wonder, then, that with such a glass a failure took place when a film was developed under the exacting conditions required to project its development on the screen.

To return to the green form of bromide, he would now take a photograph in the infra-red region of the spectrum. This was successfully done. The lecture was concluded by the taking of a photograph of the carbon points of the electric arc through a sheet of ebonite, and developed up successfully. Here, said the Lecturer, was work done by invisible rays below the red, for they could see that the ebonite was perfectly opaque to radiation which affected the eye.

FRENCH CORRESPONDENCE.

Taylor's Shellac Process—Laboratory of the Museum of Decorative Arts—Printing Process on Copper for Engraving—M. Placet and MM. Goupil and Co.

Taylor's Shellac Process.—In the year 1866 one of my friends of English origin, Mr. Arthur Taylor, published a process which was taken up by the entire photographic press, although neither from that time to this the value of the process has been considered with regard to the permanence of the image. Having in my possession prints dating from 1865, absolutely intact after nearly twenty years, I deem it a duty to publish the fact. The process was known as the shellac process. The paper selected is dipped in a solution of shellac in warm water and an aqueous solution of borax. When dry, it is sensitized in a ten or fifteen per cent. nitrate of silver bath; once more dried, and again plunged in a shellac solution, and left in a dark place. It may be thus kept for a long while. The prints obtained are fixed, first of all, in sulpho-cyanide, and afterwards in hypo. After thorough washing, the operation is finished. To prevent fading from contact with the air, moisture, or deleterious gases, the face of the print is brushed over with a varnish composed of 8 grammes of shellac in 100 c.c. of alcohol. The formulæ used are as follows:—

Borax Solution.

Water	...	...	...	100 parts
Borax	...	...	...	4 ,,
Shellac	...	...	...	8 ,,

Sulphocyanide in an 8 per cent. solution.

Hyposulphite of soda in a 15 per cent. solution.

It is entirely owing to the presence of the shellac that permanence is communicated to silver prints. Most certainly, among our collections of prints dating twenty years back, none can compare in freshness with these shellac prints. I therefore recommend this process as worthy of attention, in which renewed progress may be made as one of the several capable of giving indelible images. A description of Taylor's process is to be found in the Photographic News or 1866, p. 256.

The Laboratory Attached to the Museum of Decorative Arts.—The work of this laboratory commences on April 1st, by reproducing from casts a number of bas-reliefs from the Hotel Carnavalet. It has already been stated that all negatives shall be pellicles, as being easier of transport in case of need. I will inform my readers from time to time of the results obtained. As a similar studio exists at the South Kensington Museum, I should like to be acquainted with the processes followed. The great service rendered by such an addition to the Museum must be considerable.

Printing Process on Copper.—I have just been experimenting on a process which, although not new, is seldom used. It is that of direct impressions on copper for etching or engraving afterwards. The process consists in coating a smooth copper plate with proto-chloride of copper. The plate, well cleaned, is immersed for half-a-minute in a solution thus composed:—

Sulphate of copper	...	...	7·50 grammes
Chloride of sodium	...	...	4·50 ,,
Water	...	...	60 ,,

or, better still, in a bichloride of copper solution. It is next washed, and carefully dried with a soft cloth, then exposed behind a negative and fixed in hypo in which chloride of silver has been dissolved. The length of exposure varies from ten to fifteen minutes. Fixing should take place promptly; the plate must be removed as soon as the deposit of silver on the parts not attacked by light brings out the image in black. A thorough washing next follows. A fatty transparent varnish—wax dissolved in ether or benzole, for instance—must be applied. M. Mialaret published this process in 1865. It is true that the same results may be obtained by equally simple processes, but one cannot have too many strings to one's bow.

Placet versus Goupil and Co.—A curious action is pending at this moment between M. Placet and MM. Goupil and Co. on the subject of the heliotype process practised so successfully by the latter, and which M. Placet claims as his own. The astonishing part of it is, the Placet patents being public property, that he can obtain a hearing for his case, even admitting that the patents have been worked, in itself a very doubtful point. We therefore ask what will it come to if he proclaims himself sole inventor? His success is doubtful, and in any case it is a very delicate affair, as are all those touching on such slippery ground.

Leon Vidal.

STEREOSCOPIC PICTURES ON A QUARTER-PLATE.

BY R. OFFORD.*

In the Photographic News of Dec. 1883, page 780, will be found an abstract of an article on "Stereoscopic Portraits by a Single Camera." Thinking the idea very practical, I provided myself with a music stool, the screw of which failing to act kept the seat in a horizontal plane when revolving. Attached to it was a head-rest, which would move with the sitter. I constructed a carrier for the dark slide thus:—Four pieces of glass of such a size as to leave an opening $6\frac{1}{8}$ by $3\frac{1}{4}$ inches were laid down the outside measurement fitting the dark slide. These glasses were secured together by means of pasting stout brown paper on both sides. On one side a central opening was cut, 2 inches by $3\frac{1}{4}$; on the other side an opening $6\frac{1}{8}$ by $3\frac{1}{4}$; a ledge placed along the bottom of the opening prevented the plate from falling out. It was arranged that the quarter-plate which slides to and fro across the smaller opening and rests on the ledge should not be scratched by the brown paper in passing. Behind the spring, in the back of the dark slide, a hole was made with a needle drill, and also the same through the spring. A piece of black silk passed through both holes and knotted on that side of the spring nearest the plate, and

* A communication to the London and Provincial Photographic Association.

also close up to the outside of back, thus preventing the ingress of light. Putting a plate in position close up to one end of the 3¼ by 6½ sized hole, one-half of it was presented to the action of the lens, the spring keeping it firmly in its place. After making an exposure, and the shutter closed, the slide is raised and tilted whilst the black silk is pulled; the plate being released, the gravity of it sends it sliding to the other end of the hole, and the spring, upon being released again, secures it. Setting an electric shutter before putting back the slide, it is ready for the other exposure, taking only four or five seconds to complete the whole operation. After closing and taking one picture, the stool, with the sitter on it, is turned on one side so as to pass a prominent point (say the nose) through an arc of about half-an-inch, and the second picture is taken. I keep two sights of the stand about a foot apart, and 6 or 8 feet from the sitter, directing them to look at (say) the left for the first exposure, then the right after turning. A long focus lens is infinitely better than a lens of short focus, as a strained effect is produced if the camera is too near the sitter.

Notes.

We commence to-day a series of six lessons on "Carbon Printing."

The late Duke of Albany was a practical chemist, and well versed in photography. Indeed, with the exception of the Duke of Connaught, all the sons of her Majesty have practised photography. The Prince of Wales received his tuition from Mr. Ackland and Mr. Francis Bedford, while the Duke of Edinburgh was an apt pupil of Mr. F. York. Still the Duke of Albany had a special liking for applied science as also for literature, and was altogether of a more studious turn of mind than his royal brethren,

Dr. Carpenter, C.B., F.R.S., was recently lecturing (in connection with the Gilchrist Trust) in the provinces; in the course of the lecture a view of Niagara was projected on the lantern screen. "That," said the doctor, "gives but a poor idea of the Falls, for it is not a photograph, it is a mere painting."

A novel use of photographic negatives came under our notice the other day. A lady desiring the portrait of a relative, whom she knew had been photographed in a town in the south of France, went in search of the studio. She found it after some trouble, but she found also that the photographer had disposed of his business to somebody in another profession, who had utilized the old negatives to glaze a greenhouse! Fortunately the required portrait was discovered among a pile of negatives upon which the hands of the glazier had not been laid.

Now that Miss Mary Anderson's engagement has come to an end in London, it may be permitted to say a word respecting that lady's success as an actress, without appearing either ill-natured or bad-mannered. If ever a young woman could say with truth, "My face is my fortune," that young woman is Miss Anderson; and further, if ever photography did a person a good turn in this world, that person is likewise Miss Anderson. The American actress, who has been making more money in Mr. Irving's theatre than even Mr. Irving made himself, is one of the most charming of models, and her statuesque picture of Galatea—as dainty and as delicate as a rare piece of Dresden china—is simply ravishing to look upon.

No wonder, then, that photography has proved so powerful a means of advertising. "She is very, very pretty," you hear over and over again, as people gaze on the portraits that are everywhere—portraits that, naturally enough, send everybody to see the heaven-born Hebe. And then, the critic, as he sits himself down to enjoy the long-expected treat, suffers a strange and singular sensation. Bit by bit, to his utter dismay, the idol falls to pieces before his eyes; as the statue gradually moves and walks and has its being, he sees a rather common-place young woman, untutored in art, and, what is worst of all, with a voice that knows no pathos, and from whose whole composition you could not distil a single tear-trop. The French sometimes define an actress as one whose voice rains tears; Miss Mary Anderson is the very antithesis of this. But she is very, very pretty in a photograph, where good looks are "more than coronets," and shapely limbs "than Norman blood."

Why on earth do apparatus-makers manufacture instantaneous cameras in the form of gun or pistol? Of all things in the world that renders their owners the objects of suspicion, surely fire-arms are the worst. M. Enjalbert has now an improved photo-revolver, which is said to be of most ingenious construction, as we are quite willing to believe; but who is going to carry such an instrument? Peaceful citizens have a wholesome dread of anything in the shape of a revolver, and although the little camera will do them no harm, it may bring down mischief on the head of the unfortunate photographer. It is all very well to go skylarking about with a mock sort of pistol of this kind, but one fine day a fellow-creature may misinterpret your motive, and it is always difficult to explain matters after you have been knocked down.

The original Bolas detective camera, it will be remembered, was in the form of a boot-black's block, and few objects answer so well to disguise the camera. The notion of employing the opera-glass form is not a bad one, but you naturally look like prying when you hold it up, and thus, if your object is to get a photograph unawares, this is at once detected. A black bag, a brown paper parcel, or some ordinary portable object, is the form a detective camera should assume, and there is little doubt that the first manufacturer who fulfils the conditions satisfactorily will find a ready sale for his apparatus; for pictures of every-day life can only be properly secured when the presence of the photographer is unknown.

Mr. Seavey can do something more than paint pretty backgrounds, it seems. According to the *New York Herald*, a sea coast picture from his brush in the Water Colour Exhibition sold on the first evening for a hundred dollars.

A correspondent says: "If the proprietorship of the negative controversy ever presses a photographer too hotly, let him remember Solomon's judgment, and propose that the negative be halved." This is all very well, but then the presiding Solomon may go on with the *simile*, and hand the negative whole to the other party. Still, if the negative were destroyed, the object of the dispute would cease to exist.

We see that one of the secretaries of the Chemical Society is getting up a dinner for the other secretary, the latter having recently become president of the Society. Dr. Perkin is one of our leading chemists, as he is one of the most successful, for the discovery of Perkin's Purple has been a fortune to him. Still, as the sense of deep gratitude for something or other that he has done for his brother chemists does not strike us very keenly, we hope that "the other secretary" hereafter, when the time comes, will not forget the "one" who is doing him such a good turn.

By the way, the "preliminary list of stewards" idea for dinners, &c., was a very clever one when it was new, but it is too good to last. The honour of appearing in print (whatever it may be worth) is, of course, the only return a steward gets for sharing the extra expenses, and the "preliminary list" notion is for obtaining the greatest amount of honour at the least expense. The names printed in this list are few and select, but still they may be scattered as broadcast as you please; afterwards, when you send out invitations to join the dinner, you send out also a request for more stewards, and the accession of these good people naturally serves to diminish the expenses of those already in print.

Photographers may rejoice. A London fashion paper invites mothers to send in cabinet photographs of infants from the age of six to eighteen months for publication. Eight will be selected by the editor, and engravings of two will be published each week during the month of May, while coupons will be issued that the public may give their opinion as to which is the prettiest babe. The mother of the baby who gains the greatest number of votes will have the privilege of naming some present for her offspring up to the value of two guineas. Naturally there will be a rush to photographic studios all over the kingdom. One thing may be prophesied. The editor will please one mamma, but he will make an enemy of all the rest.

It seems that exhibitors at the International Show, which is to be opened at the Crystal Palace this month, must send in a carte size portrait before a season ticket will be given.

The question of the best light for the dark-room is occupying as much attention in the United States as it is in England. Dr. Garrison's paper, read at a recent meeting of the Chicago Amateur Photographer's Club, details the result of about two hundred experiments made with different kinds of glass. Dr. Garrison sums up in favour of two thicknesses of ruby red (flashed) glass in preference to one thickness of yellow and two of green. The actinic value of these combinations was about the same, but the visual value was enormously in favour of the ruby glass.

The question is one which perhaps concerns the manufacturers of dry plates more than it does the operator. Dr. Garrison is of opinion that up to the present time we have no really safe light for the dark-room, and that the long-continued exposure to which plates in course of manufacture are frequently subjected under the impression that the light is non-actinic, is a delusion to which is probably due most of the failures in dry-plate photography. This is undoubtedly a vital point in the manufacture of dry plates, and makers would do well to pay special attention to it.

Most photographers possess a ready means of dulling glass, whether the same is for a focussing screen or for modifying the light in a studio. Still we may mention two or three methods more or less known. A hot solution of Epsom salts mixed with a solution of gum-arabic, and applied warm, is useful for temporarily frosting windows; another scarcely less efficient plan is to wash over a strong solution of sulphate of soda, warm, and subsequently, when cold, to apply gum-water. The readiest plan of all is to dab the glass with a lump of putty, which, if done carefully and uniformly, imparts a finely-ground appearance. For permanently frosting, a piece of flat marble dipped in glass-cutters' sand and worked wet is to be recommended, powdered emery being used instead of sand at the finish, if a fine surface is desired.

Lotteries are just now very popular. Any photographer in want of a novelty to induce people to join his portrait club might try the effect of offering a prize—say a club of twenty members, each to have a dozen cabinets, and draw lots for an enlargement. Why not?

According to the *New York Sun*, a new use has been found for collodion; it is said to be invaluble in the actor's art of "making up." Gum dissolved in collodion and alcohol is one of the most satisfactory cements for attaching false mustaches and whiskers. The mixture dries immediately it is exposed to the air, is impervious to moisture, and can only be removed by spirits or grease.

Photography is gradually becoming of indispensable assistance to artists, more especially to those engaged on illustrations for periodicals. Only the other day one of the best known draughtsmen of animals expressed his intention of taking lessons, as he found many of his brethren made use of photography to great advantage.

One of the coolest requests made for a long time came under our notice the other day. A photographer who had left a studio, owing some four months' rent, and had opened in the same neighbourhood, called upon the succeeding

tenant of the studio he had quitted, and asked him to be good enough to send on any sitters who called, as he did not wish to lose the connection! Of course the request was at once acceded to.

Neither photographers nor their lady-sitters employ powder very much when posing now-a-days. But since this is sometimes considered a necessary adjunct to the studio—it is casually employed for toning down freckles and red hair—it may be worth noting that brunette face powder is better for photographic lighting than the snowy starch that pink and white complexions usually affect. The brunette powder is simply prepared with the least tinge of some brown pigment, and therefore is better calculated to soften any great contrasts of light and shade upon the face.

Patent Intelligence.

Applications for Provisional Protection.

5,647. JAMES THOMSON, 21, High Park Street, Liverpool, Lancashire, Photographer, for "Improvements in photographic camera-stands for use out-of-doors, on land, or at sea."—Dated 29th March, 1884.

5,686. WILLIAM ROBERT LAKE, of the firm of Haseltine, Lake, and Co., Patent Agents, Southampton Buildings, Middlesex, for "Improvements in frames for stretching paper for photographic purposes."—A communication to him from abroad by L'Abbe Raboisson, Paris, France.—Dated 29th March, 1884.

Notice of Application for Amendment of Specification.

In the matter of Letters Patent granted to RICHARD BROWN, and ROBERT WILLIAM BARNES, and JOSEPH BELL, all of the city of Liverpool, in the county of Lancaster, for an invention of "Improvements in and relating to the preparation of pictures and photographs to be used in the production of pictures by the art of photography and photo-engraving, and in the production of gelatine reliefs and printing surfaces therefrom." Dated 15th March, 1883, No. 1380.

Notice is hereby given, that the said Richard Brown, Robert William Barnes, and Joseph Bell, have applied under sections 18 to 21 of the Patents, &c., Act, and rules 48 to 56 made thereunder, for leave to amend the Specification filed in pursuance of the said Letters Patent, by altering the title to "Improvements in and relating to the production of gelatine reliefs and printing surfaces from pictures and photographs," and by altering the first claiming cause so that it will read, "First, the method substantially as herein set forth for the production of printing surfaces, half-tone pictures, or photographs." By striking out the whole of the 2nd and 3rd claiming causes; by altering the 4th claiming clause so that it will read, "Second, the method substantially herein set forth of giving to metal type a grained or lined surface." By altering the 5th claiming cause so that it will read, "Third, the method of levelling lead printing plates herein described." And by altering the corresponding descriptive parts of the Specification in accordance therewith.

Any person intending to oppose such application must leave particulars in writing of their objections to such proposed amendment at the Patent Office, 25, Southampton Buildings, Chancery Lane, London, W.C., within one calendar month from this date."—Dated this 1st day of April, 1884.—H. Reader Lack, Comptroller-General.

ILLUMINATION OF THE DARK-ROOM, AND SOME OPTICAL EXPERIMENTS.

BY CAPTAIN ABNEY, R.E. F.R.S.*

IN turning over some old specifications of patents I came across one by Claudet, in 1844, in part of which he says:—"The fifth and last improvement consists in performing all the operations (of taking a Daguerreotype) upon the plates, which were formerly carried out in the dark, now in a room lighted through media of various colours; but red I prefer, which having very little effect upon the plates covered with the sensitive coating, allows the operator to see how to perform the work, without being obliged, as before, to remain in a dark-room." I suppose, then, we may conclude Claudet was the first to use any light whatever in the early days of photography. Forty years later we still had the subject of illuminating the dark-room occupying our attention, though I had thought that the question as to which light was the best and safest had been pretty well settled. The subject of the canary medium has, however, revived, and, like others, I have examined its qualities.

At the January Monthly Technical Meeting of the Society I brought some samples of what I supposed to be canary medium, and showed the results I had obtained with it. The canary medium that I had manufactured was made by emulsifying chromate of lead in gelatine by means of the double decomposition of acetate of lead and bichromate of potash, and applying it to glass and paper. I also soaked paper in acetate of lead and then in bichromate of potash, and got a very good imitation of the canary medium. The results were not satisfactory. With three gelatinized glasses in front of the negative, in three and a-half minutes I was able to obtain a fully exposed transparency, whilst with the paper in a lantern, two thicknesses of same paper, impregnated with the lead chromate, enabled me to get a transparency in three minutes, the source of light in the lantern being a candle, and the negative placed a foot from it. The illumination was brilliant—much more so than when I used the common orange packing paper, which I show. With the orange paper, after five minutes' exposure, I got the very faintest trace of an image.

So far, then, my test went to prove the superiority of the orange paper. After I had made my remarks at our Monthly Technical Meeting, Messrs. Scorah and Co., of Bradford, kindly sent me a sample of the true canary medium, and with this I have experimented. The paper you will notice is thick—I may say very thick—much thicker, indeed, than the orange paper. Now, about the illuminating value of the two. I show a lantern in which we have one side formed of a square of canary medium, another of a square of orange paper, and the third side a square of stained red glass, of which I shall have to speak by-and-bye.

I think that the members of the Society will agree with me in saying that of the two paper panes, the orange is the more brilliant. Now, appearances may be deceptive, of course; so, to avoid all cavil, I made photometric tests of the two. The candle being lighted, a piece of printed matter was held in a vertical plane. The eye was kept at a fixed distance from the paper, and the lantern moved till the letters of the words could not be distinguished. In the case of the canary medium, I found that at 2 feet 0½ inch the letters first became confused, whilst at 2 feet 6½ inches they became confused when the orange light was tested.

Though not absolutely exact, the relative intensities of illumination may be taken as the squares of the distances, which would make them about as 16 to 25, or the orange paper had 1½ times as much illuminating power as the canary medium. Testing the stained red glass, I found that the light had to be moved to 4 feet 4 inches distance, or was 4½ times more luminous than the canary medium. Thus, the illuminating values of the three were about as follows:—

Canary.	Orange paper.	Stained red.
1	1½	4½

To further test this matter, closely ruled black lines, on a white ground, about $\frac{1}{30}$ inch apart, were taken and placed at 6 feet distance from a small observing telescope, and the lights moved as before. In the case of the canary medium the lamp had to be moved 3 feet 2 inches from the ruling, the orange 4 feet 1 inch, and the stained red 6 feet 7 inches. These were all the mean and three closely accordant readings. This gave the relative illuminations as—

Canary.	Orange paper.	Stained red glass.
1.	1·63	4·32

The reading test, and the more accurate test, here adopted, are closely accordant in every way. In fact, this is very much the plan that is adopted for star magnitudes, though in this case the surface of the object glass is diminished by diaphragms, instead of the stars themselves being deprived of luminosity.

So much for my own readings. It seemed that it would be curious to note any differences in individual eyesight as to the

* Read before the Photographic Society of Great Britain.

intensity of colour in these media, and yesterday I had the good fortune to secure Mr. C. Ray Woods as an observer, and later Mr. Cadett. In this case the experiment had to be slightly varied, from my dark room being only partially available, and the light and the eye were kept in a constant position, whilst the ruled lines above mentioned were moved to and from the observer. The following table gives the result of the comparison of Mr. Wood's eyesight for colour with that of my own :—

	Mr. Woods.			Captain Abney.		
	First Exp.	Second Exp.	Mean.	First Exp.	Second Exp.	Mean.
Canary paper... ...	1·00	1·00	1·00	1·00	1·00	1·00
Orange paper... ...	1·87	1·86	1·86	1·51	1·44	1·47
Stained red glass ...	5·14	4·76	4·90	3·00	3 12	3 06

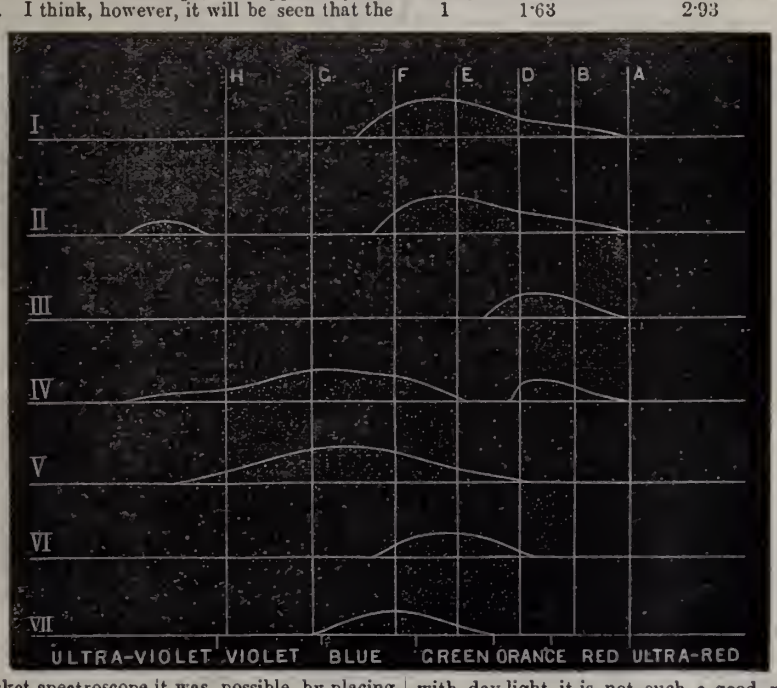
To sum up, Mr. Woods made the illuminating powers 1, 1·86, and 4·90; whilst I made mine 1, 1·47, and 3·06. It will thus be seen that as the green was cut off, so Mr. Woods' vision became more acute than mine.

Mr. Cadett's figures were again different to mine; and here I must interpolate that a more exact observer I have not met with. His observations did not vary more than $\frac{1}{4}$ of an inch on each side of the mean. His reduced readings were 1, 1·39, and 2·70. We therefore see that his eyes are less susceptible to red rays than mine, and still less so than Mr. Woods'. This last method of testing is inexact, of course, and cannot be compared for accuracy with that of the fixed lines and telescope, and apparently the results do not accord. I think, however, it will be seen that the want of accordance is more apparent than real. Taking my own observations of printed matter, for instance, when the printed matter was moved the distances, in the last experiments, from the eye (not from the light) were 21 inches, 24 inches, and 30 inches.

The angle subtended by the writing at the three distances would be inversely as the distance, and the confusion of lines would be sooner arrived at than if they always subtended the same angle, as was the case in the first experiment. To make the two readings comparable one with the other, the orange paper and stained glass readings, the last experiments must be multiplied by $\frac{24}{21}$ and $\frac{30}{21}$ respectively. This would give the reduced readings as 1, 1·63, and 4·37, which is very nearly the same as 1, 1·69, and 4·32, which were the figures of the telescope reading. However, one thing has been apparently proved, that the eyes of three persons chosen at random are not equally sensitive to the red rays. Mr. Woods informs me that he can scarcely see H and K in the extreme violet limit of the spectrum; whilst I can see not only H and K, but L, and, in bright light, M as well. It seems then as if there were in his case a general lowering of sensibility and wave length. I have not taken into account colour-blind people. This I may deal with at some subsequent period.

I may remark that with a sheet of white tissue paper in front of the glass the figures came out as—

Canary.	Orange.	Stained red, with tissue.	Stained red, bare
1	1·63	2·93	4·37



By means of the pocket spectroscope it was possible, by placing two pieces of paper alongside one another in the lantern, to examine their absorption spectra comparatively. The result showed that the red and yellow of the canary medium were decidedly fainter than in the orange paper, whilst in the former appeared more green and a little blue. *Primâ facie*, then, the orange should be the best medium to use for photographic purposes.

So far we have had merely a theoretical test for the chemical value—the question is, what is the practical one? A plate was exposed behind a negative with a piece of orange paper across one half, and a piece of canary medium across the other, with the result that after 1½ minutes' exposure to candle power 2 feet off, there were traces of an image through both, the two being nearly alike. Perhaps the orange paper had a little the best of it. Behind the stained red glass not a trace of an image appeared with the same exposure. Thus, then, the practical test leads to this conclusion, viz., that of the three media, stained red glass is the best, both as for illumination and want of effect on a plate, whilst the canary and orange papers acted alike as to their effect on the plate; but the illumination was 50 per cent. in favour of the latter. I must confess that the canary madium behaved much better than I expected in candle light. I may add that with day-light it is not such a good protection as the orange paper. Stained red glass behaves better than either of these two; and when I say stained red, I do not mean orange or flashed silver glass, which is often spoken of as stained red.

I have to lay before the meeting a photograph of the absorption spectra of different glasses, taken by the electric light; the first plate shows—

1. Chromate of lead.
2. Orange glass.
3. Stained red.
4. Flashed ruby.
5. Green glass.
6. Green glass and chromate.
7. Green glass and ruby.

Another plate I show is the same as the 1st, with the exception that it was taken with a candle as the source of illumination and that in No. 4 a very deep ruby flashed on two sides was used, and for 7, cobalt glass and ruby superposed were spectroscoped.

The orange glass lets through the ultra-violet with the electric light, but does not do so with the candle, as there are few ultra-violet rays in its light. The ruby glass lets through the green and blue in both cases. In the 2nd plate the impression

made by these colours is only faint, but still it is there; and when it is recollected that the two minutes' exposure was given to a slice of light $\frac{1}{200}$ inch broad, spread out into a spectrum four inches long, and that an impression was made by it on a sensitive plate, it will readily be seen that two minutes' exposure to undispersed light would make a far greater impression.

The use of green glass is not to be recommended, since it only cuts off red rays, which are comparatively harmless, and materially diminishes the light. In regard to canary medium, it is, I should say, paper impregnated with chromate of lead. It must be recollected, however, that chrome yellows are of different tints. Thus, ordinary chromate of lead can be altered in tint by the addition of nitric acid, and much deepened in colour. It may be, perhaps, advantageous to use such a deepened colour; but as to this I speak with some hesitation, since my experiments in this direction have been very meagre. Let me, in conclusion, say that I have no bias one way or another, and that I should not hesitate to use canary medium of such a quality as has been sent me in the development of plates. At the same time, I should not care to expose very sensitive plates long to the light coming through it, since I should expect disaster. The point is to use the safest light possible—for no light is absolutely safe—and to use the greatest quantity of it within the margin of safety. This was a point laid down by one of the speakers at the January Technical Meeting, and cannot be too much insisted upon.

A Dictionary of Photography.

ALBUMENIZING GLASS PLATES.—*See* **Collodion Process.**

ALCOHOL.—A term originally applied to the essential volatile constituent of wines and other fermented liquors, but now applied by chemists to a large group of carbon compounds which are analogous to ordiuary alcohols in their constitution. The only alcohols of photographic interest are the ordinary ethylic alcohol or anhydrous spirits of wine, C_2H_5HO, and methylic alcohol or wood spirit, CH_3HO. This latter, indeed, only possesses an indirect interest, it being used in making the mixture sold as methylated spirit.

Ordinary alcohol or ethylic alcohol is a colourless and very mobile liquid, lighter than water; its burning astringent taste, agreeable odour, and intoxicating action, being well known. Its specific gravity when pure is 0·7938 at 48·2° C., or 60° F., and its boiling point 78·3° C., or 173° F. Its chemical composition is expressed by the formula C_2H_6O, or C_2H_5HO. It is prepared by distilling liquids which have undergone vinous fermentation, such as wine or beer. The distillation is repeated once or twice, rejecting the parts which last came over, and the alcohol, being more volatile than the water, passes over first. Alcohol is frequently contaminated with *fusel-oil*, a mixture consisting mainly of amyl-alcohol, which imparts to it a peculiar, disagreeable odour. It is difficult to separate this substance from it on the small scale, and therefore care should be taken in purchasing a quantity of alcohol that no impurity of this kind exists in it. The presence of fusel-oil in alcohol may be recognized by the taste, especially after dilution with a large quantity of water, and by the unpleasant odour, especially after rubbing it between the hands, or letting it partially burn away. Alcohol, free from fusel-oil, should remain clear when mixed with nitrate of silver, and exposed to sunshine; but spirits of wine containing fusel-oil assume a faint red tint. Alcohol, in its strongest form, or *absolute alcohol*, cannot, however, be obtained by mere fractional distillation; for, although alcohol boils at 78·3° C., its vapour nevertheless takes up a quantity of aqueous vapour, hence the most highly rectified spirit obtained by repeated distillation still exhibits a density of 0·820 to 0·830. The complete dehydration of alcohol is usually effected by distilling the most highly rectified spirit over fixed substances which have a strong tendency to retain water; *quick-lime* being most usually employed. About equal weights of good quick-lime and strong spirit are left in contact with each other in a closed vessel for a few days; on being distilled in a water bath until about half the alcohol has come over, and this distillate being again treated with lime, and distilled as before, absolute alcohol is produced. *See* Distillation. In very careful experiments, however, it will be advisable to rectify the alcohol so obtained over dry charcoal powder and a little crystallized tartaric acid, in order to remove a slight smell which it has acquired, and also a little lime which may have been carried over. Alcohol may be regarded as perfectly anhydrous if sulphate of copper previously burnt white and immersed in the alcohol does not recover its blue colour after remaining in contact with it in a closed vessel for a few hours.

Of elementary substances alcohol dissolves only a few, such as sulphur, phosphorus, iodine, &c., all of the non-metallic class. Of *inorganic* substances it may be stated, as a rule, that all compounds soluble in alcohol are also soluble in water; but some compounds are soluble in water which are not soluble in alcohol; and substances which are soluble in both liquids dissolve more abundantly in water than in alcohol. There are, however, certain exceptions; thus, corrosive sublimate dissolves more abundantly in alcohol, especially in absolute alcohol, than in water. It may also be laid down as a general rule, that *efflorescent* compounds are insoluble in alcohol; and deliquescent substances, excepting carbonate of potassa and a few others, are soluble in alcohol. Many substances, when dissolved in alcohol, impart to it the property of burning with a peculiar coloured flame—*e.g.*, boracic acid, and the salts of lithia, baryta, strontia, lime, copper, &c.

Alcohol mixes in all proportions with ether. If the latter be in excess, a portion is separated on adding water; but if the alcohol is in excess, a homogeneous mixture is formed.

Subjoined is a table showing the specific gravity of mixtures containing various percentages of alcohol and water at a temperature of 48·2° C.

Alcohol per cent.	Specific Gravity.	Alcohol per cent.	Specific Gravity.	Alcohol per cent.	Specific Gravity.	Alcohol per cent.	Specific Gravity.
0·5	1·0000	25	·9652	51	·9160	76	·8581
0	·9991	26	·9638	52	·9135	77	·8557
1	·9981	27	·9623	53	·9113	78	·8533

10	·9841	36	·9470	62	·8908	87	·8305
11	·9828	37	·9452	63	·8886	88	·8279
12	·9815	38	·9434	64	·8863	89	·8254
13	·9802	39	·9416	65	·8840	90	·8228
14	·9789	40	·9396	66	·8816	91	·8199
15	·9778	41	·9376	67	·8793	92	·8172
16	·9766	42	·9356	68	·8769	93	·8145
17	·9753	43	·9335	69	·8745	94	·8118
18	·9741	44	·9314	70	·8721	95	·8089
19	·9728	45	·9292	71	·8696	96	·8061
20	·9716	46	·9270	72	·8672	97	·8031
21	·9704	47	·9249	73	·8649	98	·8001
22	·9691	48	·9228	74	·8625	99	·7961
23	·9678	49	·9206	75	·8603	100	·7938
24	·9665	50	·9184				

In this table every alternate number is the result of a direct synthetical experiment; absolute alcohol and distilled water being weighed out in the proper proportions.

Of the photographic uses of alcohol it is needless to say much, it being in most cases employed as a mere solvent. The circumstance of strong alcohol having a considerable affinity for water is of importance, as alcohol thus affords a convenient means of removing a large proportion of water from gelatinous materials in many cases. Thus, for example, if a weak jelly, a wet gelatino-bromide plate, or a piece of freshly-sensitized carbon tissue is immersed in alcohol, the water becomes more or less perfectly extracted.

Methylated alcohol is a mixture of ordinary alcohol with ten per cent. of wood spirit, and as such a mixture is sold without being subject to excise duty, a considerable economy is effected by making use of it for photographic purposes, and in the majority of cases it answers as well as the pure spirit. The so-called "methylated finish" is methylated spirit in which a small proportion of resinous gum has been dissolved, and this addition unfits it for most photographic uses. Although neither "methylated spirit" nor "methylated finish" are subject to Custom Duty, the former is only sold by persons having a licence from the Inland Revenue Department.

Methylic alcohol (CH_3HO) is a volatile liquid having properties similar to those of ordinary alcohol. It is formed during the

destructive distillation of wood, and in some of the chemical reactions. In a crude form it is sold as wood-spirit or wood-naphtha.

PHOTO-LITHOGRAPHY AND PHOTO-ZINCOGRAPHY.

BY MAJOR J. WATERHOUSE, B.S.C.,

Assistant Surveyor-General of India.

Chapter XVI.—Negative Transfer Processes.

Professor Husnik, in his *Gesammtgebiet des Lichtdrucker*, gives the following method with dextrin and albumen.

Dissolve 2 parts of dextrin in 30 parts of water, and add the solution to the whites of four eggs beaten up to froth; filter the mixture through muslin. Then take smooth Rive or Saxe paper, and float the best side on the solution. Unsalted albumenized paper may also be used, but does not leave the stone so readily as when dextrin is used. The paper is allowed to dry.

Another similar bath is now made, but to it 6 parts of spirits of wine and 1 part of bichromate of ammonia are added. Liquor ammonia is dropped in till the mixture begins to smell of it. This solution can be kept in good order for more than a fortnight without losing its sensibility. The already coated paper, or ordinary albumenized paper, is now floated on this second bath, taking care to avoid air-bubbles.

The paper will not keep in good order for more than two or three days in summer, or four or five in winter.

The exposure under a line negative should be two to four minutes in the sun, or ten to fifteen in diffused light, until all details of the image appear.

The print is then floated on water, face upwards, until the lights show a damp shiny appearance, and the coating begins to be tacky without being too soft. The paper is then laid on a large sheet of paper, and put through the press with strong pressure, so that it gradually attaches itself to the stone without folds or creases being formed.

The paper is then washed with warm water and removed. The resulting dextrin image is dried, blackened all over with transfer ink, and developed with water. The stone is then etched, rolled in, and printed in the usual manner.

Captain Hannot has lately described another method of this kind, in which the bichromate and soluble colloid, having been removed from the print after exposure to light, gum is forced through the paper from the back, and is prevented from touching the stone in the lines by the insoluble colloid (see News, vol. xxii., p. 358).

A sheet of ordinary albumenized paper is sensitized by being floated face upwards on a concentrated solution of bichromate of potash, and dried. After exposure under a negative as usual, the print is floated face upwards on water to which a little solution of ammonia has been added, and is allowed to remain thus, and protected from the light. The water gradually penetrates the paper, and dissolves the unaltered albumen and bichromate. The water and ammonia bath is renewed once or twice till all the bichromate has disappeared. The print can then be immersed in the water to finally remove all soluble matter, and is hung up to dry.

The transferring of the image is conducted as follows:—

The print is laid face downwards on a clean lithographic stone or zinc plate, either polished or finely-grained, according to the value of the picture. Over it is stretched a sheet of dry gummed paper prepared by immersion in a 5 per cent. solution of gum-arabic, and over this one or two sheets of damped paper. The stone or zinc plate must have been previously arranged in a percussion press, and, thus charged, is submitted to strong pressure for about fifteen to twenty minutes. By this means the moisture of the backing paper dissolves the gummy coating, which penetrates through the back of the print on to the stone or zinc, except in the parts corresponding to the lines of the image, which are protected by the coating of insoluble and impermeable chromated albumen. When the paper is removed, a clear negative image should be visible. The after treatment is as in the other processes before described.

The damp sheets of paper should be prepared about half-an-hour beforehand, by damping some sheets of dry paper with a sponge, and inserting others between them, when they will soon be found to be equally and evenly moistened.

The writer has little or no practical experience of these processes, which are better suited for work of moderate size, or within the limits of a single negative, than for large maps or drawings, which require to be photographed in sections; but they would seem to have several advantages:—

1. In simplicity of manipulation, the inking and washing with either hot or cold water being dispensed with.

2. In accuracy of scale, the transfer print being laid down on the stone dry, and just as it comes from the printing frame, and pressed into contact with the stone by vertical pressure, is not exposed to any alteration of scale or stretching, as is the case with transfers that have been washed and transferred by scraping or rolling pressure.

3. Greater delicacy and perfection of results, because the image is undisturbed during the operation of transfer, and the finest lines are preserved intact; whereas in the washing-off and inking-up methods they are more or less liable to damage. Any slight squeezing out of the gummy coating will tend to make the lines finer, while in greasy ink transfers the tendency is for the lines to be made coarser by the squeezing out of the ink under the action of the press.

4. In cases where the soluble coating is removed before transfer, as in Captain Hannot's new method, the transfer prints may be kept indefinitely before transfer.

On the other hand, however, there are several disadvantages and difficulties to overcome before these methods can be worked with certainty and success.

The principal difficulty is to obtain just the exact amount of moisture to communicate sufficient of the gummy ink-resisting coating to the stone, without at the same time softening it too much, and thereby causing the finer lines to be blocked out.

In using rolling or scraping pressure for transferring, some care is required in avoiding folds in the paper, and there is still more tendency for the soluble coating to spread over the lines if the proper amount of moisture be exceeded.

The paper is also sometimes difficult to remove from the stone, especially as care must be taken that no moisture gets between the paper and stone, otherwise the gummy coating will dissolve and cause white spots.

The specimens shown by Toovey and others prove conclusively that the method will give excellent results, and were therefore well worth attention.

Correspondence.

THE PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

Sir,—Your correspondent, "Councillor," of last week, seems to think that sufficient space is not devoted to the reports of the so-called "Technical Meetings" of the Photographic Society; and he also complains that you do not give sufficient prominence to the title. Since "Technical Meetings" were first instituted by the South London Society in 1872, I have been a regular visitor, and have profited much by an inspection of the novelties shown. Hoping that the new meetings of the Photographic Society of Great Britain would have some interesting features in common with the original Technical Meetings beyond the mere similarity in title, I attended the meeting at Pall Mall on the 26th of February last. When I entered, a gentleman was laboriously describing the well-known method of tracing slides for the lantern on ground glass, by laying the same on the original drawing, and pencilling

over after the fashion of the child's "transparent slate," the glass being finally varnished to render it more transparent. But the climax was reached when the same gentleman commenced passing through the lantern an interminable series of tracings which he had made from engravings of insects, &c., by drawing with the aid of the transparent slate. After remaining for about half-an-hour, I left, and in returning home I had abundant opportunity of meditating on the deceitfulness of names; and I concluded that to have learned that a member could draw tolerably well with the aid of the "transparent slate," was a poor recompense for an evening spent.

Has not the Photographic Society a Journal of its own? Cannot the members enjoy full reports in this? I was pleased to see that you did not mention the "Transparent Slate" exhibition in your report.—Yours truly,

W. L. LOWDE.

SIR,—In reference to the letter of "Councillor," which appears in your last issue, allow me to remark that I have been present at two of the new technical meetings of the Photographic Society of Great Britain, but was not very much interested, as on each occasion the only technical appliances exhibited were articles which had already been brought under discussion at the London and Provincial Photographic Society. If "Councillor" wishes to see long reports of the new technical meetings, he should get his friends to bring novelties for exhibition and discussion.

I think there is a danger of the new technical meetings being confounded with the annual technical meetings of the South London Society. These latter have, since 1872, been a notable feature in the photographic calendar.—Yours, &c., EAST END.

IVES' PROCESS.

SIR,—Your readers should understand that my original invention is not merely a particular manner of producing an inked impression of lines and stipple by pressure with a Woodburytype relief, but that it covers the principle of using the relief, ink, and lined or stippled surface, with pressure for that purpose. I distinctly specified that I did not confine myself to any particular material or apparatus for that purpose, and I only described in detail one method, because that is all that our United States Patent Law requires. My patent here would be regarded as the "mother patent," to which all such as Eggis' and Zuccato's would be subject, since they are not new processes, but mere modifications of the original "Ives' process."

I will add that there has not yet been a single modification of the original process published which I had not already tried and condemned as impracticable for commercial purposes, and not one which is worthy of comparison with my process as I now operate it. This I shall be able to demoustrate to you.—Yours truly, FRED. E. IVES.

Philadelphia.

Proceedings of Societies.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

A MEETING of this Society was held on Thursday, the 27th inst., Mr. W. M. ASHMAN in the chair.

Mr. A COWAN, in exhibiting a machine for wiping emulsion from the backs of plates, said a coating machine was very useful, but a little emulsion always found its way on the back. To keep the backs clean, he used to wipe each on a pad; this was clumsy. The pads were then placed against the wall on a couple of brackets. As the pads soon clogged, they often required shifting. Finally, he made the more complete arrangement shown, by which a shift of three-eighths of an inch in the rollers presents a fresh surface to each plate. Three yards of flannel were sufficient for one hundred and eighty plates.

A full description of this machine will be found on page 207 of the present volume.

Mr. A. L. HENDERSON enquired if the flannel could be used a second time without washing.

Mr. COWAN replied that it could.

Mr. HENDERSON demonstrated the method of making emulsion mentioned in the last report of this Society (page 206). He said: The formulæ given to-night I won't say is the best or the most perfect which can be obtained by this method, but it is capable of giving very good results, which anyone may verify, if they please. The new departure consists in forming bromide of silver in acetate of ammonia in the following manner. One hundred and forty-seven grains of carbonate of ammonia in six ounces of distilled water are neutralized with Beaufoy's acetate acid (requiring five drachms and a half); one hundred and seventy grains of nitrate of silver, in another six ounces of water, are stirred in, which, in forming acetate of silver, effervesce, giving a frothy solution, which may be, so far, treated in daylight.

Mr. A. MACKIE: Does more or less acetic acid make any difference?

Mr HENDERSON preferred using it nearly neutral. Continuing, he said one hundred and twenty grains of bromide of potassium in another six ounces of water are then slowly stirred in, when the bromide will be found to go down very rapidly. No doubt exceeding fineness could be obtained by the addition of a small quantity of gelatine to the mixture before adding the bromide. After washing the precipitate twice, the gelatine was added, the whole being warmed up. Plates were coated and passed round.

Mr. COWAN enquired if there was a possibility of making such an emulsion more rapid?

Mr. HENDERSON: Yes, by the addition of ammonia, about five or six minims to each ounce of emulsion.

Mr. W. E. DEBENHAM asked what heat the emulsion would bear after ammonia is added? He did not consider it safe to raise the temperature of an ammonia emulsion to 150° F., or fog would result.

Mr. HENDERSON only raised the temperature sufficient to melt the gelatine, about 120° F. He had a batch some time ago giving round holes, or pits; previous to coating, he added six drops per ounce of ammonia, which overcame the difficulty. Finer plates he never had.

Mr. W. B. B. WELLINGTON: How much emulsion will 170 grains of silver make?

Mr. HENDERSON: I used 170 grains, and there is rather more than eight ounces here.

Mr. DEBENHAM said the principle was very like that published by Captain Abney—viz., carbonate of silver. This he tried, but could not get rapidity.

Messrs. HENDERSON and MACKIE failed to get good results by that method, or by the chromate of silver method.

Mr. DEBENHAM exhibited a portable lantern in which cherry fabric had been substituted by yellow paper and oil silk of a pale green colour. A rapid plate was developed six inches from the lamp without trace of fog.

In reply to a question, "What is an Emulsion?"

Mr. DEBENHAM replied that there had been considerable differences of opinion on the point, and he could only give his view without pretending to consider the question as settled. He considered that emulsion consisted of a mixture of two substances—one of which must be a liquid—not chemically combined, but so intimately mixed that they would remain for a considerable time without separation.

Mr. MACKIE believed it was a mixture in which two substances would only mix on the application of a third.

Mr. W. COLE said originally the application extented to oily substances mixed with gum, afterwards to resinous substances held in solution by gum; in that sense it applies to gelatine emulsion. If a precipitate is made so fine that it takes a long time to settle, it makes it equivalent to holding a resinous powder in suspension by gum.

Mr. MACKIE passed round some instantaneous street views (Paris), stereoscopic size, made fully twenty years ago.

A communication was then read from Mr. R. Offord, on "Making Stereoscopic Pictures upon a Quarter-Plate" (see p. 215), examples being shown illustrating the relief obtainable.

A discussion then ensued on washing out glycerine and colloid bodies from bromide of silver emulsions.

The SECRETARY passed round some pamphlets relating to paper enlargements, sent by Messrs. Goodall and Stephen.

It was also announced that the next lecturette will be given on April 10th, by Mr. W. E. Debenham, "On Lenses." The following lecturette will be on May 8th, "Science of Polarised Light," by Mr. C. Darker.

Glasgow Photographic Association.

The eleventh general meeting of this Society was held in the Religious Institution Rooms, on the 20th ult., Mr. Robert Dodd, Vice-president, in the chair.

After the minutes of the previous meeting had been read and disposed of,

Mr. William Lang, Jun., read an interesting paper on "The Photographic Qualities of Biehromate Salts, and Mr. Woodbury's Stannotype Process." He also demoustrated the workiug of the process, which seemed both simple and satisfactory. A number of specimens, lent by Mr. Woodbnry for the occasion, showing first-class work at all the different stages, were very much appreciated by the meeting.

Mr. Robertson then gave a general description of the original Woodburytype process, and exhibited a number of lead printing blocks, and also impressions from them, which had been sent to the Association by Mr. Woodbury at the time the process was patented.

Votes of thanks were then awarded to Mr. Woodbury and Mr. Lang, and the hope was expressed that further practical demonstrations would be given at future meetings.

Photographic Society of Ireland.

The annual optical lantern exhibition was held on Friday, 28th inst., in the Royal College of Science, Stephen's Green, E. As on former occasions, the transparencies were taken from the negatives, the work of the members during the past year, nearly all being produced on collodion films, the majority of the pictures evidencing a marked improvement on former work. The following gained well-merited approbation:—"Interior of Ruins of Glastonbury Cathedral," by Mr. C. Fallen; "Interior of Bruges Cathedral," and "Interior of St. Paul's, Antwerp," by Mr. H. Bewley;" "A Snow Scene," by Mr. Conan. This was an exceedingly pretty picture, the snow being rendered very effectively. Mr. Pim's "Studies of Trees" were very interesting and beautiful, he having made a speciality of this branch of photography during the past summer. The yawl *White Rose*, by Mr. E. P. Johnson, was a real gem. It was taken from a punt, in Killiney Bay, Dublin, Mr. Johnson holding the camera in his hand while he made the exposure. A selection of views taken by Mr. J. L. Robinson, in Normandy, Lisieux, and Bayeux, were much admired.

The evening was most enjoyable, and, to judge from the attendance—nearly 400 ladies and gentlemen being being present—the interest taken in the exhibition was most encouraging.

The following also sent in contribntions:—Messrs. Curtis, Baker, Webb, Robertson, Bewley, Mitchell, Scott, Roper, Watson, and others.

The next ordinary meeting is intended to be held May 9th.

Liverpool Amateur Photographic Association.

The monthly meeting was held in the Free Library, on the 27th ult., Dr. Kenyon in the chair.

The minutes of the February meeting having been read and passed, Messrs. Archer, Durnford, McMurtrie, New, and Williams were elected members of the Association.

Mr. J. H. Day announced that he had received the following donations to the library:—A volnme of the Photographic News from the Rev. H. J. Palmer, the records of the Photographic Society of Philadelphia, and eighteen lantern slides from the Honorary Secretary. Mr. Day expressed a hope that many members of the Association would now follow the good example which had been set them, and present nnmerous transparencies for the lantern to the small collection at present connected with the library.

The Hon. Secretary read a letter from an American amateur, enclosing some views of American scenery, and asking for English photographs in exchange.

Mr. B. Boothroyd gave some details with regard to Rufford Hall and its surroundings, and kindly consented to undertake the management of the excursion thither on the 26th instant.

Mr. G. A. Thompson then read his paper entitled "Photographic Notes of a Voyage from Liverpool to Trieste in a Cunard Steamer, January, 1884," and exhibited a large number of interesting and beautiful pictures taken by him on his recent tour. He said, moreover, that he had used Mr. Kirkby's shutter, and also one recommended to him by Mr. Forrest. Both had given good results; but he had met with some difficulty in obtaining sharp pictures, owing to the vibration of the stand. He (Mr. Thompson) exhibited the whole of the apparatus used by him on his journies.

The Chairman, referring to the fact that some of the seascapes were over-exposed, said that lenses should be stopped down when rapid plates were exposed at sea.

Mr. Day spoke approvingly of the views of shipping, &c., taken years ago by the Rev. H. J. Palmer with a simple cardboard shutter; but he thought, on the whole, that the shutter devised by Mr. E. Roberts was the best for this class of subject.

Mr. R. Crowe remarked that over-exposed seascapes could always be saved by care and management in the development.

Mr. J. H. T. Ellerbeck spoke very highly of Edwards' shutter, and thought the results exhibited by Mr. Edwards were among the finest instantaneous pictures produced.

The Hon. Secretary reminded members of the neglected condition of the Society's album, no prints having been contributed to it for some time.

The Rev. H. J. Palmer gave an account of some further lantern experiments, which he had been making with the pamphengos and the pentaphane, since the last meeting. Mr. Watts had had one of Archer's reflectors substituted for the ordinary pamphengos reflector, but Mr. Palmer had failed to detect the slightest increase of brilliancy.

Mr. Blanchard passed round an album of views, among which were some extremely interesting pictnres taken at Lagos, and other places on the coast of Africa.

Mr. A. Beer exhibited some very fine enlargements from 10 by 8 negatives belonging to him, made by Mr. J. Harmer, of Littlehampton.

Mr. Thompson showed his camera, lenses, and shutters, a large number of views in the Mediterranean, Sicily, Naples, Trieste, and Venice, and also a portable Buckle stand with some improvements by Mr. Crowe.

The meeting was then adjourned to the last Thursday in April.

Talk in the Studio.

Photographic Society of Great Britain.—The next meeting of this Society will take place on Tuesday, April 8th, at eight o'clock, at the Gallery, 5A, Pall Mall East, when the evening will be devoted to an examination into the mode of preparation of lantern slides, and their exhibition with the Society's optical lantern (oxy-hydrogen lime light). Amongst others (illustrating the various processes, old and new), transparencies will be shown by Dr. Huggins, F.R.S. ("Astronomical"); W. F. Donkin, F.C.S., F.I.C. ("Alpine"); and by R. Meldola, F.R.A.S. ("Scenes and Natives of the Nicobar Islands.")

Presentation to Mr. P. C. Roche, of New York.—A very enjoyable gathering of the photographic fraternity was assembled on the 18th ult. at Martinelli's famous restaurant on the Avenue, New York, for the purpose of presenting that old veteran of the art, Mr. Thomas C. Roche, with a slight token of their esteem and respect. At eight o'clock quite a goodly company (upwards of sixty) sat down to an enjoyable French dinner under the chairmanship of Col. V. M. Wilcox. Mr. Bogardus made the presentation speech, and handed Mr. Roche a handsome gold watch and chain. His remarks were very felicitous, and were followed by some lively and interesting toasts and speeches. The inner case of the watch was engraved as follows:—"Presented to T. C. Roche, from brother photographers, as a mark of esteem, and in recognition of his valued services to the craft, March 18th, 1884." Nearly all the leading photographers of New York were present, and also many amateurs.

Separation of Rays of High and Low Refrangibility.—By F. V. Assche, *Compt. Rend.*, 97, 838—840).—A thin layer of selenium, obtained by compressing a drop of the fnsed substance between plates of glass at 250°, and allowing it to cool slowly under pressure, only transmits the rays between Fraunhofer's lines A—C. The amount of absorption increases with the thickness of the layer. When a beam of white light is passed through a solution of alum, and then through a film of selenium, all the luminous rays are arrested. A thin film of selenium, if heated to 250°, is apparently opaque to all luminous radiation.—*Journal of Chemical Society.*

Yet Another Application of Photography.—Drawing corks is too tedious an operation. They are now photographed by the instantaneous process.—*Funny Folks.*

Photographic Club.—At the next meetiug on April 9th, the subject for discussion will be "On the best outfit for amateur out-door photography."

To Correspondents.

*** We cannot undertake to return rejected communications.

*** Our Publishers desire us to state that next Friday being Good Friday, the News will be published one day earlier than usual. Advertisers will please note.

Scot.—Mr. A. L. Henderson, of London Bridge, was the first to propose it.

N. N.—You could get a supply, no doubt, either at Edinburgh or Glasgow; write to McGhie and Bolton, West Nile Street, Glasgow, if you have any difficulty.

F. Adams.—We are very sorry, but the Year-Book of Photography was out of print a fortnight ago.

C. Chesterman.—Please send us your full address.

Perplexed.—We have abundant reason to believe that they arise from the presence of small clots of insoluble albumen in the mixture used for coating the paper, and these clots, although scarcely showing on the face of the unsensitized paper, refuse to take up the silver solution. They generally are most numerous on the first few sheets albumenized.

H. M.—It may be copyright, and we should advise you not to sell any copies. Why not photograph the building itself, and secure a copyright in your own picture?

C. C. L.—Many doubtless call themselves photographers to the Queen with no more ground for doing so than you yourself possess, but we imagine that, according to the strictest view, the title should not be used unless some kind of warrant of appointment has been issued. 2. Why not have a phototype reduction of the letter made, and print it in your circulars and upon your mounts? 3. We are inclined to attribute them to imperfect fixation; leave them longer in the hypo, and take great care in the washing.

H. Mallins.—We do not think they have any London agent, and should recommend you to write direct.

W. J. H.—1. It is quite reliable; still, we think you would do well to work without it, as it is necessary for you to gain that experience which will render you independent of such aid. 2. You should not watch it, but keep the dish covered, and glance at it now and again. By holding it up to the lamp and looking through it you will be able to judge to some extent. No one can fully judge as to the result until the plate has been fixed, or at least taken out into a full light. 3. Yes, but we prefer to use fresh solution each time. 4. There is less objection to using this a number of times. 5. A moderate washing is sufficient; say one change of water. 6. We will consider the matter, and are obliged to you for the suggestion

J. Willis.—1. It will answer very well; nail the sheets on a light wooden framing. 2. For side light about nine feet by twelve or thirteen, and perhaps two-thirds of this for the skylight. 3. Within 12 or 14 inches.

Wm. J. T.—The reaction with iodide of starch affords strong evidence of the presence of hyposulphite, but to establish it in a sufficiently conclusive manner to support a claim in a court of justice, would involve careful and extensive analytical work. If an experiment made with a divided print, as recommended on page 113 of the present volume, does not carry conviction to the vendors of the mounts, you will have to consult an analytical chemist and a solicitor.

F. Francis.—If you have a sufficient inlet for warm air and outlet for the damp air, you will doubtless be able to dry 300 quarter-plates at a time; but unless you are pressed for time it would be well to work with less. 2. Markings are very likely to result if you do as you suggest.

Musty.—1. To give you all the directions you require would be to write a complete treatise on the gelatino-bromide process; this we can hardly do, but we should recommend you not to over-expose, and to use the ferrous oxalate developer. 2. The Autotype Company undertake such work; their address is Oxford Street, London. 3. Write to the firm and enquire.

H. D.—We fear it has found its way into the waste paper basket, but we hope not.

W. F. Bennett.—1. You would do well to add a small proportion of potassium bromide to your developer. To each four ounces add from 5 to 30 drops of a ten per cent. solution. 2. Collis to be preferred. 3. Use the bicarbonate toning bath given in the Formulary (p. 176). 4. Each set is excellent in its way, and you can only determine by considering which best meets your individual requirements.

John Mc. L.—1. Doubtless it was, but it is very likely that no inconvenience will result from the omission. 2. We know of none later. See Mr. Bird's article on page 613 of our last volume.

Subscriber.— Try soaking in weak cyanide—say 5 grains to the ounce. There is considerable risk of spoiling the negative, so you had better make as perfect a copy as possible before commencing to experiment

Emulsion.—1. It certainly does appear strange, but we are inclined to think that damp may have had something to do with it. We have found that pellicle (desiccated emulsion) which was kept in an absolute state of dryness did not gain sensitiveness by keeping, while another sample which was not carefully guarded against moisture became much more sensitive when kept for a year. 2. It is not at all necessary, as the gelatine itself fulfils the function completely. 3. We cannot tell you the method adopted by the gentleman whom you mention, but do not think anything would be gained by doing as you propose. 4. Your explanation is doubtless the correct one, and we think that the suggestion you make is a valuable one. We hope you will try the experiment, and let us know the result. The addition should be made the last thing, and we should think that 1 part for 50 of gelatine would be sufficient

Dr. Westropp.—Your original communication appears to have been lost in the post, but we have written privately to you, and hope you will be good enough to repeat your original query.

Zeta.—It is pretty clear that the mischief arises from the use of vessels of porous earthenware, the body of the vessels having become saturated with old emulsion. Discard all your present mixing jars, and use nothing but glass in future. 2. Ordinary fine muslin, such as can be obtained from any draper: but before being used it should be well washed in boiling water and dried in a place free from dust. 3. One part of water glass (soluble silicate of soda or potash) and 150 or 200 parts of water. 4. Use patent plate glass. 5. Nitric acid will dissolve it immediately; one part in four or five of water. 6. No apparatus combining all the advantages you enumerate has been invented; and we must say we do not think there is much hope of the realisation of your idea in its present form. 7. Write to the publishers on the subject. 8. No. 9. To a solution of silver nitrate, containing five grains of the salt to an ounce, add gradually enough of a saturated solution of potassium cyanide to re-dissolve the precipitate first formed. If you mix this to a cream with whiting, and rub it on the clean copper plate, a sufficiently thick film of silver will be deposited. 10. Try a 30-grain solution of chrome alum, leaving the plate in for about ten minutes.

MR. H. P. ROBINSON'S NEW BOOK.

Messrs. PIPER & CARTER beg to state that Mr. Robinson's new work, "PICTURE MAKING BY PHOTOGRAPHY," will be published very shortly, and Advertisements must reach their Office not later than Monday next.

The Photographic News Registry.

Employment Wanted.

Printer & Assist. Operator.—A. S., 47, New York-st., Manchester.
Mounter, Cutter, Spotter (lady).—H. H., 12, Croysland-rd., Chalk Farm.
Printer, Toner, General Assist.—Photo., 3, Alma Cottages, Barking-rd., E.
Retoucher and Operator, first-class.—H. S. Healey, 32, Stall-st., Bath.
Retoucher, Mounter, Finisher (lady).—B. C., 10, Patrick-st, Cork.
Op., &c. (Italian, speaks Fr.ch. & Eng).—L. S., 35, Grove-lane, Camberwell.
Printer, Retoucher, assist generally.—Argent, *Photo. News* Office.
Retoucher and Assistant Operator.—W. Leuchars, 51a, Perth-rd., Dundee.
Colourist & Ret (lady).—E. McCowen, 20, Grand Parade, St. Leonards-o-S.
Printer, generally useful.—C. R. M., Station-rd., Sleaford, Lincoln.
Operator and Retoucher, speaks French.—Franco, *Photo. News* Office.
Operator and Retoucher, wet or dry.—X. Y. Z., P. O., Bitton, nr. Bristol.
Retoucher and Assist. Op.—W. H. T., 11, Kirkwood-rd., Haverstock-hill.
Youth, to learn photography.—D. L., Pliny Villa, Godwin-rd., Forest-Gate.
Operator & Retoucher, 30s.—A. B., 21, Bethel-st., Norwich.
Operator & Retoucher (Italian).—Dal-Mistro, 64, Frith-st, Soho.
As Improver in first-class house.—W. T., P. O., Stretford, Manchester.
Gen. Assist. (21). Lond.—G. P., 6, Kensington-pk.-rd., Notting-hill-gate.
Assist. Op. & Printer in Lond.—L. W. Green, Dennett's-rd., Peckham.
Photographer of exp., free April 28.—W. F. Andersou, 5, Tarvit-st., Edinb.
Recep.-Room (Lady), gen. useful.—A. M., 28, Atlantic-rd., Brixton.

Employment Offered.

Operator, indoor or out.—C. Gillman, 107, St. Aldate's, Oxford.
Assistant, first-class.—C. Gillman, 107, St. Aldate's, Oxford
Neg. Retoucher (lady), first-class.—W. H. Mason, 89, George-st., Croydon.
Operator, clever at lighting and posing.—Artist, 22, Red Lion Square.
Operator and Retoucher, to manage.—West and Son, Eagle House, Gosport.
Printer and Assistant immediately.—S., 38, Queen's-sq., Bristol.
Neg. Ret., &c.—T. Williams, Talbot-pl., Darlington-st. Wolverhampton.
Operator, skilful & clever Ret.—S. W. Barns, 100, High-st., Ashford, Kent.
Retoucher (lady)), quick, 30/- weekly.—Stuart, 17, Brompton-rd., S.W.
Retoucher, good.—Barraud, 263, Oxford-st., W.
Assistant in Stock-dealer's Warehouse.—Ruby, *Photo. News* Office.
Youth, to develop & be useful in studio.—S. S., 55, Moorgate-st.
Assist. Operator for landscape.—Norman and Co, Tunbridge Wells.
Operator, to retouch.—T. Moss, 199, Derby-st., Bolton, Lancs.
Oper., clever with children & retouching.—Clayton, 6, Lond.-rd., Leicester.
Retoucher, to operate in principal's absence.—Reed, 16, Tottenham-ct.-rd.
Printer, Toner, Mounter, Burnisher.—Shrubsole, Davey-pl., Norwich.

THE PHOTOGRAPHIC NEWS.

VOL. XXVIII. No. 1336.—*April* 10, 1884.

CONTENTS.

BROMINE AS A FOG ELIMINATOR.

LAST week we treated the subject of "Free Bromine in Gelatine Emulsions," and stated that we had first experimented with this chemical with the view of discovering its properties as a fog eliminator. Our idea was that possibly it might be capable of removing that fog which arises from the excessive forcing of an emulsion either while using the cooking or the ammonia process, in the latter case either through very high temperatures, or through the use of very large quantities of ammonia; and that as a consequence the objection to such forcing might be removed, and we might practically attain to a greater degree of sensitiveness.

In a great measure our experiments have been rewarded with success. One important point which we have been convinced of in the course of them is, that there are two distinct kinds of chemical fog, one which may be treated with success in any of several ways, and one which cannot.

We shall describe the appearance of these two varieties, which will, we think, be at once familiar to those who have at all extensively experimented with gelatine emulsions.

In the case of the first, a plate tested wet, shows no sign of the defect. It gives a bright, clear, dense image (as images on a plate used wet go), but when dry it is very much fogged. On close examination it will be noticed that the fog is almost entirely on the surface, and that the image under this fog is really dense. If the plate be thinly coated, it will be seen that the image on the back is of the same nature as that on the front.

In the case of the second, a plate developed wet shows but a thin image. There is, apparently, not much fog by reflected light, but by transmitted light there is. When a dried plate is tested, the appearances are intensified. The image by reflected light looks clearer than does that on the first-mentioned plate. By transmitted light, however, it is miserably thin and foggy looking, and the image at the back (looked at before fixing) is of the opposite nature to that on the front. It is a positive when that on the front is a negative, and *vice versa*.

If we may venture on an explanation of the cause of these two appearances, we shall ascribe the first, which only occurs in the case of a very sensitive emulsion, to an unstable condition of the silver bromide, wherein the balance may be upset during the course of drying by the action of the air, or of some impurity in it. A small quantity of a salt reducible by the developer without the action of light results, and we have the surface fog described.

We shall ascribe the second kind of fog to a granular or spongy state of the silver bromide. It is reasonable to imagine that when such a state occurs, the gelatine surrounding the particles of haloid have lost their restraining power, and that the developer may reduce the silver bromide without the assistance of light.

Taking into consideration the explanation which we have given, a little reflection will show that the presence of free bromine in an emulsion would prevent the formation of fog of the first kind during the drying of the plates, by replacing the atoms of bromine which were liberated by the action of the air, or whatever does liberate them, or by preventing altogether their liberation.

Acting on the assumption that our reasoning was correct, we performed the following experiment.

Plates were coated with a very sensitive emulsion, which gave on drying the kind of fog first described. Whilst still wet, these were dipped for half their lengths in water containing quantities of the bromine solution described in our last week's issue, varying from half-minim to the ounce, to three minims to the ounce.

The plates were left for five minutes in this very weak bromine water, and were then dried, when the following result was obtained.

The plate which had been washed with the weakest bromine water mentioned showed a marked diminution of fog on that half which had been operated upon. A plate treated with one minim of bromine solution to each ounce of water showed an entire absence of fog without diminution of sensitiveness. The same applied to a plate treated with a solution double as strong, but on going beyond this strength, there was a marked diminution of sensitiveness.

Adding to the emulsion itself quantities of bromine water varying from half-minim to two minims to each ounce, had the same effect as treating the plates with it as described. Even sprinkling the drying box with bromine water, so that there should be a drying atmosphere more or less impregnated with free bromine, was effective.

We have not experimented with free iodine as with free bromine, but from the fact that free bromine acts as a fog eliminator as effectively in the case of a bromo-iodide as in the case of a pure bromide emulsion, we presume that iodine would have much the same effect as bromine. As we explained last week, the effect of adding bromine to an emulsion in which there is iodide of silver, is to liberate iodine.

We found all applications of bromine to an emulsion afflicted with the second kind of fog mentioned, to be without result, other than the slowing of the emulsion when the quantity was excessive.

We think the use of free bromine as we have described it may be found useful in the hands of emulsion makers. It has had the practical result in our own case of enabling us to get more sensitive plates than we otherwise could. Up till the time we tried the use of free bromine the limit of sensitiveness was reached with us when we could no longer dry our plates without fog making its appearance during the process.

Mr. A. L. Henderson some time ago stated that bromine

acted as a green fog eliminator. We find that it does mitigate, to a certain extent, the green hug-bear, and on this subject, and also on the effect of hromine as a light fog eliminator, we shall shortly have something to say.

THE WOODBURYTYPE PROCESS.

(Fifth Article.)

The difficulty of obtaining a suitable paper for the Woodburytype method and the expensive nature of the machinery required for properly rolling it, have proved one of the serious obstacles to the popularisation of the process; perhaps as great as the hindrances arising in connection with the expense of the hydraulic press required for making the mould. Of course the introduction of properly prepared paper into commerce would at once remove the difficulty, and until good prepared paper can be procured in the ordinary way of business, the popularisation of the Woodbury method will be of necessity slow work.

The primary necessity as regards the paper is that the pulp should he extremely uniform and perfectly free from knots or lumps; and few commercial papers realise these conditions in a sufficiently high degree. Probably the best paper to select is a rather thin Rives paper; just such a paper as is ordinarily used for albumenizing. The paper having hecn selected, the next step is to coat it with a film of lac or other dressing, an alkaline solution of the resin being ordinarily employed, although gelatine or albumen may be used.

To preparc the lac solution, four ounces of borax and an ounce of carbouate of soda are dissolved in threc pints of water. This solution is heated to the boiling point, aud a pound of white shellac is added, the boiling being continued till the whole is dissolved. When cold, the liquor is made up to its originial volume, aud a little carmine is added to give it a faint tint; this being an advautage, as it renders it easy to distiuguish the coated side of the paper. The room iu which the coating of the paper is carried on shonld be kept warm, and it is not desirable that the temperature should fall much below 90° Fahrenheit. The sizing solution is to be filtered into a tolerably deep dish, this heing inclined a little, so as to give an increased depth of liquid in that part of the dish next the front edge of the table. Two sheets of paper are now taken, and are held by opposite corners so as to keep two edges in close contact, and this double edge is quickly immersed in the shallow part of the dish, after which the two sheets are rapidly drawn forward and brought out of the solution at the deep edge of the dish. Under these circumstances the sheets adhere hy the edges, but the liquid does not penetrate more than an eighth of an inch from the borders if the work has been successfully performed. The double sheets are now pinned up to dry, an inclined board being so placed as to catch the drainings. When dry, the sheets are separated, the most convenient course being to cut off a slip an eighth of an inch wide from one edge, and then to use a paper-knife. Still another coating is required, as, if the gelatinous impression were made directly upon the shellac-ed surface, there would be considerable probability of separation taking place sooner or later. In order to avoid this separation, a kind of emulsion of gelatine and resinous matter is used as a sort of bond of union between the lac paper and the gelatinous image. The emulsion is made by dissolving one part of gum benzoin in ten parts of alcohol, and after the solution has been filtered, it is mixed with a warm solution of one part of gelatine in nine parts of water, care being taken that violent agitation accompanies the mixing. The milky fluid is applied to the surface of the lac-coated paper by means of a soft cloth, it being sufficient to thoroughly moisten the surface; and when the sheets are once more dry, the final operation of rolling or burnishing is to be performed, the quality of the prints obtained depending largely on the care with which this part of the work is carried on.

For rolling, the sheets are placed between thin plates of burnished steel, and passed between the rollers of a powerful rolling machine capable of giving a direct pressure of ten or twelve hundredweight, and such a machine, with a supply of steel plates, may be reckoned to cost about £200, if for sheets of demy size (22½ by 17½).

When a number of sheets have been alternated with the burnished steel plates, the whole is passed several times, backwards and forwards, through the rollers, the pressure being gradually increased; and it is sometimes advisable to change the order of the sheets, and to apply a second pressure.

The rolled paper must be handled with the greatest care, so as not to crumple or fold it, and it must not be exposed to moist air, or it might swell, aud so require to be subjected to renewed rolling.

BLISTERS IN SILVER PRINTS.

The time has gone by since blisters of varying dimensions on albumenized paper were held to be the bane, liable at any time to render futile the very best intentions of the silver printer throughout the universe; and the best thanks of those engaged in work of this class are undoubtedly due to the early workers, who studied the problem, and prescribed such specific remedies as will enable anyone to avoid—or, at all events, to overcome—the difficulty, should it by chance make its appearance. As we have implied, blisters are rarely met with now-a-days, if only an average amount of precaution is taken to prevent their occurrence. Like other phenomenon, less abstruse, in which the seasons have a more or less marked influence, we find that the latter part of the spring, and the commencement of autumn, are the proverbial seasons when troubles may arise on this score. Viewing a possible recurrence of the evil in the hands of insufficiently experienced printers, has induced us once more to open up this well-nigh defunct subject.

A good deal of attention has recently been given to silver printing. Carefully prepared papers have been read before the societies, initiating valuable discussion; but few, if any, new points have been elucidated. Certainly no mention was made of blisters. Still, a repetition of sound principles and reliable formula occasionally, is advantageous; it refreshes the memory of some, while many half-forgotten points become entirely new ones to those who have entered the ranks recently.

A prolific cause of blisters of large size—sometimes as large as a hen's egg—is the use of a strong sensitizing bath, in conjunction with a highly glazed albumen surface. This mistake is often made under the notion that a highly surfaced paper must need a strong silver solution in order to get brilliancy. We have elsewhere shown this to be a fallacy, which may be verified by the simple experiment of adding slightly diluted albumen to a thirty-grain neutral nitrate of silver solution (this operation may be performed in a test-tube, and is instructive to beginners). The remedy in this case is obvious. Dilute the sensitizing solution as much as compatible, without risk of dissolving the surface, and increase the time of floating to avoid the risk of weak prints.

Another cause of blisters—one which is seldom met with, however, except among large consumers—arises from using paper shortly after it has received its coating of albumen—that is, before it has properly matured; the form of blister met with under these circumstances is very much smaller than in the previous case, and may be known partly by the repellent nature of the paper in floating on the silver bath, and partly by the extreme care necessary to exercise in handling it during the washing operations, without disturbing the homogeneity of its surface. The remedy consists in storing the sample in a moderate temperature for a few weeks.

A cause over which the consumer has less control than

either of the foregoing, results from the sizing. If the sizing given to the paper in the process of manufacture is of too hard a character to permit a homogenous tenacity being established between the surface of the paper and its facing of albumen, it is rendered incapable of withstanding the force to which it has to be subjected in the action of washing out the soluble salts. We may look upon a print during its transit through the various aqueous solutions somewhat in the light of a sponge, charged alternately with solutions of varying densities. If a sponge saturated with a dense liquid, such as hyposulphite of soda, be placed in a less dense liquid, such as water, for a sufficient length of time, an equilibrium of density between the two liquids will be established or, in other words, a perfect mixture will take place. In the case of silver prints, a similar action takes place, but with this difference: the porosity being unequal—that is, the porosity of the paper at the back being greater than on the surface—permits a freer passage for the dense liquid to pass out of the former, while in the latter, the struggle which takes place with the liquids in their efforts to equalize, causes a separation of the two surfaces which we recognise as blisters.

Among the numerous remedies suggested for this kind of blister, perhaps there is not one so efficient as the plan of equalizing the temperature of all the solutions made use of; increasing the density of the washing waters between toning and fixing, by the addition of a handful of common salt; and diluting the hyposulphite bath gradually, instead of transferring the prints directly into the washing trough; or, what amounts to the same thing, employing salt in the first and second waters after fixing. It is very seldom blisters make their appearance until the prints have left the fixing bath, and are in the act of washing. We may here mention that there is less liability to the defect when prints are face downwards during fixing and washing.

Having indicated some of the causes and their remedies, we take leave of this part of the subject, it being impossible to deal exhaustively with every phase in the space at our disposal. A defect somewhat analogous is sometimes met with, which is liable to be very troublesome unless the change of conditions which brings it about ceases; this defect is an abrasion of a portion or the whole of the film after fixing by slight pressure in handling, or the friction produced by the prints striking against the sides of the washing machine. The subject recently came under the notice of the Photographic Society of Great Britain through the medium of the "question-box," and was discussed at one of the mid-monthly meetings; several well-known experts who were present averring the defect to be uncommon, and not met with in their own practice. In the course of the discussion it transpired that a sample of the same paper sensitized, printed, and otherwise treated in London, exhibited no indications of the defect complained of; the questioner who was present attributing the defect to the lowness of temperature in the apartment where the sensitizing was conducted. This conclusion is very likely to be the right one, seeing that the occurrence took place over five hundred miles north of London.

We remember our attention being directed to a defect of this kind during a frosty season a few years ago. At that time we were in doubt whether heat or cold was the primary cause. Upon inquiry, we found the use of very hot water for washing rendered the surface in a soft state, incapable of resisting the slightest rough treatment; further, after reducing the temperature of the washing waters, we found, upon removal of the prints, and suspending them in the drying-room, without heat in the apartment, that the surface became covered with a thin coating of ice, due to the lowness of temperature; and we noticed, that wherever any part of the frozen print was handled, there the film would be disturbed.

In concluding, it might be worth while inquiring why albumenizers issue such meagre instructions with their paper, generally contenting themselves by urging weak solutions, knowing full well, as they must do, that the same formulæ will not suit each batch alike, or the same batch under unfavourable circumstances? We do not wish to be misunderstood when we say weak solutions, because many thousands of excellent prints are made on a silver bath of less than forty grains per ounce; but the conditions must be favourable. Every practical printer knows that the conditions suitable when the temperature averages 60° F. are unsuitable when there is a variation of twenty degrees above or below that standard; this variation of temperature frequently making all the difference between easy sailing, and a host of annoyances. From a long practical observance, we are satisfied that any considerable deviation in the temperature from 60° F. prevents any hard-and-fast rule being applicable in all cases; hence the necessity of additions such as alum, camphor, methylated alcohol, and other substances, well-known to the professional printer; besides the precautions already pointed out in this article.

At Home.

SENOR E. OTERO, CARRERA DE SN. GERONIMO, MADRID.

How do the public choose a studio? What guides the selection of a visitor and gives him confidence in the one case, or causes him hesitation in another? There are several good studios in Madrid, in the neighbourhood of the Puerto del Sol, and as we pass and re-pass them, unable to make up our mind, this subject actively occupies our thoughts. We want to act as one of the public, and to choose as they choose; we want a portrait taken, and to get the best value for our money.

Here is one firm that has several handsome show-cases in different parts of the town. The pictures are not only good, but they have a "go" and chic about them, decidedly taking; but when we come to the entrance of the studio itself, whither the show-cases have directed us, it is a narrow doorway, not untidy, perhaps, but with well-worn stairs that look a little mean. No; somehow, that does not give one the impression of a first-class studio. There is a something that suggests the establishment is a little "shy," and nothing has a more decidedly negative effect on a stranger than this.

It may be very foolish on our part, but we go away. At last, after more walking up and down, the decision rests between two establishments, both of them in the Carrera de Sn. Geronimo, and both with a well-to-do entrance adorned with much handsome work, displayed in excellent taste. This exhibition of specimens is, indeed, a difficult matter, if you want to please everybody: the display must not be great and gorgeous, or you run the risk of appearing vulgar; and yet a goodly collection of pictures must be shown if you wish to do yourself justice. Just now the attractions are so evenly balanced, that it is merely the proximity of Senor Otero's studio to our hotel that turns the balance. We hesitate no longer, but walk upstairs.

It is a long way upstairs. In fact, if it were not a well-known axiom that photographers are always nearer heaven than other mortals, we might have given up the search ere we reached the fourth floor, for not a word of direction was there to be seen on our pilgrimage up the broad staircase. But it is a well-appointed studio enough, when we do reach it. You enter a neat, business-like bureau, adorned with numerous pictures, while on the mahogany counter are specimens of the ordinary portrait formats.

As our Castilian is not of the purest, we demand, in the first place, somebody who can speak French. The head of the firm comes forward to help us out of the difficulty, and we soon begin to understand one another. Our

personal appearance, after being up all night in a Spanish express, is not so becoming as it might be, but still we have a burning desire to be photographed at that particular moment, and ask to have a picture without delay.

Portraits are taken from nine to three, is an announcement that Senor Otero makes to his customers; and if you are busy during that time, all will agree that six hours in the studio is hard enough for anybody.

The charge for cartes is fifteen francs a dozen; that for cabinet pictures, thirty francs. We decide upon the latter as giving a better idea of work than the smaller size, and preliminaries being so far arranged, we are requested to enter the waiting room.

We walk in. Good gracious! It is like an evening party, except that the dress we ourselves are wearing at that moment does not resemble evening dress. There is an elegant room, the carpeted floor cleared for dancing, and sitting round the apartment on green velvet settees is a bevy of fair ladies, all without their bonnets, waiting to be asked.. Their dark dresses and showy black mantillas—not five per cent. of the ladies in Madrid wear anything else in the streets—are very engaging, and their black eyes and dark eye-brows add still further to the charm. They smile and chatter without the least concern, although they evidently take the last arrival to be something of a boor, because he refuses to join in the conversation.

But M. Otero's waiting room deserves a little more description. The effect upon the stranger—even without its fair occupants—is somewhat original. It is rather dark, for the small windows it has are fitted with figured glass, and this darkness is brought about for a reason. There is, namely, at the end of the room opposite the entrance a big panel mirror rising from the floor, and the effect of this, at first sight, is that of an open door or passage. It attracts you at once, as a moth is attracted to the light, and before you know where you are, you have closed on to the looking-glass, and are facing it in a very sheepish sort of way. At some of our London theatres the green rooms are fitted in this fashion with a cheval glass, and those apartments being but dimly lighted, the effect on the stranger is the same. The mirror in these cases is, of course, for the purpose of permitting actor or actress a last glimpse of their attire before appearing on the stage, and probably Senor Otero borrowed the idea from the theatre; in any case, it is a very good one, for by subduing the light all round in this way, you see yourself in the mirror to the very best advantage.

On the right of the waiting room a door stands open, leading to a little dressing-room or *Tocador*, while a second door, that is closed, is labelled *Galeria*. Our party is soon increased by another lady, also with a smart black mantilla and jet-black eyes, and she, tripping straight to the looking-glass, is also a little surprised to find herself face to face with the mirror. But, in true Continental fashion, she is in no way disconcerted; she proceeds with her toilet, smiling contentedly at herself the while, without the least concern. She is not shy, if we are.

There are plenty of pictures to look at, and the light is not so dull that you cannot see them to advantage. There is one new pose, we remark, albeit it is a picture that would hardly be popular in this country. It might be called the Tombstone Pose. A gentleman, presumably a widower, stands with white handkerchief in one hand, and hat in the other, beside a stone monument, sacred to the memory of his dear departed. No doubt the picture here shown was executed to order, but we doubt whether the idea is sufficiently general to induce others to be represented in like manner. Instead of suggesting sentiment or pathos, the pose hints all over of rheumatism and a cold in your head.

Gradually, the ladies are summoned, one after another, to the *Galeria*; it is a question of "place aux dames," for the latest comer precedes us thither. Still, we do not complain, for our turn comes very quickly. It is a very fine studio, some forty feet long and twenty feet broad, and apparently papered with ordinary brown paper. This papering, though, being smooth and regular, has quite an agreeable effect. The room is comparatively lofty, too—sixteen or seventeen feet—one side of it being glazed. Blue curtains, simply hung on wires stretched horizontally, are used to screen the side light, and brown curtains are looped under the roof. There is no direct sunlight, so Senor Otero is able to work with a large extent of bare glass. In our case, indeed, there were probably three feet of bare glass, both side and roof, employed to take a vignetted head, cabinet size; and although, as a result, the lights and shadows were in considerable contrast, the picture was decidedly successful. It was brilliant and vigorous, without having any inky shadows. Of course, in these circumstances, a white screen was used close up to the figure on the shadow side.

Employing so light a studio, Senor Otero also takes great care in shading his lens. The advent of very sensitive gelatine plates, indeed, makes the photographer very careful of the apparatus he employs now-a-days. A little diffused light in the camera, which was of no material importance in the old collodion days, works incalculable mischief upon the gelatine film, and we have noticed of late, in light studios especially, photographers are at great trouble to cover their apparatus. Senor Otero shades his camera with a close-fitting canopy of black velvet, which projects as a hood at least two feet beyond the lens. In this way he not only provides a shade for his lens, but is quite sure no injurious light enters by the diaphragm.

An assistant poses and goes through all the preliminaries, so that when the Senor arrives on the scene, his work is lightened somewhat. Very little, however; for he proceeds as an artist should, and completes the posing and lighting leisurely after his own fashion. "But this is not a serious affair," he presently says, alluding to a morose expression on our part; "let us have something more amusing, please."

So we try to look more lively, and our friend, by way of encouragement, chats half in French half in Spanish. He is not quite satisfied with the direction of our eyes, apparently, for presently he asks us to glance round so as to look straight into the lens. "Yes, that is very well," he says at once.

The picture is taken while we thought he was but posing; it was the first time in our experience of being portrayed without knowing it. With the light at his disposal, Senor Otero required, probably, no more than two seconds for his cabinet picture, and hence he had advantages most photographers do not enjoy. But there cannot be a doubt as to the wisdom of such a course, if it can be managed. There was no opportunity for the sitter to get up an expression; no time to feel that, as you are doing nothing, you must perforce shake the head-rest behind you with your skull; in a word, there was no time for self-consciousness to obtrude itself.

We are not permitted to depart until the plates have been satisfactorily developed, and, left to ourselves, we have time to remark that English instruments and English apparatus are not unknown in Madrid. By way of conclusion, too, we may remark that the pictures, which Senor Otero was good enough to forward within the period of a week—a fashionable London studio would keep you three times as long—were in every way satisfactory. They were, indeed, quite equal to the work that the first studios of London, Paris, Vienna, or Berlin are wont to furnish, while we certainly received more attention than, in our experience, generally falls to the lot of a casual customer visiting a high-class studio in the English metropolis.

The "By-the-Bye" next week will be "Provincial Exhibitions."

Review.

ILLUSTRATIONS POUR LES MEMOIRES D'UN FOU, DE M. N. V. GOGOL. D'après l'Acteur de Moscow, M. Andréef-Bourlak. Par M. Constantine Chapiro, Photographe de l'Academie Imperiale des Beaux Arts (*St. Petersburgh*).

A MAGNIFICENT album of studies, all of them untouched, reaches us from the studio of M. Chapiro, photographer to the Imperial Academy of Fine Arts at St. Petersburg. The album itself, with ruby plush cover and gold encrusted fastenings, is rich and elegant in the extreme; but costly as it is, the book is none too fine a casket for the rare jewels it enshrines. The pictures, in a few words, represent the labours of three clever men—a dramatist, an actor, and an artist. The "Memoirs of a Madman" is a dramatic work of Gogol, in which the changes from comedy to tragedy are so vivid and realistic, that a clever actor of Moscow, M. Andréef-Bourlak, was induced to give an acting version of the work. M. Bourlak's impersonation of the madman in Moscow and St. Petersburgh has created a wonderful sensation, and M. Chapiro, the eminent Russian photographer, conceived the happy idea of photographing the actor in various phases of the rôle, and so produce some living illustrations to Gogol's text. The album, therefore, that M. Chapiro sends us, each picture faced with the speech of the actor, is in truth a mimic representation where the part of madman is exacted in all its quaint comedy and touching earnestness.

The scene is always the same; it is a simple ward in the madhouse, with a narrow iron bedstead covered with the whitest of linen. As the madman is also habited in white cap, gown, and trousers, the whole of the studies may be called symphonies in white, difficulties, by the way, that M. Chapiro has got over with consummate skill. We have not here the space at our disposal to describe the pictures at full length—how comedy alternates with tragedy—but here are a few examples.

No. 1. The poor madman lying on the bed, raises his head, and with impressive forefinger says: "To-day is one of great rejoicing; there is a King of Spain, and he has been found."

No. 2. Kneeling erect on the bed, he adds solemnly, "That King, am I."

No. 3. The madman looks intelligent, but puzzled, as he says: "I can't imagine, though, how I first found out I was entitled to the throne. What a lucky thing nobody thought of throwing me into an asylum."

The comedy goes on, but presently changes into tragedy, and the terrorised madman is beside himself with fear. He jumps upon the bed for safety, implores aid from his mother, and sees all sorts of dangers. Then he calms down once more, and looking down from the bed, sees on the floor "the sea coast on one side and Italy on the other."

In the last picture he has jumped from the bed and is sitting laughing on the floor: "And do you know that the Bey of Algiers has a wart just under his nose?" he says.

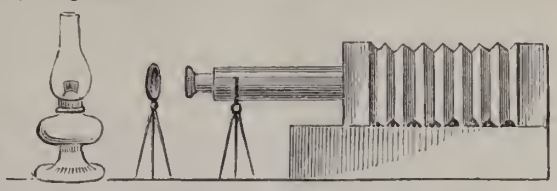
That M. Chapiro has done his work excellently well, in keenly catching the changing expressions of the actor, may be imagined from our enthusiastic remarks on the work; and we shall be much surprised if the album has not a wide circulation. The letterpress is printed in Russian and in French, but the photographs have a language that is spoken throughout the world.

PHOTO-MICROGRAPHY FOR BEGINNERS.

BY M. ALLISON.*

As some of our members are ardent microscopists as well as amateur photographers, perhaps a few remarks upon using the camera and michroscope together may prove useful, and should anyone profit, even though only in a slight degree, thereby, it will give me great pleasure to have done what lay in my power to assist him, and if possible to transfer to other persons my own ardour in this interesting branch of our art, a branch the practice of which, unfortunately, my rather weak eyesight will not allow me to pursue.

In the first place, all that is necessary for the production of photographs from microscopic slides is a good microscope, a camera of quarter or half-plate size, and a good lamp giving a steady flame. I have in my practice used a microscope of Matthews, an old-fashioned one with plenty of metal at its base, giving it a firm stand, and one which is capable of being placed in a horizontal position—the camera, an ordinary bellows-body one, being attached to the microscope by removing the eye-piece



of the latter and the lens of the former, and placing the camera with microsope attached thus in one flame, so that when the lamp is placed behind the condenser the rays of light will pass straight through the whole affair, and fall exactly in the middle of the ground glass. You can fill up the interstice betweeen the microscope and camera-front with anything suitable, such as a silk handkerchief wrapped round the brass tube; or it would of course be a better plan to make a camera front specially fit the microscope tube.

Having seen that the lamplight, condenser, object glass, tube, and centre of ground glass are all in one plane, you may commence operations with any suitable slides. In first beginning, use a one-inch or half-inch power, and practise with it until sufficient experience is obtained to warrant your proceeding to a higher power. When practicable, it is as well, or better, to use a low power, and get a sharp negative; this of course may be afterwards enlarged by the lantern to any reasonable size. This enlargement is made upon argentic enamel paper from the accompanying negative of "Saccharina Lepiscua." I do not know how many diameters it is enlarged, but you will see that one of the animalculæ is now the size of the whole of the microscopic slide, glass and all. You will also see that this "enamel" paper is very suitable for such a class of work as this, on account of its freedom from apparent granularity.

The slides with which I have worked have been almost all injected and stained histological specimens; they are about the worst subjects one could choose as a beginner, on account of their brown and red colour; the specimen photographs which I hand round will show that the most successful are from slides which have had no staining operations performed on them, such as crystals, &c., &c.

The slides should be prepared expressly for photographic purposes. If sections, the thinner they are cut the better; in fact, they cannot be cut too thin. Be content with a half-inch objective first, fasten the slide in its place, and having adjusted everything as above directed, cover your head and the camera as usual with a cloth, and focus first with the coarse, and afterwards with the fine adjustment. It is as well to remove altogether from the camera the piece of ground glass, and replace it by a piece of plane glass which has been coated with a solution of white wax in benzole, and allowed to dry. This will give a much finer and more suitable surface for the purpose than ground glass. When focussed as sharp as possible, the dark slide and slate may be inserted, and the exposure commenced. This will, of course, vary with the nature of the subject, and can only be judged by practical experience; but by using a stand and light, such as an ordinary Argand petroleum lamp, after a few trials the necessary exposure may soon be judged. By the way, in focussing, and using a half-inch objective (never mind the same not being corrected for colour) with artificial light, and getting as sharp an image as possible on the screen, it will come out sharp on development. As to development, I prefer Audra's ferrous oxalate, for with it perfect control can be obtained, and should a plate be slightly under-exposed, it may remain any length of time in the solution without fog, as in forcing with pyrogallic acid.

Again, should intensification be necessary, do not use the mercuric iodide and hyposulphite intensifier. Some of these were treated with it, and they are almost useless now; whereas,

* Read before the North Staffordshire Photographic Association.

had they been left alone, they would have made nice thin negatives, from which transpareucies could have been obtained. As regards the kind of plates most suitable for use with the microscope, do not use a quick plate; such a plate as is suitable for landscape work. One containing a fair proportion of iodide to bromide will give the best results, and be the most serviceable for use with artificial light. The exposure will vary from ten minutes to two hours, so there is pleuty of time to meditate and smoke a pipe during the operation; and as the development is done but slowly, oue plate may be exposed while another is developed. For any other information I will refer you to the excellent articles which have lately appeared in the technical journals.

NOTES ON THE LIME LIGHT.

BY T. FREDERICK HARDWICH.*

In the process known as the oxyhydrogen, or mixed gases, one-twentieth of an inch has been fonnd to be a useful size for the orificc of the burner; but, as a biunial lantern consumes a large quantity of oxygen, I have tried this year to reduce it. I find that it may be reduced to one-twenty-fifth of an inch without much loss of light, but I still give the preference to the former size when economy is not an object. The actnal size of the orifice, however, is not all which we have to cousider; the distance inwardly before the bore begins to expand must also be taken into account.

The distance of the point of the burner from the lime, measured diagonally, should be about a quarter of an inch when the angle of incidence is 45°. When the augle of incidence of the burning gases on the liue is less than 45°, the cylinder must be brought nearer. I have one burner, bent at an angle of 17°, which works best when it almost touches the lime.

I have quite discontinued working with very heavy weights on the bags, such as one and a-half or two cwts., finding the lantern more difficnlt to manage without an assistant, and the danger of accident greater. Abnndancc of light for all ordinnry purposes can be got with three-qnarters to one cwt. or an eight-foot bag, if the joints are gas-tight and the taps turned on full. I take certain precautions when working away from home, which it may be useful to mention;—1. Never allow any volunteers in the audience, who think they know "a little of magic lanterns," to come forward and help you. 2. Always strap on the weights to thc pressnre-boards, or tie them tightly with string. 3. Place the boards at a sufficieut distance from the wall so that they cannot tonch it in their desceut, and put a reliable person in charge of them, with strict injnnctions to allow no one to come near.

On the subject of "dissolving," I may allnde to the snapping noise, like that of a percussion cap, which occnrs with some burners of the blow-through kind, when there are two concentric tubes, and the outer tube of hydrogen projects beyond the inner tube for the oxygen. It was suggested to me to throw a little oxygen into the by-pass flame, and this I fonnd to answer perfectly.

I strongly advise that all dissolvers should be made with a by-pass tap to both gases.

Manufacture of Oxygen Gas.—I have a word to say on the use of chlorate of potash for preparing the oxygen. After experimenting with different samples, I am inclined to think that the kind that breaks with a conchoidal fracture, and is very hard to pulverise, is the most suitable.

Broughton's Ethoxo Lime Light.—When coal gas is not available, I still continue to use the ether process invented by Mr. Broughton, of Manchester.

In Broughton's tank the ether is not vaporised by heat, but a small quantity of oxygen is passed through it. This constitutes a source of danger, because an explosive mixture might be formed if the disengagement of ether vapour were not sufficiently copious. The oxygen should be saturated, or nearly so, after which the mixture will burn like common gas.

When you have purchased a tank, fill it with the lightest methylated ether of ·720 sp. gr., and light the flame at the jet of the lantern. If it burn yellow and luminous, like the flame of a candle, the proportion of ether will be sufficient to give you safety.

To study the colour of the flame effectually, it is not enough to turn on the tap gently and to allow it to burn against the face of the lime. The lime must be taken out of the way. Close the O tap of the jet entirely, and put on a strong pressure from the H tap of the jet until the flame shoots out, like a blow-pipe flame, to a length of six inches. You will then notice one of three different stages indicating less and less ether, before the last or explosive stage is reached.

1. In the first stage, when the ether is plentiful, the flame is yellowish, with an outer envelope of blue most marked at the base and point, the blueness being due to oxidation by the surrounding air. This flame, when allowed gently to play upon the lime cylinder, does not heat it red hot, except at the edge of the flame, but sometimes deposits carbon upon it.

2. With a smaller quantity of ether in proportion to the oxygen, the interior yellow flame dwindles away, and the outer envelope of pale blue becomes more and more pronounced, until the flame is blue throughout, with an edging of violet next to the air. This flame will heat the lime to bright redness, but it will not make it glow. By turning off the tap suddenly you find that it is not explosive.

3. In the third stage the outer envelope of violet has encroached upon the blue, just as the blue before did upon the yellow, and the whole flame is of a fine violet tint, fringed with a dull red or purple. It will now heat the lime to whiteness and make it shine, but not with the full degree of incandescence. It cannot be termed very explosive, because if you turn off the tap it goes ont quietly. I am not prepared to say, however, that it could not be sucked back or forced back into the mixing chamber.

4. In this last stage the flame is still a shade of violet; but the cone of imperfect combustion at its base, which you can easily see projecting from the point of the jet, is very much smaller in size. Instead of being three-quarters or one inch long, as it was before, it has diminished to a quarter or one-eighth of an inch, and if you find this you may be sure that there is danger.

Back-pressure valves—whether made of metal or silk—are useless for stopping flame.

My advice to persons holding crowded exhibitions is to procure two pumice chambers, to have them properly tested, and to place them—one upon the H nozzle, and the other upon the O nozzle of the tank at the end nearest the lantern. In addition to this, a back-pressure valve may be put on the O nozzle of the tank at the end furthest from the lantern, to prevent suction if a weight were to fall off the bag. In attaching the tubes, be careful to use only the thickest and best india-rubber.

Two questions have still to be answered:—Can the ether be used over and over again by simply making it up to its original bulk with fresh ether of ·720? To test this point I took five fluid ounces of ether which I had put away in a bottle as having been too often used to be reliable, and, after filling it up to eight ounces with ether of ·720, I poured it into a tank made to hold fifteen ounces. On passing the oxygen the flame burnt yellow, but slightly inclining towards blue. In half-an-hour it burnt pale blue, and in another half-hour violet. Then, in another quarter-of-an-hour, the gurgling noise in the tank became irregular, indicating that the ether was evaporating down almost to dryness, and that the last of the septa had been reached. On turning off the tap the flame went out quietly without explosion, and the tank when weighed was found to contain exactly three fluid ounces of ether. This experiment speaks for itself.

The Oxygen Bag as a Source of Danger.—This bag has been known to take fire more than once, even in the blow-through or safety process, and the cause is supposed to be an accumulation in it of a dusty or powdery substance produced by the disintegrating action of chlorine present in the oxygen as an impurity. I would suggest that a back-pressure valve should be placed on the nozzle of the bag when such a substance is known to be present. The only precantion which I take is to thoroughly purify the oxygen. Pass it through two washing-bottles, the long delivery tube of the second being closed at the end, and then perforated with a number of small holes, like what is called a "rose burner." Fill each bottle three-quarters full of solution of common washing soda in the proportion of a quarter of a pound to the pint of water, and the oxygen will then be nearly or quite free from smell. No water will enter the bag if four or five feet of india-rubber tubing of half an inch internal diameter be used to connect it with the nozzle of the second purifier.

After I had finished my "notes," and made them almost ready for the printer, I saw a report of the disastrous explosion at the Chadderton Town Hall, and of the evidence given by Professor Roscoe. He entirely condemns the use of the ethoxo light. If he had tried it, I think he would have come to a different conclusion.

The cause of the Chadderton accident was undoubtedly the

* Abstract of a paper read before the Edinburgh Photographic Society.

forcing of a little ether backwards into the oxygen bag from absence of a reserve chamber, which ought to have been provided.

NOTES ON THE LIME LIGHT.

On Rev. T. F. Hardwich's Paper.

BY LEWIS WRIGHT.*

As regards the light from jets, those I have most used have been only 1 mm. (one twenty-fifth) in bore, and I get with these ample for a disc 16 feet in diameter. I suggest that it would be a good thing if some Society would prepare and issue a "standard slide," of which copies could be had printed to one uniform density and transparency. I think the best plan for the internal bore is to use a "broach" such as watchmakers employ, which is very slightly tapered, almost imperceptibly. Then if a slightly taper steel wire be scored longitudinally, with coarse emery paper, the bore can be beautifully polished at any time by turning it round. At one-eighth inch from orifice the taper should be widened. As to distance from the lime, Mr. Hardwich, I think, reckons his "angles" with the surface itself. So reckoned, I prefer about 35°, which keeps the nipple from casting a shadow when of proper shape. But with most nipples, on trial, I find more light the nearar the orifice, and the practical point seems determined by the distance needed to avoid clogging up. With large orifices the distance does get greater. I begin with 1 cwt., and as pressure gets down put on ½ cwt. more to finish; but I certainly find more pressure, up to the capacity of the orifice, gives more light within at least certain limits. You do not, however, get light in proportion to extra gas. The best jet I know is one brought out by Mr. Place, I believe in answer to my own pressing in part; it has the great merits of cheapness, and raising the lime the proper distance at each revolution. It was this latter I so much urged upon him some time ago.

I, too, find "Excelsior" limes the best, and especially in accuracy of form. But of late, urged thereto by Dr. Maddox, so well known for his interest in photo-micrography, I have turned my attention once more to oxide of zinconium. I find the oxide can now be procured considerably cheaper than formerly.

Like Mr. Hardwich, I think the "skeleton" boards very unsteady. I never use them, preferring plain boards, with a hinged double leg at one end, and a hinged stay or stretcher which ties to it. The support is the full width, and cannot slip; and when the gas is half gone, the stretcher unties and boards go down on the floor.

It is impossible to say too much in favour of the double washing of oxygen with soda. Not the least advantage is, that yo do just as well with common chlorate at 7½d. to 9d. per pound. I only now use about one-fifth of manganese, and find the gas comes off much faster, so that I often get the bag filled in twelve or fifteen minutes—indeed, the difficulty is to avoid a "rush" of gas.

In regard to the ether light, one main point in my opinion—and here I differ very seriously and strongly from Mr. Broughton's printed directions—is to turn on the hydrogen tap from the tank first, so as to vent all pressure from the ether vapour.

I do not think anyone can use the ether light safely who has not clearly before his mind his two special dangers, and their reasons, and their method of prevention. They are (1) the risk of want of saturation; and (2) that of "back pressure." I do not think a few brief directions, and the statement that all is safe if these are followed, give that impression to an operator, and I would urge more detailed instructions very strongly. Mr. Diggle, at Chadderton, evidently had not the faintest real conception of the very serious danger when he found ether in the supply tube—I believe it was in the bag as well. He thought that when he had "poured it out," and the jet lit, all was right. The fact was, as I believe, that at first the oxygen far outweighed the vapour as regards oxygen-supply (and it was the bag which exploded). But by degrees the oxygen in the bag got exhausted, while the ether in the bag (I can't understand the bag catching fire unless ether was in it) still evaporated at the same rate, until at last it was bound to reach the exact explosive point.

All this attaches great importance to the new pumice safety-chambers. If they stand exhaustive testing, they will be a great boon and comfort to many. Hemming's packing has failed, and so has Gurney's water safety-chamber, and gauze is a sheer delusion; while anything that pretends to be "safe," and is not, is obviously more harm than good, since reliance is placed upon it which there is nothing to justify, and other care which might prevent accident is neglected. But a *bona fide* safety arrangement is another thing; and I hope Mr. Broughton's pumice-chambers may ere long receive sanction which cannot be displaced.

* Abstract of a paper read before the Edinburgh Photographic Society.

PHOTOGRAPHY CONSIDERED AS THE WORK OF RADIATION.

BY CAPTAIN ABNEY, R.E., F.R.S.

The sixth and last lecture of this series was delivered on Saturday last, April 5th.

Drawing the attention of his audience to the green bromide film on which he had photographed the infra red rays at the last lecture, the Lecturer said he could show them how he could bring this back to the orange state simply by rubbing. This was done, and showu in the lantern, and photographs of the action of the spectrum on the different films were shown to illustrate the different states in which bromide of silver could be obtained in a film. Photographs of the infra red end of the spectrum, taken by the prismatic spectroscope and by the Rutherford grating, were then shown.

The carbon points of the electric arc were then projected into the camera, with a piece of red glass intervening. A wet plate that had been exposed to the light was then placed in the camera, and a photograph reversed of the carbon points was obtained, showing that red rays could produce reversal. An exposed wet plate was then placed in the spectroscopic camera, and a reversed photograph of the red end was obtained. This phenomenon, said the Lecturer, was a very old one, but the explanation of it was by no means so ancient; it had been found that it was due to oxidation of the reduced salt under the influence of radiation, for if no oxygen or similar element were present, no such thing took place.

The Lecturer now said he must touch upon an important and interesting part of his subject, the vexed question of photography in natural colours. He could not enter into all the investigations that had been carried out with this end in view, but he would describe and illustrate the most important of them. From a little book he had with him ("The Chemical Effect of the Spectrum") he would read a short extract, detailing the experiments of Dr. Seebeck in 1810, who, by exposing a darkened chloride plate to the spectrum, got an imperfect reproduction of its colours. With the purer spectrum that had since been obtained, it was possible to get better results than Dr. Seebeck had got, and he would ask for the daylight to be let into the theatre whilst he passed a few specimens round.

On gelatino-chloride plates or paper they would see fair results, but the best were on Daguerreotype plates and the ferrotype plate he passed round. Reference to the work of Becquerel, Niepce, and others was then made, these workers having made considerable improvements in the method. Unfortunately, the results could not be rendered permanent, and would not stand a very long exposure to daylight. He (the Lecturer) had tried to get photographs of the spectrum in its natural colours without letting oxygen have access to the plate, and the result of his researches showed that oxidation played an important part. The explanation of the colour, he believed, was, that the particles were of different sizes, just as they got silver bromide of different colours according to the size of the particles. If he was asked whether he considered photography in natural colours to be possible, he said that in science he knew, and they knew, of no such word as impossible; and if scientific men would only work at it as they had worked at other problems, he saw no reason why photography in natural colours should not come to pass within (say) the next ten years or so.

Turning to another subject, the Lecturer went into the question of adding dyes to films containing salts of silver, demonstrating by experiment the effect of eosine and cyanine blue upon the plate. The sensitizing effect of one silver salt upon another was then shown. The Lecturer concluded with some experiments with rotating discs, in which an effect, which would generally be put down as an optical illusion, was shown by photography to be be perfectly genuine.

The very hearty applause at the close testified to the success of this series of lectures, and many were heard to express regret that they had come to an end. Throughout the series Capt. Abney was ably assisted by Mr. C. Ray Woods and Sergeant Jackson, R.E., the former looking to the working of the apparatus, and the latter to the photographic manipulations.

Notes.

Our Paris contemporary, *la Nature*, is rather behindhand in its news. Last week it gave an account of Ericsson's sun steam-engine, of which an illustrated description appeared in these column three months ago.

We are glad to hear that Mr. Cecil V. Shadbolt is going on with his successful photo-balloon work. He makes his first ascent this year next Monday, taking a voyage in the "Sunbeam," which is arranged to start from Birmingham on Bank Holiday. Says Mr. Shadbolt: "We are now building a beautiful little balloon—which, we hope, will carry three passengers—alternate gores of red and yellow; this, in consequence of the prospect of a large number of ascents during the present year. The No. 2 balloon is to be ready early this summer."

Anderson's charming story about the Emperor's new clothes will be fresh in the recollection of many; how two rognes received payment for pretending to weave the Emperor a suit of raiment so fine that nobody could see it, and how the fraud was only discovered when a little boy cried out that the Emperor had nothing on. Science seems now to have the power to which the rogues in question only pretended, for Mr. H. F. Read, of Brooklyn, has succeeded in drawing platinum wire so fine as to be invisible to the naked eye. The idea of producing a wire so delicate was to employ it for the cross threads in a telescope, for which its perfect opaqueness rendered it particularly applicable; but it seems that the wire is actually too fine for the purpose. Curiously enough, Mr. Read's wire can be detected by touch, albeit it is invisible under ordinary circumstances.

Photographers have now little difficulty in obtaining good samples of gelatine, but as they often employ it, not only for making emulsion, but for mounting, &c., it is as well to know an easy and simple way of testing samples for colouring matter, and impurities that are found in the commoner samples of gelatine and glue. Weigh a small piece of the material carefully, and suspend it for twenty-four hours in cold water. As the glue or gelatine swells, the colouring matter subsides; weigh again in its moist state, and the greater the increase in weight—the greater its power to absorb water, that is—the better is the material. When dry, you may weigh again, and the difference in weight between the dried samples tells you, of course, how much impurity there is. This test is taken from the *Tischler Zeitung*.

The value of good glue for mounting is just now all the more important since they say our supply of gum-arabic is getting cut off. As most of our gum-arabic comes from the Soudan, the import has of late almost ceased, thanks to the war, and the stock in the hands of London brokers is rapidly decreasing. Sweetmeats take up much of the gum imported, jujubes and gum drops containing something like thirty per cent., while some purpose or other is found for it in almost every kind of manufacture. About a million pounds annually of the product comes from the Soudan, so that naturally some anxiety exists about the supply.

While Mr. Darker was exhibiting his lantern polariscope at the last meeting of the South London Society, he used a small spirit lamp to yield the light required for his manipulations. It appeared to us that the alcohol flame was tinted with the sodium yellow, perhaps by soaking the wick in a solution of common salt and drying. At any rate, the light afforded was a convenient one, and, while strong enough for the purpose, it did not in any way interfere with the brightness of the image on the screen.

The new edition of Magnin's exhaustive treatise on Bacteriology, recently published at New York by Dr. Sternberg, affords striking illustrations of the solid work which photography may perform. The heliotype plates of the bacteria found in the yellow fever blood, and in the lesions of various diseases, are striking proofs of Dr. Sternberg's skill and patience. Few persons can appreciate the enormous difficulties of this class of work.

The lantern display at the Photographic Society on Tuesday night was certainly a good thing, only there was too much of it. There were good lantern slides, and there were bad lantern slides, and unfortunately the latter were accompanied by the most talkee-talkee; so that just when the slides ought to have moved briskly, they halted altogether, and mediocrity was accompanied by verbose explanations. The best things undoubtedly were Professor Donkin's Alpine pictures, which only monopolised five minutes from first to last.

By the way, why should it be deemed a virtue to take architectural views with a drop-shutter? One of these days we shall have held up for our admiration an instantaneous view of a milesone taken with some patent lightening snap-drop, and shall be asked to bear witness as to its absolute sharpness. Can it be that there are enthusiasts who imagine that quick exposures were invented for the pourtrayal of monuments and cathedrals, and that drop-shutters are particularly useful for taking church steeples and ancient ruins?

Who invented Baker Street as a photographic resort? It is an interesting question that is not readily answered, and as time goes on, the reply will be still more difficult. But we suppose Messrs. Southwell Brothers had more to do with the matter than any one else, a firm which, in the "palmy days," it may be remembered, kept three studios going all day long. From seventy to one hundred pounds daily were the average takings of the big Baker Street firm in those days, when cartes-de-visite were newborn, and when three guineas a dozen were sometimes asked for them.

Spurious photographic lenses, with the brass work neatly made, and sometimes engraved with the names of reputable makers, have been extensively sold in several auction-

rooms in London during the past few months. The glasses appear to be any convex lenses which come to hand, and the instruments are evidently made with a deliberate intention to defraud.

All photographers are interested in putting down a traffic of this kind, and although an auctioneer is not ordinarily responsible for the goods he sells, we imagine that if cautioned as to the fraudulent nature of goods from a certain source, he might get into serious trouble if he persisted in selling similar articles. Those who meet with spurious lenses at sales should mention the matter to the auctioneer, and let us have particulars.

To have one's photograph exposed for sale in shop windows is now-a-days evidently regarded as an important step towards obtaining a position within that charmed circle—society. Mr. Laurence Oliphant, one of the shrewdest and most brilliant writers of the day, in his clever novel "Altiora Peto," makes a wealthy and vulgar financier describe how he and his wife managed to secure recognition by the "first circles." In the course of his narrative, the financier says: "Then we began to give little dinner parties, and Dashington asked our Duchess here to invite us to her parties; we worked the press and the photographers." And, so he adds afterwards, "What with notices in the paper, and photographs in the shops, and financial plums for the poor aristocrats, and pretty women for the rich ones, we got to where we could give entertainments on a large scale, and ask some social lions." It is but fair to mention that the wife of the financier is very good looking, an important factor where photography is concerned.

A propos of pictures of "leaders of society," the camera, which has often been accused of want of flattery, never perpetrated anything so vulgar and untruthful as a series of coloured portraits of aristocratic ladies now being published monthly by a society journal.

Photography may now be said to attend us to the grave. Early on Saturday morning, just before the funeral service commenced, the coffin containing the remains of the late Duke of Albany was photographed as it rested on the bier under the crimson pall.

The evidence given at the adjourned inquest on the Chadderton explosion somewhat negatives Mr. W. Broughton's theory—given in the "Notes" of the 28th ult.—that the explosive compound was not formed in the bag on the evening of the exhibition, but some time previously. Mr. Diggle, the photographer who manipulated the lantern, went, it appears, to the Hall about half-past five o'clock in the afternoon to prepare for the exhibiton. Having all ready with the exception of the weights, he left the room to go for them, giving instructions not to allow anyone to enter in his absence; on his return, he found two persons on the top of the staircase. He then found some one had been tampering with the apparatus, as the burners would not light, and on examining the oxygen tube found liquid ether in it to the extent of two ounces or so. This was emptied, and the lantern worked all right for an hour, and exploded without the least warning. Beyond this, very little was stated which threw any light on the immediate cause of the accident.

It is odd to find photographs produced as evidence of a person's insanity. In a case last week before Mr. Justice Denman, one of the Lord Chancellor's visitors in lunacy, in speaking as to the alleged unsoundness of mind, said the person in question produced some photographs, among them a photograph of Mr. Bradlaugh, and pointing to it, said;—"Is not that a beautiful face?" If this is considered a proof of insanity we shall have to be very careful in showing photographs. It is no uncommon thing, for instance, for mothers to produce some abominably ugly portrait of a child and go in raptures over it, pointing out beauties which nobody but themselves can see. Besides, beauty is a matter of opinion. There may be people who, without being mad, may consider Mr. Bradlaugh beautiful. Besides, is there not a process of beautifying known as retouching? The witness thought the person who called upon him to admire Mr. Bradlaugh's photograph was a little "touched," but might it not be that it was Mr. Bradlaugh (we mean his photograph, of course) that was "touched?"

Oliver Wendell Holmes, whose name is familiar to readers of these "Notes," as to every other reader who delights in the "well of English undefiled," dwells with touching emphasis upon the value of a photograph. In one of his Autocrat series—the best books ever written, as we heard an enthusiastic admirer call them the other day—he thus describes an old man's impression of a mother who has died young: "Mother she remains till manhood, and by-and-bye she grows to be a sister; at last, when wrinkled and bowed and broken, he looks back upon her in her fair youth, he sees in the sweet image he caresses, not his parent, but, as it were, his child."

The gentle American poet here speaks, of course, only of the "image" in the old man's brain as in the days before photography. "If they had only taken pictures then, as they do now," is the old man's plaint. "All gone! all gone! nothing but her face as she leaned on the arms of her great chair; I would give a hundred pounds for the poorest little picture of her, such as you can buy for a shilling of anybody that you don't want to see."

To cement brass or other metal upon glass, M. Puscher employs a resin mixture made up of 1 part caustic soda, 3 parts resin, and 5 parts water, rubbed up with half its weight of plaster of Paris. Zinc white or white lead may be used instead of plaster of Paris if a slower-drying cement is wanted. Herr Wiederhold prefers to use a fusible alloy for cementing brass work to glass, made up of 4 parts lead, 2 parts tin, and 2½ parts bismuth, which melts at the temperature of boiling water; he presses the glass into the molten metal, and allows the same to cool in a warm place.

Patents Granted in America

295,608. CHARLES F. ADAMS, Worcester, Mass. — "Solar camera." Filed November 16, 1883. (No model).

Claim.—1. In a solar camera, the combination, with a reflecting-mirror and the adjusting-gear of the camera, of an adjustable hinge for attaching said mirror to said adjusting-gear, substantially as shown and described.

2. A bent hook-piece, having projections on its top part in combination with, and attached to, one side of a reflecting-mirror, in connection with cube-piece and screw, to raise or lower said mirror, substantially as shown and described.

3. In a solar camera, the combination, with an adjusting-gear and a screw for tipping the mirror, of the cube piece, attached to hook-piece on the reflecting-mirror, substantially as shown and described.

4. In a solar camera, the combination, with an adjusting-gear, of an elongated nut pivoted thereto, and the adjusting mirror-screw, substantially as shown, and for the purposes stated.

5. The combination, with the frame part, having a slot for the mirror-tipping screw, of the adjusting-gear, having a flange, substantially as shown, and for the purposes stated.

6. The combination with the frame part of camera-box, provided with shadow grooves and ridges, and having a diaphragm or plate therein, substantially as shown and described.

7. The combination with the camera-box of a wedge-shaped piece used to make the lines of the picture perpendicular on the screen, and adjustable shelf, substantially as shown, and for the purposes stated.

8. The combination with the reflecting-mirror, adjusting gear, tipping mirror-screw, and frame part, of the box part, and parts attached thereto, hinged or pivoted to said frame part, and reflecting-mirror, all to be used for a vertical camera, substantially as shown and described.

9. The combination with the frame part and the reflecting-mirror, hinged to the adjusting-gear and tipping mirror-screw of the camera-box, and parts attached thereto, all so constructed and arranged that the instrument may be used either as a right-hand or a left-hand camera, substantially as shown and described.

295,638. AUGUST HERZOG, Guttenberg, N.J.—"Photographic camera." Filed Nov. 2, 1883. (No model.)

Claim.—1. The combination of a supporting base-frame having forward-extending guide-rods, a rear frame hinged to the base-frame, means for adjusting the rear frame to the proper inclination on the base-frame, an extensible camera, a lens-carrying frame, and means whereby the lens-carrying frame can be adjusted on the guide-rods, substantially as set forth.

2. In a photographic camera, the combination of a supporting base-frame, a rear frame having means for supporting the ground glass and plate-holder, said rear frame being hinged to the base-frame, a camera in front of the rear frame, a plunger pivoted to the rear frame, a fixed cylindrical socket of the base-frame for guiding the plunger, and a clamping-screw for fastening the plunger to the socket, substantially as specified.

3. In a photographic camera, the combination of a supporting base-frame, a rear frame having means for supporting the ground glass and plate-holder, horizontal guide-rods made of two hinged sections, the shorter of which is applied to the base-frame, an extensible camera having lens-carrying frame, and means whereby the lens-carrying frame is secured to the guide-rods, substantially as and for the purpose set forth.

4. In a photographic camera, the combination of a supporting base-frame, a rear frame having means for supporting the plate-holder and ground glass, horizontal guide-sections made of two hinged sections, the shorter of which is applied to the base-frame, an extensible camera having a movable lens-carrying frame, means for guiding the latter on the guide-rods, and means for retaining the longer rod-section in upright position on the lens-carrying frame, substantially as set forth.

295,688. JUAN DE M. TERREFORTE, New York, N.Y., Assignor to himself and Antonio M. Nolina, same place.—"Art of printing and mounting photographic pictures." Filed June 27, 1883. (No specimens).

Claim.—The method herein described of taking and mounting photographic pictures, which consists in preparing upon glass or other suitable surface a film of dry collodion, then spreading upon the collodion film a sensitive coating of gelatinous or albuminous emulsion containing nitrate of silver, then drying the same, then printing and developing the picture in the ordinary manner upon said sensitized coating, then attaching paper to the picture by applying paper that is faced or coated with plain moist gelatine or albumen to the picture upon the glass, then allowing the paper to dry under pressure in contact with the picture, and then stripping the paper, and with it the picture, from the glass, all substantially as herein described.

MISCELLANEOUS LABORATORY NOTES.

BY J. VINCENT ELSDEN, B.SC. (LONDON), F.C.S.

IN photography, as in most other branches of practical science, a single experiment often suggests so many others, and leads the investigator into so many bye-paths, that, to follow out completely all his divergent ideas would be an almost endless task. The following have been selected from a crowded note-book as being, even if incomplete, of possible interest to photographers.

Hypo test-papers.—I had often wondered whether some method could not be devised for making test-papers for detecting small traces of hypo, but had by some means got the idea that the blue colour produced by iodine and starch was not permanent, having seen it so stated in chemical text-books. Having, however, prepared a solution of starch and soaked a filter paper in it, I immersed the paper in a moderately-strong solution of iodine in alcohol. The paper, when dry, was now of a dark purple colour, and, being cut into strips, was exposed to bright light for a period of more than two months. The colour remained unchanged, and when wetted became bright blue. These papers I found to answer most perfectly as a ready and delicate test for hypo; for by placing a portion of a strip in contact with an imperfectly washed gelatine negative, the bleaching action of the hypo was readily perceptible, owing to the contrast when compared with the unaltered portion of the test-paper. Possibly photographers may be induced to try this plan, and keep a few hypo test-papers always at hand, in order that no gelatine negative may be varnished until the last traces of the fixing solution are removed. I have not tried how long these papers will keep their colour, but simply state the results of this single experiment.

Experiment on green fog.—The following memorandum of an incomplete experiment on green fog may be of interest, especially as it bears upon some recent theories respecting the cause of this undesirable appearance. An *unexposed* plate, immersed for some time (a few minutes) in sulphite developer, gave abundant green fog, having under the microscope the granular appearance of reduced silver. Nitric acid caused its immediate disappearance, but hydrochloric acid changed it into *red* fog. This looks as if the green fog, in this case, were finely divided metallic silver, which, when changed into chloride by the hydrochloric acid, gave the appearance of red fog.

On fixing plates containing iodide.—One great objection to the use of iodide in emulsions is the length of time which the plates take in fixing. It is well known that the solubility of iodine is largely increased by the presence of a soluble iodide, potassium iodide solution being a common

solvent for this element. Experiments were therefore made to ascertain the influence of soluble haloid salts on the rapidity of solution of silver salts by hyposulphite. Rough preliminary experiments only have so far been attempted, but the results obtained show that they are worth repeating upon a more elaborate scale. Thus, sodium chloride appeared to increase the solubility of silver chloride in sodium hyposulphite. Potassium bromide and iodide appeared to have a similar, although perhaps not quite so marked an influence upon the solubility of silver bromide and iodide respectively. When opportunity permits I shall try the influence of these salts in the fixing bath; for prolonged fixing is not only trying to the patience, but it is a most fertile source of blisters and frilling.

New organic iron developers.—Ferrous succinate has a marked reducing action upon silver bromide, and acts as a feeble developer. The solution was made by adding potassium succinate to a solution of ferrous lactate in water, and dissolving the precipitate of ferrous succinate in ammonium tartrate. Perhaps a stronger solution would produce still more marked results.

The ferrous lactate is easily soluble in warm water; but the solution appears to have no developing action, even when made alkaline after adding tartaric acid to prevent precipitation of the iron. If to the aqueous solution of ferrous lactate even a small quantity of neutral potassium oxalate is added, the solution at once becomes a powerful developer, probably owing to the formation of ferrous oxalate by double decomposition. I am hoping to be able to compare this "lactate developer" with the ordinary oxalate process. One great advantage is its extremely easy preparation.

Action of potassium ferrocyanide on haloid silver salts.—The following observations are the results of experiments made some time ago, in company with Mr. E. H. Hills, and although circumstances have prevented their completion, some interesting facts have been established. When silver bromide or chloride is boiled with excess of potassium ferrocyanide solution, the precipitate of silver bromide becomes green in colour, and so finely divided as to run through the filter. The chloride is much more easily acted upon than the bromide, and the iodide is only decomposed partially by very prolonged boiling.

The same experiment was next performed in the cold. Silver chloride was placed in a weak solution of potassium ferro-cyanide, and in a few days the solution no longer gave any reaction with ferric chloride. After four days, however, neither the bromide nor iodide experienced any alteration in the cold solution.

In all cases where alteration had occurred, silver was found in solution, and basic iron was precipitated by prolonged boiling, showing the probable presence of silver ferro-cyanide dissolved in potassium cyanide. This view was strengthened by subsequent experiments with silver ferro-cyanide, which, on boiling with water in an open dish, invariably deposited ferric hydrate, silver cyanide remaining in solution.

Examination of the greenish precipitate, which replaced the haloid silver salt after decomposition by the ferro-cyanide of potassium, showed the probable presence of a ferro-cyanide of iron, which passed easily by oxidation into Prussian blue. Thus the addition of an acid immediately gave Prussian blue, as also did simple exposure for some time beneath water. These results prove—

1. That haloid silver salts are completely decomposed by potassium ferrocyanide, silver chloride easily, and in the cold, silver bromide and iodide with more difficulty, or on boiling. The products of the reaction appear to be silver ferro-cyanide, potassium cyanide, and a ferro-cyanide of iron.

2. Silver ferro-cyanide is decomposed by simple boiling with water, basic ferric hydrate being deposited, and silver cyanide being formed and held in solution probably by a cyanide of iron.

In Abney's "Photography with Emulsions," page 13, the following reaction is given:—

$$4Ag_2Br+2K_6Fe_2Cy_{12}=3K_4FeCy_6+Ag_4FeCy_6+4AgBr$$

also the following:—

$$Ag_4FeCy_6+4KBr=K_4FeCy_6+4AgBr$$

It is difficult to see how this latter equation especially can hold good, seeing that the substances produced on the right hand side of the equation would immediately react upon one another in the manner indicated above; for in one experiment, silver bromide was left in contact with a weak solution of potassium ferro-cyanide for some days, after which not a trace of ferre-cyanide was found in the solution, although the precipitate yielded an abundance of Prussian blue when well washed and treated with ferric chloride This points to the following reaction having taken place—

$$4AgBr+K_4FeCy_6=Ag_4FeCy_6+4KBr$$

which is in direct opposition to the equations given above.

I give these equations for the sake of illustrating the interest of these reactions in photography, and not by way of criticism; for the whole subject of the action of ferro-cyanides upon haloid silver salts is so complicated that I have not had time, up to the present, to make more than a few preliminary investigations.

DRY PLATES IN THE TROPICS—DO THEY KEEP?

BY HERBERT MANNERS.

Much has been written during the past year regarding the keeping qualities of dry plates, both before and after exposure. Complaints have been frequent of loss of sensitiveness, frilling, fogs (green, red, grey), and other minor evils. In fact, like the old nitrate bath, it seems the rule to put all failures down to the plates. Having carefully tested the plates of five different makers, besides those I generally depended on, I found that those of the good makers, if carefully kept in an air-tight tin box, would retain their good qualities for a year at least, provided they were carefully packed in the first instance; but it is the packing that the makers of many good but cheap plates fail in. The plates of several makers are packed face to face, separated only at the opposite sides by small pieces of thick bent paper, so allowing a free space between each plate. These all keep perfectly, the only difference after a year's keeping being a mark on the margin of plates where the paper presses; but this is of no consequence.

Some plates worked beautifully when first got, but will not keep; not, I think, from any defect in the plates themselves, but from the way they are packed. Those in grooved boxes are not good, as they take up nearly double the space of the others, and if roughly handled or subjected to any pressure, the sides and covers of the card boxes crack and admit light. It seems that the plates packed in very close contact sweat, and decomposition of the film sets in from the edges, spreading rapidly when the film is not protected by the tissue paper. I am confident that a little more care taken in the packing of many of these cheaper makes of plates would enable them to be got out and used with certainty; but until this is done I shall stick to the best makers in spite of the great difference in cost. Though an indigo planter, I work photography throughout my district (Tirhoot) professionally, but only charge my friends the actual cost to enable me to defray the expenses of working my hobby, which I need hardly say is an expensive amusement. Could I depend on the cheaper plates I should most certainly use them, for there is a considerable difference between 17s. and 26s. 6d., especially in these days, when the rupee means only 1s. 7d. instead of 2s. But as my work generally consists in my having to send my camera on before on a coolie's head, and riding twenty or thirty miles to take a group or bungalow, it does not do to have any doubt

regarding the plates, as I always develop on my return home, where I have everything handy. Many of even the best plates frill in the hot weather, the heat in the dark-room being intense, and of course a punkah is out of the question. This might be greatly obviated by the plates having the edges ground before coating, so that the film might take a firmer bite at the edges. Why do not the best and dearest makers do this? Ground edges were always advised for the old wet collodion. Why not with dry plates also? It would often save a good negative.

While on this subject, I must draw attention to the great variation in the prices of the plates charged by the makers themselves, and of the same plates got through one of the numerous dealers. It is a puzzle to myself and many others when looking over the advertisements in the weekly journals. For instance, take certain instantaneous 12 by 10, quoted by the makers at 26s. 6d., and the same maker's plates by the dealers at 22s. 6d., being a difference of 3s. 6d. in the dozen. This should not be; but it is obviously unfair that those who, like myself, prefer to import their plates direct from the makers, should be charged more for them than if obtained from a dealer in photographic stores. Again, it would be a great boon to us dwellers in exile in these distant lands if all advertisements gave prices and discount; so many articles are advertised without the prices being noted.

Correspondence.

THE METRICAL SYSTEM.

Sir,—Granting that there is much truth in what you say in last week's "By-the-Bye" as to the advisability of adopting the metrical system, I should like to ask why we should adopt the metre instead of the yard, when, as you say, it is acknowledged that the data assumed by the French are incorrect? It is well known that if by any chance our standard yard should be lost, it could be replaced by the determination of the length of a pendulum beating seconds at a certain level. This seems to be a more scientific method than the other. The late Sir John Herschel wrote on this subject, and the arguments in his "Popular Lectures" appear to be absolutely convincing. A decimal system has advantages, but why should it not be based on our yard measure, the length of which can always be accurately known, instead of that adopted by the French, and which may almost be called arbitrary?—Yours truly,

A. Brothers.

BROMINE AND IODINE AS DESTROYERS OF THE LATENT IMAGE.

Dear Sir,—In your article on "Gelatine as a Bromine Absorbent," you mention some interesting experiments on the effect of bromine in destroying the latent image. You say: "The effect of the free iodine appears, however, to be very similar to that of free bromine;" but in some experiments I made, using iodine instead of bromine, although I succeeded perfectly in destroying the latent image of an exposed gelatine plate, I found, on exposing the film in the camera and developing, a very weak *positive* was produced. This reversal of the image was due, no doubt, to the presence of a trace of the free iodine, which is well known to act as a powerful oxidiser. In making further experiments, I should be inclined to give the gelatine film an after-wash in a very dilute ammonia bath, which would no doubt eliminate every trace of the haloid.—Yours truly,

Arnold Spiller.

HISTORICAL ACCURACY.

Sir,—Allow me to correct a little error that occurs in your last report of the London and Provincial Photographic Association, whereby I am made to attribute Dr. Monckhoven's carbonate of silver process to Captain Abney. It was the method introduced by the latter of emulsifying washed bromide of silver that had been precipitated in the presence of a small quantity of gelatine that I said had in my hands given a fair quality of emulsion, provided that it was not attempted to get a quick one.

Whilst on the subject of historical accuracy, I would ask Dr. Eder what are the grounds upon which he divides the credit for the collodion process between Archer and Fry? Some zealous friend did, indeed, in the early days of photography, advance large claims for Mr. P. W. Fry, but these were afterwards, if I remember rightly, narrowed down to diligent practice, and to the introduction of the use of gutta-percha in collodion, by which he stated that in addition to toughness he obtained greatly exalted sensitiveness. In other hands, however, this result did not ensue.—I am, yours obediently,

W. E. Debenham.

Proceedings of Societies.

The Photographic Society of Great Britain.

The ordinary meeting of this Society was held on Tuesday, the 8th inst., at the Gallery, 5a, Pall Mall East, James Glaisher, Esq., in the chair.

The minutes of the previous meeting having received confirmation,

Mr. Robert Tandall was admitted a member.

The Chairman then stated that the exhibition of slides, which he hoped would prove technically instructive as well as interesting, would commence. He pointed out and traced the gradual progress as regards not only the production of the negative, but also of the slide, and expressed a hope that the lantern would increase in popularity as a means of exhibiting photographs.

Mr. Sebastian Davis gave an interesting *resumé* of the principal features of the methods ordinarily employed for making photographic lantern slides, with all of which he had experimented. The enormous advantage of the gelatino-bromide process as a means of securing representations of moving objects was referred to; indeed, one may consider that the means of producing the negative are as perfect as may be wished, and it is time for the experimenter to set to work with the view of finding the best methods of producing the transparencies. The collodion process certainly has the advantage of yielding clear whites, and of being thoroughly under control.

The first series, by Mr. Frank Howard, consisted principally of architectural and sylvan subjects, the positives being made by the wet collodion process. The view from Hillsborough Hill at Ilfracombe was remarkable for brilliancy, accompanied with the most perfect gradation of tone in the lighter shades. Lynmouth, including Lynton and the bridge at Lynmouth, form delightful studies; such, indeed, as may make a painter look on the camera with a feeling tinged by envy.

Perhaps the most interesting series was that exhibited by Mr. Raphael Meldola, the pictures having been taken on the eclipse expedition of 1875. The first view showed the members of the expedition on board the P. and O. steamer *Baroda*, including Dr. Vogel, Mr. H. Reynolds, Mr. Beazley, Dr. Schuster, Mr. F. Lott, and Mr. Meldola. The scene then shifted to Camorta, one of the Nicobars, where a small hill had been cleared for the work of the expedition. The unpacking of the apparatus was shown, and also the erected and adjusted instruments, including those brought from Calcutta by the party under Captain (now Major) Waterhouse, and likewise the contingent from Italy under the direction of Professor Tacchini, of Rome. Numerous interesting views illustrative of the island and its inhabitants were also shown, the main peculiarity of the villages being the circumstance that the houses are built on poles, so as to allow the tidal waters to flow underneath them. It is curious to note that the aborigines of the Nicobars, although not having any anthropological affinities to the cultured tribes of India, have certain artistic abilities, and some of the slides showed interesting examples of their wood carvings and painted mats. Various groups of the natives were shown.

Mr. Ray Woods showed several slides illustrating uranium, iron, and copper toning, these being either identical with, or

similar to, those previously exhibited by him in the same room (vol. xxvi., page 261).

Mr. England showed a selection, comprisiug tannin, coffee, collodio-albumen, and wet collodion, the wet collodion slides being, on the whole, the most effective. He also showed a series on gelatino-chloride plates, produced from wet collodion negatives.

The Sciopticon Company (reprcsented by Mr. George Smith) sent some magnificent examples of enlargements from microscopic objects, these having been priuted on glass by the Woodburytype process.

The alpine views of Professor Donkin, some on gelatino-chloride and others on gelatino-bromide plates, were much admired, and they appeared to be free from the veil or fog which often mars gelatine slides.

Mr. Moncrieff's gelatino-bromide slides were excellent as regards colour and gradation of tone; the subject beiug views of well-known localities in North Wales.

Mr. Wellington exhibited slides on gelatino-bromide plates, as exemplifying his method of varying the tone by modifying the exposure and development (see page 142).

Mr. Fincham's wet collodion slides for gelatine negatives were much admired, especially a picture of a water-fall taken near Dolgelly with so short an exposure as to almost depict the spray of the dashing water.

Dr. Huggins sent a few of his well-known stellar spectra, and a very striking photograph showing the total of the sun for 1871.

Mr. Edwards showed albumen plates toned with gold, and also some fine pictures illustrative of life in New Zealand.

The Chairman considered that collodion had held its own very satisfactorily, and he did not anticipate that the newer processes would entirely replace it for a very long time.

The next meeting of the Society will be held on the 22nd inst., and at the following meeting (May 13) a paper will be read by Mr. John Spiller on "The Fading of Prints," and Mr. W. E. Debenham will make a communication on the subject of "Dark Room Illumination."

South London Photographic Society.

The ordinary meeting of this Society was held on Thursday, the 3rd inst., at the House of the Society of Arts, John Street, Adelphi, W.C., the Rev. F. F. Statham, M.A., president, in the chair.

The minutes of the previous meeting having received confirmation,

Mr. A. G. F. Ferrol (Malta) was admitted a member of the Society.

The Chairman, in presenting the Secretary and Treasurer, Mr. F. A. Bridge, the Society's medal, said it was a duty which gave him much pleasure to perform. Its chief value to the recipient was the knowledge that it had been adjudged for the merit of his "View on the River;" but the medal would have a double value to Mr. Bridge from the knowledge that it was given by friends, as well as being adjudged by an artist of the highest standing in the artistic world.

Mr. F. A. Bridge thanked the Chairman for his kind expressions, and mentioned that Mr. Ferrol had become a member in order to compete for the Society's awards. He further stated that at the next meeting a paper on "Composition" would be forthcoming from Mr. Norman Macbeth, of the Edinburgh Royal Academy, and he trusted there would be a full meeting.

The Chairman remarked that such a paper from an artist of high standing must prove of great service to photographers. In photographing views of common objects, such as shipping on the river, they would scarcely expect to get beautiful results in composition—Mr. Bridge had done so. In the Art Journal he noticed a picture of a very commonplace subject (Cannon Street Hotel), which is a thoroughly artistic picture. With proper treatment the most common objects may be artistically treated. The Chairman then called upon Messrs. C. and T. Darker to exhibit some objects in the lantern polariscope.

Mr. C. Darker said they did not propose reading a paper, nor would they presume to teach photographers who knew as much concerning light as they themselves did; but in case any present were not versed in the subject, they would mention the principles involved in polarizing a ray of light. Commencing with the Newtonian theory, the reflecting and transmitting of ordinary light was explained, and how a beam of light falling on a bundle of glass plates at an angle of 57½° would be polarized; the undulations of light at one plane was also mentioned. Using a lantern polariscope and a disc eight feet in diameter, Messrs. Darker projected a large number of objects on the screen. Commencing with tourmaline for stopping light in one direction, a Nicol's prism was shown to act in a similar manner when rotated; their combined use gave the means of analysing light. Passing polarized light through doubly refractive bodies was illustrated, and an example of salycene was shown; it being explained that in splitting up the rays, one set of undulations are retarded more than the other, this being exemplified by a green colour and its complementary, blue, resulting. Another example, Iceland spar, was shown, in which the two colours overlapping each other produced white light. The use of selenite plates was next dealt with, and the difficulty experienced in grinding mentioned. The effect produced by a selenite plate in front of designs of insects, floral, and a cameleon was shown; the numerous changes of colour being very much admired, and in each case the colour was afterwards neutralized. Several different forms of crystallization were next shown, including the formation of crystals of benzoic acid; cross crystallization of quartz (a defect troublesome to opticians) being also shown. Compression and expansion of unannealed glass was next dealt with, and its probable effect on photographic lenses called attention to. Pressure exerted by a screw disturbing the molecular arrangement and causing colour to appear which disappeared on withdrawing pressure; heat was also shown to produce a similar effect. Annealed glass was also treated, some very exquisite designs in colour appearing, the forms of which depended on the external shape of the glass, the points showing an absence of colour through their ability to resist pressure. Convergent light was next dealt with, the uni-axial system in which one cross and set of rings appear, and the bi-axial system, having two centres, was shown; borax and sections of quartz representing the bi-axial and circular systems was introduced, right and left-handed crystallization being explained, including some very fine examples lent for the occasion by Mr. Lewis Wright, who also sent three very beautiful mica designs. From a photographic point of view, the examples of crystallization photographed by ordinary light, also by polarized light by Mr. G. Smith, junr., were most interesting, Mr. Darker dwelling on the multitude of advantages obtained in the case of mineralogical subjects if they were always photographed both ways and thrown on the screen side by side.

The Chairman said it was not necessary to make very extensive remarks in thanking Messrs C. and F. Darker for the interesting and exceedingly beautiful exhibition they had witnessed, and which he knew entailed expensive and elaborate instruments to give them such a treat as they had on that occasion. He did not think photographers were obliged to understand the science of polarized light in order to carry out their undertakings; but there is a desirability for them to give a little attention now and then to its teachings. Practically photographers are under a great obligation to polarized light, and as one of its possible adaptations he would suggest the desirability of testing samples of chemicals by its means. Mr. Darker showed the effect of pressure on glass, which he considered had a most important bearing on photographic lenses. When lenses are fitted too tightly in their cells, and there is an increase in the temperature, it would most likely produce distortion; although under these circumstances no difference may be seen on holding the lens to the light, yet it could be detected by the disarrangement of particles if examined in the polariscope. Annealing was also very important. If a sample of glass imperfectly annealed should by chance be passed, a lens with defects from this cause might find its way on the market. With these few remarks to show the practical bearing of the subject on photographic work he (the Chairman) expressed his thanks most heartily to Messrs. Darker, which was accompanied with the usual vote of thanks from the meeting.

The following from the "Question-Box" was read:—"Does the burnishing of prints produce any chemical change in them?"

Mr. Harrison was not prepared to say any chemical change took place, but he recollected a suggestion to iron prints with a hot flat-iron many years ago. He believed the suggestion emanated from Messrs. Claudet and Houghton.

Mr. E. W. Foxlee said one of the oldest books he possessed on photography recommended ironing prints.

There being no further remarks, the Chairman said he should be glad if the members would make use of their privilege—that is, each bring a friend—so that a good meeting will be assured when Mr. Macbeth reads his paper, which he considered a favour

of a high order. If any member had a subject to bring on after the discussion on Mr. Macbeth's paper, he should like notice of it.

Mr. ASHMAN would be able to show prints from negatives on Morgan and Kidd's bromide paper; at the same time, it was not desirable to have several subjects when an important paper is announced. The discussion on the chemical change in burnished prints had suffered through coming directly after such an interesting subject as Messrs. Darker's.

Mr. F. YORK suggested that a set of Mr. A. Pringle's artistic pictures be thrown on the screen, and a discussion on their artistic merit take place. They would thus get the criticism of an art critic on photographs of the highest class.

The CHAIRMAN thought that had better be a subject for another meeting, as it would not be fair to get the criticism of Mr. Macbeth without first of all mentioning the matter to him.

Mr. YORK showed a camera fitted with a revolving flange or plate for quickly altering the position from the vertical to the horizontal. A description will be found on page 63 of the present volume.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

A MEETING of this Society was held on Thursday, the 3rd inst., Mr. W. COLES in the chair.

Mr. J. B. B. WELLINGTON showed a transparency taken by contact on a plate by the cold emulsification process, and gave the formula as follows :—

A.	Nitrate of silver	50 grains
	Citric acid	50 „
	Water...	4 ounces

Ammonia sufficient to re-dissolve the precipitate of citrate of silver.

B.	Potassium bromide	45 grains
	„ iodide	1 grain
	Carbonate of ammonia	30 grains
	Gelatine	10 „
	Water	4 ounces

Add A to B and mix cold; this gives a ruby emulsion which is to stand for twelve hours; at the end of that period warm up, when it will be of blue colour. Then add—

Gelatine	200 grains

When washed, make up to 10 ounces of emulsion. In reply to a question, Mr. Wellington said "the quantity of silver to each half plate would be about 1 grain."

Mr. COWAN had made a batch of boiled emulsion, adding 5 drops of ammonia to each ounce, and at the time found no difference; but after keeping it for a few days, the plates were insensitive in places. He also called attention to the frequent assertion that a blue emulsion was the most rapid. He had come across two commercial plates by the same maker, the colour of one being blue, the other being orange; they were almost of the same rapidity, the advantage, if anything, being in favour of the orange. The density was also nearly identical.

Mr. WELLINGTON showed two enlargments (12 by 10) from lantern transparencies. They were made in the lantern on plates containing about five grains of silver, with a Ross R.S. lens 7½ inches focus, No. 16 stop (universal system), exposure two minutes.

Mr. HENDERSON, referring to a safe light for the dark room, said he had made some experiments by passing the light through glass painted with phosphorescent paint. He found he got a safe light by using three such glasses, and after two or three hours the outside glass was not luminous.

Mr. DEBENHAM: Is the safety due to phosphorescence, or to colour mixed with the paint?

Mr. HENDERSON thought to both, but more especially to the tablet absorbing much of the violet rays; he promised to show the lamp at an early meeting, and also to read a pamphlet on light written by Lord Rayleigh.

Mr. Debenham's lecturette on lenses will be delivered on the 17th inst.

DUNDEE AND EAST OF SCOTLAND PHOTOGRAPHIC ASSOCIATION.

THE Annual Meeting of this Society was held in Lamb's Hotel on Thursday, 3rd inst., at which there was a good attendance, Mr. W. D. VALENTINE presiding.

Mr. VALENTINE read a letter from Mr. J. C. Cox, expressing his regret at not being able to be present, and thanking the members for their kindness in re-electing him to the Presidentship.

The CHAIRMAN said the Society was fortunate in possessing in their President a gentleman who was an enthusiastic photographer, an acknowledged artist, and of good social position. Mr. Cox had spared neither time nor money in promoting the welfare of the Association ever since its establishment; his latest gift to the Society being a fully-equipped developing room, which is already being largely taken advantage of.

The following new members were admitted :—Messrs. W. W. Moncrieff, D. R. Mitchell, John Jones, D. R. Malcolm.

The election of office-bearers was then proceeded with, and the following is the list for 1884-85 :—

President—Mr. J. C. Cox.

Vice-Presidents—Messrs. W. D. Valentine and D. Ireland.

Council—Messrs. G. D. Macdongald, J. Geddes, H. G. Fraser, A. C. Lamb, Alfred Guthrie, and G. F. Roger.

Hon. Treasurer—Mr. John Robertson.

Hon. Secretary—Mr. D. Ireland, Jun.

Auditors—Messrs. John Moss and John R. Wilson.

A special vote of thanks was passed to the Hon. Secretary and Hon. Treasurer for the efficient manner in which they had fulfilled their duties in the past session.

Mr. G. D. MACDOUGALD then read an able paper on "Development," and gave the particulars of a new developer which yielded negatives of a peculiar rich non-actinic colour, another advantage being that all the ingredients were dry, they only requiring the addition of water to form the developer.

Some discussion took place as to whether the negative was better to be of a blue or of a non-actinic colour. The opinion of the meeting was that the latter was preferable.

Dr. TULLOCH said that a gelatine negative rarely printed quite satisfactorily without after-treatment; and that he was in the habit of applying mercury bichloride, followed by ammonia, to nearly all his negatives. This treatment seemed to bring up the detail in the shadows, while the high-lights, being already opaque, were not affected by it.

The CHAIRMAN was greatly averse to the use of mercury, as he found that negatives thus treated faded in the course of a year or two. On his motion, a vote of thanks was awarded to Mr. Macdougald.

Mr. VALENTINE also showed a negative in which the sunlight on the pillars and wall of the interior of a cathedral was perfectly clear glass, the reversal being caused by over-exposure.

A vote of thanks to the Chairman closed the proceedings.

Results of competition for February portrait taken in a room :—J. Sturrock, 200 marks; Dr. Tulloch, 150. For March competition, "Still Life," there was only one entry, Mr. D. Ireland, Junr., 200 marks.

NORTH STAFFORDSHIRE PHOTOGRAPHIC ASSOCIATION.

THE ordinary monthly meeting was held on Wednesday evening, April 2nd, at the Mechanics' Institute, Hanley, Mr. R. S. BURGESS occupying the chair.

Mr. W. F. Fishburn was elected a member of the Society.

The HON. SECRETARY exhibited a half-plate tourist apparatus by Mr. C. E. Elliot, of London. The elegant appearance and finish of the camera were much admired, the excellence of the dark slides being also remarked upon.

A paper upon and demonstration of the process of "Photo-micrography" (see page 229) having been given by Mr. Allison,

A vote of thanks was unanimously passed to that gentleman, and after some interesting conversation upon the subject of photo-micrography, and Mr. Allison had passed round some transparencies upon collodio-bromide, the meeting terminated.

MANCHESTER PHOTOGRAPHIC SOCIETY.

THE usual monthly meeting was held at the Manchester Technical Schools, on March 13th, the President, Mr. JOHN POLLITT, in the chair.

The minutes of the previous meeting were read and confirmed, and the ballot was taken, and the following gentlemen were admitted as members :—Messrs. W. Jenkinson, J. F. Lees, Levi Lambert, H. Pope, and Charles Coote.

Mr. JOS. GREATOREX read an interesting and somewhat amusing paper entitled "A Summer's Holiday," consisting of notes of a recent tour in Switzerland.

Mr. S. D. MCKELLEN gave a practical demonstration of the 'Printing on argentic bromide paper as manufactured by Messrs.

Goodall and Stevens," and also made an enlargement on the same paper, about 12 × 10, from a 3 × 4 negative. The method of enlarging adopted by Mr. McKellen was to illuminate the negative by the aid of a Scioptieon lantern, and he stated that he had found a sheet of ground glass interposed between the negative and condenser a great improvement.

The Hon. Secretary said if the condenser was large enough to cover the negative, the ground glass was unnecessary.

Several prints and enlargements were exhibited by the demonstrator, and admired for their pure whites and general brilliancy.

Votes of thanks were passed to Messrs. Greatorex and McKellen.

The Chairman then referred to the interesting paper read at the last meeting by Mr. Richton, and said, but for the lateness of the hour, he should have invited a discussion on swing-backs and swing-fronts, as he knew there were several members who had studied the subject, and desired to communicate their views. He would, therefore, have great pleasure in bringing the matter forward at the next meeting.

The Hon. Secretary said he should give them a communication, and probably a demonstration in making enlargements from small negatives, at an early date.

An interesting and enjoyable evening terminated at a late hour.

Talk in the Studio.

The Twenty-fifth Anniversary of the South London Photographic Society.—On Saturday, May 10th, a dinner will take place at the Holborn Restaurant, to celebrate the prosperous existence of the South London Society during a quarter of a century, and the Rev. F. F. Statham, who has presided over the Association during the whole of the period, is to be the honored guest of the evening. The first meeting of the Society took place on May 10th, 1859, and a report will be found on page 117 of the Photographic News for the year in question. Any persons who may wish to be present at the dinner, or who may desire to otherwise assist in the commemoration, should communicate with the Hon. Secretary, Mr. F. A. Bridge, 9, Norfolk Road, Dalston Lane, London, E.

Behaviour of Silver Chloride, Bromide, and Iodide with Bromine and Iodine.—By P. Julius (*Chem. News*, 48, 284).—By passing dry air saturated with bromine over silver iodide kept in a state of fusion, the iodide is easily and completely converted into bromide after ten minutes. In the same manner silver chloride can be converted into bromide in one or two hours. Further experiments prove that both chlorine and bromine may be expelled from their silver compounds by means of iodine vapour, although six to ten hours are required to effect this change with the chloride. Hence any halogen, if supplied in excess, can expel any other halogen from its combination with silver; at least, as far as chlorine, bromine, and iodine are concerned.—*Journal of the Chemical Society.*

Absolute Total Actinometer.—M. G. A. Hahn.—The author's apparatus consists substantially of a retort exposed to the sun, and connected with a condenser and receiver placed in the shade, but in the open air. Carbon disulphide is poured into the retort, and a vacuum is made in the apparatus so that it may contain merely the vapour given off by the liquid. As long as the sky is overcast, the liquid remains in the retort without distillation or condensation. As soon as the sun shines, the carbon disulphide begins to boil, and the liquid collected in a receiver in an unit of time is proportional to the quantity of solar heat received in the same time.—*Chemical News.* ["Total Actinometer" is not used quite in the sense in which a photographer would understand it. The instrument in question measures, after a fashion, the total radiation; not merely the chemical rays.]

The Lantern Exhibition of the Field Club.—This was held at the room of the Society of Arts, on Tuesday evening, and the honours of the occasion were carried off by Mr. Joseph Gale. Exhibits by Mr. Trueman Wood, Mr. Whiting, and others, were much admired.

Re-sittings.—For the sake of peace and quietness we will admit that the photographer is a much-abused individual, and that it *is* hard—dreadfully hard—to have to re-sit a person when the negative is chemically perfect, and is fit for a specimen. But, see here, brother photographer, what are you working for, anyhow? Money! We thought as much. Now, it seems to us that although it is very disheartening to have to give a patron a re-sitting when the first negative is good chemically, that it is killing the goose that lays the golden eggs to ride the high-horse and refuse to comply. Suppose you are getting out a circular to advertise your business, don't you want a proof to see if it meets your views? And supposing it doesn't, do you take it? Not by a jugfull. You are going to have that circular to your mind, or—go somewhere else. And in the matter of one's own face—great Cæsar! the victim is bound to have a voice in the matter. Vanity, dear sirs, vanity sticks closer to the bones than beauty. Of course you can refuse to give a re-sitting; that is the noble prerogative of every photographer. But the satisfaction is short-lived when the sitter goes elsewhere, and tells everybody that he threw your pictures into the fire. Change of dress should mean additional charge, but if the expression is not right, and the pencil cannot make it right, then—sit them again. Everything, humanly speaking, rests with the one who shows the sitter the proof. A good reception-room hand is worth her weight in gold—a bad one is ruination. A sitter, male or female, old or young, rich or poor, is tractable enough if properly handled. But there must be no hesitation—no doubt about what can or what cannot done in the way of improvement. It would, however, be well for photographer to bear this in mind, that pictures that pay are made to please the sitter, not to fill the showcase, and [illegible]etter to gain one true friend than to make a hundred good-fo[illegible]ning enemies. —*Walzl's Monthly.*

Antidote to Iodine.—A case of poisoning by iodine has come forward in Germany, and forms the subject of an article in the *Apotheker Zeitung*. The outcome of the whole affair is that this really dangerous case was combated by the administration of hyposulphite of soda. This salt, which is largely used by photographers, and has recently been resorted to in medicine as a valuable febrifuge, is not poisonous, and can be administered in solution in water, in which it is readily soluble. In cases of poisoning by iodine, when the stomach is in a state of irritation, it appears to bring on vomiting, which carries off a good deal of the poison. The journal quoted says that when this has occurred the ordinary antidote of iodine—namely, starch paste—may be administered; but it strikes us that the hyposulphite solution is a more active antidote than starch paste, as it would finally transform the free iodine into iodide of sodium, which is comparatively harmless, whilst the compound of starch and iodine appears to be only a mechanical mixture, or at least not a definite chemical combination.—*Burgoyne's Magazine.*

Photographic Club.—At the next meeting, on April 16th, the subject for discussion will be "On packing and re-packing dry plates when on a tour." On April 14th (Bank Holiday) an out-door meeting has been decided upon. Members and friends desirous of joining may ascertain particulars by application to the Hon. Secretary.

To Correspondents.

*** We cannot undertake to return rejected communications.

S. Nicholls.—It is not possible to conceive a more thorough method of washing the prints than that which you propose. We should advise that a cage made of cane or basket work would be better than a wooden box. It should be turned round on its vertical axis a few times during the period.

Edgar.—(*a*) It was made by pressing thick blotting-paper against a metal block which had been grained by means of a planing-machine. (*b*) We do not know, and we hardly think he would tell you if you asked him.

G. C. R.—The potash appears to have acted unequally on the fabric, and we would advise a longer boiling in a weaker solution.

Neophyte.—The "A B C of Photography," by Burton. It is published at our office.

Phaide.—For white, use the so-called permanent white, and alizarine lake for red. Raw or burnt sienna may also be depended on. Crimson lake and carmine are among the most fugitive of pigments.

S. C. Riley.—You are quite right; a film is not wanted. The method usually adopted in London is to make a photo-lithographic transfer, and to put it down on the block by pressure; but when the fatty transfer is once made, it is generally more convenient to put down on zinc and to etch into relief, unless the alterations required are very extensive. The same remark applies to transfers in grain or stipple. A method which gives a thin and perfect half-tone picture without any film is most suitable.

H. W. O.—During the life of the author and seven years afterwards.

HANDTYPE.—The best method is the ordinary phototype or zinc-etching method. See a series of articles on Chemigraphic Engraving which appeared in the PHOTOGRAPHIC NEWS during 1882. The first of the series is on page 673.

W.—It is probable that the mischief arises rather in connection with the camera than with the plate. Examine carefully for any projection which can shade the lower part of the plate, any crevice which may allow extraneous light to enter, or any smooth surface which is likely to reflect light.

ARCHER.—It will hardly prove a serviceable instrument in comparison with the objectives manufactured now-a-days, but many persons would value it as a curiosity. The space between the lenses must be filled with water.

J. E. H.—We will see what particulars we can gather by next week.

E. GRANT.—1. Considering that dissatisfaction was only expressed on account of the dresses, you should insist on full payment for all the pictures. 2. A fair charge for each cabinet negative would be one-half of your usual charge for a cabinet negative and six prints.

A KNOTTY POINT.—1. If copies have been sold, it is too late to secure the copyright. When a picture is made to the order of a customer, the copyright belongs to the customer. 2. It is sufficient to secure the copyright of the original photograph, as this will cover all reproductions by wood-engraving or other methods. 3. Our Publishers attend to the formalities of registration for a fee of 1s. 6d. for each picture.

H. CRUTCHLEY.—1. You certainly would act very indiscreetly if you were to use an ordinary commercial adhesive of unknown composition for mounting your pictures. 2. It appears to us as if the friction edge of the burnisher were rough, or as if some circumstance had caused the iron to bite into the face of the print. Re-face the burnisher on a good oilstone, and use a little encaustic paste (see Formulary)

SPOTS.—Cases have occurred in which mounts have contained soluble ferric salts, as, for example, the perchloride of iron, or the persulphate. Either of them will act on the silver image, and destroy it; the rapidity of the action depending on the proportion of the injurious salt present. When soluble salts of iron are present, they appear to have been used in compounding the colouring material used for tinting the mounts; and perfectly white cardboard may be relied upon as free from all deleterious salts of iron.

NITRATE.—It is not sufficiently soluble for the purpose, but by acidifying the solution with acetic acid, you will perhaps overcome the difficulty. If, however, you will explain the nature of your experiments in greater detail, we may be able to give you more definite advice.

GEORGE PRINCE.—We cannot tell you; and if, as you say, you have the complete set of volumes, it is as easy for you to make the search as for us to make it. 2. They have little or no market value.

Price 6d., by post 6½d.

A TRIP TO THE GREAT SAHARA WITH A CAMERA. BY A COCKNEY. Being an Account of a Month's Winter Holiday, with Diary of Journey and Statement of Expenses.—PIPER & CARTER, PHOTOGRAPHIC NEWS Office, 5, Castle Street, Holborn, E.C.

The Photographic News Registry.

Employment Wanted.

Youth, to learn photography.—D. L., Pliny Villa, Godwin-rd., Forest-Gate.
Operator & Retoucher, 30s.—A. B., 21, Bethel-st., Norwich.
Operator & Retoucher (Italian).—Dal-Mistro, 64, Frith-st, Soho.
As Improver in first-class house.—W. T., P. O., Stretford, Manchester.
Gen. Assist. (21). Lond.—G. P., 6, Kensington-pk.-rd., Notting-hill-gate.
Assist. Op. & Printer in Lond.—L. W. Green, Dennett's-rd., Peckham.
Photographer of exp., free April 28.—W. F. Anderson, 5, Tarvit-st., Edinb.
Recep.-Room (Lady), gen. useful.—A. M., 28, Atlantic-rd., Brixton.
Printer & Toner, Frenchman.—A. B., 6, St. Margaret's-st, Leicester-sq.
Retoucher & Assist. in Recep.-Room.—Miss J., 10, Edith-rd., Peckham.
Operator & Retoucher, well up in mono.—Photo. Artist. 54, Warren-st., W.
Recep.-Room, finish. mount, books, &c.—A. B., 1, Prior-st., Greenwich.
Op. & Ret., understands Fch., Ital., English.—A. B., *Photo. News* Office.
Recep.-Room, &c, at 18/- for permanency.—E. H. H., *Photo. News* Office.
Retoucher, can tint.—Miss Cross, Hill-st., Peckham.
Operator, can retouch, enlarge, print, manage.—X., 115, High-st, N.W.
Printer or Gen. Assist.—J. A. Randall, The Bazaar, Broadstairs, Kent.
Retoucher, Artist, &c.—W. Rubens, 28, Pond pl, S. Kensington.

Employment Offered.

Youth, to develop & be useful in studio.—S. S., 55, Moorgate-st.
Assist. Operator for landscape.—Norman and Co, Tunbridge Wells
Operator, to retouch.—T. Moss, 199, Derby-st., Bolton, Lancs.
Oper., clever with children & retouching.—Clayton, 6, Lond.-rd., Leicester.
Retoucher, to operate in principal's absence.—Reed, 16, Tottenham-ct.-rd.
Printer, Toner, Mounter, Burnisher.—Shrubsole, Davey-pl., Norwich.
Operator, good, at once.—C. K., 96, Bath-st., Glasgow.
Printer, first-class, immediately.—Hills & Saunders, Aldershot.
Recep.-Room Lady for Brighton.—C. H., Clermont, Preston-pk., Brighton.
Operator, who can retouch, for month.—Norman May, Malvern.

THE EVERY-DAY FORMULARY.

THE GELATINO-BROMIDE PROCESS.

Emulsion.—A—Nit. silver 100 grains, dist. water 2 oz. B—Bromide potassium 85 grains, Nelson's No. 1 gelatine 20 grains, dist. water 1½ oz., a one per cent. mixture of hydrochloric acid and water 50 minims. C—Iodide potassium 8 grains, dist. water ½ oz. D—Hard gelatine 120 grains, water several oz. When the gelatine is thoroughly soaked, let all possible water be poured off D. A and B are now heated to about 120° Fahr., after which B is gradually added to A with constant agitation; C is then added. Heat in water bath for half an hour, and stir in D. After washing add ¾ oz. alcohol.

Pyro. Developer.—No. 1—Strong liq. ammonia 1½ oz., bromide potassium 240 grains, water 80 oz. No. 2—Pyro. 30 grains, water 10 oz. In case of an ordinary exposure mix equal vol.

Iron Developer.—Potassium oxalate sol. (1 and 4) 80 parts, ferrous sulphate sol. (1 and 4) 20 parts, dist. water 20 parts. To each 4 oz. of the mixed developer add from 5 to 30 drops ten per cent. sol. potassium bromide, and 30 drops sol. sodium hyposulphite (1 and 200).

Substratum or Preliminary Preparation.—Soluble silicate of soda 1 part, white of egg 5 parts, water 60 parts. Beat to froth and filter.

Fixing.—Sat. sol. of sod. hypo. 1 pint, sat. sol. of alum 2 pints, mixed.

Cowell's Clearing Solution.—Alum 1 part, citric acid 2 parts, water 10 parts. Edwards makes this sherry coloured with perchloride iron.

Eder's Method of Intensification.—The negative is whitened by soaking in sat. sol. of mercuric chloride, and after thorough rinsing immersed in potass. cyan. 10 parts, potass. iod. 5 parts, mercuric chloride 5 parts, water 2,000 parts. As film becomes dark brown, the actinic opacity is increased; but prolonged action causes brown tint to become lighter, until at last the negative is no denser than at first.

Fol's Backing Sheets.—A chromographic paste is prepared with gelatine 1 part, water 2 parts, glycerine 1 part, and a very small addition of Indian ink. Strong paper or shirting is coated, and the sheets are laid, face downward, on waxed glass to set. Press to back of glass plate.

THE WET COLLODION PROCESS.

The Nitrate Bath.—Water 14 oz., nit. silver 1 oz., nitric acid 1 drop. Before using coat a small plate, and immerse it for 20 minutes.

Cleaning Preparation for New Plates.—Alcohol 4 oz., Jeweller's rouge ¼-oz., liquid ammonia ½-oz.

Film-removing Pickle for Old Plates.—Water 1 pint, sulphuric acid 4 fluid oz., bichromate potassium 4 oz.

Substratum.—Whites of 2 eggs well beaten, 6 pints of water, and 1 dr. liq. ammon.

Negative Collodion for Iron Development.—Alcohol 1 pint, pyroxyline of suitable quality 250 grains, shake well and add ether 2 pints, *Iodize this by mixing with* one-third of its volume of alcohol ½ pint, iod. ammon. 80 grains, iod. cadm. 80 grains, brom. ammon. 40 grains.

Normal Iron Developer.—Water 10 oz., proto-sulphate iron ½ oz., glacial acetic acid ½ oz., alcohol ¾ oz. The amount of proto-sulphate iron may be diminished to ¼ oz. when full contrasts are desired, or increased to 1 oz. when contrasts are unduly marked. With new bath quantity of alcohol may be reduced to ¼ oz.; but when bath is old more is wanted.

Intensifying Solution.—Water 6 oz., citric acid 75 grains, pyro. 30 grains. When used, add a few drops of the silver bath to each ounce.

Lead Intensification.—After neg. washing, immerse in dist. water 100 parts, red pruss. potash 6 parts, and nit. lead 4 parts. When it is yellowish white wash and immerse in liquid sulphide ammon. 1 part, water 4 parts.

Fixing Solution.—1. Potass. cyanide 200 grains, water 10 oz. 2. Sat. sol. of sod. hypo.

Varnish.—Shellac 2 oz., sandarac 2 oz., Canada balsam 1 dr., oil of lavender 1 oz., alcohol 16 oz.

PRINTING PROCESSES.

Albumen Mixture for Paper.—White of egg 18 oz., 500 grs. ammon. chlor. in 2 oz. of water. Beat to a froth, stand, and filter.

Sensitizing Solution.—Nit. silver 50 grs., water 1 oz., sod. carb. ½ gr.

Acetate Toning Bath.—Chl. gold 1 gr., acet. soda 20 grs., water 8 oz.

Lime do.—Chl. gold 1 gr., whiting 30 grs., boiling water 8 oz., sat. sol. chl. lime 1 drop. Filter cold.

Bicarbonate do.—Chl. gold 1 gr., bicarb. soda 3 grs., water 8 oz.

Fixing Bath.—Sodium hypo. 4 oz., water 1 pint, liq. ammon. 30 drops.

Reducer for Deep Prints.—Cyan. potass. 5 grs., liq. ammon. 5 drops, water 1 pint.

Encaustic Paste.—Best white wax 1 oz., oil of turpentine 5 oz.

Sensitizing Bath for Carbon Tissue.—Bichromate potash 1½ oz., water 30 oz., ammonia 1 dr., methylated spirit 4 oz.

Enamel Collodion.—Tough pyroxyline 120 grs., methylated alcohol 10 oz., ether 10 oz., castor oil 20 drops.

Mountant.—1. Fresh solution of best white gum. 2. Fresh starch.

Collotypic Substratum.—Soluble glass 3 parts, white of egg 7 parts, water 10 parts.

Collotypic Sensitive Coating.—Bichromate potash ½ oz., gelatine 2½ oz., water 22 oz.

Collotypic Etching Fluid.—Glycerine 150 parts, ammonia 50 parts, saltpetre 5 parts, water 25 parts.

Printing on Fabric.—Remove all dressing from fabric by boiling in water containing a little potash, dry, and albumenize with ammonium chloride 2 grammes, water 250 cubic cents., and the white of 2 eggs, all being well beaten together. A 70-grain silver bath is used, and the remaining operations are as for paper.

Cyanotype Printing.—Water 1 oz., red prussiate of potash (ferricyanide) 1 dr., ammonio citrate of iron 1 dr. Prepare and preserve in the dark. Float the paper and dry. Fixation by mere soaking in water.

VARIOUS.

Luckardt's Retouching Varnish.—Alcohol 300 parts, sandarac 50 parts, camphor 5 parts, castor oil 10 parts, Venice turpentine 5 parts.

Matt Varnish.—Sandarac 18 parts, mastic 4 parts, ether 200 parts, benzole 80 to 100 parts.

Encaustic Paste.—Best white wax, in shreds, 1 oz, turpentine 5 oz.; dissolve in gentle heat, and apply cold with piece of flannel.

FERROTYPES.

Collodion.—Ammonium iodide 35 grains, cadmium iodide 25 grains cadmium bromide 20 grains, pyroxyline 70 grains, alcohol 5 oz., ether 5 oz.

Bath. Silver nitrate 1 oz., water 10 oz., nitric acid 1 drop.

Developer.—Ferrous sulphate 1 oz., glac. acetic acid 1 oz., water 16 oz.

Fixing and Varnish.—Same as wet collodion process.

THE PHOTOGRAPHIC NEWS.

VOL. XXVIII. No. 1337.—*April* 18, 1884.

CONTENTS.

DROPS OF LIQUID.

PHOTOGRAPHERS so often employ liquids in the form of drops that some experiments recently made by M. Boymond, to get at the weight and volume of certain drops, must have an interest for them. We all of us know that drops vary very much in size, and we can guess, if we do not know, that drops of water and drops of alcohol are of different weight. Nevertheless, it is very usual among photographers to regard a minim as made up of a fixed number of drops, no matter how these drops are formed, or of what liquid they consist. Now M. Boymond tells us some very interesting points on the forming of drops, and has tabulated the weight of such liquids as are most in use in chemical and other manipulations.

In the first place, M. Boymond reminds us that the weight of a drop depends upon the *exterior* diameter of the tube from which the liquid falls, and not upon the *interior* dimensions, the latter having only an influence upon the rapidity with which the liquids flow.

Next, the nature of the liquid (water, alcohol, ether, chloroform, acetic acid) alone influences the weight of a drop, no matter what proportion of soluble matter it may contain.

Thirdly, to obtain drops of distilled water, going twenty to a gramme (temperature 15° C.) it is necessary to have a dropping-tube with an *exterior* diameter measuring exactly three millimetres.

Using this three-millimetre tube, M. Boymond has established the weight of drops of various liquids as under :—

One gramme of		
Distilled water	equal to	20 drops
Alcohol of 90°	,,	61 ,,
,, of 60°	,,	52 ,,
Alcoholic tincture with alcohol of 60°	,,	53 ,,
,, of 80°	,,	57 ,,
,, of 90°	,,	61 ,,
An ethereal tincture	,,	82 ,,
A fatty oil (variable) about		48 ,,
A volatile oil (variable) about		50 ,,
An aqueous solution, diluted or saturated		20 ,,
A wine (variable according to amount of alcohol)		33 to 35 ,,
Laudanum (variable) about		33 to 35 ,,

JUSTICE GROVE ON PATENTS.

MR. JUSTICE GROVE, who laboured among the pioneers of photography, and who, if not the first to produce a printing surface by the etching of a Daguerreotype plate, was at least among the first to effect this, has, in the case of Neilson *v.* Rosenthal, made some highly pertinent remarks upon the patent question ; and if those readers who contemplate taking out patents in relation to photography will study what Mr. Justice Grove has to say, we may hope that in the future our patent columns will record fewer claims for processes and methods which have long been in use and are well known, and fewer specifications intended to conceal and mislead. Mr. Justice Grove said :—

Originally the Crown granted monopolies, and could grant monopolies for almost anything it liked. The Crown granted monopolies on salt, sugar, or anything else, excluding other persons from that monopoly ; but in the reign of James II. a statute was passed, which remains law to this day, declaring that monopolies should be abolished ; or rather it declared that they were contrary to the laws of the realm, except Letters Patent granted to the true and first inventor of any manner of new manufacture (I am quoting from memory, and if I am not right counsel will correct me, for I do not happen to have the statute before me), which others could not have used ; that is to say, a person should be allowed to have a monopoly to preclude other persons from using for fourteen years (which was the term originally given, but it is not material how long at present, because this is within fourteen years), any manner of new manufacture, except the true and first inventor. Therefore, the invention must be new. It must not have been used before, and it must be an invention of a manufacture. An invention of an idea or mathematical principle alone, mathematical *formulæ*, or anything of that sort, could not be the subject of a patent. For instance, supposing a person discovered that three angles of a triangle are equal to two right angles, that is an abstract discovery, and would not be the subject of a patent. It must be a manufacture, and it must be a manufacture which must be new in this realm. Shortly afterwards, it was found necessary for the protection of the public that the Patentee should enrol a specification, and in that he was required to describe the nature of his invention, in order that the rest of the public might know what his invention really is, so that they may not unintentionally infringe it, and so that they may know what they are prohibited from using without his leave or licence. He must also describe the means of performing his invention, in order that when his patent expires, people may know how to make it. Letters Patent are, in fact, granted to a person, so to speak, upon the condition that he enrols a specification in which he states truly the nature of his invention and the means of performing it.

Otherwise a patentee might do this: first of all, he might say nothing about the nature of his invention, and he might simply describe the thing he makes, *e.g.*, "This stay is my patent," and than the public might say, "In this stay there is a good deal that is old as well as something that may be new ; the cloth is old, the whalebone is old, the direction of the whalebone or the direction of the cloth is old, and the gores are old," and therefore the public would not know, unless he specified it, what the patentee claimed to be his invention, and the public would not know whether they were infringing or not when they made other sets of stays. They might know that he did not claim the gores, for instance, but when they made a gore, they might be infringing his patent. Therefore, he is bound to state in what the nature of his

invention consists. Then he is also bound so to describe it in his specification as that any workman acquainted with the subject, being a practical workman, would know how to make it; and the reason of that is this, that if he did not do so, when the patent expired he might have some trade mystery which people would not be able actually to use in accordance with his invention (although they had a right to use it after his invention had expired), because they would not know how to make it. That would not apply to a thing of this sort, but to some things it might apply. Therefore he is bound to do these two things—namely, to tell the public what is the nature of his invention, and to tell them how the invention is to be made in practice. Take, for instance, a chemical invention. A man might make a chemical discovery, and he might claim a patent for it, and call it by his own name, "Thomas's this" or "Thomas's that"; and when the patent came to an end, the public might not know the least in the world how to make it, and he would still continue by that means to have a monopoly which he had no right to continue, and which was granted to him for 14 years only, unless it was prolonged, and then, when the 14 years were at an end, the public might not know how his chemical invention is made. It might be a particular sort of varnish. He might make the varnish and sell it for 14 years, and not tell the public how it was made, and then he might get not only 14 years, but twice or three times 14 years' monopoly by keeping secret his manufacture. Therefore, in the interest of the public, the law says the Patentee must fairly and properly describe the nature of his invention in what is now publicly called his claim, and also the means or mode by which it can be performed.

A patented invention must have some utility beyond that which, with regard to a particular thing, has been known before. If it has any utility beyond that, the patent is good; if it has not any such utility—that is, if it is not a bit better than anything that went before—then the patent is bad.

That brings me to another matter which is very important, and which you should have in your mind—namely, that it is not necessary to the infringement of a patent to infringe the whole of it. There may be some patents of which it would be difficult to infringe any part without infringing the whole of it. The claim may be that the entire thing is a novelty. It is difficult to suppose such patents in the present day, because, generally, patents are for only one or two particular improvements in detail. But it may theoretically be so, and in such a case a man infringes if he infringes a substantial or material part of a patent, provided the Patentee in his specification makes it manifest that that part is material. Then again, if that material part which he has infringed existed before the patent, the patent is bad, because the Patentee has claimed that as being his invention, and as having a right to preclude others from using that which others have a full right to use. His patent is bad if he has claimed that which he has no right to claim. In applying your minds to this case, you will apply the same rule to the question of infringement that you do to the question of novelty. I will explain what I mean by that. The Patentees use the word "substantially" in their claim thus: "in an oblique direction substantially as and for the purpose hereinbefore described." That word, to my mind, is an utterly and entirely useless word, because the law gives it him without using it. The law says, if a man, although not literally infringing the letter of the patent, yet substantially infringes it, it is an infringement. But then you must apply the same words to the novelty. You must not tie it down on one side, if I may use the expression, and enlarge it for the other. For instance, take this illustration. If the Patentee's patent is intended to be for seams straight in themselves, placed vertically with regard to the perpendicular of the body, a man who uses the straight seams will infringe the patent. But then, supposing a man uses a seam slightly curved. If that is substantially the same thing, then the man infringes the patent, although the seam he uses is not quite straight, but is nearly straight, because he would "substantially" infringe the patent. But then you must apply the same rules to the alleged anticipation. If the Patentees have a right to claim, as substantially their invention, slightly curved lines, then slightly curved lines made and used before this patent would be an anticipation of the invention. They cannot have it both ways. They cannot claim the benefit of the word "substantially" in support of their invention, and ignore the word "substantially" in respect of anticipations of their invention. You must administer the same measure, so to speak, to both. If the Patentees say, "Our invention is nominally a straight line" (we cannot have an absolutely straight line in practice), "and, therefore, if a man curves it a little he infringes our invention," then they are met with this answer: "If you claim to that extent, and say your invention is either for straight lines or for lines which have a small degree of curvature, and it is proved that small degree of curvature has been used before, then the small degree of curvature is as much an anticipation of the invention as a straight line." You must apply the same rule to both. A Patentee cannot claim for his patent the privilege of a different construction of the same word. If a man claims a curved line, and if it can be shown that that curved line has been used before, his invention is bad. He cannot have it both ways.

It would be interesting to consider what proportion of photographic patents would stand if measured by the rigorous, but strictly just, rules of Mr. Justice Grove; but it is to be regretted that in the trial of patent actions, it rarely happens that the judge is actually competent to deal with the complex technical points raised. But let us hope that the new patent law will inaugurate a period when some effort will be made to have patent cases tried before judges whose training and education have fitted them to deal with them.

STOKES ON LIGHT.

PROFESSOR G. G. STOKES publishes, through Messrs. Macmillan and Co., the first of three volumes on light. This first volume which is now announced treats of the *Nature of Light*, and from it are extracted the following, relative to the two theories of light, viz., the emission and undulatory theories.

"*Primâ facie* there is much to be said in favour of the theory of emission. It lends itself at once to the explanation of the rectilinear propagation of light, and the existence of rays and shadows. It falls in at once with the law of aberration. The laws of reflection and refraction admit of an easy explanation in accordance with it; at least if we accept the existence of both reflection and refraction; for according to this theory we should have expected beforehand that light would have been either reflected or refracted, according to circumstances, not that incident light should have been divided into a portion reflected and a portion refracted.

"The theory of undulations, on the other hand, presents at the outset considerable difficulties. In the first place it requires us to suppose that the interplanetary and interstellar spaces are not, strictly speaking, a vacuum, but a plenum; that though destitute of ponderable matter they are filled with a substance of some kind, constituting what we call a medium, or vehicle of transmission of the supposed undulations. When I speak of this medium as a substance, or as material, I mean that it must possess that distinctive property of matter, inertia; that is to say, a finite time must be required to generate in a finite portion of it a finite velocity."

* * * * * * * * *

"The necessity of assuming the existence of some kind of substance in what we commonly speak of as a vacuum does not appear to have been a serious preliminary difficulty in the way of the reception of the theory of undulations. A far more formidable difficulty appeared at first to be presented by the existence of rays and shadows. It was this that led Newton to adopt the theory of emission, though even he was led in the course of his researches on light to suppose that there was some sort of medium through which the particles of light moved, and in which they were capable in certain cases of exciting a sort of undulation. But the supposition of particles darted forth seemed to him necessary to account for shadows."

* * * * * * * * *

"There is no difference of explanation as regards light and as regards sound, save what depends on the difference of scale entailed by the difference of wave-length. Take as regards light the case of a small circular hole, say the tenth of an inch in diameter, and of distances from the luminous point to the screen in which the hole is pierced, and from that again to the screen on which the light is received, of say 8 feet 4 inches, or 100 inches, each. In this case, regarding the luminous patch on the screen as a whole, there would be no great diffusion of light, but the phenomena of diffraction would nevertheless be fairly pronounced. There ought to be a corresponding case of diffraction for sound; but on what scale? Take 50 inches as the length of a wave of

sound, which would correspond to a musical note of moderate pitch. Taking $\frac{1}{50000}$ part of an inch as the wave-length for light, the length of the wave of sound will be two-and-a-half million times as great as the wave-length of light. Consequently, to obtain the corresponding case of diffraction for sound, our 'small' circular hole would be obliged to have a diameter of rather more than four miles, say four miles, and the distance from the source of sound to the hole through which it passes, and from that, again, to the place where the sound is listened to, would have to be 4,000 miles each.

"It is remarkable that the existence of rays, which formed the great stumbling-block in the way of the early reception of the theory of undulations, is now shown to belong to a class of phenomena, those of diffraction, the complete and marvellously simple explanation of which afforded by the theory of undulations now forms one of the great strongholds of that theory."

The second of Dr. Stokes' volumes will deal with "Researches in which light has been used as a means of investigation," in which we may expect a reference to photography; and the third will treat of "Light considered in relation to its beneficial effects."

By-the-Bye.

PROVINCIAL EXHIBITIONS.

The past few years have abounded in exhibitions. In the north, in the west, and in the midlands, exhibitions have followed one another thick and fast, and photographers no longer grumble at the expense of framing pictures which are to be shown all round the country. Certainly, photographic societies which have the welfare of their members at heart, no less than the progress of photography itself, can do no better than foster these periodical gatherings, for the best demonstration, after all, of advancement in the art is afforded by a display of the pictures that are produced year after year. The members benefit, because they have placed before them, side by side with their own work, some of the best productions of their brethren from afar; while the progress of photography is served by the fact that the producers of good pictures are thus afforded more ample means of showing these to the public. As photography suffers much from lack of publishers to put before the world pictures of merit, these exhibitions of photographs all over the kingdom are, in the absence of such publishers, the best way to make new pictures known.

Photographers, therefore, have much to be grateful for to the societies of our big towns which foster undertakings of this sort. The pictures framed for the London Exhibitions—for the collections in provincial towns are for the most part made up of photographs from Pall Mall—are forwarded subsequently to various parts of the kingdom, and thus the exhibitor, no less than the local visitor, gains by the arrangement. Nay, there may possibly be some who would not go to the expense of mounting prints to be shown only in London, and take into consideration the fact that the frames can be sent elsewhere afterwards, before committing themselves to an outlay; so that the provincial exhibitions also aid that of London indirectly.

Again, there is this good to be derived from the gatherings of provincial Societies, when these give away medals; they serve to equalise and "trim" any doubtful awards, and to emphasise awards which may be thought to be doubtful. To take a recent example of the latter kind. Mr. West, of Gosport, secured a medal in Pall Mall for his frame of yachts. Were these really worth a medal, or had the London jury erred on the side of good-nature in making the award? This was the question that arose afterwards. But Newcastle-on-Tyne and Bristol at once disposed of the matter satisfactorily by definitely clinching the previous judgment.

In the case of pictures which are not honoured in London, but which earn distinction in the provinces, there is, as a rule, equal cause for satisfaction. Not only are judges only men, and, as such, liable to err, but they are sometimes men ill-fitted to be judges; men who act to the best of their ability, who are honest, straightforward, and just, and yet make woeful mistakes by reason of their lack of experience and acumen.

The judges of provincial exhibitions are not influenced by the verdict of the London judges, or, if they are, the influence is rather to reverse that verdict. We mean that a sort of induction arises, positive approval inducing negative approval, and negative, again, positive. There is not much harm in this, and perhaps in the end it leads to a more uniform distribution of awards. In any case, as we cannot expect perfection in the bestowal of honours, we thus get a sort of give-and-take arrangement, which, probably, is the best that can be effected.

In readjusting the balance of awards, then, and in exhibiting to their members and the public generally the best pictures produced in this country and abroad, our provincial societies do a vast amount of good; and we hope, now that we have duly acknowledged the obligation, we may be permitted to speak without offence on two points in connection with certain exhibitions out of London that have scarcely received due recognition. The first is in respect to refusing awards to old pictures. Of course no Society is likely to give medal after medal to the same picture every year, and it is an unwritten law, indeed, in exhibitions, that the same work cannot be exhibited twice. But it is to the interest of a Provincial Society to secure the best collection possible, and, with this end in view, invitations are sent out broadcast to photographers to forward pictures. Now, unless the age of contributions is distinctly mentioned, it is but natural in these circumstances for a photographer to send in the best things he has ever produced, provided always they have not been exhibited before in that locality. In fact, the Society and the photographer are generally at one in the matter so far, for the former is always desirous of including in its collection popular and attractive pictures that have been so well spoken of and so justly honoured in other parts of the country. As regards the exhibiting of the pictures, then, both parties are content, and it is only when the awards begin to be talked about that any difficulty arises. Shall Mr. Sunshine have a medal for his well-known picture, "Butter for Breakfast," or Mr. Shadow receive a prize for that "Breaking Morn" study he did years ago? Both productions are exceedingly meritorious, no doubt, but they are almost as old as the hills, and have been hawked round the country to every exhibition to get a medal for their owners. It is surely high time that something fresher and newer should receive the honours, argue the judges, and "Butter for Breakfast" and "Breaking Morn" are consequently left out in the cold.

"And a good job, too!" will be the general exclamation, in which we are sorely tempted to join. Only, is such a course fair? If Mr. Sunshine and Mr. Shadow have been tempted to send their work by a circular in which nothing is said of old pictures, and if their respective pictures are, despite the date of production, still the best things in the Exhibition, and new to that locality, these gentlemen are surely entitled to the honours. It will not do for hanging committee or judge to take upon themselves to say that age has excluded a picture when no proviso of this nature appears upon the programme. If the officers of a Society are willing to accept such pictures into their collection because the prints are attractive and the Society is ready to absorb the credit which such pictures bring to their collection, then there should be no hesitation about letting these works have medals, if it is their due. Old pictures, even if not previously exhibited, can easily be excluded from an exhibition, by putting a line in the programme to that effect, and it is unfortunate this is not done if old pictures are to be denied honours.

And this first point leads us to the second, which is

equally important, viz., the classification of pictures for medals. The judges nominated by a Society are supposed to act free and independently, and so, doubtless, they do, directly they begin their work. But it may happen that their action, free and independent as it is, runs up and down a groove already made for them. For instance, it may happen that a medal is to be given for landscapes, and the judges, therefore, begin by looking over the landscapes. To facilitate the work, the landscapes have all been hung together, so the judges have nought to do but confine their attention to a section of the pictures. But who has hung the landscapes together, and pronounced upon the all-important question, what is a landscape and what is not a landscape? The person or persons who have done this have a lot to answer for in making the award; for although a resolute member of the jury may look about him a bit, he is hardly likely to influence the judgment. There is a foreshore with a boat and the crisp waves beyond; why is not that among the landscapes? Because, is the answer given, it has been considered a sea-study, or to come under the heading of instantaneous work. But who is it who takes upon himself to say it shall only come under the heading of instantaneous work? It is true there is water in the picture, and it has been secured with a drop shutter, but it is none the less a landscape. Instances of this kind might be repeated indefinitely.

Some time ago we spoke about the absurdity of throwing every picture in which figures found a place, out of the category of landscapes, as if painters never put a figure into their works of this class. Unless it was a bald bit of country made up merely of hedgerows, grassy slopes, and trees, a photographer had no claim to the landscape class, and thus those who attempted to introduce a little "life," or to give "an eye" to their picture by means of animated nature, were relegated to the "genre" class, where the prizes were few and scant. The "Instantaneous" class leads to the same difficulty. Let us suppose a medal or series of medals to be given for this work; how is the word "instantaneous" to be defined, and are we to include only *tours de force*, or, so to speak, marvels of rapid exposure in the category? Such things as a man leaping a gate, or a horse running, are wonders in a way, if well done, but they are not more instantaneous pictures than some of the little landscapes that Gale and Brightman have shown us. Yet these last examples of still life would never be classed as "instantaneous," but would have to take their chance, side by side with big, broad, landscapes, whose effects eclipse them entirely.

It would, then, we submit, be better if in future our exhibitions were to admit no pictures but those qualified to take medals (if medals form part of the programme), and if only those appointed as judges should classify the pictures, supposing the awards are divided into classes. In regard to the latter point, however, we repeat what we said on a former occasion, that the less classification there is the better. An exceedingly good plan is, to place a certain number of medals in the hands of the judges, and to depend upon these gentlemen to make the best distribution they can of such awards.

FRENCH CORRESPONDENCE.

The Pavloffski Process—Mechanical Printing with Gum—New Photo-Engraving Process—M. Mauduit's Electric Shutter—Wide Angle Lenses on Rozmouski's Principle—Death of T. B. Dumas—Exposures and Photometric Tables.

The Pavloffski Process.—After reading the description of this process in the last number but one of the Photographic News, I was struck with the possibility of adapting it to ceramic decoration. Unfortunately, the process was not fully described, as many metallic oxides and other colouring matters are altered by bichromate of potash, resulting in combinations not sensitive to light, while the oxide is modified, as with oxide of iron, for instance. The same thing does not occur when the powder process is employed, as the powder is used dry with the sticky glaze, and no time allowed for a chemical action to produce any harmful reaction; and as the coloured powder is not applied until after the light has done its work, there can be no loss of sensitiveness.

Method of Mechanical Printing with Gum.—This led me to try a mechanical method of Woodburytype printing with ink made of gum-arabic dissolved in water, added to vitrifiable colouring matter, made sufficiently thick. In my first experiment, I made a 25 per cent. solution of gum-arabic, and let it evaporate in the water-bath until it was of a semi-syrupy consistency. The colouring powder ground on a muller with gum-water was next introduced in small quantities at a time, shaking it well to disperse the colour throughout. The liquid, filtered through muslin, and left for a moment, was poured on a Woodburytype mould previously greased. A piece of smooth paper, having been pressed against the mould for a minute, was backed by unsized paper soaked in rectified alcohol, and pressure was again applied for five or ten minutes. The alcohol coagulating the gummy ink, allowed the image to detach itself from the mould just as if gelatinous ink had been employed. All vitrifiable powders, provided they are not too heavy to be held in suspension in the gum, may be used in this way. The surface of the paper ought to be well sized and glossy, at the same time permeable to the alcohol. The bare principle of my process is here indicated, but details will be given after making a sufficient number of experiments.

New Photo-Engraving Process.—If I mistake not, the Talbot photo-engraving process consists in a copper plate coated with a film of bichromated gelatine exposed behind a negative, and bitten with perchloride of iron. It seems to me that an interesting modification may be made. A smooth plate of copper must first be covered with a five per cent. alcoholic solution of resin. After evaporation, the resin will be left on the surface in a finely powdered state, and is made to adhere to the copper by heating it. This done, a print is taken from a positive on carbon paper and stuck down to the copper, then developed with hot water in the ordinary way. A negative image remains adhering to the copper by the resinous film. When dry, the edges and back of the plate are protected with bituminous varnish, and it is bitten with an aqueous solution of perchloride of iron. The liquid biting through the gelatine passes also through the resin, which gives a fine and regular grain over the whole surface.

M. Mauduit's Electric Shutter.—M. Mauduit has changed the action of his instantaneous shutters by substituting for the compressed air cylinder another cylinder having iron pistons working by electricity. It is very simple, and allows of the exposure being regulated at a much greater distance from the camera. The generator is a pocket sulphate of mercury battery.

Wide-Angle Lenses on M. Rozmoustri's Principle.—Two employés of M. Rozmouski have set up together to make the wide-angle lenses they had previously constructed with this clever optician. The lenses are very small. The 9 by 12 and 8 centimetres focal length measures only 15 millimetres in external diameter, by 15 to 16 in length. The 13 by 18, with 12 c.c. focal length, is only 20 millimetres in diameter by 24 in length. They embrace an angle of 80°, and are excellent, in spite of their dimensions. It is to be hoped that MM. Jarres and St. Martin will be encouraged in their work.

Death of M. Dumas.—The sad news of the death of this illustrious chemist has reached me. Photography, in particular, owes a great deal to M. Dumas for the service he has rendered since its birth. He assisted Daguerre with his purse, in his researches leading to the discovery of fixing the image on silver plates. But since then he gave great help to

the art; no one among our *savans* interested himself so much in it as he. His death will be a great loss to science, and Dumas did not live to the age of eighty-four without accomplishing the most complete work that a man ambitious in the right sense could dream of realising.

New Edition of Calculations for Exposures and Photometric Tables.—The second edition of my "Calcul des Temps de Pose" has just come out at the publisher's, Gauthier-Villars. It is the forerunner of the "Manuel de Touriste Photographe," with which it will be indispensable.

Leon Vidal.

TRACING ON GLASS FOR THE LANTERN.

BY W. B. WOODBURY.

Some four or five years ago, possibly more, I gave, in one of the almanacs, a process for tracing designs on glass for the lantern, which, if it had only been followed up, would, I am sure, have been much in use at the present day, and such things as ground glass *a la* transparent slate, and other like systems would be put entirely in the shade. It was simply a varnish composed of dammar in benzole or chloroform, to which a few drops of india-rubber solution had been added. After an hour's drying, it was ready for use. With a fine lithographic pen dipped in indian ink the finest drawing can be executed. I have myself written my name in full, "Walter Bentley Woodbury," in the diameter of a four-penny piece; and by means of a small piece of damped card attached temporarily, have, by the aid of drawing instruments, made some fifty circles in the space of a couple of inches. The advantages are that the glass is perfectly transparent, and even under a high power the lines show no sign of raggedness.

I should be glad if some of your readers, interested in this work, would give it a trial and report on it—*pro bono publico.*

POITEVIN'S PHOTO-RELIEFS.

BY WILLIAM LANG, JUN.*

In my former communication to the Society, I made a passing reference to what the French chemist, Poitevin, had done in the way of forming relief pictures; but I was unable to bring before you any examples to illustrate his method of procedure. Since our last meeting I have made several experiments, following out, with some slight modifications, the lines laid down by Poitevin in his "Traité des Impressions Photographiques." A copy of this work is lying on the table. It is the second edition brought out last year by M. Leon Vidal, who is, as you are aware, a no mean authority in photographic matters. Each chapter is followed by an appendix, written by M. Vidal, which adds greatly to the value of the book, and enables the reader to form a more correct estimate of the truly original nature of Poitevin's researches.

It is not only interesting, but instructive, to go over the ground traversed by the pioneers of photography; and among the many processes that have become historical, Helioplastie, the name given to his process by Poitevin, or sun-modelling, as it may be rendered in English, is by no means one of the least suggestive. It is simplicity itself. There are not many processes where all the development required consists in immersing the plate in cold water. When we consider that it was about the year 1848, almost forty years ago, that Poitevin conducted his experiments, the wonder is that long ere this there has not been some practical application of the work he then did. For your inspection I have here an intaglio in moist gelatine produced from a negative, and its accompanying plaster cast. Here is an electrotype, got from one of these plaster productions, which will give an infinite number of prints with gelatine ink in a Woodbury press. I have drawn one or two just to illustrate the principle before coming to the meeting, and they can be examined, although somewhat rough in appearance; this is due, not to any imperfection in the process, but to my not having prepared the plaster cast in a sufficiently careful manner for the delicate operation of electrotyping.

* Read before the Glasgow and West of Scotland Amateur Photographic Association.

To show the difference in the nature of the reliefs obtained when employing a positive, and when a positive picture and a negative one, here is a gelatine relief picture which has been exposed behind a positive, and with it the plaster reproduction. It seems to me some of you professional men might revive with advantage to yourselves these sun-modelled pictures; they would be something new, I think, to the present generation. The face as seen in profile would undoubtedly be the best pose; further, having got your plaster-mould, casts could be taken in white wax. There is no end to the many modifications that one could work out in these matters. To show how perfectly the minutest detail is preserved in these plaster pictures, here is a small landscape subject. It occurred to me that it would be interesting to try the effect of producing a plaster relief from a photograph of some statue. I accordingly got a print which you see here; it represents the goddess Hebe. Having waxed it and put it into a frame in front of a prepared film, on developing, the mould presented the appearance it has here, and the plaster cast from it reproduces very fairly in bas-relief the original character of the statue. It wants, of course, the rounded character of the original figure, but perhaps, by shading the outer portions of the figure, a rounded character could be conferred to the mould, and subsequently, of course, to the plaster cast. I have not had, however, the necessary time to do anything in this direction.

I may mention that the films used in these experiments were prepared from Nelson's gelatine, one ounce to eight ounces of water, a certain amount of sugar and glycerine having been dissolved in the water. Poitevin seems to have worked with gelatine pure and simple, but you will readily understand that plates prepared thus dry badly. I dried the plates at a temperature of 90° F. or thereabouts—not exceeding it, however—in a drying-box after England's pattern. A concentrated solution of bichromate of potash was added to the warm gelatine just before coating, sufficient to give a slightly yellowish colour to the solution. Contrary to what might be expected, a very thick film is of no advantage. In coating, I first got a level place on the table, put the plate down, and surrounded it with strips of thick plate-glass, cuttings of shop window glass, arranged to form temporary slides; when set, the glass was withdrawn, and the plates removed to the drying-cupboard. Filled up to the level of these thick glass sides there is always a uniform quantity of gelatine left on the plate.

PHOTO-MICROGRAPHY.

BY WILLIAM GOODWIN.*

Those who use the microscope for the study of natural history are fully alive to the value of photography as a means of registering their observations; but the great majority are deterred from attempting its use by the idea that it is difficult as regards manipulation, and costly as regards apparatus. The various text-books of microscopy are greatly to blame for this, and certainly their descriptions of heliostats, electric lamps, and special microscopes are alarming. I hope, however, to show you that in these days of dry plates much may be done with very simple apparatus and little trouble.

There are microscopists whose interest lies rather in raising the microscope to the highest pitch of optical perfection than in its use for the purpose of study; and doubtless, with the enormous magnifying powers now at their command, manipulation does become difficult, and apparatus costly, when they call in the aid of photography to test the latest optical triumph. The other, and larger, class, who, in pursuit of knowledge, use the microscope only as a tool necessary for their work, would welcome photo-micrographs for their indisputable truth and manifest advantages over camera-lucida drawings. For such work as they require, you see here all that are necessary—a good, firm microscope, a quarter-plate camera, with dark slides (the lens, of course, is removed), and a source of light, which, in this instance, is a magic lantern, although a paraffin lamp will do as well. The condenser between the lantern and object is the "bull's-eye" provided with every microscope. The body of the microscope should be short, if possible. Mine, as you see, has a short body, with sliding tube for lengthening. As this tube contains a diaphragm which would lessen the field if used full-length, I keep it pushed in, and make up the length by means of this wider tube on the camera-front. A pasteboard tube, well blackened, would do for this purpose. It is advisable that there should not be a rigid connection betwixt the microscope and the camera, as putting

the dark slide in place might disturb the focus. The eye-piece as a rule, is removed, though very minute objects may require its use, but then the loss of light is enormous.

Microscopic lenses or "objectives" are, in all good microscopes, achromatic combinations, and may be divided into two classes, wide angle and ordiuary. The first have greater revolving power—that is, the power of showing minute details of structure which might escape the narrow angle objectives; but, on the other hand, these latter have more penetrating power or "depth of focus,' and when the object is of appreciable thickness will show, with comparative sharpness, parts lying in different planes. This is the more fortunate, since the ordinary lenses are much less costly than those of wide angle, and are the class generally supplied with so-called "college" or "medical" microscopes.

Here is the leus I find most useful; it is called a one-inch objective, and is so called because it has the magnifying power of a single lens of one inch focal length. To increase its penetration, I have reduced its aperture by a-half with a paper diaphragm, and have still plenty of light. Here is one of quarter-inch focus, much more powerful. Here is another, to which I would direct your special attention. It is now of 1½ inch power, but by turning this collar I can decrease its power by degrees to 4½ inches. This means that a comparatively large object may be viewed as a whole, and magnified a few diameters, and then the power being increased, it may be examined in detail. There is a scale on the revolving collar for registering the power employed. In photography this lens is remarkably useful, as the object can be enlarged just sufficiently to cover the focussing screen; it is, however, only available for comparatively large objects.

I should like to ask any of our members who are well up in optics, if there is any reason why we should not have a variable lens like this for landscape work? It would be peculiarly useful to us in the West of Scotland, where at one time we are doiug a "bit" in a glen with most of the picture within a few yards of the camera, and next minute have to deal with hills ten miles away. Under these circumstances a lens of variable focal length would be very desirable.

The greatest difficulty in photo-micrography is to judge exposure. It varies with every objective and with every object. The thickness, and particularly the colour, of the preparation must be considered. Parts of insects are, as a rule, of a reddish-brown tint, very non-actinic, and require long exposures; while botanical preparations are generally colourless, or green, and require much less time.

As a rule, with an object which is new to me, I give an exposure which I know must be full, and develop with hydrokinone, using a minimum of sodium carbonate to begin with. The image comes up very slowly, and is perfectly under control. When I know the right exposure, I give it, and use Edwards' developer, which seems to give a very fine grain to the negative. Too much density should be avoided, as it is often desirable to make lantern transparencies, or gelatino-bromide prints, from micro-negatives, and for such work a rather thin negative, with lots of detail, is best.

It is generally stated in works on microscopy that the chemical and visual foci of objectives do not coincide, and that after focussing, the objective should be moved closer to the object to an extent only to be found by experiment. This is doubtless true in theory; but so far as any of my lenses are concerned, I have found that a sharply-focussed image gives a sharp negative. It will, however, be found that, when using a low power, the objective may be moved through a very minute fraction of an inch on each side of the point of absolute sharpness without apparent detriment to the image; in such a case, it is advisable that it should be moved to the nearest point to the object consistent with sharpness; it will then be in focus for the blue rays.

My subject may not be of much interest to the most of you, but, after seeing the operation of making a micro-photograph, you may be able to convince some doubting friend that it is not so very difficult, after all. It is interesting to note, by the way, that probably the first gelatino-bromide plates were used for this work since Dr. Maddox, to whom, I believe, we owe the process, is an eminent mioroscopist, and uses photography largely in his researches.

The apparatus I have shown you is simple and inexpensive enough, but good work may be done with a home-made camera. My first attempts were made with a curious-looking affair made from some old boxes and a bit of black velvet, and were quite successful. I found, however, that some objects required direct sunlight to do them justice, and then a well-made camera and dark slide are assuredly necessary.

LANDSCAPE PHOTOGRAPHY FOR AMATEURS.

BY J. P. GIBSON.*

The art of feeling or faculty is, I believe, much more common to humanity than is generally thought. The power of expressing this art feeling is very rare with us. Much as has been done by our schools of art and by our wonderful illustrated literature, we are still very far behind our neighbours, the French, in the individual power of artistic expression.

I am afraid no words of mine can do justice to the value of photography as a means of giving expression to this art feeling, and as one of the most powerful auxiliaries to artistic training that exists. It has taught us, as nothing else could teach, the value of form, and has impressed on our artists the necessity of careful and accurate drawing; it has swept away ruthlessly the wretched and ill-drawn book and periodical illustrations so commou a few years ago, and is gradually but surely filling their places by its own productions or reproductions. But what more especially concerns us to-night is that it places in the hands of the man who is possessed of artistic feeling, but who is devoid of artistic training, a wonderful pencil by which he can give form, expression, and vitality to the art faculty within him; that pencil is the pencil of nature. Nature in her varied moods lays herself at his feet.

To merely enumerate all things that photography enables us to do would occupy more than the time at my disposal, so I must pass on without delay to the pleasure that can be obtained in doing these things, aud proceed to consider photography as a means of recreation. Landscape photography is a specially out-door occupation, and it lures us away from the office, the counter, the workshop, out of the reeking and murky atmosphere of the steam-driven town, to what the master of word painting, Ruskin, calls "the wild yet gentle country life, monotonous as the succession of the noiseless waves, patient and enduring as the rocks, but peaceful, and full of health and quiet hope, and sanctified by the pure mountain air and baptismal dew of heaven, falling softly between days of toil and nights of innocence;" and to do this it is not necessary that we should travel to Switzerland or the Rhine. We need not even go to North Wales or "bonnie Scotland."

Wandering with my camera by the banks of South Tyne last month, I met a south country gentleman, who, after some conversation on Tyneside scenery, said:—"I had heard all my life long of the beauties of Cumberland, and came North specially to see it; I have seen it, and, fine as it undoubtedly is, it is not a patch upon Tyneside." Had my in-bred Northumbrian reserve not held me back, I could have embraced him on the spot. We Northumbrians may well be proud of our old borderland couuty, which possesses historical associatious equalled by few, surpassed by none. She has aptly been termed the castled shire, for feudal castles crown her gentle slopes and wave-beaten precipices, and remains of the peel towers, into which our forefathers drove their herds to prevent them being harried by the invading Scots, are to be found in almost every hamlet. Archæological and architectural subjects for the camera meet us at almost every turn, even within the precincts of this very city, and when man has done so much for Northumberland, what has not nature done? Those who are acquainted with our Northumbrian rivers and their numerous and beautiful tributaries "the burns," from which our great Tyneside artist, Thomas Bewick, drew much of his inspiration, can fully testify to the truth of this. And here let me recommend to landscape photographers, as being most rich in subjects suitable to the camera, the river scenery of England.

To those present I would specially recommend the scenery of our own grand river, which we are accustomed to hear spoken of so slightingly as the "Coaly Tyne." Poets have sung the beauties of most of our English rivers, but have been strangely silent about the Tyne. This can arise from only one cause, that is, that the upper reaches of the Tyne until recently have been little seen and known, except by those earning their livelihood on its banks, who are not, I am sorry to say, a poetic race. The Waverly route of the North British Railway has opened out the beauties of the North Tyne to all in search of the picturesque and the beautiful, and some of its most charming scenes can be reached in little more than an hour's ride from Newcastle.

Lawn tennis, bicycling, cricket, and football, are each admirable in their special way as recreations for young men, but to those who have passed their first youth, or to whom such violent

* Abstract of a paper read at the Annual Lantern Meeting of the Newcastle and Northern Counties' Photographic Association.

exercise is objectionable, I would most strongly recommend landscape photography as a recreation. It gives us fresh air and exercise, combined with an amount of excitement and mental occupation sufficient to render it thoroughly interesting and enjoyable.

Laudscape photography will meet all your requirements, furnishing you with the requisite exercise, as well as the motive for taking it; and if physicians would only prescribe its practice as a remedy, instead of giving nauseous draughts and pills, renewed strength and vigour would accrue to their patients in a marvellous manner.

And as no tragedy attains to perfection without some trace of comedy in it, so no occupation can be a perfect recreation unless it is enlivened by occasional gleams of fun and humour. These gleams are met with oftener in photography than in any other art or calling.

An expensive outfit is not by any means requisite for landscape photography. It is, I think, most convenient for an amateur to commence with a quarter-plate camera—that is, one taking photographs on plates 4¼ by 3¼ inches—as it is much less costly to work, and much more portable than those of larger size; for lady amateurs this size is specially suitable. From the negatives taken in such a camera, carte-de-visite views and magic lantern slides can be got by direct printing, and by the aid of an enlarging lantern bromo-gelatine paper prints can be made, up to about 16 by 12 inches, with very good results. A portable camera of this kind, with three or four double dark slides for the prepared plates, can easily be carried in the pocket of a shooting-coat, or in a very small satchel. A light stand may be got which can be used as an alpenstock in hill climbing. Such an apparatus can be had complete from about £3 to £12.

After having thoroughly mastered the technical details of dry plate work, the amateur may proceed to attempt photographs of a larger size; when the camera is required to be carried for long distances by the photographer himself, a camera taking plates 7½ by 5 inches is very convenient, as a whole-plate camera —that is, one taking views up to 8½ by 6½ inches—is very apt to feel heavy at the close of a long day's tramp over rough country roads.

By the use of a simple adapting back, quarter-plate views can be taken in the larger camera, and with six large and six quarter-plate dark slides filled with plates, the amateur is fully equipped for a long summer day's work. I prefer double dark slides to any arrangement for changing the plates during the day's work, the latter wasting time in the most valuable part of the day, and also causing a considerable risk of injury to the plates. In selecting an apparatus, let the beginner carefully avoid one having many loose pieces, and before starting to work, let him make out a written list of the materials required for his day's work, and carefully check it off before starting, to see that he has forgotten nothing. It is a little depressing to find, when miles away from home, that the lens, has been left behind.

Coming to actual out-door work, let me recommend beginners to try at first simple effects of lighting, such as can be obtained with the sun on one side of and slightly behind the camera, as brilliant and satisfactory looking negatives are most easily got by this method of lighting. With the sun straight behind the camera a direct front light is thrown upon the landscape, which is usually the very worst form of lighting possible to work with, the resulting pictures being flat, tame, and spotty. Occasionally, with subjects which possess great contrasts of light and shade in themselves, even a front light may be utilized.

In photographing wooded landscape, the sun almost immediately in front of the camera, and just kept from shining on the lens by a sky shade, gives perhaps the greatest chance of obtaining artistic effect to the photographer, who has thorough mastery over manipulative detail, as nature seen right under the sun reveals many beauties otherwise hidden. Under the sun the shadows are broad and massive, and the heavy summer foliage seems surrounded by a halo of light caused by the reflections from the upper leaves, which glisteu and sparkle in the glad sunshine like numberless jewels. In attempting to obtain effects of this kind, every possible precaution must be taken to prevent the evil known to photographers as halation. Fine effects may often be got on days when there is no direct sunshine; a weak diffused light suits best heavy masses of foliage and deep wooded glens, such as those in which most of our "linns" are situated.

While the attention of the photographer is directed to the landscape, atmospheric effects should not be neglected, and an opportunity of taking a fine sky should never be lost, as he who does not make his skies a material part of his picture neglects to avail himself of one of his greatest aids. In the works of all the great landscape painters the skies seem to sympathise with and form part of their subject.

The practice, so common with photographers not long ago, of treating the sky as a white sheet thrown behind their landscape, is now fast becoming obsolete, and in almost all exhibition pictures, and in many procurable in the shops of photograph dealers, we find natural skies either produced in the negative by the use of a sky shade during exposure, or by the more troublesome but more effective way of printing-in a sky from a separate negative taken specially for that purpose. Mr. H. P. Robinson, of Tunbridge Wells, our leading art photographer in England, whose fine pictures at the last Newcastle Photographic Exhibition attracted so much attention, in one of his recent publications on artistic photography, insists strongly on the fact that almost all successful photo-landscapes recently exhibited have had skies printed in from separate negatives; and chief among books that may be studied as helps to the landscape photographer, let me recommend Robinson's "Picture Making by Photography;"* also Ruskin's "Elements of Drawing;" and last, but not least, Frank Howard's "Sketcher's Manual."

Having surmounted technical difficulties, the amateur will find it to his advantage in every way to turn his attention to some special and definite purpose. To attain excellence in a special line is better than to be content with mediocrity in many, and it is by steady, earnest, effort in one direction that the best results are most easily accomplished.

I may point out a few of the special objects easy of attainment to many among us. The amateur whose bent is towards natural history may devote himself to animals, flowers, and ferns, or may turn his attention to micro-photography. The geologist may find subjects in a series of the out-cropping rock strata of our own county, which, I believe, has never been systematically photographed. To the archæologist there exists a great choice of subjects, a few of which I may mention:—The Roman Wall and antiquities connected with it, Northumbrian feudal castles and peel towers, our old parish churches, Saxon crosses, and quaint gravestones and tomb covers, picturesque old houses and thatched cottages which are rapidly disappearing from among us, too often, alas! to clear the way for the "jerry" builder; and bits of old Newcastle, which daily are becoming rarer, and of which it is well to keep pictorial record.

Let me conclude with a word of warning to the beginner—Do not attempt too much at first. There comes in photography a quick and stern Nemesis; frequently it comes after a tour with the camera amid beautiful and enchanting scenery, when in the silence and lurid red light of his developing chamber he attempts to bring out the images of beauty latent on his plates. One after another is plunged into the developing solution, but instead of the expected pictures there results only fog! fog! hopeless and universal fog! We may all take warning by the fate of the ambitious youth of heathen mythology, Phæton, who essayed to drive the horses of the sun; and we must remember that the horses of the sun-god whom we photographers so ardently worship will not be driven, but must be gently led.

Notes.

Next week Dr. Eder will communicate an important article on "Increasing the Sensitiveness of Gelatine Plates to Coloured Rays."

Mr. W. J. A. Grant has sailed again North, with Sir Henry Booth as a companion, in the little yacht *Kara*. This time it is a sporting expedition to the Polar Seas that these gentlemen are engaged in, the little 40-ton craft having on board a full equipment of guns and harpoons. But Mr. Grant has not forgotten his camera on this, his eighth trip to the arctic regions, and hopes to bring back with him some pictorial reminiscences of sport in high latitudes.

* Published by Piper & Carter, 5, Castle Street, Holborn.

Major Elsdale, R.E., who has just been appointed superintendent of military balloons at Chatham, has obtained some very successful balloon photographs from small free balloons. He permits the balloon to rise with an automatic camera, which takes photographs as soon as a certain altitude is reached, and the balloon with apparatus is recaptured on its descent. Supposing a city to be beleagured, the investing force would thus be able, by taking advantage of a favourable breeze, to reconnoitre with success. In one little picture Major Elsdale has taken, a party of troops may be counted by the white dots of their helmets.

Here is an interesting case just decided by the Paris tribunals. A painter of Paris authorised M. Lecadre to photograph and publish photographic prints of two paintings, but he afterwards sold the paintings in question for 3,000 francs to M. Barboza, informing the latter, however, of the photographer's rights. M. Lecadre sold photographs of the paintings, but also photo-gravures of them, and to the latter M. Barboza took exception. He asked the court to interfere, and to order the destruction of the copper-plates employed to produce the photo-engravings. But the law has decided in favour of M. Lecadre. It is admitted, says the judgment, that photographs might be sold, and also Woodburytypes; why not, therefore, photo-gravures? It is true an engraver might be necessary, as M. Barboza says, to retouch the copper plate in places, but retouching is also necessary in an ordinary photographic print. M. Lecadre is, however, forbidden to sell coloured photographs, as these are outside the rights he acquired.

Mr. J. P. Mayall is publishing a monthly photographic work entitled "Artists at Home," each edition containing four portraits of academicians or associates taken in their studios "while surrounded by the pictures, sculptures, and other objects of art" characteristic of the different artists. Possibly, there is no class that speaks more deprecatingly of photography than painters, nor patronises it more extensively.

The ink ordinarily used with india-rubber stamps is a solution of an aniline colour in glycerine, and the impressions are generally so fugitive that a few hours' exposure to bright summer sunshine reduces them nearly to invisibility. We have, however, found that by stamping with a mixture of equal parts of a saturated solution of nitrate of silver and glycerine, excellent impressions are obtained. These are of course invisible at first, but they gradually become jet black. Still, it has surprised us to find that in ordinary cases the maximum intensity is not attained for some months.

We communicated our observations to the enterprising bill-sticker, to whom we suggested the use of bichromated paste (vol. xxvii., p. 681), and we regret tosay that he has been printing advertisements in railway carriages with the silver ink. Strange to say, the impression holds very well to the surface of paint.

Other applications of the method suggest themselves. By making an ink with an iridium solution and glycerine, we have obtained impressions on glass which became very vigorous and distinct when fired. Gold, platinum, cobalt, and other metallic solutions can thus be used for decorating glass and pottery.

"The greatest difficulty in photo-micrography is to judge exposure. It varies with every objective and with every object. The thickness, and particularly the colour, of the preparation must be considered." So says Mr. William Goodwin in a paper which will be found in another part of the News.

Says the *Artist*: "The directors of the 'Musées Nationaux de France' have just taken an important step. A contract has been passed with Messrs. Braun for the reproduction by photography of 7,000 of the best paintings in the collection, and these will be offered for sale at a relatively moderate price. After a lapse of thirty years the negatives will become the property of the government.

English photographic literature is looking up. It is only the other day we announced that Mr. H. P. Robinson's "Pictorial Effect" was appearing in French; now we find that, under the auspices of the Vienna Photographic Society, it is to be translated into German.

Messrs. Piper and Carter promise Mr. H. P. Robinson's new work "Picture Making by Photography" next week; it will be profusely illustrated.

Mr. Alfred Brothers wants to know "why we should adopt the metre instead of the yard" as a basis for decimal measurement. Unfortunately, his question comes a little too late. There might be a hundred reasons as good as the one Mr. Brothers mentions in favour of the yard, but they would be to no purpose. All scientific men, those in England included, have long since given in their adherence to the metre, which is, moreover, in domestic use in France, Germany, Italy, and Austria. The only question for discussion really is, how long the photographer in Great Britain will hold out against the metre; it is a mere matter of time.

Dumas, the eminent French chemist, who died last week, was secretary of the *Academie Française*, and one of the representative men of European science. His "Chemistry Applied to the Arts" was the first work to earn him fame, but since the year 1821 he had been before the Paris public. Dumas took much interest in the invention of Daguerre, and was consulted by Madame Daguerre on the sanity of her husband just prior to the latter making known to the public the marvels of Daguerreotype. Still, in spite of his age, Dumas was not the Nestor of French savans; Chevreul, a brother academician, who is still alive and well, and who but the other day reminded his brethren how he had addressed them in the year 1813, was ten years older than Dumas, who was born with the century.

Photography has pretty well killed one branch of art—the painting of magic lantern slides. This is not a matter for much regret, as the calling does not appear to have been particularly lucrative. An artist who has now risen to celebrity once told us that in his early struggling days he was offered an engagement at the Polytechnic Institution to paint slides for the dissolving views. The salary was not high, but he would have accepted it had it not been coupled with one drawback—the painter was expected to take a part in the then newly-invented "Ghost Entertainment!" Our friend thought it was necessary to draw the artistic line somewhere, and he drew it at the personal representation of hobgoblins.

Some very droll errors appeared in the M.S. index to the applications made during last year to the Patent Office. Under the heading "boats" is classed the common dinner table article known as a "butter boat," while ship's fenders are put down under "fire-irons." After this, one would not be surprised at hearing that gelatine plates were classed as "crockery ware," an improvement in sliding fronts as "wearing apparel," or instantaneous shutters as belonging to "shop fronts" or "window fastenings!"

On the occasion of the late Duke of Albany's obsequies, says *Truth*, the Queen telegraphed to Portsmouth, ordering that as soon as the *Osborne* arrived from Cherbourg, a photograph was to be taken of her dining-saloon, in which the coffin was placed, and which had been fitted up for the occasion in accordance with directions transmitted from Windsor. In the evening the electric light was fitted on board the Royal yacht by the Dockyard electrician, and an admirable photograph was taken, of which copies were ready next morning, and the Prince of Wales took several with him to Windsor.

We are hardly at one with the chairman of the South London Photographic Society in his statement that "in photographing views of common objects, such as shipping on the river, they would scarcely expect to get beautiful results in composition." On the contrary, some of the most picturesque bits possible can be got from the shipping in the River Thames, say about the Pool; and the wonder is that more has not been done in this direction by photographers. Of course if Mr. Statham meant that it was difficult to get anything beautiful out of the bare iron hull and gaunt steam funnel of an ocean-going trading steamer, we agree with him. But there is so much that is picturesque in the quaint Medway barges, the colliers, the ships of foreign build, and the innumerable small craft, that selection ought to be easy enough. Tall chimneys and huge blocks in the way of wharves and warehouses are certainly awkward, but even these may sometimes be dealt with effectively. We should be inclined to think that the thing to be avoided in photographing Thames shipping is that of attempting too much. The simpler the materials the less chance of getting something in the picture which spoils the composition.

Mr. Richard Keene, of Derby, has just published an "extra edition" of Mr. Edward Bradbury's "All about Derbyshire," illustrated by a dozen charming platinotypes in Mr. Keene's best style. It is a pity Mr. Bradbury strikes a discord in his interesting little work about people neglecting their own sweet country in favour of foreign lands. He complains that his countrymen "are strangely ignorant and scandalously neglectful of the beauty spots in our midst." Now we have generally found that a traveller abroad is generally a traveller at home, and moreover, that when a person deprecates foreign travel, he is not very strong upon home travel. We appreciate Derbyshire so highly that three of our summer holidays have been passed in the district, and we would make bold to avow that any average Englishman who travels on the Continent is as well acquainted with his native land as one who knows "All about Derbyshire."

We once heard a similar plaint by a lecturer on Scotland at the Polytechnic; he had been exhibiting some charming photographs of the land o' cakes, and wound up his discourse by regretting that Britons, instead of visiting the beautiful country at their threshold, must needs go off to Switzerland and the Tyrol. Why did they do this? he said reproachfully. We could easily have told him; the reason, as he himself would have known, if he enjoyed any practical experience in the matter, was simply that you can travel in the Tyrol for half the money it costs you in Scotland.

Patent Intelligence.

Applications for Provisional Protection.

6242. Jasper Wetter, Engineer, 67, Strand, Westminster, for "A new or improved process for obtaining photographic images on porcelain and enamelled or glazed surfaces."—A communication to him from abroad by Jean Antone Charles Burel, Nevers, France.—Dated 10th April, 1884.

6312. William Henry Preece, Wimbledon, Surrey, Civil Engineer, and Alexander Pelham Trotter, Furnival's Inn, Middlesex, Electrical Engineer, for "An improvement in photometers."—Dated 12th April, 1884.

6323. Heinrich Hugo Hund, Queen Victoria Street, London, Commission Agent, for "Improvements in frames for holding photographs and other pictures."—A communication to him from abroad by Albert Brüning, Berlin, Germany, Fancy Goods Manufacturer.—Dated 12th April, 1884.

Notice to Proceed.

5681. William Robert Lake, of the firm of Haseltine, Lake, and Co., Patent Agents, Southampton Buildings, London, for an invention of "Improvement in and relating to colour-printing, also partly applicable for producing coloured photographs and for similar purposes."—A communication to him from abroad by Auguste Bissen, of Paris, France, Heliographic Engraver.—Dated 8th December, 1883.

Patent Sealed.

712. Frederick Hazeldine, of Lant Street, Borough, in the county of Surrey, Contractor, for "Improved apparatus for use in washing photographic prints and other articles or materials."—Dated 4th January, 1884.

Notice of Application for Amendment of Specification.

In the matter of an application for a Patent made by George Duncan Macdougald, of Dundee, in the county of Forfar, North Britain, Chemist, for an invention of "Improvements in apparatus for storing and conveying developing and other chemicals required for the production of photographic pictures," No. 416, dated 2nd January, 1884.

Notice is hereby given, that the said George Duncan Macdougald has, under the sections 18 to 21 of the Patents, &c., Act, 1883, and Rules 48 to 56 of the Rules made thereunder, applied for leave to amend his Specification by (referring to the Queen's Printer's copy thereof) inserting in line 13 of page 2 the words "by the fingers," and in line 22 of the said page 2 the words "sufficiently to allow of the vessel being broken by the fingers," and on the said page 2 by striking out the paragraph commencing at line 28 with the words "another convenient form," and ending at line 32 with the words "releasing the chemicals," and also by inserting in line 13 of page 3, after the word "invention," the following words, "but I wish it to be understood that I do not claim as of my invention, or a modification thereof, ordinary sealed vessels without projecting tubes or without weakening incisions," and also to amend the drawing annexed to the said Specification by eliminating therefrom Fig. 3

Any person intending to oppose such application must leave particulars in writing of their objections to such proposed amendment at the Patent Office, 25, Southampton Buildings, London, W.C., within one calendar month from this date.—Dated this 11th day of April, 1884.—H. Reader Lack, Comptroller General.

Patent Granted in America.

296,055. Homer E. Pierce, Brooklyn, N.Y.—"Stereoscope." Filed January 14th, 1884. (No model).

The claim relates to an adjustable arc joint for varying the angle of a stereoscope on its standard. The arc piece is toothed on its face like a gear-wheel, and a pin passing through the support serves to lock the arc at the required angle.

ELECTRICITY IN A PROVINCIAL STUDIO.

Something less than an hour's ride by rail, ten minutes' walk through a small country town, and we are at our journey's end. A small show-case, with half-a-dozen pictures mounted on gilt-edged blocks, secured to a backing of quilted "old gold" satin, marks the house. The sides of the interior of the case we strongly suspect to be coated with luminous paint. Passing through the usual reception room, with specimens of glass cases and frames, we descend to the garden, where printing is being carried on. We observe a turn-table for vignettes, which consists of a large hoop across which copper wires are stretched, to give a rest for the frames, rotation being obtained by the old-fashioned method of a hank of worsted some five feet in length. Good worsted, we are told, will keep the hoop moving quietly for about half-an-hour, and will last out of doors for more than six months.

To reach the studio, some ninety feet of garden must be traversed; a bad thing for sitters in wet weather, we should say. Several miniature telegraph lines are swinging across between the studio and house, for purposes we shall note presently.

The studio presented its light side to the north by an area of glass some twenty-five feet long by twelve high, placed at such an angle that the top was considerably over the centre of the floor. The blinds were fitted with the old-fashioned spring rollers, some black and some white, and seemed to afford perfect control over the lighting.

From the hanging arrangements for plants, creepers, &c.—some green even now—it would present a pleasant aspect during six months or more of the year. The most conspicuous object was a large-faced electric clock on the south side, which at the time of our visit had been going for twelve months without any more attention than one filling up of the battery which works it, and an occasional adjustment to time. It was provided with a half-second pendulum, plainly seen and equally plainly heard, and this was invariably used for ordinary exposures. One complete oscillation of two arcs would, of course, be a second, one arc half a second, and half-an-arc one quarter second, the shortest time required in any studio portraiture, and that actually given last summer for full length *mignonne* cartes with short focus lens.

Attached to this clock, we remarked, was a wire independent of that which applied the electric motive power This was one of the lines passing from the studio through the air outside, and was employed to transmit periodical currents at one-minute intervals to the house. The object was to work another clock, which should keep fairly correct time without any alteration whatever, and we were told that it entirely answered its purpose. The arrangement for transmitting periodical currents was novel, but would take up too much room to explain here; but we are quite at liberty to communicate it to anyone desirous of knowing. The secondary clock was worked on a French system, and was exceedingly simple.

There were three cameras, on stands, available for work, one being a 12 by 18 for enlargements, each one fitted with an electrical shutter for exposure, and all worked by a battery of three cells, hanging to the usual portrait camera-stand; connection with the other cameras being made instantly by the same means as that employed in the carriages on the South Eastern Railway. By this means one long flexible wire-cord and electric push answers for every description of work. The shutters in one were arranged to act on the guillotine principle, being really two shutters or screens, formed of cardboard and leather, to fold up like a camera-bellows, occupying a very small space just behind the lens.

After finding that both screens were raised, a process quickly done by the touch without looking into the camera, and upon the pressure of electric button, one screen dropped, and a second pressure allowed the other screen to fall, and concluded the exposure. The whole process seemed to be very simple and certain, and a glance at the clock pendulum before described—the press button being in the hand—renders it easy to regulate the time for rapid plates. The shutter is thus made to act with two separate currents, to allow time when copying with wet plates or slow, dry films, as in the case of chloride emulsion, thereby causing economy of battery power in several minutes' exposure; the plan is to have the press button near the studio or dark-room door, and work the shutter from either point to assure perfect absence of vibration from movement in studio, and yet leave the operator free to utilize the time during exposure. Another piece of apparatus to be presently described is also sometimes employed, by which, after opening the shutter from a distance, the place can be left entirely, the closing at the right time being done automatically, and notice of same given upon a bell.

We have before remarked upon the wisdom of having some cheerful object towards which to direct the sitter's eye in place of some ordinary photograph from stock of samples; and we here observed several humorous pictures produced by copying from pen-and-ink or from American journals, and printed in cyanotype—not an unpleasant colour for the sight to rest upon.

The dark-room was lighted by a window of an area of four square feet, and glazed with deep cathedral amber and green, over which tissue paper was secured, development being effected within eighteen inches thereof.

For very dull days and late exposures, this was supplemented by a reflecting lantern, somewhat like that suggested by Mr. Cowan, with yellow paper reflecting surface, and deep amber glass in front. In every case, however, to ensure a fairly equal density in all negatives, the proper duration of development was judged by glancing through them at the direct rays from a small lamp with a circular opening of one inch and a-half, covered with one thickness of ruby glass, varnished with canary varnish.

We noticed a rocking table or slab with pendulum, upon which plates were developed, the weight of which, hanging near the ground, was formed of a large bottle of water, painted over with luminous paint, so that its movement could be noted in the shadow, even when the table was covered to protect plates from light during prolonged development. Close at hand was a telephone with its transmitter, and key to work an electric bell. The dark-room

being some hundred and fifty feet from the reception-room, laboratory, and printing department, it seemed calculated to save time and trouble to have this facility for calling for anything required, or intimating the arrival of sitters, and stating their requirements, while the work at the studio was going on. The like arrangement we afterwards saw in the printing room, at the other end of one of the aërial lines upon which we have remarked. The telephones were such as could be purchased at any electrical shop in parts, only the bobbins of wire usually supplied were replaced by somewhat larger ones, combining about one ounce and a-half of No. 36 silk-covered copper-wire. The transmitters, we were told, might possibly be the subject of some patent, but were evidently within the province of anyone possessed of a little ingenuity to construct for himself. The heads of a pair of telephone cases were used for the purpose, and at the bottom of each box-like opening was fastened a disc of common tin plate. The top was fitted up like a telephone with a diaphragm of ferrotype plate, only the varnish had been removed from the back of the plate, and the iron laid bare. This iron had been dipped for a second in acid solution of cupric sulphate, washed, and then immersed for a few seconds in a weak solution of mercuric nitrate, to amalgamate it, and after washing attached to the wire from the zinc pole of a weak galvanic battery, and plunged into an old cyanide fixing-bath rich in silver. The carbon of the battery had previously been fastened to an old silver spoon, which was also immersed in the cyanide-bath. After a few hours sufficient silver had been deposited on the plate to answer the purpose, and it had been washed and rubbed with whitening and was ready for use. The space, some five-eighths of an inch, left below the tin-plate and the silvered back of the diaphragm, had been filled up somewhat loosely with small pieces of coke, the largest about the size of a small pea, and the smallest not less than the tenth of an inch. This completed the transmitter; and when the tin-plate was connected with the telephone, and the diaphragm with one pole of three old Leclanché cells, the other pole of the battery being connected with the earth or gas-pipe, and the other end of the telephone attached by a switch to the line running between the places, the apparatus was capable of transmitting messages with clearness and power. It was evident that a disc of stout silver would have at once proved to be the best for diaphragm and back-plate, and have saved considerable trouble.

An arrangement something like that adopted by the telephone companies was employed to cut off the battery, and substitute the bell and key for the telephone, by means of the weight of the latter when it was not in immediate use. The developer then in use, we were told, was pyro and carbonate of potash with sulphite of soda.

Passing through the studio on our way out, we noticed that at one end several backgrounds were hinged at the side, so that they could be changed in a moment as desired.

A somewhat novel electrical arrangement was pointed out to us in the laboratory, where paper was being sensitized. It was a common little round American clock of the type that is sold for some four or five shillings. The minute-hand had been removed, and the disc of bone firmly fixed in its place. On the edge of this disc was a deep notch, and a pointer was attached, which made the same circuit of the face that the removed hand would have made. At the side of the case was soldered a brass pin projecting forward, and a light bar of wood worked on this pin right across the face, just above the centre; there was a pin at the back of this bar which rested on the bone disc, and, when that disc was in a certain position, would fall into the notch. At the end of the wooden bar was a piece of brass wire, which, when the pin fell into the notch on the disc, was, by the gravity of the bar, brought into contact with the upper spring of a pair projecting from the opposite side of the disc, thereby pressing them together. The springs were attached to a piece of wood screwed to the case, and were tipped with little pieces of platinum wire, which came in contact when the arm pressed the upper spring. The other ends of the springs were attached by wires, one to a two-celled Leclauché battery, and the other to an electric bell, or rather, to the terminals of two bells. The other pole of the battery, and the other terminals of the bells, were attached to the gas-pipe.

The spot to which the pointer was directed when the arm-pin fell into the notch was distinctly marked on the face. To use the instrument for floating or fuming paper, the disc was turned back, say three minutes from the mark referred to, and the arm allowed to drop on the edge of the disc. At the expiration of these three minutes, bells are set ringing close by and in the studio, and continue until the printer turns back the wooden arm. To float a sheet of paper, and then to turn to frames which require filling, or to others outside which require examining, would be a safe procedure, as the bell would give warning of the necessity for attention at the sensitizing-bath. This apparatus, placed at the studio door, would, we can understand, equally well time a lengthened exposure, and give notice of its termination.

The washing of negatives was being effected in a somewhat uncommon fashion. A series of shallow zinc troughs about five inches wide, one and a-half deep, and twenty long, were arranged one above another, forming a sort of zig-zag channel for water to flow down, holes being made in the lower end of each. The plates were placed in these trays, face up, two of their edges resting on the sides, which sloped outwards for the purpose. The negatives were so close to each other that the water, falling in a thick spray upon the first one in the top tray, passed over all in a continuous rapid stream. After a good rinsing under the tap in dark-room, three hours in this apparatus would, we think, be a fair amount of washing.

A propos of the telephone, some of our readers may not know that a recent decision in an American court gives the priority of its invention to one Drawbaugh. "One hundred and forty-five witnesses" have proved him to have perfected a similar telephone to Bell's between the years 1867 and 1876, in which latter year Bell's patent was taken out. Edison's transmitter was also embodied in principle by Drawbaugh's instrument, made ten years before; Reiss' discovery being, however, in front of either. The question is simply: "Was this discovery known in England before 1876?" If so, telephones will be cheaper, and therefore more universally employed by photographers.

Correspondence.

THE ETH-OXYGEN LIGHT.

Dear Sir,—In the News of March 14, page 166, I find a reference to my patent ether light apparatus which is very misleading, and shows that the writer, Mr. Wright, has not used, nor probably even examined, my apparatus. He says:—"The vendors of this generator, in their circular, actually contemplate the blowing off the ends of the generator, and its catching fire, as an event to be by no means unexpected," &c. Now, the fact is, as Mr. Wright may see if he will examine the circular again, it is distinctly stated that such an accident cannot occur unless the operator uses adulterated ether, or otherwise fails to follow the printed instructions. I have been using this apparatus for giving an average of from three to four exhibitions a month for nearly two years, without ever once having the flame retreat into the "saturator." The safety caps, which are an important feature of my apparatus, are there for the benefit of operators who are deceived in the purchase of ether, or who *will not* follow printed instructions until they learn, by ex-

perience, that they must; and the safety caps do actually secure against the possibility of a dangerous explosion. Mr. Wright admits that with other apparatus "there is only one method; and those who cannot depend on themselves never to vary it, are in danger." This alone is sufficient proof of the importance of safety caps or valves of some kind, since experience has demonstrated that a great many operators who will use the lime-light in public cannot be relied upon to exercise the judgment and care necessary to secure against the possibility of accident. Of course, "safety jets" can be used; but if made reliable, it is necessary to use a much greater pressure of gas, and perfect dissolving is, I believe, out of the question with such jets.

Mr. Wright also says:—"Such methods fail to insure saturating the gas, as the supply of ether is apt to prove insufficient at the end." This is true only when an attempt is made to use the saturator for a longer time than it is intended for; and the same objection could be made against any other ether-light apparatus. I have run the saturator two hours, and had the oxygen perfectly saturated with ether to the very last.

I am satisfied that Mr. Wright intended no misrepresentation; but there are some points in the construction of the patent saturator which are not mentioned in the circulars, and it will really do some things which Mr. Wright thinks it will not. In nearly every case where purchasers have had the flame retreat into the saturator, it has been proved either that adulterated ether was used, or that an attempt was made to run it longer than the instructions warranted; and when such slight explosion did occur, no damage whatever resulted. The "explosion" is confined exclusively to the mixture in the tubing, and in the small passage through the centre of the cotton rolls. — Very respectfully yours, Fred. E. Ives.

THE TRICYCLE AND PHOTOGRAPHY.

Sir,—Will you allow me to draw the attention of both amateur and professional photographers, but especially the former, to the great convenience of a tricycle for enabling one to get into the very heart of the country, and so obtain views which otherwise would either be missed altogether, or only obtained at considerable cost?

As an old tricyclist and a two-year-old photographic novice, I can most distinctly give it as my opinion that the two pursuits go most admirably together; in fact, neither is complete without the other.

I, personally, find that a 5 by 4 camera, four backs, tripod, &c., can be carried on a tricycle without the rider being conscious of the additional weight. No doubt a much larger camera could be comfortably carried by a stronger man.

At the same time, as recommending the use of the tricycle, I would point out that there are certain kinds of machines which especially suit the peculiar wants of the photographer, and it is also, unfortunately, my duty to state that there are now machines in the market which are so dangerous in their construction that anyone conversant with the necessary qualities of a tricycle would consider it suicidal policy to mount one. It is necessary, therefore, for anyone contemplating the purchase of an "iron horse" to obtain the advice of an experienced person, otherwise it is not at all improbable that the selected tricycle will turn out to be just what is *not* wanted.—Yours truly,

S. H. R. Salmon.

PHOTO-MICROGRAPHY.

Dear Sir,—Will you allow me, as a photo-micrographer of a few years' experience, to make some remarks on Mr. Allison's paper on "Photo-micrography for Beginners"? He mentions a negative of "Saccharina Lepiscua" (*sic*), and speaks of an enlargement of "one of the animalculæ." Now, I suppose Mr. Allison means *Lepisma Saccharina*, or sugar-runner, an apterous insect, about one-third of an inch in length, belonging to the *Thysanura*; but what does he call "one of the animalculæ"? The scales of *Lepisma* were once used as tests for the highest powers of the microscope, but are now regarded as easy tests for medium powers. They can be easily photographed with an ordinary $\frac{1}{4}$-inch or $\frac{1}{10}$-inch; yet they are hardly "animalculæ!" Surely this must be a printer's error.

As regards the practical part of the paper, an ordinary bellows-camera is far too short for working without the eye-piece; as sharp negatives can be obtained with the eye-piece as without, for the only objection to its use is, that it cuts off too much light with the higher powers. Yet I once obtained a capital photograph of *Gomphonema geminatum* with a $\frac{1}{16}$-inch and eye-piece; the exposure, however, was prolonged. Generally speaking, for real work with powers from $\frac{1}{8}$-inch upwards, a camera of four feet or five feet is not too long.

Focussing can be performed well enough on fine ground glass with powers up to $\frac{1}{4}$-inch, or even higher; but for $\frac{1}{12}$ or $\frac{1}{16}$ I prefer plain glass, and a focussing eye-piece. It is always best to arrange the focussing and illumination before attaching the camera to the microscope. The final focussing can be done afterwards, but the illumination or resolution must be satisfactorily arranged first. It would be difficult, if not impossible, to resolve a diatom for photographing otherwise. Even the expert finds illumination a difficult and delicate task. To pass the rays of light "straight through the whole affair" is certainly simple enough, but would hardly answer where structure is to be shown.

Quarter-plates answer very well for many objects, but with a good lens there is no loss of definition if the image be made to fill a whole-plate. If the lens be strained to give an enlargement really beyond its powers, then certainly the definition will suffer, but not if the lens be up to its work. For beginners, $\frac{1}{4}$-plates are doubtless best, being cheap, for the experienced worker often spoils a plate, and the beginner need not be disappointed if he gets only one good negative out of every dozen plates exposed. I have known experts spoil more than a dozen over a difficult diatom.

Slides need not be expressly prepared for photography. I have photographed many hundred objects, chiefly diatoms, and have never had any slides specially prepared. They may be selected, and, in the case of insect preparations, should always be, as many are so strongly yellow or brown as to be absolutely useless for photography.

Mr. Allison's exposures astonish me. He says: "From ten minutes to two hours." I use powers varying from five inches to $\frac{1}{16}$ inch, and my exposures vary from one second to half an hour, using a broad-wick paraffin lamp. With the $\frac{1}{16}$ inch, and magnesium ribbon as source of light, I find ten seconds to fifteen seconds ample.

As to plates, I find rapid plates are really best, especially with high powers, as yellow light is so inert. Many of my best negatives were taken on Swan's plates marked "30 times collodion," and others on plates prepared by Messrs. Mayfield, of this town, that were even more rapid. Still, using slow plates does not, to my mind, explain Mr. Allison's two hours' exposures.

For development, I once used ferrous oxalate, but discarded it after some months' trial. I have used sulphopyrogallol for the past two years, and desire nothing better. I usually get good density; but in the few cases where a negative turns out too thin, I intensify with mercuric chloride and ammonia. I have negatives thus intensified that were taken four years ago, which have been in the printing-frame frequently, and yet retain a good colour. All photo-micro negatives are somewhat slow in starting when the developer is poured on them, but afterwards proceed as any other negative. However, plates exposed to magnesium light develop as rapidly as plates exposed to daylight. No developer will ever make

anything of an under-exposed plate; the exact worker will destroy all such unsatisfactory results, and try again.

To conclude. Although photo-micrography is spoken of by some as a pleasant amusement, I find it really hard and exhausting work. Taking photographs of easy objects with low powers may be amusement; but after an evening's work with an $\frac{1}{8}$ inch, $\frac{1}{12}$ inch, or $\frac{1}{16}$ inch, one does not feel exactly amused. I confess, after such an evening, to aching bones, exhaustion, and, if all has not gone right, a racking headache. It is work, but, spite of its arduous nature, fascinating work to the enthusiast.—I am, sir, yours faithfully, J. H. Jennings.

THE HISTORY OF PHOTOGRAPHY.

Dear Sir,—In the last number of the Photographic News, Mr. W. E. Debenham asks why, in my table (Photographic News, page 203), I divide the credit for the collodion process between Archer and Fry.

I wrote: "Silver salts in collodion . . . Le Grey (Archer and Fry) 1850," while Hunt in his historical table wrote, "Glass plate collodion, Archer and Fry, 1850." It was Hunt, therefore, who wrote, and not I, that the discovery of the collodion process was due to Archer *and Fry*, 1850. I myself attributed the discovery to Le Grey, although his first formula for collodion was a bad one. Frederick Scott Archer, on the other hand, worked out the process technically in a most perfect manner, and deserves greater credit for its practical introduction; in this respect, without doubt, he deserves greater honour than Fry, although the latter is also mentioned by Hunt. In fact, Hunt, as knowing the English journals of the time, is my guarantee on this point. For this reason I placed the two names together, and mentioned Archer before Fry, although the latter might well have been left out.—Believe me, dear sir, yours very truly, Dr. J. M. Eder.

Vienna, April 14.

A TOURIST CAMERA WANTED.

Dear Sir,—I am in want of a camera particularly suited for tourist work, and being so distant, and without opportunity for inspection and selecting from the makers, I venture to ask you to be good enough to give me your advice as to the camera best suited, in your opinion, for use in a rough country, where lightness and compactness are essential. As to size, I fancy one of about 8 by 5. It is necessary that every part should be compact, and fit perfectly in a waterproof or leather case.

You will perhaps remember my name in connection with some rocky mountain views lately sent you. The camera with which I took those is much too heavy for an exploring expedition on which I shall shortly start, and I wish to provide myself with one better adapted for mountainous work. I trust that you will give me what assistance you can, and I shall have pleasure in sending you specimens of my work on returning.—Yours faithfully, James R. Waghorn.

Land Department, Canadian Pacific Railway Company,
March 28, 1884. *Winnipeg.*

[The best thing we can do for Mr. Waghorn is to print his note.—Ed. P.N.]

A NEW ADAPTATION OF THE IVES' METHOD AND OF EGGIS' CRAYONOTYPE PROCESS.

Sir,—Some experiments which I have made with the above processes have led me to to the discovery of a simple modification, and, like Mr. Eggis, I would rather publish my discovery than that it should become the subject of a patent, and stand as a hindrance in the way of photographic progress. Ives, it will be remembered, takes an impression from an inked photographic relief on a grained paper, and this serves as a transfer or mother print; while Eggis, instead of inking the relief, interposes between the relief and the grained paper a film which is inked.

Now I have found that excellent impressions can be obtained upon a grained stone (lithographic) or upon a grained zinc plate, by inking the relief and pressing it against the rough stone or the zinc, while by adopting the Eggis method of the intermediate inked film, I can in many cases work with greater ease. I use for the Eggis modification gold-beater's skin inked on one side. The relief may either be developed on a rigid surface such as a metal plate or a slab of thick glass, or it may be used in film form; but in the latter case it is sometimes well to place one or more thicknesses of paper behind it to give softness. Your readers will find particulars of the Eggis process on page 789 of your last volume, and on page 130 of your present volume, and the novelty I claim is the use of a grained stone or zinc instead of the grained paper. Of course, either stone or zinc may be etched into relief by well-known methods, and either a swelled gelatine relief or a Woodburytype relief may be used. I enclose a print.—Yours truly, John E. Philbrick.

Proceedings of Societies.

London and Provincial Photographic Association.

A meeting of this Society was held on Thursday, the 10th inst., Mr. A. Mackie in the chair.

Mr. H. E. Moule had recently photographed a distant view at night, illuminated only by flashes of lightning occurring during an hour's exposure. Although the distance was very well shown, little or no detail was visible in the foreground.

Mr. W. E. Debenham, referring to his remarks at the previous meeting on Capt. Abney's precipitation process, said he made a batch that morning. The negative now shown was coated one hour and a-half after weighing out the chemicals; perhaps the member who was searching for slow plates would be good enough to give these a trial. Thirty grains of silver was employed; no iodide was used.

Mr. A. Cowan: What exposure did this plate receive?

Mr. Debenham: Twenty seconds on one half, and forty seconds on the other; No. 2 stop, about equal to $\frac{f}{6}$ of the universal system; both were under-exposed. Plates may be made quicker by this process if the digestion is longer, but there would be risk of fog. He mixed at 120° F., and left it an hour, when the temperature would be about 100° F. Mr. Debenham then went through the manipulations of making the emulsion, contending that all the silver was precipitated, and using less than half a grain of gelatine. The liquid was not clear on the first washing, but clear on the second. The finer particles of bromide would go down if left long enough.

The Chairman said Mr. Debenham had carried out all he said he could do, and he should like to hear a few remarks from others experienced in precipitating methods.

Mr. A. L. Henderson took exception to Mr. Debenham using acid. By using concentrated solutions, he (Mr. Henderson) could precipitate bromide of silver in large flakes, leaving a perfectly clear solution. He believed Mr. Stebbing first pointed out the method, a fine emulsion being obtained immediately, as a member present could testify.

Mr. C. H. Cooke corroborated.

Mr. Cowan: Was Mr. Henderson's clearer than this?

Mr. Cooke: Yes.

Mr. Henderson: Neither acid, gelatine, nor chloride was used. He then showed a new form of dark-room lantern, made from a plate-box. The grooves contained plates coated by Ihlee and Horne with phosphorescent paint, also plates of aurine, cathedral green, and ground-glass; a small paraffine lamp placed behind the various media, and a square aperture cut in front, completed the arrangement. Plates giving 18 on the sensitometer were exposed two, four, and six minutes respectively to the light passing through the following:—One phosphorescent plate and two of aurine, an image being obtained in each case six inches from the box. Two phosphorescent plates, and two of aurine, a six minute exposure having no effect. Two phosphorescent plates, no effect 18 inches from the box, sufficient light to see the hands of a watch nine feet away. One phosphorescent plate, two

aurine, and one cathedral green, six inches from the lamp, gave a very slight indication. Two phosphorescent plates, two aurine, one cathedral green, no indication at six inches distance.

The Chairman considered the phosphorescent plates stopped the large amount of actinic rays.

Mr. Cowan thought the rays were stopped by absorption.

A discussion followed on the value of certain rays in exciting a phosphorescent tablet, and why that plate farthest from the light was not phosphorescent, yet permitting rays to pass through which were safe for developing purposes. It was thought that the light was sufficient only to sensitize the plate nearest the flame. Sensitizing with a weak light and de-sensitizing with another colour, was said to have some bearing on the subject. The effect of passing violet rays into a solution of quinine was given as an example, fluorescence being obtained in one cell, but none in the second; and in reply to a question from the Chairman, Mr. Haddon mentioned violet rays as having the greatest sensitizing action on luminous paint.

Edinburgh Photographic Society.

The sixth meeting of this Session was held in 5, St Andrew Square, on April 2nd, Mr. Wm. Neilson in the chair.

The minutes being passed, the following gentlemen were unanimously elected ordinary members:—Messrs. Archibald Brown, John M'Laren, J. Keith Chisholm, David Munro, and Thomas Young.

Mr. Craig Christie moved that the Secretary be instructed to insert in the minutes expression of the sincere regret at the death of His Royal Highness the Duke of Albany, and that he prepare addresses of condolence to Her Majesty and the Duchess of Albany, to be signed in the name of the Society by the President, Vice-Presidents, and Secretary. This was passed without dissent.

Mr. Craig Christie moved that the following be added to the rules of the Society:—"That the Secretary shall call Council meetings after consultation with the President, and that he shall give three days' notice to members."

The Secretary said that he had no objection to the proposal, save that it did occasionally happen that some matter of importance cropped up which necessitated prompt action, and when such was the case it might be greatly to the disadvantage of the Society if a delay of four or five days were made obligatory. He suggested that as the Council were about to revise the rules, this matter might be referred to the Council. This was agreed to.

The Secretary then intimated that he had been favoured with two important papers by the Rev. Mr. Hardwich and Mr. Lewis Wright respectively, and proposed that the programme be departed from in order that these papers might receive the earliest publicity. Mr. G. G. Mitchell had courteously acceded to this, and proposed reading his paper at the next meeting, subject to the will of the meeting.

The proposal having been passed by acclamation, a paper by Mr. Hardwich, entitled "Notes on the Lime-light," was read by the Secretary, and immediately after, Notes on the same paper by Mr. Lewis Wright (see pp. 230 and 231).

Mr. J. M. Turnbull said that with one or two exceptions he agreed entirely with everything that Mr. Hardwich had said in his paper. He thought that the proper angle for the burning gases to strike the lime cylinder should be the greatest that could be given, without giving a shadow on the screen, *i.e.*, as near a right angle as possible. He agreed with Mr. Hardwich that "light for all ordinary purposes could be got with ¾ to 1 cwt. on each bag"; but where the very best light is wanted to fill a 20 ft. screen, he believed in having plenty of pressure. Square weights ought always to be used, or still better, a long flat-sided weight cast for the purpose, in shape like a piece of pig metal. With regard to the ether generator, he had used it many times with convenience to himself, and believed it was quite capable of giving a light equal to the mixed gases. He thought it quite safe in competent hands, but it should not be trusted in the hands of those who were beginners, or who had only a slight knowledge of what they were doing. In making experiments with the generator packed in ice, Mr. Hardwich did not seem to be aware that all properly made ether generators are jacketed or encased in a thick coating of some non-conductor of heat, such as cork raspings or sawdust, and subsequently not easily affected by cold, or by a little heat such as that of a crowded room. With regard to the Chadderton accident, he quite agreed with the opinion of Mr. Hardwich, Mr. Wright, and the published opinion of Mr. Broughton, that the cause of the explosion was that there was ether in the bag. He thought Mr. Wright's suggestion to open the hyrogen tap of the generator first to relieve any pressure a most valuable one. He did not think Mr. Wright's first objection to ether, viz., want of saturation, a serious one, as he had proved to his own satisfaction that either air or oxygen could be very easily saturated with ether to make them burn freely; but the second objection (that of back-pressure) was one that would require to be seriously met and remedied either by the construction of a generator that could be blown back without sending the ether back through the tubes, or by interposing some thoroughly tried safety contrivance. He had very little faith in back pressure valves, &c., and the newly-suggested pumice chambers would require to be thoroughly tested before they could be said to be safe.

Mr. Hume said, with regard to the preparation of the oxygen, he did not find it necessary to weigh the ingredients; but when making the gas himself, he simply blackened the chlorate with the manganese dioxide. When once the flow of gas begins, the heat should be kept low, for a kind of fusee action goes on in the mixture till all the oxygen comes off regularly if a moderate heat is kept up below the retort. It is of the greatest importance that the tube leading from the retort be ranged out with a stout spiral wire each time the gas is made, for so much solid matter is carried over that it would ultimately choke the pipe if neglected after several makings, and to this cause he attributed some of the accidents that had happened. For those who suspect black materials like manganese dioxide, and do not feel sure of the tests for it, he mentioned that red oxide of iron would suit quite as well; indeed, it was much preferred in some chemical laboratories, as giving the gas more free from chlorous compounds. Common sea-sand would also help to give a steady flow of oxygen when mixed with the potass chlorate. He had used the mixing burner he exhibited very frequently for the past five or six years with oxygen and coal-gas in separate bags under one hundredweight pressure each, without any approach to a casualty; indeed, he considered it the safest arrangement that could be used. The mixing chamber in this burner has no packing whatever. It is not desirable or safe that the weights should fall off the bags; but the last time he gave an exhibition in this room, one of the weights fell off the oxygen bag without anything going wrong except the diminution of light, and all went right when his assistant replaced the weight. On former occasions, too, while the light was burning, he had lifted weights off and put them on again without any accident or even a snap.

Mr. G. A. Wilson said, with reference to the pumice safety-chamber, his objection to it was that, after being repeatedly used or knocked about, some of it was apt to get pulverized and blown into the nozzle of the burner, and so choke it up. The only safety-chamber he used was a common piece of cane inserted in the tubing near the burner. Through this no light will pass, no matter what the composition of gases may be, and no dust will pass from it into the burner. The diameter and length will depend upon the pressure available or necessary. He had found, with 1 cwt. on the bags, a piece of cane ½ inch in diameter and 1 inch or 1½ inch long, thoroughly efficient. If a piece of cane such as he described were attached to each burner, he had not found it possible that an accident could occur, no matter what suction takes place by the weights falling off, or in whatsoever proportion the gases are mixed, because they will not explode without a light, and the light is stopped at the cane. With reference to the ethoxo lime light, he considered it safe so long as kept burning sufficiently to make the lime incandescent; but the moment it is turned down with the tap for the purpose of dissolving with a double lantern, it becomes dangerous. He thought the danger due to the dissolving tap being at a considerable distance from the ether generator, and the intervening tube became filled with oxygen gas saturated with ether, and as the little escaping, or rather burning, at the nozzle is not issuing at high pressure, the flame rushes back as soon as the dissolving tap is turned on. Some lanternists held that it was not possible for the flame to travel along tubing; but he maintained that such was not only possible, but certain when using the mixed burner if the weights should fall off the hydrogen bag, causing a suction of oxygen gas into the hydrogen bag. It was an undoubted fact that bags sometimes catch fire when the weights fall off, and this he believed might account for it. With reference to the lantern microscope, he had also been giving his attention to it, and had succeeded in showing a flea (the object, not the dise), six to twelve feet in size, clear and distinct on the screen, by using a specially constructed lens of wide aperture and high power.

Hearty votes of thanks were accorded to Mr. Hardwich and Mr. Lewis Wright for their valuable papers.

A vote of thanks to the Chairman terminated the proceedings.

Glasgow and West of Scotland Amateur Photographic Association.

The usual monthly meeting of the above Society was held in the Religious Institution Rooms on Tuesday, the 8th inst., Mr. Hugh Reid (President) in the chair.

The following new members were admitted:—Messrs. H. Gillespie, R. T. Cochrane, Jas. S. Stewart, Jas. Bell, Chas. S. Mair, Wm. France, and Wm. Reid.

Mr. J. Y. McLellan then exhibited and explained Warnerke's sensitometer. Mr. McLellan, however, did not consider it altogether satisfactory, as from his observations it tended to deteriorate with age. Plates which he found of the same rapidity in practice last year gave the number 20 quite distinctly, this year only gave a little over 14.

Mr. Goodwin suggested that temperature had a great effect on these phosphorescent tablets, and the discussion was continued by Messrs. Lang, Reid, and others. Of the two plates tested by Mr. McLellan both out of the same batch, one exhibited the number 14, and the other only 10. The plate exhibiting 14 had previously been treated by the President with Dr. Eder's formula for rendering plates more sensitive viz.:—

Nitrate of silver...	50 grains
Citric acid	50 ,,
Water	1 ounce

Plates soaked for three minutes in one drachm of this solution to twelve ounces of alcohol. This showed an increase of sensitiveness in the ratio of three to one, which corresponds with Dr. Eder's results.

Mr. W. C. Bergins then exhibited his novel form of portable tourist camera, and in the course of a few introductory remarks said that a really portable tourist camera which would unite all the qualities of a studio camera, an enlarging camera, and a landscape camera, was as impossible as a horse which would combine all the qualities of a race-horse, a Clydesdale, and a Shetland pony. His aim in designing this camera had been extreme lightness as well as the necessary strength. In showing the camera, which had been made throughout from his own designs and under his own superintendance, Mr. Bergins pointed out that it was a whole-plate solid camera made so that the four sides, two fronts, two lenses, and all other necessary apparatus were carried inside. The principal points were extreme lightness, his whole apparatus, carrying seven plates, weighing only eleven and a-half pounds, very small bulk; and although the camera was made solid, it would focus from 5" to 11" by putting the slides nearer to or more distant from the front, the exact focus being attained by rack-and-pinion lenses. The tripod was made of bamboo cane, going up like a walking stick, and when a silk cover was drawn over, had the exact appearance of an old-fashioned umbrella.

While the members were examining and admiring Mr. Bergins' camera, he kindly answered a great many questions regarding it.

Mr. W. Goodwin then read a short lecturette, and gave a demonstration of photo-micrography (see page 245).

The meeting was very much pleased with Mr. Goodwin's deftness of hand, and with his extremely clear method of working; and doubtless many will now go in for this branch of photography.

The President then showed a camera-finder and view-meter which he had got made at a trifling cost according to the directions in the Year-Book for 1884. The meeting considered both very useful, especially the view-meter.

It was agreed, after a little discussion, that the first out-door meeting of the season should be held on the first Monday in May, that the place be "Brig o' Turk and Trossachs," and that members leave Glasgow by the 6.50 or 9 a.m. trains.

After the usual votes of thanks, a very large and successful meeting adjourned.

Newcastle-on-Tyne and Northern Counties' Photographic Association.

The ordinary meeting of this Association was held in the Patent Room of the Literary and Philosophical Society's Institute, on the 9th instant, Colonel Sheppee in the chair.

The minutes having been confirmed,

Mr. W. C. Fletcher was nominated for membership, and Messrs. J. H. Inness, F. W. Morgan, J. Russell, and A. Ross were duly elected members.

A report from the Council with reference to the exhibition and to out-door meetings was adopted unanimously. It contained recommendations from the Council as follows:—That no open competition be held this year. That a private exhibition of members' work be held in the autumn, at which a print be selected for exhibition to members, the print selected not to be smaller than half-plate, nor larger than 10 by 8. The members to be the judges.

The following offers, by gentlemen members of the Association, had been accepted with thanks:—Mr. George Borrow: A silver medal for the best set of three pictures taken by a member at the Society's out-door meetings this year. Mr. J. P. Gibson: A prize for the two best pictures taken at the Society's out-door meetings this year, the successful competitor not to have previously received a medal or diploma. Mr. J. A. Maling: A silver medal for the best set of three transparencies taken by a member.

The meeting then adjourned to the adjoining lecture theatre, where

Mr. J. P. Gibson gave an interesting lecture on "Landscape Photography for Amateurs" (see page 246), for which a hearty vote of thanks was passed.

Mr. Allison, assisted by the Hon. Secretary, then proceeded with the lantern exhibition. Some beautiful slides were shown, and much appreciated. The best thanks of the Association are due to Mr. Allison for his kindness in bringing his lantern, superintending the arrangements therewith, and for the loan of a very fine set of Egyptian slides. Also to Messrs. York and Son, and Messrs. Watson and Sons, of London; Messrs. Mawson and Swan, Morgan, and Mr. J. F. Maling, of Newcastle; and Mr. J. Hedley Robinson, of Tonemount, for contributions of slides.

The Hon. Secretary read a communication he had received from the Rev. T. F. Hardwich, in the course of which that gentleman said:—

"I speak advisedly when I say that nine out of every ten accidents at lantern exhibitions with the oxy-hydrogen or eth-oxo lime-light are due to a sudden stoppage of the pressure by which the two gases are forced forwards, and to a return of one of the gases in the wrong direction. A lecturer using the lime light should examine his tubing with the same care that the coal-miner examines his ropes; and, if the exhibition is likely to be a crowded one, he should put on a back-pressure valve to secure himself against a return current of gas. If some photographic society were to offer a prize for the valve and tube most free in action and least liable to get out of order, the ingenuity of mechanicians would soon supply the want. It must be borne in mind that back-pressure valves are intended to stop gas, and not flame; whereas safety-tubes are meant to stop flame, but not gas. My own experiments, so far, seem to indicate that an effectual safety-tube can be made without any difficulty, when it is protected from suction or forcing by the addition of a suitable valve. In my own practice I have seldom used these appliances; but if I be spared to see another winter I shall, when lecturing away from home, employ the blow-through or safety jet, if practicable."

Talk in the Studio.

Balloon Photography.—It is not "all honey," apparently, in ballooning, for thus says our friend Mr. Shadbolt:—"Balloon photography impossible on Monday last at Birmingham—blowing half a gale—badly knocked about, both starting and landing—worst experience ever had. No bones broken, but much shaken and stiff about the arms and shoulders. Camera-holder (not camera itself, luckily) smashed off before we even got clear. Landed at Worcester—travelled between thirty and forty miles an hour.—Cecil V. Shadbolt."

Messrs. Wratten and Wainwright are good enough to forward us four instantaneous views of the boat race; they illustrate "Clearing the Course," "The Race," "Steamers Following," and "After the Race."

Instantaneous Views of the Funeral of the Duke of Albany.—Mr. G. P. Cartland sends us a series of six half-plate pictures which he secured on the 4th instant at Windsor, while the funeral procession was passing. The best of the series are

the Queen's carriage, drawn by six white horses, and the gun-carriage upon which the coffin was borne. As the exposures were extremely short (estimated at one-sixtieth of a second), no signs of movement are obvious, and the detail is all that could be wished for. We understand that the Queen has expressed much satisfaction with Mr. Cartland's work.

Non-Influence of an Electric Current upon Light.—Dr. Lecher has made an experiment of great interest. A ray of light was divided, as in many experiments on interference, into two parts, which, after passing through two parallel glass troughs, were caused to reunite, giving the usual interference-bands. The troughs contained strong solutions of nitrate of silver. By means of electrodes of silver an electric current of 6 amperes strength was carried in opposite directions along the troughs, so that in one trough the current flowed with the light, and in the other against it. But in no case was any displacement of the fringes observed. Dr. Lecher concludes that the velocity of light is not influenced by a current flowing through the medium.—*Nature.*

Chemical Action of Light; Decomposition of Oxalic Acid by Ferric Chloride.—By G. Lemoine (*Compt. Rend.*, 97, 1208—1212).—Solutions of ferric chloride and oxalate acid containing a gram-molecule of the respective substances per litre were mixed in different proportions and exposed to light under comparable conditions, the carbonic anhydride which was given off being collected over glycerol and measured. Decomposition takes place in accordance with the equation $Fe_2Cl_6 + H_2C_2O_4 = 2FeCl_2 + 2HCl + 2CO_2$ (Marchand; Jodin). The rate at which decomposition takes place depends on the intensity of the light. For a given intensity, it is at first almost uniform, but when about half the total quantity of carbonic anhydride has been given off, the rate of decomposition gradually diminishes. The greater the volume of the liquid, the longer, of course, is the time before decomposition slackens. When the two solutions are separately exposed to light for several hours and then mixed, decomposition takes place more rapidly than if the solutions had not been previously insolated. Other conditions being equal, dilution with water increases the rate of change, an effect which may be due either to the partial decomposition of the ferric chloride by the water, or to a diminution in the absorptive effect of the ferric chloride due to dilution. When ferric chloride is in excess, less gas is given off than when the two substances are present in equivalent proportions; a similar effect is produced by adding ferrous chloride to the mixed solution. An excess of oxalic acid exerts an effect similar to that produced by dilution. Water exerts little or no absorptive effect on the waves which bring about the reaction, but a screen of ferric chloride solution almost entirely prevents the decomposition.—*Journal of the Chemical Society.*

Photographic Club.—At the next meeting, on April 23rd, the subject for discussion will be "On Lighting in Landscape Photography."

To Correspondents.

*** We cannot undertake to return rejected communications.

Russell Steele.—You cannot do better than to adopt the combination of orange glass and ground glass, as recommended by us on page 50 of the present volume. See also page 61.

J. E. H.—We have tried the process to which you refer, and find it by no means so well adapted for the work as the new method of Pavloffski, described on p. 194. The carbon process may answer, but you will require a tissue rich in pigment, and consequently containing but a moderate proportion of gelatine.

Albert.—1. When it is stated that the specific gravity is ·9228, it is meant that if a volume of the alcohol equal to that of one unit of water (say one pound) be taken, the alcohol will weigh ·9228 of a pound. 2. The first should be read 27 and 4-10ths, while the second is read 13 and 7-10ths. The first figure to the right of the decimal point indicates tenths, the second hundredths, the third thousandths, and so on. Thus, ·9228 is something over 9-10ths, or $\frac{9228}{10000}$.

A. Brown.—The etching ground (such as is used for ordinary plate work) can be obtained in the solid or the liquid form from M. Cornelissen, Artists' Colourman, Great Queen Street, London, W.C. If you obtain it in solid form, it should be dissolved in oil of lavender.

R. W. Taut.—Unless we have misunderstood you, this is a very bad case of piracy. If you prosecute, and the pirate is sentenced to a term of imprisonment, he may modify his view as to his *right* to appropriate your property. 2. You had better take proceedings against the vendor, but you should purchase from the printer if possible. Let us know how you get on.

John G. M.—Some years ago we used a tricycle of the make known as "Coventry" with perfect success for out-door work, but we can hardly give a decided opinion as to which is the best. You must of course consider your individual requirements.

Geo. Mackie.—1. It does not matter at all in ordinary cases, as the citric acid will render it strongly acid; but in most instances you will find that commercial samples possess a very feeble alkaline reaction. 2. In such a case there is something decidedly wrong, and a preparation so decidedly alkaline should not be sold. You had better return it, ask for another sample, and demand from the dealer as much pyrogallic acid as you have wasted.

J. M. K.—The actinic power of the light varies very much indeed, and sometimes when a yellowish tint pervades the atmosphere the exposure required is enormously greater than on an average day. Indeed, assuming the first day you mention to have been a decidedly unfavourable one, we see nothing surprising in your experiences.

C. Sutton.—Transfer a collotypic impression to the wood. You will find full directions on page 402 of our volume for 1883.

Gilbert Wilson.—We have never used such an ink, but have no doubt that a satisfactory preparation may be made as follows:—Mix clear solutions of barium chloride and sodium sulphate, and wash the precipitate which is thrown down by stirring it in a large quantity of water, allowing it to settle, and pouring off the clear liquid. The remainder should be thickened with a little gum.

M. Wills.—It may be kept for any length of time if perfectly protected against contact with the air, but if exposed to the atmosphere it soon becomes oxidized, and consequently useless.

M. W.—1. You can obtain it from Johnson and Cumbers, Lithographic material warehouse, Farringdon Street, near the Viaduct. You should ask for it "uncoated," or they may serve you with a transfer paper made on material you require. 2. Thank you for your kind offer, which we we will bear in mind.

R. Harcourt.—1. It is very probable that the paper is made from wood pulp, as such paper ordinarily becomes first yellowish and ultimately brown under the influence of light. It is, however, not the actual fibre, but the incrusting matter, which undergoes the alteration, and it is quite possible to so far purify the wood pulp as to obtain a paper which will stand the action of light as well as that made from rags. A dilute solution of acid hydrochlorate of aniline will serve as a rough test for the incrusting matter, as it stains the imperfectly purified wood paper bright yellow. To prepare the solution, you may dissolve a drachm of aniline in a mixture of half-an-ounce of hydrochloric acid and five ounces of water. 2. We do not understand your question, but if you will explain what you mean by "a solution of uranate," we may be able to comprehend your meaning. 3. Add a solution of chrome alum (30 grains to the ounce) drop by drop until the gelatinous solution shows signs of thickening or coagulation, and then add sufficient acetic acid to bring it back to a state of complete fluidity. 4. Probably you will be able to obtain a sufficiently good cast with sulphur or the so-called Spence metal; but in melting the sulphur you must take care that no portion is heated much above its melting point, as otherwise it will become thick and viscous. 5. Ordinary washing soda will answer.

The Photographic News Registry.

Employment Wanted.

Recep.-Room, &c., at 18/- for permanency.—E. H. H., *Photo. News* Office.
Retoucher, can tint.—Miss Cross, Hill-st., Peckham.
Operator, can retouch, enlarge, print, manage.—X., 115, High-st, N.W.
Printer or Gen. Assist.—J. A. Randall, The Bazaar, Broadstairs, Kent.
Retoucher, Artist, &c.—W. Rubers, 28, Pond pl., S. Kensington.
Operator & Retoucher.—A. D. Thissack, 1, Woodside-ter., Douglas, I. of M.
Retoucher (German), first-class.—30, Stean-st., Haggerston.
Assistant, well up in dry plates.—Photo., 148, St. James'-rd., Holloway.
General Assistant.—Z., Mr. Gregory, High-st., Marboro'.
Printer and Toner.—F. Knight, 40, Brooksby-st., Liverpool-rd., N.
Reception Room Lady in Lond.—M. A. S., 17, The Drapery, Northampton.
Operator & Retouch., first-class.—W. H. H., Art Studio, 3, Cheapside, E.C.
Operator & Ret., mod. salary.—Operator, 58, Campden-st., Kensington, W.
Photo. Colourist, gen. useful.—G. Manton, 49, Hurley-rd., Kennington-la.
Operator & Ret. in good house.—D. Prodger, The Broadway, Ealing, W.
Operator and Retoucher, could manage.—Artist, 1, Hove-st., W. Brighton,
Youth, as Assistant in dark room.—H. Eckhardt, 12, Bath-st., Brighton.

Employment Offered.

Operator, good, at once.—C. K., 96, Bath-st., Glasgow.
Printer, first-class, immediately.—Hills & Saunders, Aldershot.
Recep.-Room Lady for Brighton.—C. H., Clermont, Preston-pk, Brighton.
Operator, who can retouch, for month.—Norman May, Malvern.
Assistant in Stock-dealer's Warehouse.—Ruby, *Photo News* Office.
Oper., clever with children & retouching.—Clayton, 6, Lond.-rd., Leicester.
Printer, with first-class references.—Stiles, 8, Kensington High-st., W.
Operator, Retoucher, manage branch.—C. Keeping, 1, Exe-bridge, Exeter.
Out-door Operator, first-class.—Taylor, 70, Queen Victoria-st., E.C.
Operator for Studio.—Hills and Saunders, Eton, Bucks.
Ferro Oper., to travel.—Mr. Griffith, 5, Northampton-bldgs, Clerkenwell.
Lady, exp., Recep.-room.—Hughes & Mullins, Regina House, Ryde, I.W.
Printer, well up in vignetting.—Winter, Midland-rd., Derby.
Oper. & Retoucher, good at lighting & pos.—Shrubsole, Davy-pl. Norwich.
Printer & Gen. Assist.—E. R. Gyde, Cheltenham House, Aberystwith.

THE PHOTOGRAPHIC NEWS.

VOL. XXVIII. No. 1338.—*April* 25, 1884.

CONTENTS.

THE IVES PROCESS FOR MAKING PHOTO-TINT BLOCKS.

Now that the production of phototypic blocks from the ordinary gradated negative has become a matter of almost every-day practice, and such blocks are coming into general use as a means of magazine and book illustrations, every advance in the methods of production becomes of great interest, and we are pleased to be able to publish some of the details of the latest method devised by Mr. Fred. E. Ives, of Philadelphia. We need do no more than refer to the old form of the Ives process, in which a gelatine relief is inked with printer's ink, and an impression is taken on a sheet of grained paper; the gradation of the print being produced by the more or less complete crushing down of the grain of the paper by the inked relief, and the print thus produced being either re-photographed or used as a transfer.

Mr. Ives has recently much improved his method, as he now takes a cast in plaster from the relief, and impresses an inked stipple on this by means of an elastic stamp. Under these circumstances the grains of ink unite to solid blacks where the relief is highest and the pressure greatest; while in the deeper portions of the cast the spots of ink deposited from the elastic stamp are extremely minute. The next problem is to obtain a transfer from the inked plaster without re-photographing it in the camera. And as regards this point, we can quote Mr. Ives' own words under date November 7th, 1883. He says:—

"I no longer reproduce the impression on the plaster relief by photography in the camera. I have this improved method in regular and perfectly successful operation now, and will describe it to you. After making the impression on the plaster relief, I flow it with plain collodion, which penetrates the ink, but does not make it 'run.' When dry, I wet it with a solution of gelatine in acidified water, then strip it off, and make a negative by contact printing on a collodio-bromide dry plate. Negatives can be made much quicker and better this way; and by reversing the stripped image I avoid the necessity for making a reversed negative. We can also preserve the stripped picture in a book, so as to make new plates whenever they may be required.

"The plaster reliefs which I make (from swelled gelatine) do not preserve their surface for more than a week or two, becoming 'frosted' on the surface after a certain amount of exposure to a moist atmosphere. For this reason, I cannot well send you one for examination; but I enclose in this letter one of the stripped 'impressions' from which my negatives are now produced.

"The entire process, as now operated, is very simple and reliable, all minor difficulties having been overcome by patient experiment."

Quite recently further progress has been made, and the necessity for the production of a contact negative from the stripped transfer has been obviated, Mr. Ives having found that a fatty transfer or impression can be conveyed from surface to surface (as from the plaster to stone or to zinc) without the spreading which results when paper is used. Once more we may quote Mr. Ives' own words (under date April 7, 1884):—

"You may remember that I told you, some time ago, I had succeeded in transferring the inked impression from the plaster relief to stone or zinc, but that I did not practise that method because I could get better results by 'photo-engraving' from contact negatives of the impression stripped by means of a collodion film. I found the latter method a great improvement upon photographing in the camera, but I now do much better than that. I temporarily abandoned the transfer method because the ink spread or 'smeared' in transferring just enough to seriously affect the result.

"Learning later that sheet rubber could be employed for transferring, and that it would take and give a sharp impression when paper would not, it occurred to me that it might be just what I required, especially as the rubber would follow the uneven surface of the relief better than paper. So I have experimented with it until I am now able to put a perfect transfer upon zinc or stone within five minutes after the impression on the plaster-relief is made. This greatly simplifies the process."

Mr. Ives promises shortly to send us an example of his latest work, in which the improvements to which we have referred will be embodied.

Information as to the Ives' process will be found in our volume for 1883, pages 498, 677, and 739; also in the present volume, pages 130 and 253.

ON THE CHARACTER OF LIGHT REFLECTED BY GREEN FOLIAGE, AND ITS REPRODUCTION IN PHOTOGRAPHY.

THE colour in which trees and shrubs appear to us is never actually green, though to the eye foliage may be verdant enough; and if a photograph is to be taken to reproduce in their true intensity the light and shadows upon foliage, it will be necessary to have a film specially sensitive to the colours presented to it. The problem is not a new one, as everybody knows, and as long ago as 1842, the attention of that eminent French chemist, the late M. Dumas, was called to it; while again, in 1854, we find the subject once more receiving the attention of Helmholtz. Both of these authorities were of opinion that the light reflected by green leaves was bereft of chemical rays, from the circumstance that these particular rays were absorbed by the plant to do a certain amount of chemical work. Later on, indeed, Roscoe, as also August Vogel, demonstrated the fact that very few rays, capable of acting upon silver salts, could get through green leaves.

Very little has been known about the character of the light that is reflected by green foliage. Recently, however,

Lommel, and still more lately, Reinke, have made an investigation of the matter, and they have found that this reflected green light is composed of rays similar in all respects to light that has been transmitted through a single leaf. In a word, the green-reflected light consists of rays of extreme red, say before B in the spectrum, and of rays between C and E—that is, of orange, yellow, and light green. There are also weak rays of dark green and blue present. The absorption spectrum of chlorophyll is seen to advantage in a spectroscopic examination of this green-reflected light.

The reason why this light reflected by green foliage, and which consists, as we have said, for the most part, of red and green rays, seems to us only green, and nothing more, is explained by Reinke; he says that red rays are far less appreciated by the retina of the eye than the green, and hence it is as we said at the outset, that the real colour (to speak phys'ically) of leaves and foliage, as we see it, is never green.

The sensitive plate does not, however, behave like the retina of the eye. We have had many examples of this, and we know full well that the photographic plate will take notice of things that are unseen by the eye. The reasoning upon Lommel and Reinke's experiments would go to prove that, for practical landscape photography, it would be well to employ a film, if it can be had, that is particularly sensitive to yellow-green, yellow, and orange rays. Eosine-stained bromide plates answer the purpose to a slight extent, but their sensitiveness in this respect requires to be more exalted than that usually found in these films. Dr. Vogel seems to have made a stride in the proper direction, for he undoubtedly has obtained films more sensitive to the yellow and yellow-green than to the blue; but, unfortunately, he has told us nothing as yet of his mode of preparation. Still, from indications that come to us from more sides than one, there seems a good chance that the hopes of Herrn Lommel and Rienke will be fulfilled, and that a sensitive film, fit to photograph foliage, will soon be forthcoming.

PHOTOGRAPHIC OPTICS.

At a recent meeting of the London and Provincial Photographic Association, Mr. W. E. Debenham lectured on the subject of photographic lenses. The lecture itself will be found in our columns. The discussion which followed was very instructive in several respects.

For instance, the remarks made by Mr. Cadett were particularly worthy of notice. He was speaking of the different opinions which are expressed as to the powers of different lenses, and he pointed out that the possible qualities of a lens ought not to be a matter of opinion at all, but that it ought to be possible to say, "A lens ground with such and such curves, and having glass used of such and such densities, is capable of giving this certain amount of definition (or, more strictly speaking, want of absolute definition), for a central pencil, will have exactly so much curvature of field, and will exhibit so much astigmatism." He pointed out that it is merely a matter of correct data and sufficient mathematical skill, and these things may be worked out definitely and absolutely for a given lens—the assumption, of course, being in such a case that the grinding of the glass is absolutely correct.

Mr. Cadett had himself gone through a course of optical mathematics which would have enabled him to perform the necessary calculations, but he had found it impossible to get the required data. Thus, opticians do not inform the purchasers of lenses either to what radii the surfaces of glass are ground, nor do they tell them what is the density of the glass; and, as a matter of fact, Mr. Cadett had found his labour of acquiring this necessary optical mathematics so much work thrown away.

Mr. Warnerke had, it appears, also gone through a similar course of mathematics with the view of enabling himself to judge of the capabilities of various lenses, but after all, came to the conclusion that the best means of judging of a lens was to fix it to the camera, to take a photograph with it, and to judge from that.

In spite of this, there can be no absolute impossibility of doing what Mr. Cadett recommends. It would be quite possible, were any one of sufficient capacity to take the work in hand, to have it stated of any lens, what is the utmost that it is capable of doing; but it must be borne in mind that the statement would only be one of what the lens *might* do, not necessarily of what it *would* do, because it involves an assumption of perfect workmanship. Thus, of a portrait lens it might be said, "A central pencil of light will focus into a disc of ·001 inch diameter:" but this would only mean that this was the smallest possible disc which might represent a point in the object; that is to say, nothing *better* than this could be expected, something *worse* might. Nor is it to be supposed that, as a rule, lenses even by the best makers give results so near the theoretical ones that the errors due to defects of workmanship can be entirely disregarded.

The curves of a photographic lens are, as a rule, worked out mathematically to begin with, and every lens which was perfectly ground would give a certain ascertained result, and every one would give the same result as another made according to the same formula; but, as a matter of fact, we know that in the case of the lenses turned out by our very best opticians there is considerable difference of quality. This is especially the case when we come to lenses of long focus and large diameters. In such cases, if we take two similar lenses, and examine the central definition under a high power eyepiece, we shall often find great difference between the one and the other.

In spite of all this, such a work as Mr. Cadett suggests would be a most valuable one, and we look to see it undertaken some day. The labour would be excessive, however. We were a little while ago talking to an optician in connection with whose firm there works a most eminent optical mathematician. It came under discussion whether it might not be possible to make a lens uniting certain qualities not found in any one photographic lens at the present time. The mathematician in question had, our friend informed us, told him that in his opinion it was possible, but that the working out of the mathematical problem would be a thing involving several months' hard work!

Although the calculations involved in discovering the defining quality, the curvatures of field, and the amount of astigmatism given by any lens are most difficult and complicated, there are some facts concerning lenses which are so easily understood and calculated, that it is wonderful they are not better known.

To take a couple of examples: the amount of depth of focus which a lens exhibits is absolutely fixed by the aperture of the lens, and by the focal length of the lens. It decreases as the aperture increases, and decreases as the focal length increases; any apparent departure from this rule being caused by differences in the maximum sharpness given, which may make it *appear* that with different lenses of the same aperture and focal length there are different depths of focus. This rule is absolute with our present knowledge of optics, and it appears likely that it may remain so, although it is dangerous to predict in such a case.

The rapidity of a lens depends on the ratio of the aperture to the focal length, increasing as the ratio increases. Assuming that the lenses are not stained, and making a very slight allowance for different degrees of concentration of the pencils of light between the front lens and the diaphragm, this law also holds absolutely true through a moderate angle.

We should not have thought it worth while to mention again these often repeated rules, but that in the discussion which followed Mr. Debenham's lecture, and in spite of the fact that Mr. Debenham had mentioned the rules in question

a member stated that he had an old portrait lens which exhibited extraordinarily more depth of focus than others of the same aperture and focal length, and that he had found that apertures and focal lengths bearing the same ratio to each other lenses of large diameter, were more rapid than those of small diameter.

DEATH OF THE REV. F. F. STATHAM.

On Tuesday morning, at about half-past seven, the venerable President of the South London Photographic Society breathed his last. As president of the South London Society, he has, by his universally kind and genial manner, won the affection of all, and numerous as have been the changes in the staff of the Society, we believe that during the twenty-five years of its existence, no proposal has ever been made to place any other person in the presidential chair. It was intended, as we have already announced, to hold a festival dinner of the Society at the Holborn Restaurant on Saturday, the 10th of May, in order to celebrate the twenty-fifth anniversary, and Mr. Statham, with his usual good nature, had promised to be present.

Mr. Statham was not informed that it was the intention of the members of the Society to present him with a memorial on this occasion, in the shape of a silver inkstand or some other article for the study table. As about thirty pounds has already been collected, it is proposed to collect such further subscriptions as may be offered, and to allow the memorial to take such a form as may be in accordance with the wishes of Mr. Statham's family.

Looking back into our volume for 1859, we find that at the first meeting of the South London Society, held on the 10th of May, Mr. A. H. Wall occupied the chair, but at the following meeting, held on the 9th of June, the following gentlemen were appointed as the officers of the Society:—*President*—Rev. F. F. Statham; *Vice-President*—Mr. W. Ackland; *Treasurer*—Mr. F. Howard; *Hon. Secretary*—Mr. A. H. Wall; *Committee*—Messrs. Cotton, Clarke, Herve, Hannaford, Leake, sen., and Leake, jun.

SOME *INTERIM* NOTES ON THE COLOUR SENSITIVENESS OF GELATINE EMULSION.

BY DR. J. M. EDER.

Some experiments I have recently made in a Steinheil's spectrograph with bromide and bromo-iodide gelatine plates have given me a few results which I think may be put on record, inasmuch as a good deal of attention has recently been given to the particular subject of which they treat. I will be very brief in what I have to say. Bromo-iodide of silver, in which the iodide and bromide of silver are emulsified and digested together, is more sensitive to green and yellow rays than pure bromide of silver. A mixture of one molecule of iodide of silver and eight to twenty molecules of bromide of silver is possessed of great colour sensitiveness.

Pigments act differently as optical sensitizers according as they are wet or dry when exposed with bromide or bromo-iodide of silver. For instance, fluorescein with soda, exposed wet, shows great sensitiveness for light-green and yellow-green, giving a dark absorption band; in a dry state, on the other hand, it has little effect.

Acid fuchsine and fluorescent blue raises the sensitiveness of the film for blue rays. Eosine alone has but little effect; but eosine with ammonia, whether used wet or dry, increases the sensitiveness for yellow and yellow-green. The plates produced by Attout and Clayton, of Paris, are prepared with brom-eosine; iod-eosine plates, which do not seem to have been experimented upon, will be found to exhibit this increased sensitiveness to a more marked degree still.

Braun, of Dornach, has recently brought out commercially a collodion, for the wet process, which is apparently treated with eosine, and which produces colours by photography, if not actually in their true light, at any rate with more truth than ordinary collodion gives. Hanfstaengel, of Munich, also, we believe, employs a similar method for reproducing paintings.

I have recently received from Dr. H. W. Vogel, of Berlin, a photograph of a picture coloured with yellow, blue, and gold pigments, which photograph most admirably reproduces the yellow lighter than the blue. So that altogether we seem to be making great progress towards perfection in photographing coloured objects.

At Home.

M. JEAN GEISER IN THE RUE BABAZOUN, ALGIERS.

There are certainly two studios of first class order in Algiers, if not more, for the capital of Algeria attracts the élite of Europe, and every winter a migration of fashionable and wealthy visitors sets in, swallow-like, towards this sunny seaport of the Mediterranean. From every section of Europe they come, but chiefly from France and England, some following doctors' advice to seek a milder climate, some simply following their own sweet will to escape a foggy November or drizzling February. Thus a favourite winter resort of well-to-do people, its handsome shops, and cafés, and theatres flourish exceedingly, and there is little doubt that for many years to come the town will increase in wealth and importance.

The two studios to which we specially refer are those of MM. Klary et Poter and of M. Jean Geiser. M. Klary, a name well-known to our readers, has for some time quitted Algiers; but still, for his sake, we resolved to pay his former studio a visit first of all. Unfortunately M. Poter was "très occupé" when we presented our card, although good enough to send a message that if we called again he would be happy to see us. So we promised we would call again; and when next we feel inclined for a trip of three thousand miles, and our fancy lead us Algiers-wards, we hope to become further acquainted with the studio.

In the meantime it was best, we thought, to bend our steps toward M. Geiser's establishment, and accordingly passed under the old-fashioned colonnades of the Rue Babazoun to where the studio is located. M. Jean Geiser follows the example of his Parisian brethren, and takes care to exhibit some pleasing pictures in various parts of the town. His show cases are exceedingly smart and fine, and the specimens of his work are of a quality that begets confidence in the photographer forthwith. But he makes this mistake; at the studio itself the examples of portraiture he exhibits are not only less attractive, but are exhibited in a less attractive manner. That is to say, when we entered and desired to have a portrait taken, instead of a series of choice examples being already set out for our edification, these had to be taken from certain japanned boxes. Not only are cartes and cabinets scarcely seen at their best in these circumstances, but since they get handled and shuffled over and over again, it is impossible to keep them fresh and attractive. No doubt they answer the purpose very well of patterns, but it would be far better to have them in cases or frames, where they are set out to advantage, and where there is no need to touch them. Soiled pictures discourage the customer a good deal, and although we freely admit that the specimens put into our hands were bright and fresh enough, it is impossible, in these circumstances, to keep them so. Still we prefer these japanned cases to dirty thumbed albums, which many studios have on the reception room table.

Algiers prices are Paris prices. For instance, in the studio of MM. Klary et Poter, the cost of a dozen cartes is 25 francs, and for a dozen cabinets 50 francs, panels being at the rate of 40 francs for the first copy, and 100 francs for

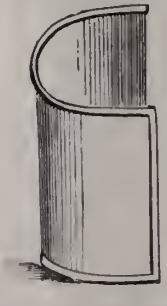
half-a-dozen. M. Jean Geiser charges also 25 francs a dozen for his best cartes, which are satinées, and for his cabinet pictures 30 or 50 francs according as they are plain or enamelled. But then we must admit that the work is quite equal to the best Paris work, and warmer praise it would be difficult to bestow.

We choose cabinet pictures, and are forthwith led up stairs into the studio. An assistant takes charge and demands a little more information. Would we like the portrait highly finished as in the specimen? We would. Would we like a picture with a large bold head? Certainly. Would we like to be taken in Arab costume? We would like, so we give our companion to understand, everything we can get; and, laughingly, the assistant invites entrance into a retiring room beside the studio to make our toilet.

This is a lovely little boudoir. There are soft Persian rugs on the floor, gilded furniture, luxurious settees, rich drapery of Turkey red, and handsome mirrors. Off come coat and waistcoat, and then our friend begins to robe us magnificently in strange and complicated vestments. We are wound round the body and head with drapery and sheeting, a bead necklace is put about the neck, and a sort of yarn twisted many times around the skull. It is rather hot, and uncomfortable, and stuffy all this, but one can well afford to suffer a little, to be surrounded by such pomp and circumstance. But just another word of approval on the subject of the retiring room before we quit it; the little room was not only one of the most brilliant and elegantly-appointed boudoirs we have ever seen, but its convenient position in respect to the studio enhanced its value to the visitor fourfold.

The studio is a blue studio. That is to say, its walls are blue, and it is glazed with blue glass. Of course there is plenty of light in a spot like Algiers, and therefore this little modification in the illumination is probably welcome. Moreover, a very small proportion of the studio only is glazed; it may be likened to a room with a very large window on one side, except that there is a sloping roof of ground glass just above the window, the latter rising from about six inches from the floor, and being eleven feet square. There are curtains to screen the blue glass, but this is bare opposite the sitter; still, the light is not permitted to pass straight to the model. Between him and the window is a delicate screen of blue tarlatan, which seems to soften the light without apparently weakening it. This screen is simply a folding frame (like a clothes horse), measuring 7 feet by 4 feet, with a double thickness of blue tarlatan stretched over it. Something of the same kind we have seen in Mr. Slingsby's studio in Lincoln, that gentleman employing, instead of blue tarlatan, a gauze of fine white muslin.

M. Geiser's favourite background is one of grey cloth of alcove formation. This is about six feet high, and measures



the same across. The cloth is simply nailed top and bottom to hoop-like frames of a solid character, so that it has no fastening, and is therefore perfectly smooth, where it acts as background. As we have said, the top light comes through ground glass, but a large white banner screen, measuring 30″ by 20″ is brought into requisition above the head of the sitter. For a cabinet portrait we sat five seconds, so that the illumination was not very strong; as our dress had a great deal of white about it, no doubt M. Geiser preferred not to have a very short exposure. The camera and camera-stand were exceedingly stable, the latter being of iron.

M. Geiser himself does not make his appearance until the last moment. The assistant goes on with the work by himself until the moment actually arrives for exposure, when the principal is called. The latter, however, is not by any means disposed to take things as he finds them. Although he very quietly expresses approval, admiringly saying, "La pose est très bien; mais c'est très bien," he nevertheless proceeds to change most of the details. He both re-arranges the posture and alters the lighting, taking great pains as to the pose of the head and the fall of the drapery. In a word, he not only impresses the sitter with the fact that he is doing his best, but that he is doing it with heart and soul.

We are rather a troublesome model, neither patient nor steady, and albeit his words express satisfaction, we feel we are giving a world of trouble. The head will droop, no matter how firm we mean to be, and when at last M. Geiser appears to be satisfied, the wretched turban seems to be gradually but surely falling off behind. However, all's well that ends well, and the result, it must be admitted, is an excellent one. In fact, we do not know that we have ever sat for a better picture.

"Will you be good enough to leave your name at the bureau?" is the request, as we are bowed out of the studio. We descend and make our way to the office, where we find a gentleman ready to book the order. "On est prié de regler la moitié de la somme d'avance," says a neat little placard over the desk, intimating that half the amount of the order is to be deposited; but as, in our case, there might be some difficulty in forwarding the other half, we tender the whole payment at once. It is some time before the man of business can understand this, but when he does he is very anxious our name may be properly booked—so anxious, indeed, that he thinks it is not spelt correctly on the card we tender him, and therefore proceeds to alter a D into a T to make it conform better to his ideas of it.

The time occupied in booking, making out the account, and paying, suffices amply to permit the negative being developed, and allows the photographer to make sure the photograph is a good one before the visitor departs. It is a much better arrangement than keeping him waiting in the studio, for it economises his time—which is often of value, notwithstanding many photographers' view of it—and also does away with the purposeless waiting to which sitters are unfortunately subject. Finally, the plan impresses the sitter with the idea that the studio is well governed, and that the photographer knows his business. This is the lesson to be learnt from an African studio.

THE SPECTROSCOPE AND ITS RELATION TO PHOTOGRAPHY.

BY C. RAY WOODS.

VI.—The Reducing Action of the Spectrum on the Haloid Salts of Silver, etc., applied to the Making and Working of Sensitive Films.—*Continued.*

In considering the relative values of the different haloid salts of silver for ordinary photographic purposes, the question arises—"What rays can we most conveniently work with?" There can be no question as to what rays would be most suitable, if we could get a good ground for them to act upon, for since the yellow rays have the greatest effect upon the eye, the photographer would obtain results more nearly approaching to what we see in nature by using a medium more sensitive to that part of the spectrum than to any other. But, as he knows full well, these rays have an almost inappreciable effect upon

the substances he finds most readily workable. Taking the three compounds, chloride, bromide, and iodide of silver, and arguing from theory alone, the choice lies between the two first. Could iodide of silver be obtained in an emulsion in a readily developable condition, it possesses a great drawback in its comparatively small range of sensibility to the spectrum. The fact that its sensitiveness ends abruptly in the dark blue near G would place it out of the competition unless it could be rendered very sensitive indeed, and though it extends lower in the spectrum when sensitized by nitrate of silver, it will be readily seen what an advantage was gained in the wet process by the addition of bromide to the collodion. Chloride of silver is sensitive almost as low down as bromide, but its maximum of sensitiveness is in the ultra violet. Now since the ultra violet rays are largely absorbed both by the atmosphere and by glass, there can be no doubt, theoretically, that the practical man is doing right by making bromide of silver the corner stone of his industry. In bromide of silver he has a substance possessing a great range of sensitiveness, and he is using rays the quantity of which can be to some extent estimated by the eye. Chloride and iodide of silver can both be added to emulsions with advantage, but they must occupy only a secondary place. Chloride of silver, which is not so often present in a film as it might usefully be, will be found to confer a great increase in sensitiveness in summer weather, and for work in tropical climates is an invaluable addition to plates used for so-called instantaneous exposures.

The writer has found that emulsions containing about ten per cent. of chloride and three to five per cent. of iodide, whilst possessing at home all the good qualities of a slow working plate, latitude in exposure, density, &c., have been found to be more rapid in the tropics than many plates which he has regarded as highly sensitive at home. It is a moot question whether chloride of silver should be added to a bromide of silver emulsion after boiling, or should be emulsified at the same time and boiled with it. Adding the chloride emulsion after boiling would appear to be the best method of procedure, for this reason—that chloride of silver cannot be boiled as long as the bromide without running the danger of fogging it. It would seem advisable, therefore, to make an ordinary bromide or bromide and iodide emulsion first, raise it to the highest possible degree of sensitiveness, and then add the desired quantity of a chloride emulsion that has received as much boiling as it will stand, and will give a clean transparency with ferrous-citro-oxalate developer. There is still the question whether chloride and bromide of silver when emulsified together form a double molecule? But if so, this cannot greatly affect the result, for the double molecule is, in the other case, formed during exposure. One disadvantage in the addition of chloride may be mentioned here, though it does not come directly within the scope of these articles—viz., that with the alkaline developer one runs a greater risk of green fog, and the ferrous-oxalate has to be used for safety's sake.

The use of iodide in an emulsion in anything like the small proportion usually adopted is rather a question for the emulsion maker than the spectroscopist. When present in a small proportion, it has many beneficial effects—notably, cleanness in working, latitude in exposure, and prevention of halation. Emulsions should not contain more iodide than is found sufficient to produce these effects; five per cent. will generally be found sufficient, and at most it is hardly advisable to go beyond eight per cent. Even with this small proportion, there is, according to Captain Abney, a slight loss of sensitiveness near G, although the emulsion itself may be quite as sensitive in the camera as one of pure bromide. Where a large proportion of iodide is used, the image obtained is usually thin. Another advantage in favour of a small percentage of iodide is, that it lowers the sensitiveness of the emulsion towards the red, and enables one to work with a brighter light in the developing room; and as the sensitiveness of a gelatino-bromide plate to the less refrangible rays is very small as compared with its sensitiveness to the blue rays, an advantage is met with in actual practice by doing away with the sensitiveness to the yellow and red altogether, if possible. The general opinion is, that iodide is best emulsified after the bromide and before boiling, in order to get as fine a state of division as possible; and though an emulsion containing iodide takes longer in the boiling process than one of pure bromide, quite as high a sensitiveness may be obtained, with less danger of over-boiling.

In considering the behaviour of different substances when exposed to the spectrum, there is one point which must not be overlooked; this is, the relation existing between the colour of the substance and the rays which act upon it, or, in other words, the relation between absorption and work. The best illustration of this that can be given is the case of some transparent medium such as an alkaline bichromate. In the accompanying diagram, taken from a transparency kindly lent me by Captain Abney, and shown by him at several of his lectures, it will be seen that the rays which the bichromate absorbs are those rays which reduce it in the carbon printing process.

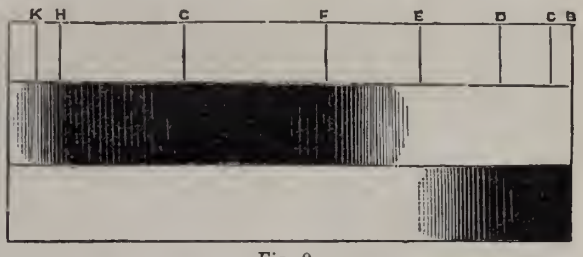


Fig. 9.

1. Fraunhoferic lines. 2. Spectrum on bichromate (carbon tissue) 3. Rays bichromate allows to pass through.

With the haloid salts of silver, this relation of absorption to work is not quite so noticeable, as, instead of a transparent substance, we have a number of semi-opaque particles, and a certain amount of white light passes through in addition to that rejected by the particles. Nevertheless, the absorption of light in the parts of the spectrum which act on the sensitive film is sufficiently marked to render prominent the distinctions between chloride, bromide, and iodide of silver.

It has been shown (fig. 8, Nos. 1 and 2) that in the case of chloride we can have it in two states, yellow and bluish-grey, the former being unboiled, and the latter the boiled. Iodide can also be obtained in two corresponding states, but the effect of heat can best be studied with bromide of silver, for the simple reason that we know more about it. The increase in sensitiveness is usually regarded as a consequence of the increase in the size of the particles brought about by boiling; the boiling may be carried, so far, however, as to produce a very coarse—almost insensitive—form. There are several different states in which bromide of silver can be obtained, but the differences are in some cases not so marked spectroscopically as they are to the eye.

We have, in the first place, the orange form of bromide; on boiling, or by the ammonia process, this is converted into a bluish grey, perfectly distinct to the eye. When acted upon by the spectrum, and developed, however, it is found that there is very little difference in them after all, the boiling having been mainly instrumental in rendering the compound more sensitive; the maximum remains the same, but the blue-grey form extends further towards the red. It does not appear likely, therefore, that we shall be able successfully to borrow an idea from the Bessimer steel process, and see, by the spectroscope, when our emulsion is sufficiently cooked; for if the light passing through a boiled and an unboiled emulsion be examined

by the spectroscope, it will be found that the cooked bromide derives its bluish tint from a small amount of orange-red and red light which it absorbs over and above its absorption when unboiled. The eye-test without the spectroscope will be found the best guide.

It is still a moot question whether silver bromide in gelatine differs from the same salt suspended in collodion. Spectroscopically, the difference is not very noticeable, but with the previously-mentioned example showing what a contrast to the eye a slight difference in absorption may produce, this cannot be allowed much weight. On various grounds, given at length in the PHOTOGRAPHIC NEWS, Dr. Vogel draws a marked distinction between the two, calling the silver bromide in gelatine the blue-sensitive form as distinct from indigo-sensitive, the term he applies to silver bromide in collodion. According to Dr. Vogel, the sensitiveness of modern dry plates is due to the blue-sensitive form becoming considerably more sensitive on boiling than the indigo-sensitive form. It must be noted here, that Dr. Vogel is careful to use the terms *blue-sensitive* and *indigo-sensitive*, not *blue* and *indigo*, the term *blue-sensitive* applying as much to the boiled as the unboiled bromide of silver in gelatine; the term indigo-sensitive has a similar application, referring to the point in the spectrum at about which the maximum comes.
