ANATOMY

DESCRIPTIVE AND SURGICAL

BY

HENRY GRAY, F.R.S.

FELLOW OF THE ROYAL COLLEGE OF SURGEONS
LECTURER ON ANATOMY AT ST GEORGE'S HOSPITAL MEDICAL SCHOOL

THE DRAWINGS BY H. V. CARTER, M.D.

LATE DEMONSTRATOR OF ANATOMY AT ST GEORGE'S HOSPITAL

WITH ADDITIONAL DRAWINGS IN LATER EDITIONS

FOURTEENTH EDITION

EDITED BY

T. PICKERING PICK

SENIOR SURGEON TO ST GEORGE'S HOSPITAL; SENIOR SURGEON VICTORIA HOSPITAL FOR CHILDREN
H.M. INSPECTOR OF ANATOMY IN ENGLAND AND WALES

LONGMANS, GREEN, AND CO.

TO

SIR BENJAMIN COLLINS BRODIE, BART.

F.R.S., D.C.L.

SERJEANT-SURGEON TO THE QUEEN

CORRESPONDING MEMBER OF THE INSTITUTE OF FRANCE

THIS WORK IS DEDICATED

IN ADMIRATION OF

HIS GREAT TALENTS

AND IN REMEMBRANCE OF

MANY ACTS OF KINDNESS SHOWN TO THE AUTHOR

FROM AN

EARLY PERIOD OF HIS PROFESSIONAL CAREER

PREFACE

TO

THE FOURTEENTH EDITION

IN this edition the whole work has undergone a careful revision, and in some parts sections have been almost entirely re-written. Many new illustrations have been added, and in some places old illustrations have been eliminated and have been replaced by others.

In connection with the Peritoneum, it was thought that the description of its complex folds would be rendered more intelligible by studying its simple primitive type in the embryo and by describing its development. The Editor has therefore availed himself of the pen of Dr. Fred. T. Brockway, Assistant Demonstrator of Anatomy, College of Physicians and Surgeons, (Columbia University) New York, who has written a very clear and concise account of the Development of the Peritoneum, which was published in the last issue of the American edition of this work. This the Editor, by the kind permission of Messrs. Lea Brothers & Co., of Philadelphia, has introduced into the present edition.

It is hoped that this edition will maintain the reputation which the work has for so many years enjoyed.

CONTENTS

GENERAL ANATOMY

	PAGE
The Blood	1
The Lymph and Chyle	6
The Animal Cell	7
Epithelium	12
Connective Tissues	15
Adipose Tissue	20
Pigment	21
Cartilage	21
White Fibro-cartilage	23
Yellow or Reticular, Elastic Cartilage	24
Bone	25
Development of Bone	30
Muscular Tissue	35
Striped Muscle	36
Unstriped Muscle	39
Nervous Tissue	40
The Brain	44
The Nerves	45
The Sympathetic Nerve	46
Origin and Termination of Nerves	47
The Ganglia	50
The Vascular System	51
The Arteries	52
The Capillaries	54
The Veins	55
The Lymphatics	57
The Lymphatic Glands	58
The Skin and its Appendages	61
The Nails	64
The Hair	64
The Sebaceous Glands	66
The Sudoriferous Glands	66
Serous Membranes	68
Synovial Membranes	69
Mucous Membranes	69
Secreting Glands	70

DEVELOPMENT

Origin and Development of the Body	72
The Ovum	72
Fertilisation of	74
Segmentation of	74
Blastodermic Membrane	76
First Rudiments of the Embryo	79
Formation of Membranes	84
The Amnion	84
The Chorion	85
The Allantois	85
The Decidua	86
The Placenta	87
Development of the Embryo	88
The Spine	88
The Ribs and Sternum	90
The Cranium and Face	90
The Nervous Centres	93
The Nerves	96
The Eye	97
The Ear	99
The Nose	100
The Skin, Glands, and Soft Parts	100
The Limbs	100
The Muscles	101
The Blood-vascular System	101
Vitelline Circulation	101
Placental Circulation	103
The Alimentary Canal and its Appendages	108
The Respiratory Organs	110
The Urinary Organs	110
The Generative Organs	112
Ovary	113
Testicle	113
External Organs	115
Chronological Tables of the Development of the Fœtus	117

THE SKELETON

The Skeleton	119
Number of the Bones	119
Form of Bones	119
The Spine	
General Characters of a Vertebra	120
Characters of the Cervical Vertebræ	121
Atlas	122
Axis	124
Seventh Cervical	125
Characters of the Dorsal Vertebræ	125
Peculiar Dorsal Vertebræ	127
Characters of the Lumbar Vertebræ	127
Structure of the Vertebræ	129
Development of the Vertebræ	129
Atlas	130
Axis	130
Seventh Cervical	131
Lumbar Vertebræ	131
Progress of Ossification in the Spine	131

272. Costo-transverse Articulation . . . . . *Arnold* 324
273. Diagrams showing the Axis of Rotation of the Ribs in the movements of Respiration . . . . . *Kirke* 325
274. Chondro-sternal, Chondro-xiphoid, and Inter-chondral Articulations, anterior view 327
275. Articulations of Pelvis and Hip, anterior view 329
276. Articulations of Pelvis and Hip, posterior view 330
277. Side View of Pelvis, showing greater and lesser Sacro-sciatic Ligaments . 331
278. Vertical Section of the Symphysis Pubis 333
279. Sterno-clavicular Articulation 335
280. Shoulder-Joint, Scapulo-clavicular Articulations, and proper Ligaments of Scapula 337
281. Vertical Section through the Shoulder-Joint . . . . *Henle* 340
282. Left Elbow-Joint, showing anterior and internal Ligaments . . . 344
283. Left Elbow-Joint, showing posterior and external Ligaments . . . 344
284. Sagittal Section of the Right Elbow-Joint . . . . *Braune* 345
285. Ligaments of Wrist and Hand, anterior view . . . *Arnold* 349
286. Ligaments of Wrist and Hand, posterior view . . . *do.* 350
287. Longitudinal Section of Forearm and Hand . . . *Braune* 351
288. Vertical Section of Wrist, showing the Synovial Membranes . . . 355
289. Articulations of the Phalanges 356
290. Left Hip-Joint, laid open 358
291. Ilio-femoral Ligament . . . . . *Bigelow* 359
292. Vertical Section through Hip-Joint . . . . . *Henle* 359
293. Muscles in relation with Hip 360
294. Right Knee-Joint, anterior view 364
295. Right Knee-Joint, posterior view 364
296. Right Knee-Joint, showing internal ligaments 365
297. Head of Tibia, with Semilunar Cartilages, seen from above . . . 366
298. Longitudinal Section through Knee-Joint . . . . *Braune* 367
299. Posterior Surface of the Patella 369

FIG. PAGE
300. Ankle-Joint, Tarsal and Tarso-metatarsal Articulations, internal view . . 373
301. Ankle-Joint, Tarsal and Tarso-metatarsal Articulations, external view . . 374
302. Section of Right Foot . . . . . *Braune* 375
303. Ligaments of Plantar Surface of the Foot 378
304. Synovial Membranes of the Tarsus and Metatarsus . . . *Arnold* 382

MUSCLES AND FASCIÆ

305. Plan of Dissection of the Head, Face, and Neck 387
306. Muscles of the Head, Face, and Neck 388
307. Horner's Muscle 391
308. Muscles of the Right Orbit 393
309. The relative position and attachment of the Muscles of the Left Eyeball . 394
310. The Temporal Muscle 401
311. The Pterygoid Muscles 402
312. Cervical Fascia 405
313. Muscles of the Neck, and Boundaries of the Triangles 408
314. Muscles of the Neck, anterior view . . . . . *Quain* 410
315. Muscles of the Tongue, left side 414
316. Muscles of the Tongue, from below 415
317. Muscles on the Dorsum of the Tongue 415
318. Coronal Section of Tongue . . . . *Altered from Krause* 416
319. Muscles of the Pharynx, external view 418
320. Muscles of the Soft Palate 420
321. The Prevertebral Muscles . . . . . *Quain* 423
322. Muscles of the Neck 425
323. Plan of Dissection of the Muscles of the Back 427
324. Muscles of the Back—first, second, and part of the third layer . *Quain* 428
325. Muscles of the back—deep layers 433
326. Posterior Surface of Sternum and Costal Cartilages 442
327. The Diaphragm, under surface 443
328. Plan of Dissection of Abdomen 447
329. The External Oblique Muscle 448
330. The Internal Oblique Muscle 451
331. The Transversalis, Rectus, and Pyramidalis 454
332. Transverse Section of Abdomen in Lumbar Region . . . *Quain* 455
333. Side View of Pelvis, showing Levator Ani 460
334. The Perinæum 461
335. The Muscles attached to the front of the Pelvis 462
336. Superficial Muscles and Vessels of the Perinæum 463
337. Triangular Ligament or Deep Perineal Fascia 464
338. Muscles of Female Perinæum 466
339. Plan of Dissection of Upper Extremity 468
340. Muscles of the Chest and Front of the Arm, superficial view 469
341. Muscles of the Chest and Front of the Arm, with the boundaries of the Axilla . 471
342. Serratus Magnus 472
343. Muscles on the Dorsum of the Scapula and the Triceps 476
344. Front of the Left Forearm, superficial muscles 483
345. Front of the Left Forearm, deep muscles 484
346. Posterior Surface of Forearm, superficial muscles 487
347. Supinator Brevis 490
348. Posterior Surface of Forearm, deep muscles 490
349. Transverse Section through the Wrist, showing the Annular Ligaments and the Canals for the passage of the Tendons 492
350. Transverse Section through Carpus . . . . . *Henle* 493
351. Diagram showing the arrangement of the Synovial Sheaths of the Palm and Fingers 493
352. Palmar Fascia 494
353. Muscles of Thumb 496
354. Muscles of the Left Hand, palmar surface 498
355. Dorsal Interossei of Left Hand 500

FIG.		PAGE
356.	Palmar Interossei of Left Hand	500
357.	Fracture of the Middle of the Clavicle *Hind*	503
358.	Fracture of the Surgical Neck of the Humerus *do.*	504
359.	Fracture of the Humerus above the Condyles *do.*	504
360.	Fracture of the Olecranon *do.*	505
361.	Fracture of Shaft of the Radius *do.*	505
362.	Fracture of the Lower End of the Radius *do.*	506
363.	Plan of Dissection of Lower Extremity, front view	510
364.	Muscles of the Iliac and Anterior Femoral Regions	511
365.	Muscles of the Internal Femoral Region *Quain*	516
366.	Plan of Dissection of Lower Extremity, posterior view	519
367.	Muscles of the Hip and Thigh	520
368.	Obturator Externus Muscle	523
369.	Muscles of the Front of the Leg	526
370.	Muscles of the Back of the Leg, superficial layer	529
371.	Muscles of the Back of the Leg, deep layer	531
372.	Muscles of the Sole of the Foot, first layer	537
373.	Muscles of the Sole of the Foot, second layer	538
374.	Muscles of the Sole of the Foot, third layer	539
375.	Dorsal Interossei	540
376.	The Plantar Interossei	540
377.	Fracture of the Neck of the Femur within the Capsular Ligament *Hind*	543
378.	Fracture of the Femur below the Trochanters *do.*	544
379.	Fracture of the Femur above the Condyles *do.*	544
380.	Fracture of the Patella *do.*	544
381.	Oblique Fracture of the Shaft of the Tibia *do.*	544
382.	Fracture of the Fibula with Dislocation of the Foot outward (Pott's fracture) *do.*	545

ARTERIES

383.	The Arch of the Aorta and its Branches	548
384.	Plan of the Branches of the Arch of the Aorta	548
385.	Relations of Great Vessels at Base of Heart	551
386.	Superficial Dissection of the Right Side of the Neck, showing the Carotid and Subclavian Arteries	556
387.	Plan of the Branches of the External Carotid	556
388.	The Arteries of the Face and Scalp	563
389.	The Internal Maxillary Artery and its Branches	568
390.	Plan of the Branches of the Internal Maxillary Artery	568
391.	The Internal Carotid and Vertebral Arteries	576
392.	The Ophthalmic Artery and its Branches	578
393.	The Arteries of the Base of the Brain	579
394.	Vascular Area of the Internal Surface of the Cerebrum *Charcot*	580
395.	Distribution of Middle Cerebral Artery *do.*	582
396.	Diagram of the Arterial Circulation at the Base of the Brain *do.*	583
397.	Distribution of the Cortical Arteries *do.*	584
398.	The Subclavian Artery, showing its relations	588
399.	Plan of the Branches of the Right Subclavian Artery	591
400.	The Scapula and Circumflex Arteries	595
401.	Internal Mammary Artery and its Branches	597
402.	The Axillary Artery and its Branches	599
403.	The Brachial Artery	606
404.	The Radial and Ulnar Arteries	609
405.	Ulnar and Radial Arteries, deep view	612
406.	Arteries of the Back of the Forearm and Hand	615
407.	The Abdominal Aorta and its Branches	620
408.	The Cœliac Axis and its Branches, the Liver having been raised, and the Lesser Omentum removed	623
409.	The Cœliac Axis and its Branches, the Stomach having been raised, and the Transverse Mesocolon removed	624
410.	The Superior Mesenteric Artery and its Branches	626

FIG.			PAGE

452.	Longitudinal Section of Cord	*do.*	722
453.	Transverse Section through the White Matter of the Cord	*Klein and Noble Smith*	722
454.	Medulla Oblongata and Pons Varolii, anterior surface		728
455.	Posterior Surface of Medulla Oblongata		730
456.	Section of the Medulla Oblongata	*Schwalbe*	732
457.	Superficial Dissection of the Medulla and Pons	*Ellis*	735
458.	Upper Surface of the Brain, the Arachnoid having been removed		736
459.	Convolutions on the Outer Surface of the Cerebral Hemisphere		737
460.	Convolutions of the Orbital Lobe		740

FIG.		PAGE
461.	Convolutions on the Inner Surface of the Cerebral Hemisphere	741
462.	Side View of the Brain, showing the localisation of the various functions *Ferrier*	742
463.	Top view of the Brain, showing the localisation of the various functions *do.*	743
464.	Cranio-cerebral topography *Macalister*	745
465.	Cranio-cerebral topography *Reid*	746
466.	Base of the Brain	747
467.	Section of the Brain, made on a level with the Corpus Callosum	752
468.	The Lateral Ventricles of the Brain	753
469.	Horizontal Section through Cerebrum *Ellis*	754
470.	Transverse Vertical Section of the Brain *After Hirschfeld and Leveillé*	755
471.	Transverse Section of the Middle Horn of the Lateral Ventricle	756
472.	The Fornix, Velum Interpositum, and middle or descending Cornu of the Lateral Ventricle	758
473.	The Third and Fourth Ventricles	760
474.	Vertical Median Section of Encephalon, showing the parts in the middle line *After Sappey*	761
475.	Grey Matter of the Cerebral Cortex *Meynert*	765
476.	Upper Surface of the Cerebellum	769
477.	Under Surface of the Cerebellum	770
478.	Vertical Section of the Cerebellum *Arnold*	771
479.	Vertical Section through Grey Matter of Cerebellum *Klein and Noble Smith*	773
480.	A Corpuscle of Purkinje *do.*	774
481.	Floor of the Fourth Ventricle	775

CRANIAL NERVES

482.	The Optic Nerves and Optic Tract	778
483.	Course of the Fibres in the Optic Commissure *Bowman*	778
484.	Nerves of the Orbit, seen from above *After Arnold*	780
485.	Plan of the Motor Oculi Nerve *After Flower*	780
486.	Nerves of the Orbit and Ophthalmic Ganglion, side view *After Arnold*	783
487.	Plan of the Fifth Cranial Nerve *After Flower*	785
488.	Distribution of the Second and Third Divisions of the Fifth Nerve and Submaxillary Ganglion *After Arnold*	787
489.	The Spheno-Palatine Ganglion and its Branches	789
490.	The Otic Ganglion and its Branches *After Arnold*	793
491.	Relation of Structures passing through Sphenoidal Fissure	796
492.	The Course and Connections of the Facial Nerve in the Temporal Bone *After Bidder*	797
493.	Plan of the Facial Nerve *After Flower*	799
494.	The Nerves of the Scalp, Face, and Side of the Neck	800
495.	Origin of the Glosso-pharyngeal, Pneumogastric, and Spinal Accessory Nerves, their Ganglia and Communications *Bendz*	802
496.	Plan of the Glosso-pharyngeal, Pneumogastric and Spinal Accessory Nerves *After Flower*	804
497.	Course and Distribution of the Glosso-pharyngeal, Pneumogastric, and Spinal Accessory Nerves	805
498.	Plan of the Hypoglossal Nerve *After Flower*	810
499.	Hypoglossal Nerve, Cervical Plexus, and their Branches	811

SPINAL NERVES

500.	Posterior Divisions of the Upper Cervical Nerves	815
501.	Plan of the Cervical Plexus	817
502.	Plan of the Brachial Plexus	821
503.	Cutaneous Nerves of Right Upper Extremity, anterior view	824
504.	Cutaneous Nerves of Right Upper Extremity, posterior view	824
505.	Nerves of the Left Upper Extremity, front view	825
506.	The Suprascapular, Circumflex, and Musculo-spiral Nerves	829
507.	The Posterior Branches of the Spinal Nerves *After Hirschfeld and Leveillé*	833

FIG.			PAGE
508.	Plan of the Lumbar Plexus		837
509.	The Lumbar Plexus and its Branches	*Altered from Quain*	838
510.	Cutaneous Nerves of the Lower Extremity, front view		840
511.	Nerves of the Lower Extremity, front view		840
512.	The Posterior Sacral Nerves	*Altered from Ellis*	844
513.	The Sacral Plexus and its Branches		846
514.	Cutaneous Nerves of the Lower Extremity, posterior view		848
515.	Nerves of the Lower Extremity, posterior view		848
516.	The Plantar Nerves		851
517.	The Sympathetic Nerve		855
518.	Plan of the Cervical Portion of the Sympathetic	*Flower*	857
519.	Lumbar Portion of Sympathetic	*Henle*	863

ORGANS OF SENSE

520.	Upper Surface of the Tongue		867
521.	The three kinds of Papillæ of the Tongue, magnified	*Bowman*	868
522.	Circumvallate Papillæ	*Stohr*	869
523.	Minute Structure of Taste Goblet		870
524.	Under Surface of Tongue, showing Glands of Blandin and Nuhn		870
525.	Under Surface of Tongue, showing Distribution of Nerves		871
526, 527.	Cartilages of the Nose	*Arnold*	874
528.	Bones and Cartilages of Septum of Nose, right side	*do.*	875
529.	Transverse Vertical Section of Nasal Fossæ	*Henle*	876
530.	Nerves of Septum of Nose, right side	*Arnold*	877
531.	A Horizontal Section of the Eyeball	*Allen*	881
532.	The Choroid and Iris, enlarged	*Altered from Zinn*	883
533.	The Veins of the Choroid, enlarged	*Arnold*	884
534.	The Arteries of the Choroid and Iris, the Sclerotic having been mostly removed, enlarged	*Arnold*	885
535.	Section of the Ciliary Region of the Eye	*Waldeyer*	886
536.	The Arteria Centralis Retinæ, Yellow Spot, &c., the anterior half of the Eyeball having been removed, enlarged		888
537, 538.	Vertical Sections of the Human Retina	*Frey*	889
539.	Layers of the Retina	*Altered from Schultze*	891
540.	The Crystalline Lens hardened and divided, enlarged	*Arnold*	893
541.	The Meibomian Glands, &c., seen from the inner surface of the Eyelids	*do.*	898
542.	The Lachrymal Apparatus, right side		899
543.	The Pinna, or Auricle, outer surface		902
544.	The Muscles of the Pinna	*Arnold*	903
545.	A Front View of the Organ of Hearing, right side	*Scarpa*	904
546.	View of Inner Wall of Tympanum, enlarged		906
547.	The Small Bones of the Ear, seen from the outside, enlarged	*Arnold*	908
548.	The Osseous Labyrinth, laid open, enlarged	*Sömmerring*	912
549.	The Cochlea, laid open, enlarged	*Arnold*	914
550.	The Membranous Labyrinth	*C. Stewart*	915
551.	Floor of Scala Media, showing the organ of Corti, &c.	*do.*	916
552.	Longitudinal section of the Cochlea	*do.*	917

ORGANS OF DIGESTION AND THEIR APPENDAGES

553.	Sectional View of the Nose, Mouth, Pharynx, &c.		922

GENERAL ANATOMY

THE **fluids** of the body, which are intended for its nutrition, are the lymph, the chyle, and the blood. There are other fluids also which partially subserve the same purpose, as the saliva, the gastric juice, the bile, the intestinal secretion; and others which are purely excrementitious, as the urine. But there is no need to describe the rest in this place, since they are the secretions of special organs, and are described, as far as is judged necessary for the purposes of this work, in subsequent pages. We shall here speak first of the blood, and next of the lymph and chyle.

THE BLOOD

The blood is a thickish, opaque fluid, of a bright red or scarlet colour when it flows from the arteries, of a dark red or purple colour when it flows from the veins. It is viscid, and has a somewhat clammy feeling; it is salt to the taste, and has a peculiar faint odour. It has an alkaline reaction; its alkalinity varies in degree; it is greatest after a meal and least after severe muscular exertion. Its specific gravity at 60° F. is about 1·055, and its temperature is generally about 100° F., though varying slightly in different parts of the body.

General Composition of the Blood.—When blood is drawn from the body and allowed to stand, it solidifies in the course of a very few minutes into a jelly-like mass, which has the same appearance and volume as the fluid blood, and, like it, looks quite uniform. Soon, however, drops of a transparent yellowish fluid begin to ooze from the surface of this mass and to collect around it. Coincidently with this the clot begins to contract, so that, in the course of about twenty-four hours, the original mass of coagulated blood has become separated into two parts: a 'clot' or 'coagulum,' considerably smaller and firmer than the first-formed jelly-like mass, and a large quantity of yellowish fluid, the *serum*, in which the clot floats.

The clot thus formed consists of a solid, colourless material, called *fibrin*, and a large number of minute cells or corpuscles, called *blood-corpuscles*, which are entangled and enclosed in the fibrin. The fibrin is formed during the act of solidification. In the fluid blood in the living body there are two substances, named *fibrinogen* and *paraglobulin* or *serum globulin*, which may be termed fibrin-factors. These two materials, when withdrawn from the body, become acted upon by a third material, also contained in the blood, and named a *fibrin-ferment*, and unite together, forming a solid substance, *fibrin*. This latter in its process of solidification encloses and entangles the blood-corpuscles, and thus the clot is formed.

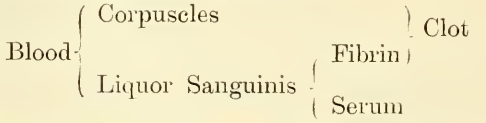
It must be stated, however, that recent observations have shown that, in the act of clotting outside the body, solutions of fibrinogen, on addition of fibrin-ferment, clot firmly, provided that the solution has a trace of a calcium salt. Consequently paraglobulin would not appear to be necessary for this process; it

18.

merely plays an accessory part, leading to the formation of a firmer and more abundant fibrin. The act of clotting outside the body, which is evidence of the death of the blood, is a process dissimilar to that which occurs inside the body. In the former case a body, fibrinogen, is acted upon by the fibrin-ferment, which appears only after the death of the white corpuscles. In the latter, intravascular clotting can be produced in two ways: (1) by directly stimulating living blood, as by the transfixion of an artery by a needle; or (2) by injection of proteid bodies, which contain lecithin, and which, when injected into the blood, kill in a few minutes by producing intravascular clotting. Further, injection of fibrin-ferment into the blood has negative results; and, again, addition of proteid and lecithin to blood, removed from the body, does not in any way affect the ordinary coagulation process.

We may now consider the constituents of the blood in another way. If a drop of blood is placed in a thin layer on a glass slide and examined under the microscope, it will be seen to consist of a number of minute bodies or corpuscles floating in a clear fluid; and, on more minute examination, it will be found that these corpuscles are of several kinds. Some, greatly preponderating in point of numbers, are termed *coloured corpuscles*; others, fewer in number and less conspicuous, are termed *colourless corpuscles*. From this we learn that blood is a fluid holding a large number of corpuscles of different varieties in suspension. The fluid is named *liquor sanguinis* or *plasma*, and must not be confused with the serum spoken of above in connection with the coagulation of the blood; for it differs from it in this important particular that it contains fibrinogen, while serum contains no fibrinogen.

The relation of these various constituents of blood to each other will be easily understood by a reference to the subjoined plan.



The **Blood-corpuscles.**—The bodies suspended in blood plasma are of three kinds: (1) Erythroblasts, (2) Chromocytes, (3) Leucocytes.

1. *Erythroblasts* are nucleated corpuscles, variable in size and containing hæmoglobin. They occur in the embryo, and in the adult are found in the spleen and red marrow, also in blood after excessive hæmorrhage.

2. *Chromocytes* comprise the ordinary non-nucleated red discs. They develop from erythroblasts, which lose their nuclei either by extrusion from the protoplasm or by solution in this substance. Blood-plates are minute chromocytes destitute of a nucleus in mammals, but possessing one in birds, fish, and amphibia.

3. *Leucocytes.* These are the colourless corpuscles. They multiply by division of the nucleus. The daughter cells are lymphocytes.

Coloured corpuscles (*chromocytes*) when examined under the microscope and viewed on the flat are seen to be circular, like a coin, and present a slight central depression, which sometimes appears as a dark centre surrounded by a light ring; but on altering the focus appears as a light centre surrounded by a dark ring. When viewed in profile, each corpuscle is seen to be cupped on both surfaces, presenting the appearance of a dumbbell. Hence, they may be described as biconcave discs (fig. 1). When examined singly by transmitted light, their colour appears to be of a faint reddish-yellow when derived from arterial blood, and greenish-yellow in venous blood. It is to their aggregation that blood owes its red hue. Their size varies slightly even in the same drop of blood, but it may be stated that their average diameter is about $\frac{1}{3200}$ of an inch, their thickness about $\frac{1}{12000}$, or nearly one-quarter of their diameter. Besides these, especially in some anæmic and diseased conditions, certain corpuscles are found of a much smaller size (*microcytes*), about one-third or

half the size of the ordinary one. These, however, are very scarce in normal blood. The number of red corpuscles in the blood is enormous; between 4,000,000 and 5,000,000 are contained in a cubic millimètre. Power states that the red corpuscles of an adult would present an aggregate surface of about 3,000 square yards. Human blood-discs present no trace of a nucleus. They consist of two parts: a colourless stroma, which is composed largely of fatty material, *lecithin* and *cholesterine*; and a coloured fluid contents, which is a solution of a substance named *hæmoglobin*. *Hæmoglobin* resembles a proteid in chemical constitution, but differs from it in containing iron in addition to the ordinary proteid constituents. It has a great affinity for oxygen, and when removed from the body crystallises readily under certain circumstances. It is readily soluble in water, and the addition of this fluid to a drop of blood speedily dissolves out hæmoglobin from the corpuscle.

If the web of a frog's foot is spread out and examined under the microscope, the blood is seen to flow in a continuous stream through the vessels, and the corpuscles show no tendency to adhere to each other or to the wall of the vessel. Doubtless the same is the case in the human body; but when drawn and examined on a slide without reagents, the blood-globules often collect into heaps like rouleaux of coins (fig. 1, *c*).

During life the red corpuscles may be seen to change their shape under pressure so as to adapt themselves to some extent to the size of the vessel. They

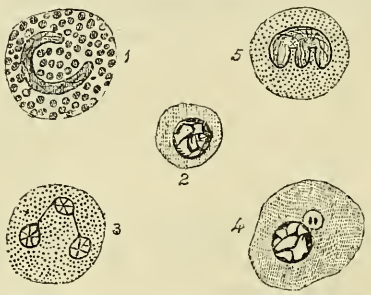
a. Seen from the surface. *b*. Seen in profile. *c*. United in rouleaux. *d*. Rendered spherical by water. *e*. decolorised by the same. *f*. Crenate or stellate red corpuscles.

Fig. 2.—Varieties of leucocytes found in human blood.



1. Eosinophile cell with coarse granules and horse-shoe shaped nucleus. 2. Lymphocyte. 3. Polynuclear or finely granular oxyphile cell. 4. Hyaline cell, showing nucleus with chromatin threads and two centrosomes in clear protoplasm. 5. Finely granular leucocyte; the nucleus is lobed, the granules stain with basic dyes, such as methylene blue.

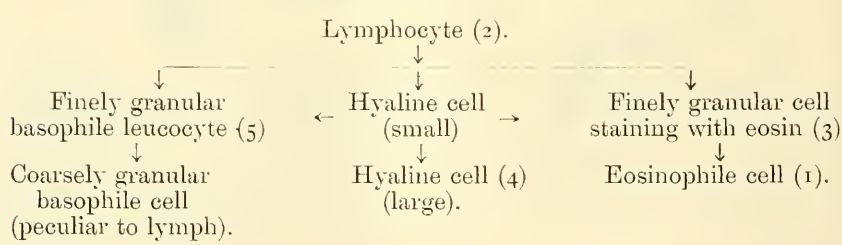
are also highly elastic, for they speedily recover their shape when the pressure is removed. They are soon influenced by the medium in which they are placed, and by the specific gravity of the medium. In water they swell up, lose their shape, and become globular; subsequently the hæmoglobin becomes dissolved out, and the envelope can be barely distinguished as a faint, circular outline. Solutions of salt or sugar, denser than the serum, give them a stellate or crenated appearance (fig. 1, *f*); and the usual shape may be restored by diluting the solution to the proper point. The same crenated outline may be produced as the first effect of the passage of an electric shock; subsequently, if sufficiently strong, the shock ruptures the envelope. A solution of salt or sugar of the same specific gravity as serum merely separates the blood-globules mechanically without changing their shape.

The **white corpuscles** (*leucocytes*) are of various sizes; some are no larger than the red corpuscles, and some are even smaller, but the majority are rather larger than the coloured ones in human blood, measuring from about $\frac{1}{2000}$ to $\frac{1}{2500}$ of an inch in diameter (fig. 2). They consist of a minute mass of nucleated protoplasm, and several varieties are met with in the blood. (1) The most

numerous and important are spherical in shape, and are characterised by a nucleus, which often consists of two or three parts, connected together by fine threads of chromatin. The protoplasm is clear and contains a number of very fine granules, which are only very faintly stained with acid dyes, as eosin (fig. 2, 3). (2) A leucocyte, characterised by the presence of a lobed nucleus and a protoplasm with fine granules which stain with basic dyes, such as methylene blue, is found constantly in the blood. These cells are very few in number (fig. 2, 5). (3) A third variety comprise about 2·4 per cent. of the leucocytes. They are larger than the previous kind, and are made up of a coarsely granular protoplasm, the granules being highly refracting particles, grouped together around a single nucleus. They are deeply stained with eosin, and are therefore often termed *eosinophile* cells. The nucleus is reniform or horse-shoe in shape (fig. 2, 1). (4) The fourth variety is called the *hyaline* cell. They are usually about the same size as the eosinophile cell, and when at rest are spherical in shape and contain a single round or oval nucleus. Their protoplasm is free from granules, but is not quite transparent, having the appearance of ground glass. About 2 per cent. of the leucocytes consist of this variety (fig. 2, 4). (5) The fifth kind of colourless corpuscle is designated the *lymphocyte* (fig. 2, 2), because it is identical with the lymphoid cell, which is derived from the lymphatic glands, the spleen, tonsil, and thymus. It is of small size, and consists chiefly of a spheroidal nucleus, with very little surrounding homogeneous protoplasm. It is regarded as the immature form of all the varieties of corpuscles met with in the blood.

The following scheme of Gulland illustrates the relations of the leucocytes to each other. The numbers refer to those of fig. 2.

Mitosis in Leucocytes



The white corpuscles are very various in shape in living blood, because they have the power of constantly changing it—that is to say, they have the power of sending out finger-shaped or filamentous processes of their own substance, by which they move and take up granules from the surrounding substance. In locomotion the corpuscle pushes out a process of its substance—a *pseudopodium*, as it is called—and then shifts the rest of the body into it (fig. 3). In the same

Fig. 3.—Human colourless blood-corpuscle, showing its successive changes of outline within ten minutes when kept moist on a warm stage. (Schofield.)

way, when any granule or particle comes in its way, it wraps a pseudopodium round it, and then withdrawing it, lodges the particle in its own substance. By means of these amœboid properties they have the power of wandering or emigrating from the blood-vessels, by penetrating their coats, and thus finding their way into the perivascular spaces.

In addition to these corpuscles, another variety is found in mammalian blood. These, as stated above, are minute chromocytes. They are pale circular or oval

discs, about one-quarter or one-third the size of the red blood-corpuscles, and apparently contain no nucleus. They have been named *blood-platelets* or *blood-plaques*, and are supposed by Bizzozero to originate the fibrin-ferment, and to be especially concerned in the coagulation of the blood.

The white corpuscles originate from lymphoid tissue generally—that is to say, from lymphatic glands, the spleen, and adenoid tissue—and the view was long maintained that they eventually became developed into red corpuscles; but no observations have ever been made which conclusively prove that this is so, and this theory must be regarded merely as a supposition.

The red corpuscles during embryonic life are developed from mesoblastic cells in the vascular area of the blastoderm. They are at first nucleated and resemble white corpuscles, except in their colour, and, like them, are possessed of amœboid movements. They are succeeded by smaller, non-nucleated corpuscles, having all the characters of adult coloured corpuscles, probably formed by a conversion of the former into the latter. So that at birth the nucleated red corpuscles have disappeared. In after life, an important source of the red corpuscles is the red marrow of bones, in which certain cells found in the marrow are converted into coloured blood-corpuscles by the loss of their nuclei, and by their protoplasm becoming tinged with yellow. A second source of the red corpuscles is believed by Hayem to be the blood-platelets, to which he gives the name of hæmatoblasts. It is probable, also, that the spleen may be a place for the formation of red corpuscles. This theory, which was formerly universally believed, and was then discarded for the hypothesis that the spleen was concerned in the destruction of the red corpuscles, has lately been revived by Bizzozero. The question must still be regarded as *sub judice*. The chief seats of the destruction of the red corpuscles in the adult are believed to be the spleen and the liver. The proportion of white corpuscles appears to vary considerably in different parts of the circulation, being much larger in the blood of the splenic vein and hepatic vein than in other parts of the body, while in the splenic artery they are very scanty.

The **liquor sanguinis** or **plasma** is the fluid part of the blood, and is composed of a permanently fluid portion, the *serum*, and of fibrinogen, which during coagulation becomes converted into or gives rise to fibrin. There is also another proteid in the plasma, and also to a small extent in the colourless corpuscles, named paraglobulin, which, however, is not an essential factor in coagulation. It can be obtained by diluting the liquor sanguinis with ten times its volume of ice-cold water, and then transmitting through it a stream of carbon-dioxide. Fibrinogen may be obtained in the same way as paraglobulin, but the liquor sanguinis must be still further diluted and the current of carbon-dioxide must pass for a much longer time. Fibrin may be obtained by whipping the blood, after it has been withdrawn from the body, with a bundle of twigs, to which the fibrin, as it coagulates, adheres. Fibrin may also be obtained by filtering the freshly drawn blood of an animal whose corpuscles are large, care being taken to retard coagulation as long as possible. Under these circumstances the corpuscles are retained on the filter, and the liquor sanguinis, passing through, coagulates and separates into fibrin, free from corpuscles, and serum.

Fibrin, thus obtained, is a white or buff-coloured substance, presenting a stringy appearance, and under the microscope exhibiting fibrillation. When exposed to the air for some time, it becomes hard, dry, brown, and brittle. It is a proteid compound, insoluble in hot or cold water, alcohol or ether. Under the influence of dilute hydrochloric acid it swells up, but does not dissolve; but when thus swollen it is easily dissolved by a solution of pepsin. If heated for a considerable time in a solution of dilute hydrochloric acid, it gradually dissolves.

Serum differs from liquor sanguinis in that it contains no fibrinogen. It is a straw-coloured fluid, having a specific gravity of 1·027, with an alkaline reaction. Upon boiling it becomes solid, on account of the albumen which it contains. It contains also salts, fatty matters, sugar, and gases.

Gases of the Blood.—When blood is exposed to the vacuum of an air-pump, about half its volume is given off in the form of gases. These are carbon-dioxide, oxygen, and nitrogen. The relative quantities in 100 volumes of arterial and venous blood, at 0° C. and 1 m. pressure of mercury, are shown in the accompanying table:

	Oxygen	Carbon-dioxide	Nitrogen
Arterial blood . .	16 vols.	30 vols.	1 to 2 vols.
Venous blood . .	6 to 10 vols.	35 vols.	1 to 2 vols.

Roughly stated they are as follows: Carbon-dioxide about two-thirds of the whole quantity of gas, oxygen rather less than one-third, nitrogen below one-tenth (Huxley). The greater quantity of the oxygen is in loose chemical combination with the hæmoglobin of the blood-corpuscles as oxyhæmoglobin, but some part is simply absorbed, just as it would be by water. The carbon-dioxide is in a state of chemical combination with the salts of the serum, especially the sodium, with which it is combined partly as a carbonate and partly as a bicarbonate. The nitrogen is unimportant. It (or at least the greater part of it) is merely absorbed from the atmosphere under the pressure to which the blood is exposed, and can therefore be mechanically removed.

Blood-crystals.—Hæmoglobin, as stated above, when separated from the blood-corpuscles, readily undergoes crystallisation. These crystals, named *hæmoglobin crystals*, all belong, with the exception of those obtained from the squirrel, to the rhombic system. In human blood they are elongated prisms (fig. 4, A). In the squirrel they are hexagonal plates. Other crystals may be

FIG. 4.—Blood-crystals.

A. Hæmoglobin crystals from human blood. B. Hæmin crystals from blood treated with acetic acid. C. Hæmatoidin crystals from an old apoplectic clot.

obtained by mixing dried blood with an equal quantity of common salt, and boiling it with a few drops of glacial acetic acid. A drop of the mixture placed on the slide will show the crystals on cooling. These are named *hæmin* crystals, and consist of small acicular prisms (fig. 4, B). Occasionally in old blood-clots a third form of crystal is found, the hæmatoidin crystal (fig. 4, C).

LYMPH AND CHYLE

Lymph is a transparent, colourless, or slightly yellow fluid, which is conveyed by a system of vessels, named *lymphatics*, into the blood. These vessels take their rise in nearly all parts of the body, and take up from the worn-out tissues that portion which is still available for purposes of nutrition, and return it into the veins close to the heart, there to be mixed with the mass of the blood. The greater number of these lymphatics empty themselves into one main duct, the *thoracic duct*, which passes along the front of the spine, and opens into one of the large veins at the root of the neck. The remainder empty themselves into a smaller duct, which terminates in the corresponding vein on the opposite side of the neck.

Chyle is an opaque, milky-white fluid, absorbed by the villi of the small intestines from the food, and carried by a set of vessels similar to the lymphatics, named *lacteals*, to the commencement of the thoracic duct, where it is intermingled with the lymph and poured into the circulation through the same channels. It must be borne in mind that these two sets of vessels, lymphatics and lacteals, though differing in name, are identical in structure, and that the character of the fluid they convey is different only while digestion is going on. At other times the lacteals convey a transparent, nearly colourless fluid not to be distinguished from lymph. Both these sets of vessels, in their passage to the central duct, pass through certain small glandular bodies, termed *lymphatic glands*, where their contents undergo elaboration.

Lymph, as its name implies, is a watery fluid. It closely resembles the liquor sanguinis, but is more dilute, containing about 5 per cent. of proteids and 1 per cent. of salts. When examined under the microscope it is found to consist of a clear colourless fluid, in which are floating a number of corpuscles, *lymph-corpuscles*. These bodies are identical in structure, and not to be distinguished from the white blood-corpuscles previously described. They vary in number in different parts of the lymphatic vessels, and indeed are said by Kölliker to be absent in the smaller ones. They are always increased in number after the passage of the lymph through a lymphatic gland, and are said to be increased in size as the fluid ascends higher in the course of the circulation. They are constantly furnishing a fresh supply of white corpuscles to the blood.

Chyle is a milk-white fluid, which exactly resembles lymph in its physical and chemical properties, except that it has in addition to the other constituents of lymph an enormous amount of fatty granules, 'the molecular base of chyle,' and it is to the presence of these molecules that chyle owes its milky colour. Under the microscope it presents a number of corpuscles, named 'chyle-corpuscles,' which are indistinguishable from lymph-corpuscles or white blood-cells, and the molecular base, consisting principally of fatty granules of extreme minuteness (fig. 5, *a*), but also of a few small oil-globules. Lymph and chyle after their passage through their respective glands, if withdrawn from the body and allowed to stand, separate more or less completely into a clear liquid, which is identical with the serum of the blood, and a thin jelly-like clot, consisting of a fibrillated matrix in which lymph-corpuscles or chyle-corpuscles and fatty molecules, as the case may be, are entangled.

Fig. 5.—Chyle from the lacteals.

a. Molecular base.

If the contents of the thoracic duct are examined, especially after a meal, there may be found in it corpuscles with a reddish tinge. These were formerly regarded as *immature* red corpuscles, or lymph and chyle corpuscles in process of transformation into blood-globules. Mature red corpuscles have also sometimes been found, but these are regarded by most observers as accidental, i.e. introduced into the lymphatics by the rupture of some of the small vessels.

THE ANIMAL CELL

All the tissues and organs of which the body is composed were originally developed from a microscopic body (the *ovum*), consisting of a soft gelatinous granular material enclosed in a membrane, and containing a vesicle, or small spherical body, inside which are one or more solid spots (see fig. 75). This may be regarded as a perfect cell. Moreover, all the solid tissues can be shown to consist largely of similar bodies, differing, it is true, in external form, but essentially similar to an ovum. These are also cells.

In the higher organisms all such cells may be defined as 'nucleated masses of protoplasm of microscopic size.' The two essentials, therefore, of an animal cell in the higher organisms are, the presence of a soft gelatinous granular material, similar to that found in the ovum, and which is usually styled *protoplasm*; and a small spherical body embedded in it, and termed a *nucleus*;* the remaining constituents of the ovum, viz. its limiting membrane and the solid spot contained in the nucleus, called the *nucleolus*, are not considered essential to the cell, and in fact many cells exist without them.

Protoplasm (*sarcode*, *blastema*, *germinal matter*, or *bioplasm*) is a proteid compound, consisting largely of muco-globulin. It also contains certain inorganic substances, as phosphorus and calcium, which latter appears to be essential to its life and function. It is of a semi-fluid, viscid consistence, and appears, sometimes, either as a hyaline substance, homogeneous and clear, or as a granular substance, consisting of minute molecules embedded in a transparent matrix. These molecules are regarded as adventitious material taken in from without, and often probably of a fatty nature, since they are soluble in ether. Under a high power of the microscope, in most cells, protoplasm appears to consist of a network or honeycombed reticulum, containing in its meshes a homogeneous substance. The former of these is known as the spongioplasm, the latter as the hyaloplasm. The size and shape of the meshes of the spongioplasm vary in different cells and in different parts of the same cell. In many fixed cells, e.g. epithelial cells, the external layer becomes denser than the rest, and often altered by the deposition in it of some chemical substance, so as to constitute a membrane which encloses the rest of the protoplasm and forms the cell wall. The relative amount of spongioplasm and hyaloplasm to each other varies in different cells; the latter preponderating in the young cell and the former increasing in amount, at the expense of the hyaloplasm, as the cell grows. Protoplasm is insoluble in water, coagulates at 130° Fahr., and has a great affinity for certain staining reagents, as logwood or carmine.

The most striking characteristics of protoplasm are its vital properties of *motion* and *nutrition*. By motion is meant the power which protoplasm has of changing its shape and position by some internal power in itself, which enables it to thrust out from its main body an irregular process, into which the whole of the protoplasmic substance is gradually drawn, so that the mass comes to occupy a new position. This, on account of its resemblance to the movements observed in the Amœba or Proteus animalcule, has been termed 'amœboid movement.' Ciliary movement, or the vibration of hair-like processes from the surface of any structure, may also be regarded as a variety of the motion with which protoplasm is endowed. Nutrition is the power which protoplasm has of attracting to itself the materials of growth from surrounding matter. When any foreign particle comes in contact with the protoplasmic substance, it becomes incorporated in it, by being enwrapped by one or more processes projected from the parent mass which enclose it. When thus taken up, it may remain in the substance of the protoplasm for some time without change, and finally may be extruded again.

The **Nucleus** is a minute body, embedded in the protoplasm, and usually of a spherical or oval form, its size having little relation to the size of the cell. It is usually surrounded by a well-defined wall, the *nuclear membrane*, which encloses the nuclear contents. This, known as the nuclear substance, is composed of a homogeneous amorphous material and a stroma or network. The former is probably of the same nature as the hyaloplasm of the cell, but the latter, which forms also the wall of the nucleus, differs from the spongioplasm of the cell substance. It is sometimes known as the nucleoplasm, and consists of a network of fibres or filaments arranged in a reticular manner. These filaments stain very readily with certain dyes; they are therefore named *Chromatin*; while the

* In certain lower forms of life, masses of protoplasm without any nucleus have been described by Huxley and others, as cells.

interstitial substance does not stain readily, and is hence called *Achromatin*. In some resting nuclei the nuclear filaments do not form a network, but present the appearance of a convoluted skein, similar in appearance to what is found in a nucleus about to undergo division, and which will be immediately described.

Within the nuclear matrix are one or more highly refracting bodies, termed *Nucleoli*, connected with the nuclear membrane by the nuclear filaments. They are regarded by some as mere local condensations of the nucleoplasm ; by others as distinct bodies, differing both in nature and chemical composition. The nuclear substance differs chemically from ordinary protoplasm in containing nuclein, in its power of resisting the action of acids and alkalies, in its imbibing more intensely the stain of carmine, hæmatoxylin, &c., and in its remaining unstained by some reagents which colour ordinary protoplasm—as, for example, nitrate of silver.

The process of reproduction of cells commences in the nucleus, and is usually described as being brought about by *indirect* or by *direct division*. *Indirect division* or *karyokinesis* (*karyomitosis*) has been observed in all the tissues—generative cells, epithelial tissue, connective tissue, muscular tissue, and nerve tissue, and it may be that it will hereafter be shown that the division of cells always takes place in this way, and that the process of reproduction of cells by direct division is, as is believed by some observers, merely a sort of imperfect or abnormal karyokinesis.

The process of reproduction by *indirect* division commences in the nucleus, the stroma of which undergoes complex changes, leading to the division of this body previous to the cleavage of the protoplasm of the cell. The changes consist briefly of the following. At the commencement of the process the nuclear network is well developed, but shows only slight indications of activity. The chromatic fibrils forming the nuclear network, after rearranging themselves, become thicker, and probably combined in one long filament, which forms a loose convolution. This is called the *spirem* or *skein*. At the same time a number of achromatic fibrils, arranged in the form of a spindle, appear at a definite point in the nucleus, towards which the loops of the glomerulus or skein are directed. This point is known as the polar end of the nucleus. From this point the spindle, which is called the *achromatic spindle*, moves gradually towards the centre of the nucleus, where it takes up its position ; the two extremities of the spindle, known as the *poles of the spindle*, reach the limit of the nucleus at either side ; here they are connected with a central protoplasmic granule, the *polar corpuscle*, and from this the achromatic fibrils of which the spindle is composed radiate outwards into the protoplasm of the cell. The line midway between the poles, and bisecting at right angles a line connecting the two, is called the *equator*. As the achromatic spindle leaves the polar end of the nucleus in order to assume its permanent position it carries with it the loops of the chromatic filaments of the skein, and by the time it has reached the centre of the nucleus these filaments, which have now become V-shaped, assume a stellate arrangement around the equator, and form a festooned ring or star in this situation. This is known as the *mother star* or *monaster*. The chromatic fibrils of which the loops forming the star are composed now undergo a longitudinal cleavage and become divided into two exactly similar, but smaller fibrils. This cleavage or division begins at the apices of the V-shaped loops and gradually extends along the limbs. As soon as this cleavage has taken place, one division of each loop turns to either pole and, passing along the fibrils of the achromatic spindle, by which they appear to be guided, converge to either pole of the spindle. The limbs of the loops remain for some time connected, but afterwards become separated and remain simply attached to each other by a delicate achromatic fibril. When viewed in the axis of the spindle, there appear now to be two stellate arrangements of the looped chromatic filaments, one at either pole. These are known as *dyaster* or *daughter stars*, and have been formed by the longitudinal splitting of the loops

FIG. 6.—Karyokinesis: or indirect cell-division.

which formed the monaster or single star. The chromatic fibrils now begin to lose their regular arrangement in loops, and becoming joined together, present a convoluted appearance at either extremity of the achromatic spindle constituting the daughter skein or dispirem. Cleavage of the protoplasm now commences and continues until it is complete, except where the achromatic threads are found. By further convolution and contraction the loops of the chromatic fibrils become fused together and again form a network. The protoplasm is now again in contact with the nuclear network, which serves to form a wall around the nuclei, and two daughter cells with nuclei are formed. The remains of the achromatic threads bridge across the intercellular substance constituting the prickles of prickle cells.

The diagram on the preceding page, by Professor S. Delépine, is intended to explain the formation of some of the most important chromatic and achromatic figures observed in nuclei of cells during karyokinesis (mitosis); it is based chiefly on the work of Flemming, Strasburger, E. van Beneden, Rabl, O'Hertwig, Henneguy, &c. A. *Resting nucleus.* Nucleolus and nuclear membrane visible. A polar corpuscle (centrosome) is represented diagrammatically at some distance from the nucleus in the protoplasm of the cell, but such a body is usually very difficult to recognise in ordinary cells. B. *Skein* or *spirem* (*close*). Closely packed, much convoluted chromatic filaments. Evidence of longitudinal splitting begins to be distinct in several parts. The polar corpuscle has divided; the nuclear membrane is becoming indistinct. C. *Skein* or *spirem* (*open*). Chromatic filaments thicker, less closely packed; distinctly arranged in loops occupying a definite position in relation to the polar area. The polar corpuscles are widely separated, and the space between them is occupied by the achromatic spindle. (Two arrows indicate the position which the polar corpuscles will ultimately occupy; during their passage to these points the achromatic spindle seems to be within the nucleus.) The nuclear membrane has disappeared. D. *Mother star, aster, astroid.* The nuclear segments (chromosomes) resulting from the breaking-up of the chromatic filament into fragments of nearly equal length have moved towards the equatorial plane of the spindle, where they now form an equatorial plate. These segments are all split longitudinally, and their internal ends are free. The homœotypic form of division is here represented. E. *Metakinesis.* One half of each chromosome moves towards one pole and the other half towards the other pole, being guided and possibly pulled towards the polar corpuscles by contracting achromatic filaments attached to them. F. *Daughter stars* or *dyaster.* G. *Daughter skeins* or *dispirem, beginning to form.* Segments in the form of thick loops not closely packed. H. *Daughter skeins* or *dispirem, formed.* Segments more closely packed and less distinct, owing to the formation of anastomoses. A depression corresponds to the polar area on each side. I. *Resting daughter nuclei.* Cell completely divided, but bridges remain between them in the region previously occupied by the achromatic filaments, these being specially distinct in certain cells (e.g. prickle cells). The nucleus has a distinct nuclear membrane and a nucleolus.

In the reproduction of cells by *direct* division the process is brought about either by segmentation or by gemmation. In reproduction by *segmentation* or *fission*, the nucleus first splits, by becoming constricted in its centre, and thus assuming an hour-glass shape. This leads to a cleavage or division of the whole protoplasmic mass of the cell; and thus we find that two new cells have been formed, consisting of the same substance as the original one, and each containing a nucleus. These daughter cells are of course at first smaller than the original mother cell; but they grow, and the process may be repeated in them, so that multiplication may rapidly take place. In reproduction by *gemmation*, a budding-off or separation of a portion of the nucleus and parent cell takes place, and, becoming separated, forms a new organism.

The **cell-wall**, which is not an essential constituent, and in fact is often absent, is merely the external layer of the protoplasm, firmer than the rest of the cell,

and often thickened by the deposit in it of certain chemical substances. It forms a flexible, transparent, finely striated membrane, sometimes furnished with minute pores, so as to be permeable to fluids.

As far as is known, every animal cell is derived from a pre-existing cell. The death of cells is accomplished either by their mechanical detachment from the surface, preceded possibly by their bursting and discharging their contents, or by various forms of degeneration—fatty, pigmentary, or calcareous.

EPITHELIUM

All the surfaces of the body—the external surface of the skin, the internal surface of the digestive, respiratory, and genito-urinary tracts, the closed serous cavities, the inner coat of the vessels, and the acini and ducts of all secreting and excreting glands, the ventricles of the brain and the central canal of the spinal cord—are covered by one or more layers of simple cells, called *epithelium* or *epithelial cells*. These cells are also present in the sensory and terminal parts of the organs of special sense, and in some other organs, as the pituitary and thyroid bodies. They serve various purposes, forming in some cases a protective layer, in others acting as an agent in secretion and excretion, and again in others being concerned in the elaboration of the organs of special sense. Thus, in the skin, the main purpose served by the epithelium (here called the *epidermis*) is that of protection. As the surface is worn away by the agency of friction or change of temperature new cells are supplied, and thus the surface of the true skin and the vessels and nerves which it contains, are defended from damage. In the gastro-intestinal mucous membrane and in the glands, the epithelial cells appear to be the principal agents in separating the secretion from the blood or from the alimentary fluids. In other situations (as the nose, fauces, and respiratory passages) the chief office of the epithelial cells appears to be to maintain an equable temperature by the moisture with which they keep the surface always slightly lubricated. In the serous cavities they also keep the opposed layers moist, and thus facilitate their movements on each other. Finally, in all internal parts they ensure a perfectly smooth surface.

Of late years there has been a tendency on the part of many histologists to divide these several epithelial linings into two classes: into (1) *epithelial tissue proper*, consisting of nucleated protoplasmic cells, which form continuous masses on the skin and mucous surfaces and the linings of the ducts and alveoli of secreting and excreting glands; and (2) *endothelium*, which is composed of a single layer of flattened transparent squamous cells, joined edge to edge in such a manner as to form a membrane of cells. This is found on the free surfaces of the serous membranes; as the lining membrane of the heart, blood-vessels, and lymphatics; on the surface of the brain and spinal cord, and in the anterior chamber of the eye.

1. **True epithelial tissue** consists of one or more layers of cells, united together by an interstitial cement-substance, supported on a basement-membrane, and is naturally grouped into two classes according as there is a single layer of cells (*simple epithelium*) or more than one (*stratified epithelium*). The various kinds of epithelium, whether arranged in a single layer or in more than one layer, are usually spoken of as squamous or pavement, columnar, spheroidal or glandular, and ciliated.

The *pavement* epithelium (fig. 7) is composed of flat nucleated scales of various shapes, usually polygonal, and varying in size. These cells fit together by their edges, like the tiles of a mosaic pavement. The nucleus is generally flattened, but may be spheroidal. The flattening depends upon the thinness of the cell. The protoplasm of the cell presents a fine reticulum or honeycombed network, which gives to the cell the appearance of granulation. This

kind of epithelium, forming a single layer (endothelium), is found lining serous membranes, blood-vessels, the anterior chamber of the eye, and in some other situations.

The *columnar* or *cylindrical* epithelium (fig. 8) is formed of cylindrical or rod-shaped cells set together so as to form a complete layer, resembling, when viewed in profile, a palisade. The cells have a prismatic figure, more or less flattened from mutual pressure, and are set upright on the surface on which they are supported. Their protoplasm is always more or less reticulated, which gives them a granular appearance, and they contain a nucleus which is oval in shape and contains an intranuclear network.

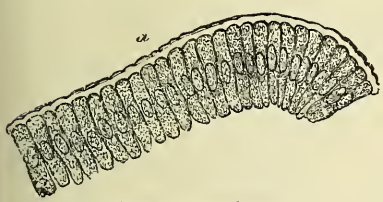
Fig. 7.—Simple pavement epithelium.

This form of epithelium covers the mucous membrane of nearly the whole gastro-intestinal tract and the glands of that part, the greater part of the urethra, the vas deferens, the prostate, Cowper's glands, Bartholini's glands, and a portion of the uterine mucous membrane.

Goblet or *chalice* cells are a modification of the columnar cell. They appear to be formed by an alteration in shape of the columnar epithelium (ciliated or otherwise) consequent on the secretion into the interior of the cell of *mucin*, the chief organic constituent of mucus, which distends the upper part of the cell, while the nucleus is pressed down towards its deep part, until the cell bursts and the mucus is discharged on to the surface of the mucous membrane as shown in fig. 9).

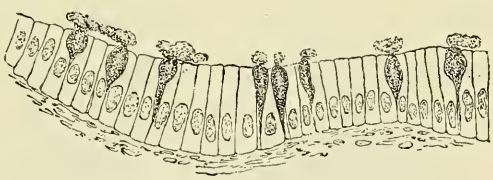
The *spheroidal* or *glandular* epithelium (fig. 10) is composed of circular or polyhedral cells. Like other forms of epithelial cells, the protoplasm is a

Fig. 8.—Epithelium of the intestinal villi of the rabbit. Magnified 300 times.



a. Basement-membrane.

Fig. 9.—Simple columnar epithelium, from the mucous membrane of the intestine, with goblet-cells pouring out their contents. (Klein and Noble Smith.)



fine reticulum, which gives to the cell the appearance of granulation. They are found in the terminal recesses of secreting glands, and the protoplasm of the cells usually contains the materials which the cells secrete.

Ciliated epithelium (fig. 11) may be of any of the preceding forms, but usually inclines to the columnar shape. It is distinguished by the presence of minute processes, which are direct prolongations of the cell-protoplasm, like hairs or eyelashes (cilia) standing up from the free surface. If the cells are examined during life or immediately on removal from the living body (for which in the human subject the removal of a nasal polypus offers a convenient opportunity) in a weak solution of salt, the cilia will be seen in lashing motion; and if the cells are separate, they will often be seen to be moved about in the field by this motion.

The situations in which ciliated epithelium is found in the human body are:

the respiratory tract from the nose downwards to the smallest ramifications of the bronchial tubes, except a part of the pharynx and the surface of the vocal

Fig. 10.—Spheroidal epithelium. Magnified 250 times.

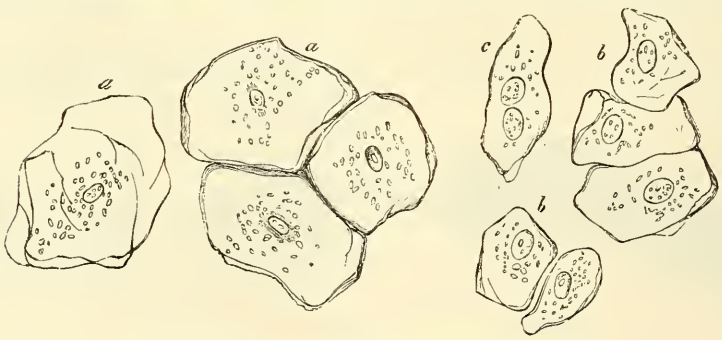
cords ; the tympanum and Eustachian tube ; the Fallopian tube and upper portion of the uterus ; the vasa efferentia ; coni vasculosi ; the first part of the excretory duct of the testicle ; and the ventricles of the brain and central canal of the spinal cord.

Stratified epithelium consists of several layers of cells superimposed one on the top of the other and varying greatly in shape. The cells of the deepest layer are for the most part columnar in form, and as a rule form a single layer, placed vertically on the supporting membrane ; above these are several layers of

Fig. 12.—Epithelial cells from the oral cavity of man. Magnified 350 times.



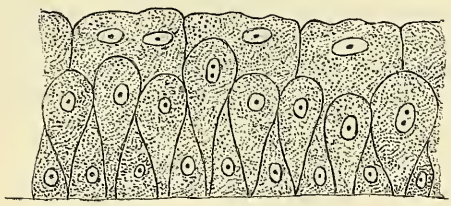
a. Large. *b*. Middle sized. *c*. The same with two nuclei.

spheroidal cells, which as they approach the surface become more and more compressed, until the superficial layers are found to consist of flattened scales (fig. 12), the margins of which overlap one another so as to present an imbricated appearance. They here undergo a chemical change from the conversion of their protoplasm into a horny substance.

A variety of squamous epithelium which is found in the deeper layers of stratified pavement-epithelium has been termed *prickle cells*. These cells possess short fine fibrils which pass from their margins to those of neighbouring cells, serving to connect them together. Since they are not here closely connected together by cement-substance, but are separated from each other by intercellular channels, across which these fine fibrils may be seen bridging, this gives to the cell, when isolated, the appearance of being covered over with a number of short

spikes, in consequence of the fibrils being broken through. They were first described by Max Schultze and Virchow, and it was believed by them that the cells were dovetailed together. Subsequently this was shown not to be so by Dr. Martyn, who pointed out that the prickles were attached to each other by their apices; and recently Dr. Delépine has stated that he believes the prickles of prickle cells are parts of fibrils forming internuclear bundles between the nuclei of the cells of an epithelium in a state of active growth (see page 11, and fig. 6).

Fig. 13.—Transitional epithelium.



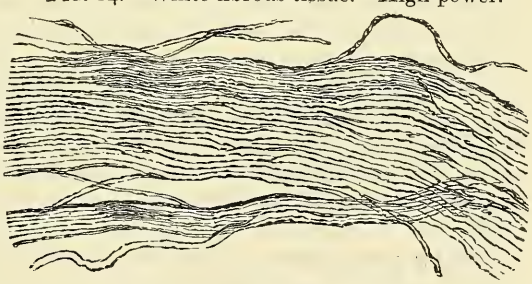
Another form of stratified epithelium is found in what has been termed *transitional* epithelium, such as exists in the ureters and urinary bladder. Here the cells of the most superficial layer are cubical, with depressions on their under surfaces, which fit on to the rounded ends of the cells of the second layer, which are pear-shaped, the apices touching the basement-membrane. Between their tapering points is a third variety of cells, filling in the intervals between them, and of smaller size than those of the other two layers (fig. 13).

CONNECTIVE TISSUES

By the term **connective tissue** we mean a number of tissues which possess this feature in common, viz. that they serve the general purpose in the animal economy of supporting and connecting the tissues of the frame. These tissues may differ considerably from each other in external appearance, but they present nevertheless many points of relationship, and are moreover developed from the same embryonal elements. They are divided into three great groups: (1) the fibrous connective tissues, (2) cartilage, and (3) bone.

The fibrous connective tissues.—Three principal forms or varieties of fibrous connective tissue are recognised:—(1) White fibrous tissue. (2) Yellow elastic tissue. (3) Areolar tissue. They are all composed of a matrix in which cells are embedded, and between the cells are fibres of two kinds, the white and yellow or elastic. The difference between the three forms of tissue depends on the relative proportion of the two kinds of fibre, in the first variety enumerated the *white* fibre preponderating; in the second variety the *yellow elastic* fibres being greatly in excess of the white; and in the third form, areolar tissue, the two being blended in much more equal proportions.

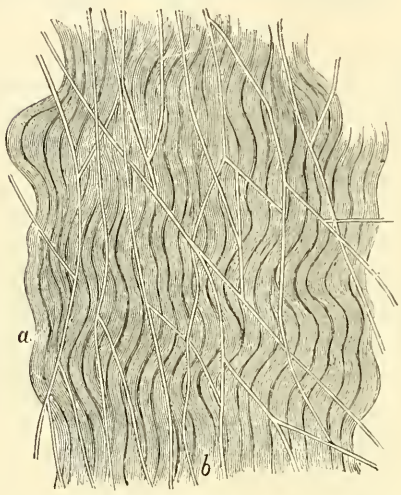
Fig. 14.—White fibrous tissue. High power.



The **white fibrous tissue** (fig. 14) is a true connecting structure, and serves three purposes in the animal economy. It serves to bind bones together in the form of ligaments, it serves to connect muscles to bones or other structures in the form of tendons, and it forms an investing or protecting structure to various organs in the form of membranes. Examples of where it serves this latter office are to be found in the muscular fasciæ or sheaths, the periosteum, and perichondrium; the investments of the various glands (such as the tunica albuginea testis, the capsule of the kidney, &c.), the investing sheath of the nerves (epineurium), and of various organs, as the penis and the eye (sheath of the corpora cavernosa and corpus spongiosum and of the sclerotic). But in all these

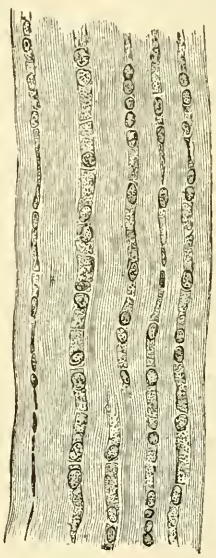
parts the student must bear in mind that the elastic tissue enters in greater or less proportion. It presents to the naked eye the appearance of silvery white glistening fibres, covered over with a quantity of loose, flocculent tissue which binds the fibres together and carries the blood-vessels. It is not possessed of any elasticity, and only the very slightest extensibility; it is exceedingly strong, so that upon the application of any external violence the bone with which it is connected will fracture before the fibrous tissue will give way. When examined under the microscope it is found to consist of waving bands or bundles of minute, transparent, homogeneous filaments or fibrillæ, held together by an albuminous semi-fluid cement-substance (fig. 15). In ligaments and tendons these bundles run parallel with each other; in membranes they intersect one another in different

Fig. 15.—Connective tissue. (Klein and Noble Smith.)



a. The white fibrous element—a layer of more or less sharply outlined, parallel, wavy bundles of connective-tissue fibrils. On the surface of this layer is *b*, a network of fine elastic fibres.

Fig. 16.—Tendon of mouse's tail, stained with logwood, showing chains of cells between the tendon-bundles. (From Quain's 'Anatomy.' E. A. Schäfer.)



places. The bundles have a tendency to split up longitudinally or send off slips to join other bundles and receive others in return. The cells occurring in white fibrous tissue are often called 'tendon cells.' They are situated on the surface of groups of bundles and are quadrangular in shape, arranged in rows in single file, each cell being separated from its neighbours by a narrow line of cement-substance. The nucleus is generally situated at one end of the cell, the nucleus of the adjoining cell being in close proximity to it (fig. 16). Upon the addition of acetic acid to white fibrous tissue it swells up into a glassy-looking indistinguishable mass. When boiled in water it is converted almost completely into gelatin.

Yellow elastic tissue.—In certain parts of the body a tissue is found which when viewed in mass is of a yellowish colour, and is possessed of great elasticity; so that it is capable of considerable extension, and when the extending force is withdrawn returns at once to its original condition. This is *yellow elastic tissue*, in which the elastic fibres greatly preponderate, to the almost complete exclusion of the white fibrous element. It is found in this condition in the ligamenta subflava, in the vocal cords, in the longitudinal coat of the trachea and bronchi, in the inner coats of the blood-vessels, especially the larger arteries, and to a very considerable extent in the thyro-hyoid, crico-thyroid, and stylo-hyoid ligaments. It is also found in the ligamentum nuchæ of the lower animals. When viewed

under the microscope (fig. 17) it is seen to consist of an aggregation of curling fibres, with a well-defined outline. They are considerably larger in size than the fibrillæ of the white fibrous element, and vary much, being from the $\frac{1}{24000}$ to the $\frac{1}{4000}$ of an inch in diameter. The fibres form bold and wide curves, branch and freely anastomose with each other. They are homogeneous in appearance, and have a tendency to curl up, especially at their broken ends. In some parts where the fibres are broad and large and the network close, the tissue presents the appearance of a membrane, with gaps or perforations corresponding to the intervening space. This is to be found in the inner coat of the arteries, and to it the name of *fenestrated membrane* has been given by Henle. The yellow elastic fibres remain unaltered by acetic acid.

FIG. 17.—Yellow elastic tissue. High power.

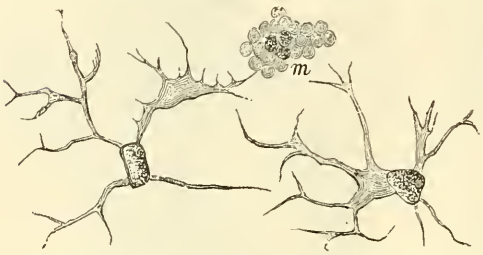
Areolar tissue is so called because its meshes are easily distended, and thus separated into areolæ or spaces, which all open freely into each other, and are consequently easily blown up with air, or permeated by fluid, when injected into any part of the tissue. Such spaces, however, do not exist in the natural condition of the body, but the whole tissue forms one unbroken membrane composed of a number of interlacing fibres, variously superimposed. Hence the term 'the cellular membrane' is in many parts of the body more appropriate than its more modern equivalent. The chief use of the areolar tissue is to bind parts together; while by the laxity of its fibres, and the permeability of its areolæ, it allows them to move on each other, and affords a ready exit for inflammatory and other effused fluids. It is one of the most extensively distributed of all the tissues in the body. It is found beneath the skin, in a continuous layer all over the body, connecting it to the subjacent parts. In the same way it is situated beneath the mucous and serous membranes. It is also found between muscles, vessels, and nerves, forming investing sheaths for them, and connecting them with surrounding structures. In addition to this, it is found in the interior of organs, binding together the various lobes and lobules of the compound glands, the various coats of the hollow viscera, and the fibres of muscles &c., and thus forms one of the most important connecting media of the various structures or organs of which the body is made up. In many parts the areolæ or interspaces of areolar tissue are occupied by fat-cells, constituting *adipose tissue*, which will presently be described.

Areolar tissue presents to the naked eye a flocculent appearance, somewhat like spun-silk. When stretched out, it is seen to consist of delicate soft elastic threads interlacing with each other in every direction, and forming a network of extreme delicacy. When examined under the microscope it is found to be composed of white fibres and elastic fibres intercrossing in all directions, and united together by a homogeneous cement or ground-substance, and filled by cellular elements, which contain the protoplasm out of which the whole is developed and regenerated.

These cell-spaces may be brought into view by treating the tissue with nitrate of silver, and exposing it to the light. This will colour the fibres and ground-substance, leaving the cell-spaces unstained.

The cells of areolar tissue (fig. 18) are of three kinds: 1, flattened transparent cells, more or less branched, and often united together by thin-branched processes, thus forming a network in the ground-substance. They are composed of clear cell-substance, in which is contained a large oval nucleus; 2, other cells, instead of presenting a clear cell-substance, are distinctly granular, and to these the term *granular cells* is applied. These granules, which are albuminous in character, like one form of leucocyte, stain deeply with eosin; 3, a third class of cells are distinguished from the other two by containing large vacuoles; these are termed *plasma cells*. The vacuoles are filled with fluid, and the protoplasm between the spaces is clear, with occasionally a few scattered granules.

Fig. 18.—Connective-tissue corpuscles. (Klein and Noble Smith.)



m. Granular connective-tissue cell. The other two are the ordinary branched cells, each with an oblong nucleus.

Vessels and Nerves of Connective Tissue.—The *blood-vessels* of connective tissue are very few—that is to say, there are few actually destined for the tissue itself, although many vessels may permeate one of its forms, the areolar tissue, carrying blood to other structures. In white fibrous tissue the blood-vessels usually run parallel to the longitudinal bundles and between them, sending transverse communicating branches across, and in some forms, as in the periosteum and dura mater, being fairly numerous. In yellow elastic tissue, the blood-vessels also run between the fibres, and do not penetrate them. *Lymphatic* vessels are very numerous in most forms of connective tissue, especially in the areolar tissue beneath the skin and the mucous and serous surfaces. They are also found in abundance in the sheaths of tendons, as well as in the tendons themselves. *Nerves* are to be found in the white fibrous tissue, where they terminate in a special manner; but it is doubtful whether any nerves terminate in areolar tissue; at all events, they have not yet been demonstrated, and the tissue is possessed of very little sensibility.

Development of Connective Tissue.—Fibrous connective tissue is developed from embryonic connective-tissue cells, derived from the mesoblast. At an early period of development it consists of nucleated cells and a muco-albuminous fluid, which subsequently becomes a pellucid jelly, and forms the ground-substance. In this ground-substance the two varieties of fibres become developed. As to the manner in which they do so there are two theories, some believing that they are developed from the protoplasm of the cells, others that they are formed by a deposit in the ground-substance. In the former case the protoplasm of the cells is converted wholly into elementary fibres, the nucleus disappearing; or else the peripheral part of the protoplasm produces the fibrous tissue, the original cell growing again to its original size, and then throwing off a fresh portion to form a new fibre, and itself persisting in contact with the fibres it has formed as a permanent connective-tissue corpuscle.

Yellow elastic fibres are said by some to be formed by the processes of stellate embryonal cells, which, joining with processes of other cells, form the elastic fibres.

Three special forms of connective tissue must be described: the mucoid, the lymphoid or retiform, and basement-membranes.

1. The **mucoid** or **gelatinous** connective tissue exists chiefly in the 'jelly of Wharton,' which forms the bulk of the umbilical cord, but is also found in some other situations in the fœtus, as in the pulp of young teeth, and in certain stages of the development of connective tissue in various regions. In the adult, the

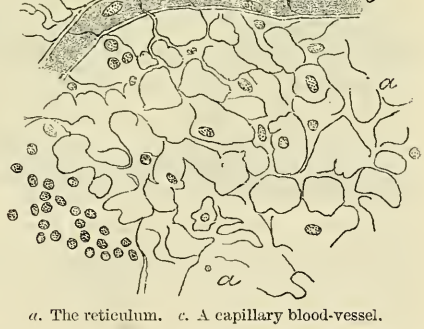
vitreous humour of the eye is formed of the same material. This tissue consists of nucleated cells, which branch and become connected so as to form trabeculæ, in which is contained a jelly-like substance, containing the chemical principle of mucus, or *mucin*, and in smaller quantities albumen, but no gelatin (fig. 19). Sometimes, as in the vitreous humour of the eye, the cells disappear, and the jelly only remains.

2. **Retiform** connective tissue is found extensively in many parts of the body, forming the framework of some organs and entering into the construction

Fig. 19.—Mucoid or gelatinous connective tissue.

of many mucous membranes. It is formed of an interlacement or network of very fine fibres, which closely resemble white fibrous tissue, and in certain situations may be demonstrated to be continuous with it. In many places flattened cells may be seen connected with the fibres and partially concealing them, presenting an appearance as if the tissue were formed of a network of branching and anastomosing cells. This, however, is not so, as the cells can be removed or brushed away, leaving the fibres intact. In many situations the interstices of the fibres are filled with rounded granular corpuscles, and the tissue is then termed **lymphoid** or **adenoid tissue** (fig. 20).

Fig. 20.—Retiform connective tissue, from a lymphatic gland; most of the lymph-corpuscles are removed. (From Klein's 'Elements of Histology.')



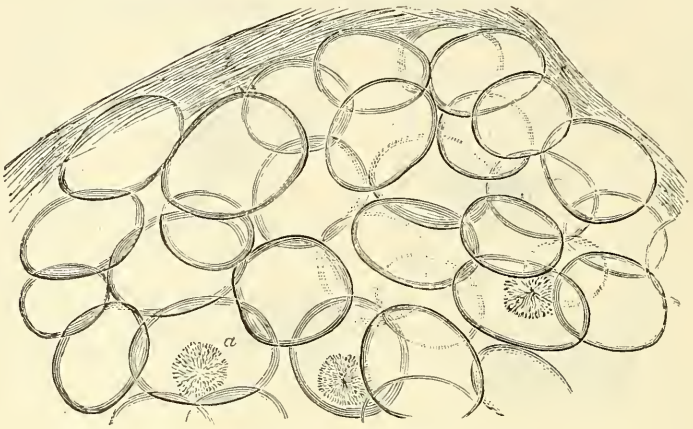
a. The reticulum. *c*. A capillary blood-vessel.

3. **Basement-membranes**, formerly described as homogeneous membranes, are really a form of connective tissue. They constitute the supporting membrane, or membrana propria, supporting the epithelium of mucous membranes or secreting glands, and in other situations. By means of staining with nitrate of silver they may be shown to consist of flattened cells in close apposition, and form therefore an example of an epithelioid arrangement of connective-tissue cells. In some situations the cells, instead of adhering by their edges, give off branching processes, which join with similar processes of other cells and so form a network, rather than a continuous membrane.

ADIPOSE TISSUE

In almost all parts of the body the ordinary areolar tissue contains a variable quantity of fat. The principal situations where it is not found are the subcutaneous tissue of the eyelids, the penis and scrotum, the nymphæ, within the cavity of the cranium, and in the lungs, except near their roots.

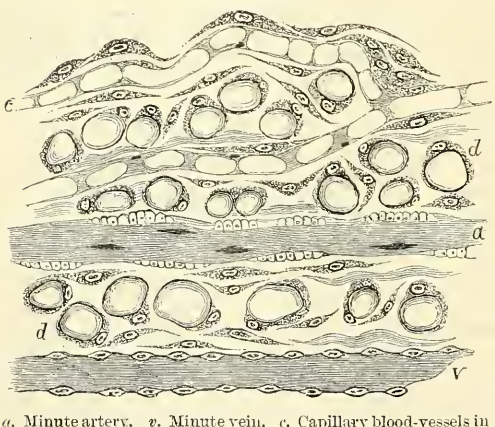
FIG. 21.—Adipose tissue. High power.



a. Starlike appearance, from crystallisation of fatty acids.

Nevertheless its distribution is not uniform; in some parts it is collected in great abundance, as in the subcutaneous tissue, especially of the abdomen; around the kidneys; on the surface of the heart between the furrows, and in some other situations. Lastly, fat enters largely into the formation of the marrow of bones. A distinction must be made between fat and adipose tissue; the latter being a distinct tissue, the former an oily matter, which in addition to forming adipose tissue is also widely present in the body, as in the fat of the brain and liver, and in the blood and chyle, &c.

FIG. 22.—Development of fat. (Klein and Noble Smith.)



a. Minute artery. *v*. Minute vein. *c*. Capillary blood-vessels in the course of formation; they are not yet completely hollowed out, there being still left in them protoplasmic septa. *d*. The ground-substance, containing numerous nucleated cells, some of which are more distinctly branched and flattened than others, and appear therefore more spindle-shaped.

Adipose tissue consists of small vesicles, *fat-cells*, lodged in the meshes of areolar tissue. The fat cells (fig. 21) vary in size, but are of about the average diameter of $\frac{1}{500}$ of an inch. They are formed of an exceedingly delicate protoplasmic membrane, filled with fatty matter, which is liquid during life, but becomes solidified after death. They are round or spherical where they have not been subjected to pressure; otherwise they assume a more or less angular outline. A nucleus is always present and can be easily demonstrated by staining with logwood; in the natural condition it is so compressed by the contained oily matter as to be scarcely recognisable. These fat-cells are contained in clusters in the areolæ of fine connective tissue, and are held together mainly by a network of capillary blood-vessels, which are distributed to them.

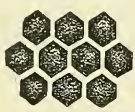
Fat is an inorganised substance, consisting of a liquid material (glycerine) in combination with certain fatty acids, stearic, palmitic, and oleic. Sometimes the acids separate spontaneously before the fat is examined, and are seen under the microscope in a crystalline form, as in fig. 21, *a*. By boiling the tissue in ether or strong alcohol, the fat may be extracted from the vesicle, which is then seen empty and shrunken.

Fat is said to be first detected in the human embryo about the fourteenth week. According to Klein, the fat-cells are formed by the transformation of the protoplasmic connective-tissue corpuscles, in which small globules of fat are deposited, and increase until they distend the corpuscle into the thin mantle of protoplasm which forms the cell-wall, and in which its nucleus is still to be seen (fig. 22). Others of the connective-tissue corpuscles are transformed into the vessels and the lymphatic tissue which accompanies the vessels.

PIGMENT

In various parts of the body **pigment** is found ; most frequently in epithelial cells and in the cells of connective tissue. Pigmented epithelial cells are found forming the external layer of the retina (fig. 23) and on the posterior surface of the iris. Pigment is also found in the epithelial cells of the deeper layers of the cuticle in some parts of the body—such as the areola of the nipple and in coloured patches of skin and especially in the skin of the coloured races, and also in hair. It is also found in the epithelial cells of the olfactory region, and of the membranous labyrinth of the ear.

FIG. 23.—Pigment-cells of retina.



In the connective-tissue cells pigment is frequently met with in the lower vertebrates. In man it is found in the choroid coat of the eye, and in the iris of all but the light blue eyes and the albino. It is also occasionally met with in the cells of retiform tissue and in the pia mater of the upper part of the spinal cord. These cells are characterised by their larger size and branched processes, which, as well as the body of the cells, are filled with granules. The pigment consists of dark brown or black granules of very small size closely packed together within the cells, but not invading the nucleus. Occasionally the pigment is yellow, and when occurring in the cells of the cuticle constitutes 'freckles.'

CARTILAGE

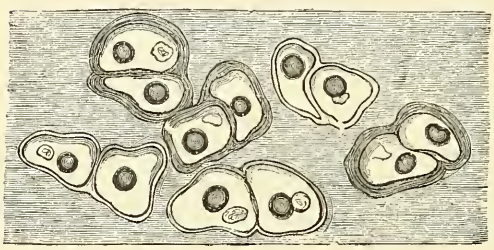
Cartilage is a non-vascular structure which is found in various parts of the body—in adult life chiefly in the joints, in the parietes of the thorax, and in various tubes, such as the air-passages, nostrils, and ears, which are to be kept permanently open. In the fœtus at an early period the greater part of the skeleton is cartilaginous. As this cartilage is afterwards replaced by bone, it is called *temporary*, in contra-distinction to that which remains unossified during the whole of life, and which is called *permanent*.

Cartilage is divided, according to its minute structure, into true or hyaline cartilage, fibrous or fibro-cartilage, and yellow or elastic or reticular cartilage. Besides these varieties met with in the adult human subject, there is a variety called *cellular cartilage*, which consists entirely, or almost entirely, of cells, united in some cases by a network of very fine fibres, in other cases apparently destitute of any intercellular substance. This is found in the external ear of rats, mice, and some other animals, and is present in the chorda dorsalis of the human embryo, but is not found in any other human structure. The various cartilages in the body are also classified, according to their function and position, into articular, interarticular, costal, and membraniform.

Hyaline cartilage, which may be taken as the type of this tissue, consists of a gristly mass of a firm consistence, but of considerable elasticity and of a pearly-

bluish colour. Except where it coats the articular ends of bones, it is covered externally by a fibrous membrane, the *perichondrium*, from the vessels of which it imbibes its nutritive fluids, being destitute of blood-vessels; nor have any nerves been traced into it. Its intimate structure is very simple. If a thin slice is examined under the microscope, it will be found to consist of cells of a rounded or bluntly angular form, lying in groups of two or more in a granular or almost homogeneous matrix (fig. 24). The cells, when arranged in groups of two or more, have generally a straight outline where they are in contact with each other, and in the rest of their circumference are rounded. The cell-contents consist of clear translucent protoplasm, containing fine interlacing filaments and minute granules, and embedded in this are one or two round nuclei, having usually a granular appearance, but occasionally being clear and occupied by one or more nucleoli. The cells are embedded in cavities in the matrix, called *cartilage lacunæ*, which are lined by a distinct transparent membrane termed the *capsule*. Each lacuna is generally occupied by a single cell, but during the division of the cells it may contain two, four, or eight cartilage-cells. By boiling the cartilage for some hours and treating it with concentrated mineral acid, the capsule may be freed from the matrix and can then be demonstrated as a distinct vesicle containing the cell or cells. By exposure to the action of an electric shock the cell assumes a jagged outline and shrinks away from the interior of the capsule.

Fig. 24.—Human cartilage-cells, from the cricoid cartilage. Magnified 350 times.



The matrix is transparent and apparently without structure, or else presents a dimly granular appearance, like ground glass. Some observers have shown that the matrix of hyaline cartilage, and especially the articular variety, after prolonged maceration, can be broken up into fine fibrils. These fibrils are probably of the same nature, chemically, as the white fibres of connective tissue. It is believed by some histologists that the matrix is permeated by a number of fine channels, which connect the lacunæ with each other, and that these canals communicate with the lymphatics of the perichondrium, and thus the structure is permeated with a current of nutritious fluid.

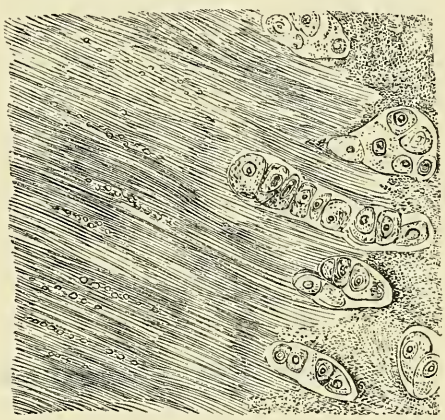
Articular cartilage, costal cartilage, and temporary cartilage are all of the hyaline variety. They present minute differences in the size and shape of their cells and in the arrangement of their matrix. In **articular cartilage,** which shows no tendency to ossification, the matrix is finely granular under a high power; the cells and nuclei are small and are disposed parallel to the surface in the superficial part, while nearer to the bone they become vertical. Articular cartilages have a tendency to split in a vertical direction, probably from some peculiarity in the intimate structure or arrangement of the component parts of the matrix. In disease this tendency to a fibrous splitting becomes very manifest. Articular cartilage is not covered by perichondrium, on its free surface, where it is exposed to friction, though a layer of connective tissue can be traced in the adult over a small part of its circumference continuous with that of the synovial membrane, and here the cartilage-cells are more or less branched and pass insensibly into the branched connective-tissue corpuscles of the synovial membrane.

Articular cartilage forms a thin incrustation upon the joint-surfaces of the bones, and its elasticity enables it to break the force of any concussion, whilst its smoothness affords ease and freedom of movement. It varies in thickness according to the shape of the bone on which it lies; where this is convex the cartilage is thickest at the centre, where the greatest pressure is received; and the reverse is the case on the concave surfaces of the bones. Articular cartilage

appears to imbibe its nutriment partly from the vessels of the neighbouring synovial membrane, partly from those of the bone upon which it is implanted. Mr. Toynbee has shown that the minute vessels of the cancellous tissue as they approach the articular lamella dilate and form arches, and then return into the substance of the bone.

In **costal cartilage** the cells and nuclei are large, and the matrix has a tendency to fibrous striation, especially in old age (fig. 25). These cartilages are also very prone to ossify. In the thickest parts of the costal cartilages a few large vascular channels may be detected. This appears at first sight an exception to the statement that cartilage is a non-vascular tissue, but is not so really, for the vessels give no branches to the cartilage-substance itself, and the channels may rather be looked upon as involutions of the perichondrium. The ensiform cartilage may be regarded as one of the costal cartilages, and the cartilages of the nose and of the larynx and trachea resemble them in microscopical characters, except the epiglottis and cornicula laryngis, which are of the reticular variety.

Fig. 25.—Costal cartilage from a man seventy-six years of age, showing the development of fibrous structure in the matrix. In several portions of the specimen two or three generations of cells are seen enclosed in a parent cell-wall. High power.

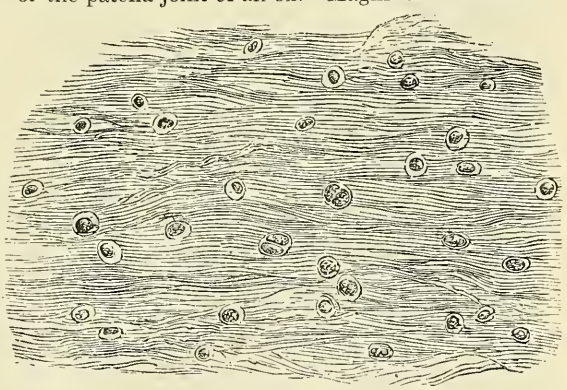


Temporary cartilage and the process of its ossification will be described with bone.

The hyaline cartilages, especially in adult and advanced life, are prone to calcify—that is to say, to have their matrix permeated by the salts of lime without any appearance of true bone. The process of calcification occurs also and still more frequently, according to Rollett, in such cartilages as those of the trachea, which are prone afterwards to conversion into true bone.

White fibro-cartilage consists of a mixture of white fibrous tissue and cartilaginous tissue in various proportions; it is to the first of these two constituents that its flexibility and toughness are chiefly owing, and to the latter its elasticity. When examined under the microscope it is found to be made up of fibrous connective tissue arranged in bundles, with cartilage-cells between the bundles; these to a certain extent resemble tendon-cells, but may be distinguished from them by being surrounded by an investing capsule and by their being less flattened (fig. 26). The fibro-cartilages admit of arrangement into four groups—interarticular, connecting, circumferential, and stratiform.

Fig. 26.—White fibro-cartilage from the semilunar disc of the patella joint of an ox. Magnified 100 times.



1. The **interarticular fibro-cartilages** (*menisci*) are flattened fibro-cartilaginous plates, of a round, oval, triangular, or sickle-like form, interposed between the articular cartilages of certain joints. They are free on both surfaces, thinner

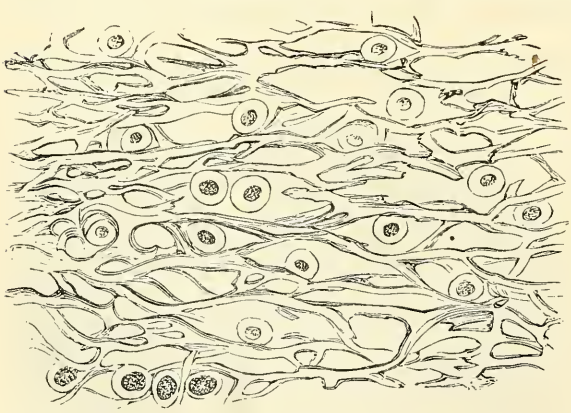
towards their centre than at their circumference, and held in position by their margins and extremities being connected to the surrounding ligaments. The synovial membrane of the joint is prolonged over them a short distance from their attached margins. They are found in the temporo-maxillary, sterno-clavicular, acromio-clavicular, wrist and knee joints. These cartilages are usually found in those joints which are most exposed to violent concussion and subject to frequent movement. Their use is—to maintain the apposition of the opposed surfaces in their various motions; to increase the depth of the articular surfaces and give ease to the gliding movement; to moderate the effects of great pressure and deaden the intensity of the shocks to which the parts may be subjected. Humphry has pointed out that these interarticular fibro-cartilages serve an important purpose in increasing the variety of movements in a joint. Thus, in the knee-joint, there are two kinds of motion, viz. angular movement and rotation, although it is a hinge joint, in which, as a rule, only one variety of motion is permitted; the former movement takes place between the condyles of the femur and the interarticular cartilage, the latter between the cartilage and the head of the tibia. So, also, in the temporo-maxillary joint, the upward and downward movement of opening and shutting the mouth takes place between the cartilage and the jaw-bone, the grinding movement between the glenoid cavity and the cartilage, the latter moving with the jaw-bone.

2. The **connecting fibro-cartilages** are interposed between the bony surfaces of those joints which admit of only slight mobility, as between the bodies of the vertebræ and between the pubic bones. They form discs, which adhere closely to both of the opposed surfaces, and are composed of concentric rings of fibrous tissue, with cartilaginous laminæ interposed, the former tissue predominating towards the circumference, the latter towards the centre.

3. The **circumferential fibro-cartilages** consist of a rim of fibro-cartilage, which surrounds the margin of some of the articular cavities, as the cotyloid cavity of the hip, and the glenoid cavity of the shoulder; they serve to deepen the articular surface, and to protect the edges of the bone.

4. The **stratiform fibro-cartilages** are those which form a thin coating to osseous grooves through which the tendons of certain muscles glide. Small masses of fibro-cartilages are also developed in the tendons of some muscles, where they glide over bones, as in the tendons of the peroneus longus and the tibialis posticus.

Fig. 27.—Yellow cartilage, ear of horse. High power.



Yellow, or reticular, elastic cartilage is found in the human body in the auricle of the external ear, the Eustachian tubes, the cornicula laryngis, and the epiglottis. It consists of cartilage-cells and a matrix, the latter being pervaded in every direction, except immediately around each cell, by a network of yellow elastic fibres, branching and anastomosing in all directions (fig. 27). The fibres resemble those of yellow elastic tissue, both in appearance and in being unaffected by acetic acid; and according to Rollett their continuity with the elastic fibres of the neighbouring tissue admits of being demonstrated.

The distinguishing feature of cartilage as to its chemical composition, is that it yields on boiling a substance called *chondrin*, very similar to gelatin, but differing from it in not being precipitated by tannin. According to Kühne there

is a small amount of gelatin in hyaline cartilage. Virchow believes that the semilunar discs in the knee-joint are wrongly denominated cartilages, since they yield no chondrin on boiling; and he appears to regard them as a modification of a tendinous structure, which, however, agrees with the cartilages in the important particular of being non-vascular.

BONE

Structure and Physical Properties of Bone.—Bone is one of the hardest structures of the animal body; it possesses also a certain degree of toughness and elasticity. Its colour, in a fresh state, is of a pinkish white externally, and deep red within. On examining a section of any bone, it is seen to be composed of two kinds of tissue, one of which is dense in texture, like ivory, and is termed *compact tissue*; the other consists of slender fibres and lamellæ, which join to form a reticular structure; this, from its resemblance to lattice-work, is called *cancellous*. The compact tissue is always placed on the exterior of the bone; the cancellous is always internal. The relative quantity of these two kinds of tissue varies in different bones, and in different parts of the same bone, as strength or lightness is requisite. Close examination of the compact tissue shows it to be extremely porous, so that the difference in structure between it and the cancellous tissue depends merely upon the different amount of solid matter, and the size and number of spaces in each; the cavities being small in the compact tissue and the solid matter between them abundant, whilst in the cancellous tissue the spaces are large and the solid matter in smaller quantity. There is, moreover, no abrupt limit between the two, but the one tissue gradually merges into the other.

Bone during life is permeated by vessels and is enclosed in a fibrous membrane, the *periosteum*, by means of which many of these vessels reach the hard tissue. If the periosteum is stripped from the surface of the living bone small bleeding points are seen, which mark the entrance of the periosteal vessels; and on section during life, every part of the bone will be seen to exude blood from the minute vessels which ramify in it. The interior of the bones of the limbs presents a cylindrical cavity filled with marrow and lined by a highly vascular areolar structure, called the *medullary membrane* or *internal periosteum*, which, however, is rather the areolar envelope of the cells of the marrow, than a definite membrane.

The **periosteum** adheres to the surface of the bones in nearly every part, excepting at their cartilaginous extremities. Where strong tendons or ligaments are attached to the bone, the periosteum is incorporated with them. It consists of two layers closely united together, the outer one formed chiefly of connective tissue, containing occasionally a few fat-cells; the inner one, of elastic fibres of the finer kind, forming dense membranous networks, which can be again separated into several layers. In young bones the periosteum is thick and very vascular, and is intimately connected at either end of the bone with the epiphysial cartilage, but less closely with the shaft, from which it is separated by a layer of soft blastema, containing a number of granular corpuscles or 'osteoblasts,' in which ossification proceeds on the exterior of the young bone. Later in life the periosteum is thinner, less vascular, and the osteoblasts have become converted into an epithelial layer, which is separated from the rest of the periosteum in many places by cleft-like spaces, which are supposed to serve for the transmission of lymph. The periosteum serves as a nidus for the ramification of the vessels previous to their distribution in the bone; hence the liability of bone to exfoliation or necrosis, when denuded of this membrane by injury or disease. Fine nerves and lymphatics, which generally accompany the arteries, may also be demonstrated in the periosteum.

The **marrow** not only fills up the cylindrical cavity in the shafts of the long bones, but also occupies the spaces of the cancellous tissue and extends into the

larger bony canals (Haversian canals) which contain the blood-vessels. It differs in composition in different bones. In the shafts of adult long bones the marrow is of a *yellow* colour, and contains, in 100 parts, 96 of fat, 1 of areolar tissue and vessels, and 3 of fluid, with extractive matter, and consists of a matrix of retiform connective tissue, supporting numerous blood-vessels and cells, most of which are fat-cells, but some few are 'marrow-cells.' In the flat and short bones, in the articular ends of the long bones, in the bodies of the vertebræ, in the cranial diploë, and in the sternum and ribs, it is of a *red* colour, and contains, in 100 parts, 75 of water and 25 of solid matter, consisting of albumen, fibrin, extractive matter, salts, and a mere trace of fat. The red marrow consists of a small quantity of areolar tissue, blood-vessels, and numerous cells, some few of which are fat-cells, but the great majority roundish nucleated cells, the true 'marrow-cells' of Kölliker. These marrow-cells resemble in appearance the white corpuscles of the blood, though they are larger and have a relatively larger nucleus and a clearer protoplasm, but, like them, possess amœboid movements. Amongst them may be seen smaller cells, which possess a slightly pinkish hue; and it has been stated by Neumann that they are then in a transitional stage between marrow-cells and red blood-corpuscles, and that one of the principal sources of blood-globules is the marrow of the spongy bones.

Giant-cells (*myelo-plaques, osteoclasts*), large, multi-nucleated, protoplasmic masses, are also to be found in both sorts of adult marrow, but more particularly in red marrow. They were believed by Kölliker to be concerned in the absorption of bone-matrix, and hence the name which he gave to them—*osteoclasts*. They excavate small shallow pits or cavities, which are named *Howship's lacunæ*, in which they are found lying.

Vessels of Bone.—The blood-vessels of bone are very numerous. Those of the compact tissue are derived from a close and dense network of vessels ramifying in the periosteum. From this membrane, vessels pass into the minute orifices in the compact tissue, and run through the canals which traverse its substance. The cancellous tissue is supplied in a similar way, but by a less numerous set of larger vessels, which, perforating the outer compact tissue, are distributed to the cavities of the spongy portion of the bone. In the long bones, numerous apertures may be seen at the ends near the articular surfaces, some of which give passage to the arteries of the larger set of vessels referred to; but the most numerous and largest apertures are for the veins of the cancellous tissue, which run separately from the arteries. The medullary canal in the shafts of the long bones is supplied by one large artery (or sometimes more), which enters the bone at the nutrient foramen (situated in most cases near the centre of the shaft), and perforates obliquely the compact structure. The *medullary* or *nutrient* artery, usually accompanied by one or two veins, sends branches upwards and downwards, to supply the medullary membrane, which lines the central cavity and the adjoining canals. The ramifications of this vessel anastomose with the arteries both of the cancellous and compact tissues.* In most of the flat, and in many of the short spongy bones, one or more large apertures are observed, which transmit, to the central parts of the bone, vessels corresponding to the medullary arteries and veins. The veins emerge from the long bones in three places (Kölliker)—(1) by one or two large veins, which accompany the artery; (2) by numerous large and small veins at the articular extremities; (3) by many small veins which arise in the compact substance. In the flat cranial bones the veins are large, very numerous, and run in tortuous canals in

* This view is not, however, entertained by all anatomists. Mr. Charles Stewart believes that, in many cases at all events, the vessels of the periosteum supply only the circumferential lamellæ on the surface of the shaft of the bone, which are formed from this membrane, and that the whole of the rest of its structure is supplied by the vessels of the medullary membrane, and that only very exceptionally does any anastomosis take place between the two sets of vessels. Certainly, in one microscopic section which I had an opportunity of examining, through the kindness of Mr. Stewart, this appeared to be the case.

the diploic tissue, the sides of the canals being formed by a thin lamella of bone, perforated here and there for the passage of branches from the adjacent cancelli. The same condition is also found in all cancellous tissue, the veins being enclosed and supported by osseous structure, and having exceedingly thin coats. When the bony structure is divided, the vessels remain patulous, and do not contract in the canals in which they are contained. Hence the occurrence of purulent absorption after amputation, in those cases where the stump becomes inflamed, and the cancellous tissue is infiltrated and bathed in pus.

Lymphatic vessels, in addition to those found in the periosteum, have been traced, by Cruikshank, into the substance of bone, and Klein describes them as running in the Haversian canals.

Nerves are distributed freely to the periosteum, and accompany the nutrient arteries into the interior of the bone. They are said by Kölliker to be most numerous in the articular extremities of the long bones, in the vertebræ and the larger flat bones.

Minute Anatomy.—The intimate structure of bone, which in all essential particulars is identical in the compact and cancellous tissue, is most easily studied in a transverse section from the compact wall of one of the long bones after maceration, such as is shown in fig. 28.

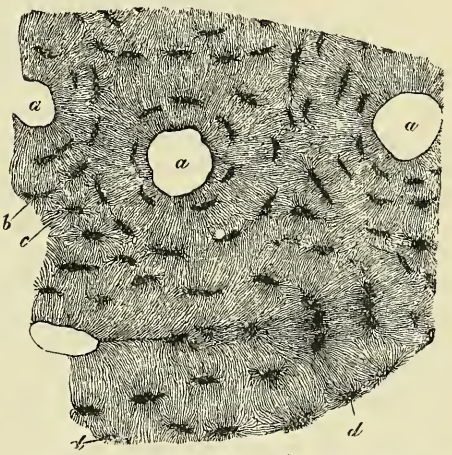


FIG. 28.—From a transverse section of the diaphysis of the humerus. Magnified 350 times.

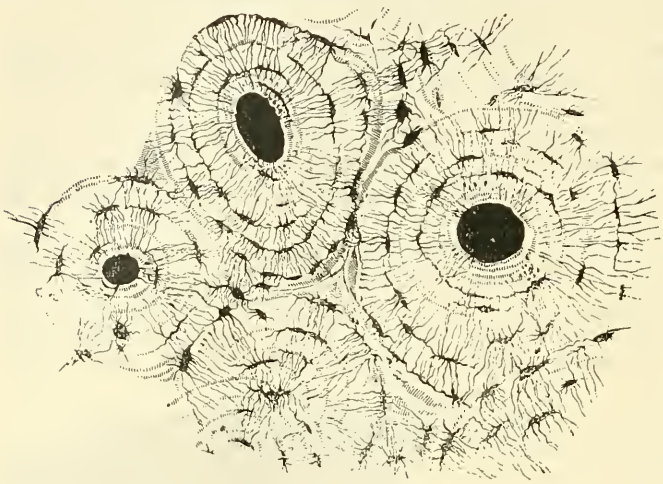
a. Haversian canals. *b*. Lacunæ, with their canaliculi in the lamellæ of these canals. *c*. Lacunæ, of the interstitial lamellæ. *d*. Others at the surface of the Haversian systems, with canaliculi given off from one side.

If this is examined with a rather low power the bone will be seen to be mapped out into a number of circular districts: each one of which consists of a central hole surrounded by a number of concentric rings. These districts are termed *Haversian systems*; the central hole is an *Haversian canal*, and the rings around are layers of bone-tissue arranged concentrically around the central canal, and termed *lamellæ*. Moreover, on closer examination, it will be found that between these lamellæ, and therefore also arranged concentrically around the central canal, are a number of little dark specks, the *lacunæ*, and that these lacunæ are connected with each other and with the central Haversian canal by a number of fine dark lines, which radiate like the spokes of a wheel and are called *canaliculi*. All these structures—the concentric lamellæ, the lacunæ, and the canaliculi—may be seen in any single Haversian system, forming a circular district round a central, Haversian, canal. Between these circular systems, filling in the irregular intervals which are left between them, are other lamellæ, with their lacunæ and canaliculi, running in various directions, but more or less curved (fig. 29). These are termed *interstitial* lamellæ. Again, other lamellæ, for the most part found on the surface of the bone, are arranged concentrically to the circumference of bone, constituting, as it were, a single Haversian system of the whole bone, of which the medullary cavity would represent the Haversian canal. These latter lamellæ are termed *circumferential*, or by some authors *primary* or *fundamental* lamellæ, to distinguish them from those laid down around the axis of the Haversian canals, which are then termed *secondary* or *special* lamellæ.

The *Haversian canals*, seen as round holes in a transverse section of bone at or about the centre of each Haversian system, may be demonstrated to be true canals, if a longitudinal section is made, as in fig. 31. It will then be seen that

these round holes are tubes cut across, which run parallel with the longitudinal axis of the bone for a short distance, and then branch and communicate. They vary considerably in size, some being as large as $\frac{1}{200}$ of an inch in diameter; the average size being, however, about $\frac{1}{500}$ of an inch. Near the medullary cavity the canals are larger than those near the surface of the bone. Each canal, as a rule, contains two blood-vessels, a small artery and vein; the larger ones also contain a small quantity of delicate connective tissue, with branched cells, the processes of which communicate with the branched processes of certain bone-cells in the substance of the bone. Those canals near the surface of the bone open upon it by minute orifices, and those near the medullary cavity open in the same way into this space, so that the whole of the bone is permeated by a system of blood-vessels running through the bony canals in the centre of the Haversian systems.

Fig. 29.—Transverse section of compact tissue of bone. Magnified about 150 diameters. (Sharpey.)



The *lamellæ* are thin plates of bone-tissue encircling the central canal, and might be compared, for the sake of illustration, to a number of sheets of paper pasted one over another around a central hollow cylinder. After macerating a piece of bone in dilute mineral acid, these lamellæ may be stripped off in a longitudinal direction as thin films. If one of these is examined with a high power under the microscope it will be found to be composed of a finely reticular structure, presenting the appearance of lattice-work made up of very slender, transparent fibres, decussating obliquely, and coalescing at the points of intersection so as to form an exceedingly delicate network. In many places the various lamellæ may be seen to be held together by tapering fibres, which run obliquely through them, pinning or bolting them together. These fibres were first described by Sharpey, and were named by him *perforating fibres*.

Fig. 30.—Nucleated bone-cells and their processes, contained in the bone-lacunæ and their canaliculi respectively. From a section through the vertebra of an adult mouse. (Klein and Noble Smith.)

The *lacunæ* are situated between the lamellæ, and consist of a number of oblong spaces. In an ordinary microscopic section, viewed by transmitted light, they appear as dark, oblong, opaque spots, and were formerly believed to be solid cells. Subsequently, when it was seen that the Haversian canals were channels which lodge the vessels of the part, and the canaliculi minute tubes by which the plasma of the blood circulates through the tissue, it was taught that the lacunæ were hollow spaces filled during life with the same fluid, and only lined (if lined at all) by a delicate membrane. But this view appears

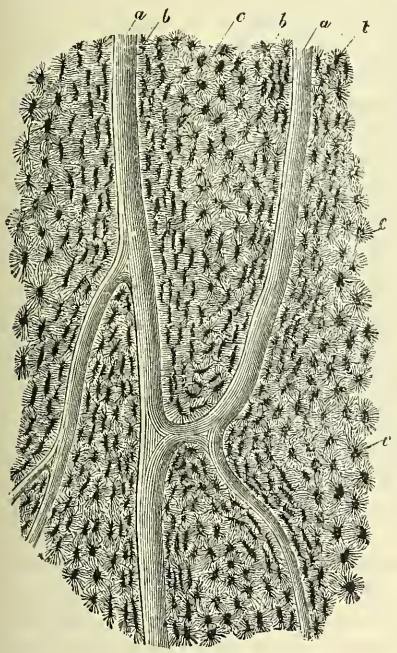
also to be delusive. Examination of the structure of bone, when recent, led Virchow to believe that the lacunæ are occupied during life by a nucleated cell, the processes from which pass down the canaliculi—a view which is now universally received (fig. 30). It is by means of these cells that the fluids necessary for nutrition are brought into contact with the ultimate tissue of bone.

The *canaliculi* are exceedingly minute channels, which pass *across* the lamellæ and connect the lacunæ with neighbouring lacunæ and also with the Haversian canal. From this central canal a number of the canaliculi are given off, which radiate from it, and open into the first set of lacunæ arranged around the Haversian canal, between the first and second lamellæ. From these lacunæ a second set of canaliculi are given off, which pass outwards to the next series of lacunæ, and so on until they reach the periphery of the Haversian system; here the canaliculi given off from the last series of lacunæ do not communicate with the lacunæ of neighbouring Haversian systems, but after passing outwards for a short distance form loops and return to their own lacuna. Thus every part of an Haversian system is supplied with nutrient fluids derived from the vessels in the Haversian canal and traversing the canaliculi and lacunæ.

The *bone-cells* are contained in the lacunæ, which, however, they do not completely fill. They are flattened nucleated cells, which Virchow has shown are homologous with those of connective tissue. The cells are branched, and the branches, especially in young bones, pass into the canaliculi from the lacunæ.

If a longitudinal section is examined, as in fig. 31, the structure is seen to be the same. The appearance of concentric rings is replaced by that of lamellæ or rows of lacunæ, parallel to the course of the Haversian canals, and these canals appear like half-tubes instead of circular spaces. The tubes are seen to branch and communicate, so that each separate Haversian canal runs only a short distance. In other respects the structure has much the same appearance as in transverse sections.

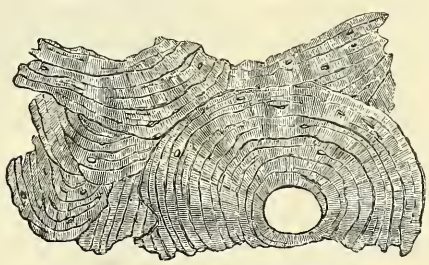
Fig. 31.—Section parallel to the surface from the shaft of the femur. Magnified 100 times.



a. Haversian canals. *b*. Lacunæ seen from the side. *c*. Others seen from the surface in lamellæ which are cut horizontally.

In sections of thin plates of bone (as in the walls of the cells which form the cancellous tissue) the Haversian canals are absent and the canaliculi open into the spaces of the cancellous tissue (medullary spaces), which thus have the same function as the Haversian canals in the more compact bone.

Fig. 32.—Section of bone after the removal of the earthy matter by the action of acids.



Chemical Composition.—Bone consists of an animal and an earthy part intimately combined together.

The animal part may be obtained by immersing the bone for a considerable

time in dilute mineral acid, after which process the bone comes out exactly the same shape as before, but perfectly flexible, so that a long bone (one of the ribs, for example) can easily be tied in a knot. If now a transverse section is made (fig. 32) the same general arrangement of the Haversian canals, lamellæ, lacunæ, and canaliculi is seen, though not so plainly as in the ordinary section.

The earthy part may be obtained separate by calcination, by which the animal matter is completely burnt out. The bone will still retain its original form, but it will be white and brittle, will have lost about one-third of its original weight, and will crumble down with the slightest force. The earthy matter confers on bone its hardness and rigidity, and the animal matter its tenacity.

The animal base is often called cartilage, but differs from it in structure, in the fact that it is softer and more flexible, and that when boiled with a high pressure it is almost entirely resolved into gelatin.

The organic constituent of bone forms about *one-third*, or 33·3 per cent.; the inorganic matter, *two-thirds*, or 66·7 per cent.; as is seen in the subjoined analysis of Berzelius:—

Organic matter	Gelatin and blood-vessels	33·30
Inorganic or Earthy matter	Phosphate of lime	51·04
	Carbonate of lime	11·30
	Fluoride of calcium	2·00
	Phosphate of magnesia	1·16
	Soda and chloride of sodium	1·20
		100·00

Some chemists add to this about 1 per cent. of fat.

Some difference exists in the proportion between the two constituents of bone at different periods of life. In the child the animal matter predominates, whereas in aged people the bones contain a larger proportion of earthy matter, and the animal matter is deficient in quantity and quality. Hence in children it is not uncommon to find, after an injury to the bones, that they become bent or only partially broken, whereas in old people the bones are more brittle and fracture takes place more readily. Some of the diseases, also, to which bones are liable mainly depend on the disproportion between the two constituents of bone. Thus in the disease called rickets, so common in the children of the poor, the bones become bent and curved, either from the superincumbent weight of the body, or under the action of certain muscles. This depends upon some defect of nutrition by which bone becomes deprived of its normal proportion of earthy matter, whilst the animal matter is of unhealthy quality. In the vertebræ of a rickety subject, Dr. Bostock found in 100 parts 79·75 animal and 20·25 earthy matter.

Development of Bone.—In the fœtal skeleton some bones, such as the long bones of the limbs, are cartilaginous; others, as the cranial bones, are membranous. Hence two kinds of ossification are described: the *intracartilaginous* and the *intramembranous*; and to these a third is sometimes added, the *subperiosteal*; this, however, is the same as the second, only taking place under different circumstances.

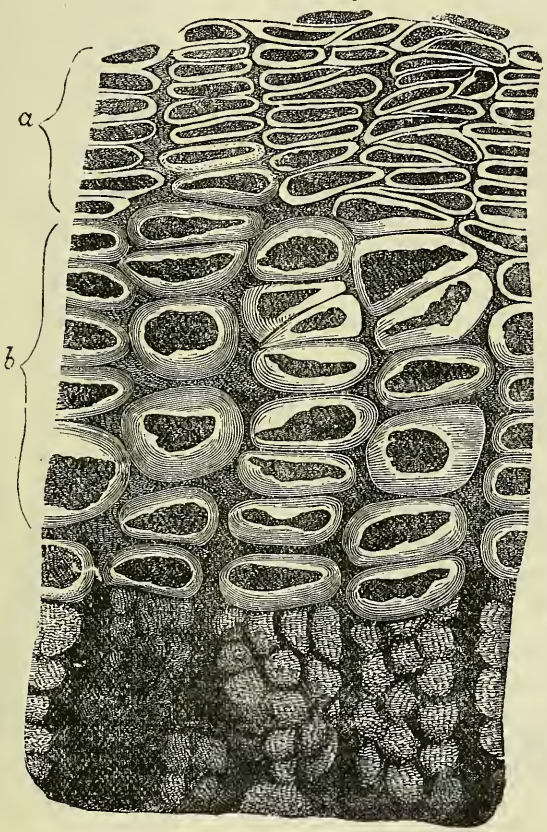
Intracartilaginous Ossification.—Just before ossification begins the bone is entirely cartilaginous, and in a long bone, which may be taken as an example, the process commences in the centre and proceeds towards the extremities, which for some time remain cartilaginous. Subsequently a similar process commences in one or more places in those extremities and gradually extends through it. The extremity does not, however, become joined to the shaft of the bone until growth has ceased, but remains separated by a layer of cartilaginous tissue termed *epiphysial cartilage*.

The first step in the ossification of the cartilage is that the cartilage-cells, at the point where ossification is commencing and which is termed a *centre of ossification*, enlarge and arrange themselves in rows (fig. 33). The matrix in which they are embedded increases in quantity, so that the cells become further separated from each other. A deposit of calcareous material now takes place in

this matrix, between the rows of cells, so that they become separated from each other by longitudinal columns of calcified matrix, presenting a granular and opaque appearance. Here and there the matrix between two cells of the same row also becomes calcified, and thus we have transverse bars of calcified substance stretching across from one calcareous column to another. Thus we have longitudinal groups of the cartilage-cells enclosed in oblong cavities, the walls of which are formed of calcified matrix. These cavities are called the *primary areolæ* (Sharpey).

At the same time that this process is going on in the centre of the cartilage of which the fœtal bone consists, certain changes are taking place on its surface. This is covered by a very vascular membrane, the *perichondrium*, on the inner surface of which, that is to say, on the surface in contact with the cartilage, are a number of cells called *osteoblasts*. By the agency of these cells a thin layer of bony

FIG. 33.—Longitudinal section through the ossifying portion of a long bone in the human embryo.

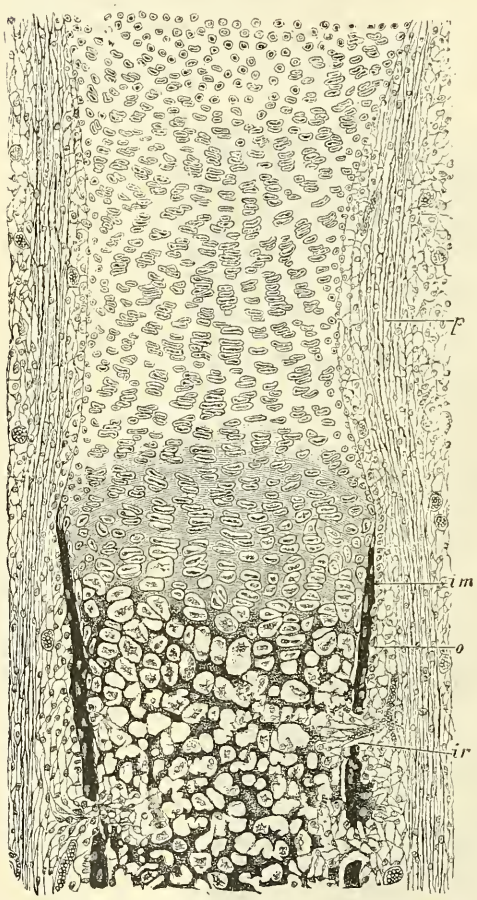


a Cartilaginous region. *b*. Region of calcified matrix.

tissue is being formed between the perichondrium and the cartilage, by the *intramembranous* mode of ossification presently to be described. We have then, in this first stage of ossification, two processes going on simultaneously: in the centre of the cartilage the formation of a number of oblong spaces, formed of calcified matrix and containing the cartilage-cells enlarged and arranged in groups, and on the surface of the cartilage the formation of a layer of true membrane-bone. The second stage consists in the prolongation into the cartilage of processes of the deeper or osteogenetic layer of the perichondrium, which has now become periosteum (fig. 34, *ir*). The processes consist of blood-vessels and cells (osteoblasts). They excavate passages through the new-formed bony layer by absorption, and pass through it into the calcified matrix (fig. 34). Wherever

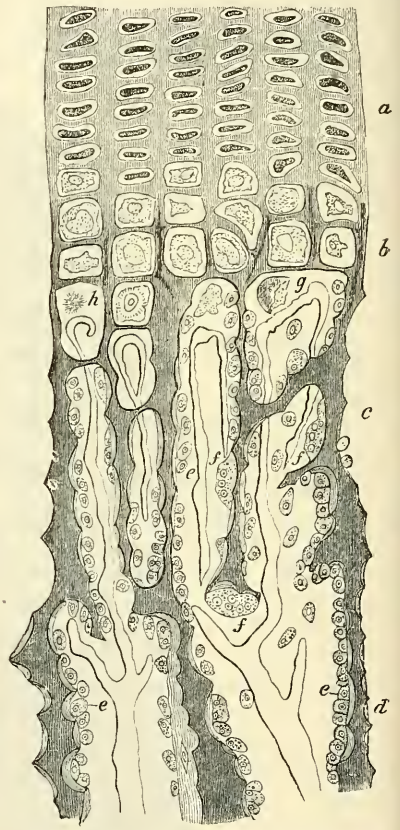
these processes come in contact with the calcified walls of the primary areolæ they absorb it, and thus cause a fusion of the original cavities and the formation of larger spaces, which are termed the *secondary areolæ* (Sharpey) or *medullary spaces* (Müller). In these secondary spaces the original cartilage-cells disappear, and their cavities become filled with embryonic marrow, consisting of osteoblasts and vessels, and derived, at all events in part, in the manner described above, from the osteogenetic layer of the periosteum (fig. 35). What becomes of the cartilage-cells is not finally determined. By most histologists they are believed to be converted, after division, into osteoblasts,

Fig. 34.—Section of fœtal bone of cat.



ir. Irruption of the subperiosteal tissue. *p*. Fibrous layer of the periosteum. *o*. Layer of osteoblasts. *im*. Subperiosteal bony deposit. (From Quain's 'Anatomy,' E. A. Schäfer.)

Fig. 35.—Part of a longitudinal section of the developing femur of a rabbit.



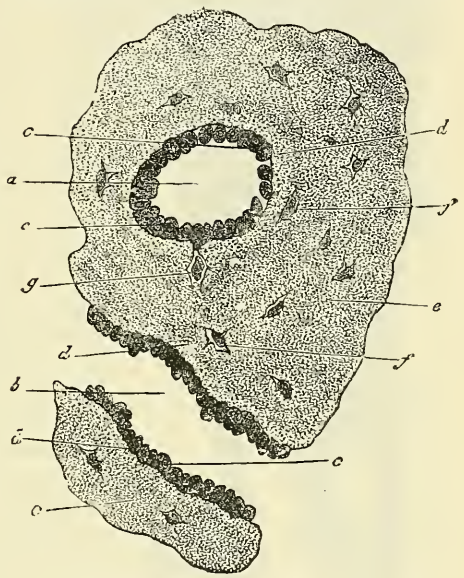
a. Flattened cartilage-cells. *b*. Enlarged cartilage-cells. *c*, *d*. Newly formed bone. *e*. Osteoblasts. *f*. Giant-cells or osteoclasts. *g*, *h*. Shrunken cartilage-cells. (From 'Atlas of Histology,' Klein and Noble Smith.)

and so assist in forming the embryonic marrow. Others, on the other hand, believe that they are simply absorbed and take no part in the formation of bone.

Thus far, then, we have got enlarged spaces (secondary areolæ), the walls of which are still formed by calcified cartilage-matrix, containing an embryonic marrow, derived from the processes sent in from the osteogenetic layer of the periosteum, and consisting of blood-vessels and round cells, osteoblasts (fig. 35), some of which probably are derived from the division of the original cartilage-cells, which have disappeared. The walls of these secondary areolæ are at this time of only inconsiderable thickness, but they now become thickened by the deposition of layers of new bone on their interior. This process takes place in the following manner. Some of the osteoblasts of the embryonic marrow, after

undergoing rapid division, arrange themselves as an epithelioid layer on the surface of the wall of the space (fig. 36). This layer of osteoblasts forms a bony stratum, and thus the wall of the space becomes gradually covered with a layer of true osseous substance. On this a second layer of osteoblasts arrange themselves, and in their turn form an osseous layer. By the repetition of this process the original cavity becomes very much reduced in size, and at last only remains as a small circular hole in the centre, containing the remains of the embryonic marrow—that is, a blood-vessel and a few osteoblasts. This small cavity constitutes the Haversian canal of the perfectly ossified bone. The successive layers of osseous matter which have been laid down and which encircle this central canal, constitute the lamellæ of which, as we have seen, each Haversian system is made up. As the successive layers of osteoblasts form osseous tissue, certain of the osteoblastic cells remain included between the various bony layers. These continue persistent and remain as the corpuscles of the future bone, the spaces enclosing them forming the lacunæ (fig. 36). The mode of the formation of the canaliculi is not known.

FIG. 36.—Transverse section from the femur of a human embryo about eleven weeks old.



a. A medullary sinus cut transversely; and *b*, another longitudinally. *c*. Osteoblasts. *d*. Newly formed osseous substance of a lighter colour. *e*. That of greater age. *f*. Lacunæ with their cells. *g*. A cell still united to an osteoblast.

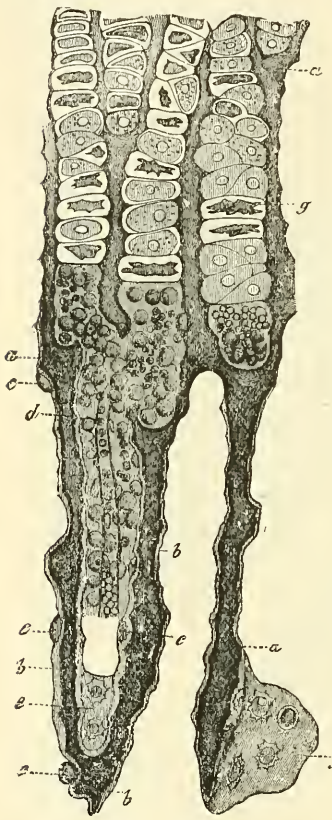
Such are the changes which may be observed at one particular point, the centre of ossification. While they have been going on here a similar process has been proceeding in the same manner towards the end of the shaft, so that in the ossifying bone all the changes described above may be seen in different parts, from the true bone in the centre of the shaft to the hyaline cartilage at the extremities. The bone thus formed differs from the bone of the adult in being more spongy and less regularly lamellated.

Thus far, then, we have followed the steps of a process by which a solid bony mass is produced, having vessels running into it from the periosteum, Haversian canals in which those vessels run, medullary spaces filled with fœtal marrow, lacunæ with their contained bone-cells, and canaliculi growing out of these lacunæ.

This process of ossification, however, is not the origin of the whole of the skeleton, for even in those bones in which the ossification proceeds in a great measure from a single centre, situated in the cartilaginous shaft of a long bone, a considerable part of the original bone is formed by intramembranous ossification beneath the perichondrium or periosteum; so that the girth of the bone is increased by bony deposit from the deeper layer of this membrane. The shaft of the bone is at first solid, but a tube is hollowed out in it by absorption around the vessels passing into it, which becomes the medullary canal. This absorption is supposed to be brought about by large 'giant-cells,' which have long been recognised as a constituent of fœtal marrow, and which are believed by Kölliker to have the power of absorbing or dissolving bone, and he has therefore named them 'osteoclasts' (fig. 35, *f*). They vary in shape and size, and are known by containing a large number of clear nuclei, sometimes as many as twenty. The occurrence of similar cells in some tumours of bones has led to such tumours being denominated 'myeloid.'

As more and more bone is removed by this process of absorption from the interior of the bone to form the medullary canal, so more and more bone is deposited on the exterior from the periosteum, until at length it has attained the shape and size which it is destined to retain during adult life. As the ossification of the cartilaginous shaft extends towards the articular ends it carries with it, as it were, a layer of cartilage, or the cartilage grows as it ossifies, and thus the bone is increased in length. During this period of growth the articular end, or epiphysis, remains for some time entirely cartilaginous, then a bony centre appears in it, and it commences the same process of intracartilaginous ossification; but this process never extends to any great distance. The epiphyses remain separated from the shaft by a narrow cartilaginous layer for a definite time. This layer ultimately ossifies, the distinction between shaft and epiphysis is obliterated, and the bone assumes its completed form and shape. The same remarks also apply to the processes of bone which are separately ossified, such as the trochanters of the femur. The bones, having been formed, continue to grow until the body has acquired its full stature. They increase in length by ossification continuing to extend in the epiphysial cartilage, which goes on growing in advance of the ossifying process. They increase in circumference by deposition of new bone, from the deeper layer of the periosteum, on their external surface, and at the same time an absorption takes place from within, by which the medullary cavity is increased.

Fig. 37.—Vertical section from the edge of the ossifying portion of the diaphysis of a metatarsal bone from a fœtal calf. (After Müller.)



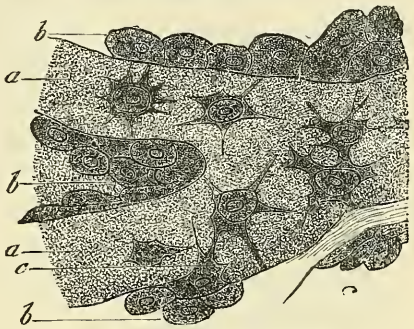
a. Ground-mass of the cartilage. *b*. Of the bone. *c*. Newly formed bone-cells in profile, more or less embedded in intercellular substance. *d*. Medullary canal in process of formation, with vessels and medullary cells. *e*, *f*. Bone-cells on their broad aspect. *g*. Cartilage-capsules arranged in rows, and partly with shrunken cell-bodies.

The medullary spaces which characterise the cancellous tissue are produced by the absorption of the original fœtal bone in the same way as the original medullary canal is formed. The distinction between the cancellous and compact tissue appears to depend essentially upon the extent to which this process of absorption has been carried; and we may perhaps remind the reader that in morbid states of the bone inflammatory absorption produces exactly the same change, and converts portions of bone, naturally compact, into cancellous tissue.

Intramembranous Ossification.—The intramembranous ossification is that by which the bones of the vertex of the skull are entirely formed. In the bones which are so developed, no cartilaginous mould precedes the appearance of the bone-tissue. In the membrane which occupies the place of the future bone, a little network of bony spiculæ is first noticed, radiating from the point of ossification. When these rays of growing bone are examined by the microscope, they are found to consist of a network of fine clear fibres and granular corpuscles, with a ground-substance between. The fibres are termed *osteogenic* fibres, and soon become dark and granular from calcification, and as they calcify they are found to enclose the granular corpuscles or 'osteoblasts' (fig. 38). The calcification not only involves the osteogenic fibres, but also the ground-substance of the tissue in which they are contained. The corpuscles at first lie upon the osteogenic fibres, so that they can be removed

by brushing the specimen with a hair-pencil, in order to render the fibres clear; but they gradually become involved in the ossifying matrix, and form the corpuscles of the future bone, the spaces in which they are enclosed constituting the lacunæ. As the tissue increases in thickness, vessels shoot into it, grooving for themselves spaces or channels, which become the Haversian canals. Thus, the intramembranous and intracartilaginous processes of ossification are similar in their more essential features.

FIG. 38.—Osteoblasts from the parietal bone of a human embryo thirteen weeks old. (After Gegenbauer.)



a. Bony septa with the cells of the lacunæ. *b*. Layers of osteoblasts. *c*. The latter in transition to bone-corpuscles.

The number of ossific centres is different in different bones. In most of the short bones ossification commences by a single point in the centre, and proceeds towards the circumference. In the long bones there is a central point of ossification for the shaft or diaphysis: and one or more for each extremity, the epiphysis. That for the shaft is the first to appear. The union of the epiphyses with the shaft takes place in the reverse order to that in which their ossification began, and appears to be regulated by the direction of the nutrient artery of the bone. Thus, the nutrient arteries of the bones of the arm and fore-arm are directed towards the elbow, and the epiphyses of the bones forming this joint become united to the shaft before those at the opposite extremity. In the lower limb, on the other hand, the nutrient arteries pass in a direction from the knee: that is, upwards in the femur, downwards in the tibia and fibula; and in them it is observed that the upper epiphysis of the femur, and the lower epiphysis of the tibia and fibula, become first united to the shaft.

Where there is only one epiphysis, the medullary artery is directed towards that end of the bone where there is no additional centre; as towards the acromial end of the clavicle, towards the distal end of the metacarpal bone of the thumb and great toe, and towards the proximal end of the other metacarpal and metatarsal bones.

Besides these epiphyses for the articular ends, there are others for projecting parts or processes, which are formed separately from the bulk of the bone. For an account of these, the reader must be referred to the description of the individual bones in the sequel.

A knowledge of the exact periods when the epiphyses become joined to the shaft is often of great importance in medico-legal inquiries. It also aids the surgeon in the diagnosis of many of the injuries to which the joints are liable; for it not infrequently happens that, on the application of severe force to a joint, the epiphysis becomes separated from the shaft, and such injuries may be mistaken for fracture or dislocation.

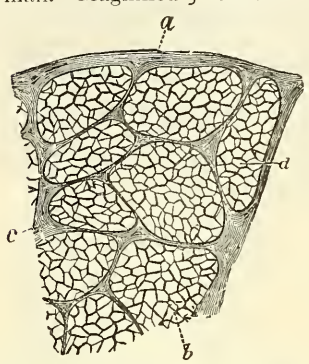
MUSCULAR TISSUE

The **muscles** are formed of bundles of reddish fibres, endowed with the property of contractility. Two kinds of muscular tissue are found in the body, viz. that of voluntary or animal life, and that of involuntary or organic life. The former of these, from the characteristic appearances which their fibres exhibit under the microscope, are known as the 'striped' muscles, and from the fact that they are capable of being put into action and controlled by the will, as the 'voluntary' muscles. The fibres of the latter do not present any cross-striped appearance, and for the most part are not under the control of the will; hence they are known as the 'unstriped' or 'involuntary' muscles. The muscular fibres of the heart

differ in certain particulars from both these groups, and they are therefore separately described as 'cardiac' muscular fibres.

The **striped** or **voluntary muscles** are composed of bundles of fibres enclosed in a delicate web called the 'internal perimysium,' in contradistinction to the sheath of areolar tissue which invests the entire muscle, the 'epimysium' or 'external perimysium.' The bundles are termed 'fasciculi'; they are prismatic in shape, of different sizes in different muscles, and for the most part placed parallel to one another, though they have a tendency to converge towards their tendinous attachments. Each fasciculus is made up of a bundle of *fibres*, which also run parallel with each other, and which are separated from one another by a delicate connective tissue derived from the perimysium, and termed *endomysium* (fig. 39). This does not form the sheath of the fibres, but serves to support the blood-vessels and nerves ramifying between them. The fibres are enclosed in a separate and distinct sheath of their own, but it is not areolar tissue and is therefore not derived from the perimysium.

FIG. 39.—Transverse section from the sterno-mastoid in man. Magnified 50 times.



a. External perimysium. *b*. Fasciculus. *c*. Internal perimysium. *d*. Fibre.

A *muscular fibre* may be said to consist of a soft contractile substance enclosed in a tubular sheath, named by Bowman the *sarcolemma*. The fibres are cylindrical or prismatic in shape, and are of no great length, not exceeding, it is said, an inch and a half. They end either by blending with the tendon or aponeurosis, or else by becoming drawn out into a tapering extremity which is connected to the neighbouring fibre by means of the sarcolemma. Their breadth varies in man from $\frac{1}{2000}$ to $\frac{1}{6000}$ of an inch, the average of the majority being about $\frac{1}{4000}$. As a rule, the fibres do not divide or anastomose; but occasionally, especially in the tongue and facial muscles, the fibres may be seen to divide into several branches. The precise mode in which the muscular fibre joins the tendon has been variously described by different observers. It may, perhaps, be sufficient to say that the sarcolemma, or membranous investment of the muscular fibre, appears to become blended with a small bundle of fibres, into which the tendon becomes subdivided, while the muscular substance terminates abruptly and can be readily made to retract from the point of junction. The areolar tissue between the fibres appears to be prolonged more or less into the tendon, so as to form a kind of sheath around the tendon bundles for a longer or shorter distance. When muscular fibres are attached to the skin or mucous membranes, their fibres are described by Hyde Salter as becoming continuous with those of the areolar tissue.

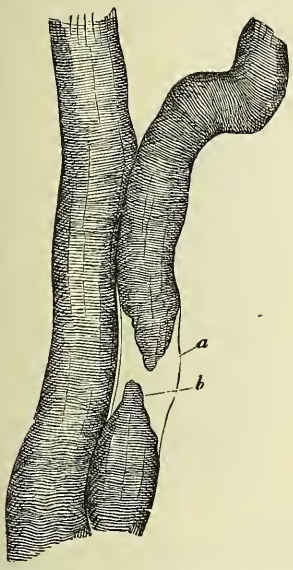
The *sarcolemma*, or tubular sheath of the fibre, is a transparent, elastic, and apparently homogeneous membrane of considerable toughness, so that it will sometimes remain entire when the included substance is ruptured (see fig. 40). On the internal surface of the sarcolemma in mammalia, and also in the substance of the fibre in the lower animals, elongated nuclei are seen (fig. 57), and in connection with these a row of granules, apparently fatty, is sometimes observed.

Upon examination of a muscular fibre by transmitted light under a sufficiently high power, it is found to be apparently marked by alternate light and dark bands or striæ, which pass transversely, or somewhat obliquely, round the fibre (fig. 40). The dark and light bands are of nearly equal breadth, and alternate with great regularity. They vary in breadth from about the $\frac{1}{12000}$ to the $\frac{1}{17000}$ of an inch. Other striæ pass longitudinally over the fibres, though they are less distinct than the former. This longitudinal striation gives the fibre the appearance of being made up of a bundle of fibrillæ. The muscular fibre can

be broken up either in a longitudinal or transverse direction (fig. 41). If hardened in alcohol, it can be broken up longitudinally, and forms the so-called fibrillæ of which some suppose the fibre to be made up. Each fibril is marked by transverse striæ, and appears to consist of a single row of minute quadrangular particles, named 'sarcous elements' by Bowman. A still further division, however, is capable of being made, and each of these fibrillæ may be divided into minute threads (fig. 42, B, *b*), consisting of an alternate dark and light spot. After exposure to the action of dilute hydrochloric acid, the muscular fibre can be broken transversely (fig. 41, B). It then forms discs or plates, consisting of the same quadrangular particles, attached by their lateral surfaces.

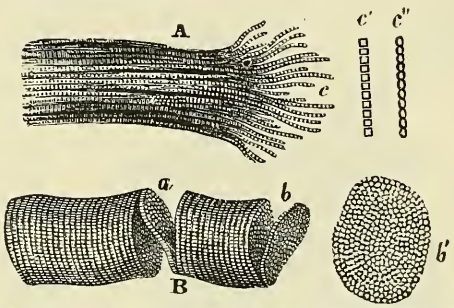
Upon closer examination with a very high power the appearances become more complicated and are susceptible of various interpretations. The transverse striation, which in figs. 40 and 41 appears as a mere alternation of dark and light bands, is resolved into the appearance shown in fig. 42, which shows a series of broad dark bands, separated by a light band, which is itself divided into two by a

FIG. 40.—Two human muscular fibres. Magnified 350 times.



In the one, the bundle of fibrillæ (*b*) is torn, and the sarcolemma (*a*) is seen as an empty tube.

FIG. 41.—Fragments of striped elementary fibres, showing a cleavage in opposite directions. Magnified 300 diameters.



A. Longitudinal cleavage. The longitudinal and transverse lines are both seen. Some longitudinal lines are darker and wider than the rest, and are not continuous from end to end. This results from partial separation of the fibrillæ. *c*. Fibrillæ separated from one another by violence at the broken end of the fibre, and marked by transverse lines equal in width to those on the fibre. *c'* *c''* represent two appearances commonly presented by the separated single fibrillæ (more highly magnified). At *c'* the borders and transverse lines are all perfectly rectilinear, and the included spaces perfectly rectangular. At *c''* the borders are scalloped and the spaces bead-like. When most distinct and definite the fibrilla presents the former of these appearances.

B. Transverse cleavage. The longitudinal lines are scarcely visible. *a*. Incomplete fracture following the opposite surfaces of a disc, which stretches across the interval, and retains the two fragments in connection. The edge and surfaces of this disc are seen to be minutely granular, the granules corresponding in size to the thickness of the disc, and to the distance between the faint longitudinal lines. *b*. Another disc nearly detached. *b'*. Detached disc, more highly magnified, showing the sarcous elements.

dark streak. This streak is termed Krause's membrane; it is continuous at each end with the sarcolemma investing the muscular fibre. Thus it may be said that the fibre is divided into a number of transverse compartments by this membrane, each compartment containing in the centre a dark plate with a bright border above and below; that is to say, between the dark central part and the membrane of Krause. A muscular fibre presents, then, the appearance of the following layers in regular alternation: a dark layer, the *transverse disc*; a bright transparent layer, the *lateral disc*; a dark line, the *intermediate disc* or *membrane of Krause*; then another lateral disc, a transverse disc, and so on (figs. 42 and 43). This appearance, following the observations of Rollett, is due to the mode of formation of a muscular fibre, which is made up of two principal parts: 1, fibrillæ; and 2, a hyaline or faintly granular substance, resembling protoplasm, and called *sarcoplasm*. The fibrillæ are arranged in bundles called *muscular columns* or *sarcostyles*, and these again in larger groups, which, collected together,

form the fibre. The fibrillæ are surrounded by the sarcoplasm, which encloses also the columns and groups of columns, being in these latter situations greater in amount than between the fibrillæ. So that on transverse section a muscular fibre is seen to be divided into a number of areas, called the *areas of Cohnheim*, more or less polyhedral in shape, and consisting of the columns of fibrillæ surrounded by transparent series of sarcoplasm. And these areas are collected into larger or smaller groups, which in the same manner are surrounded by transparent sarcoplasm. Each area of Cohnheim presents a granular appearance due to the cross-section of its constituent fibrillæ, surrounded by a small amount of the hyaline sarcoplasm. The fibrillæ extend throughout the whole length of, and are parallel to, the long axis of the muscular fibre. They present the following appearances in regular alternation : (1) a dim prismatic or rod-shaped element, the *sarcous element of Bowman* ; (2) a thin bridge, which joins the sarcous element to (3) a dark granule. Then again another thin bridge joining the same granule to the next sarcous element, and so on (fig. 42, B, *d*). When

Fig. 42.—A. Portion of a medium-sized human muscular fibre. Magnified nearly 800 diameters. B. Separated bundles of fibrils, equally magnified. *a*, *a*. Larger, and *b*, *b*, smaller collections. *c*. Still smaller. *d*, *d*. The smallest which could be detached.

a. Sarcolemma. *b*. Membrane of Krause : owing to contraction during hardening, the sarcolemma shows regular bulgings. At the side of Krause's membrane is the transparent lateral disc.
Several nuclei of muscle-corpuscles are shown, and in them a minute network.

these fibrillæ are collected together into columns, and the columns into muscular fibres, the appearance mentioned above is produced. The sarcous elements, when arranged side by side and almost touching each other, with very little sarcoplasm between them, represent the transverse disc. The bridges, being much thinner than the sarcous element or the dark granules, have between each other a much larger amount of sarcoplasm, and this gives to this part the transparent appearance of the lateral disc. And, lastly, the granules joined edge to edge in a row present the appearance of a membrane, which represents the intermediate disc.

On the muscular fibre, immediately beneath the sarcolemma, the sarcoplasm becomes here and there collected into small, plate-like masses. They contain oval nuclei, and are termed ' muscle corpuscles.' Finally, in the centre of each sarcous element a transparent lighter band can sometimes be discerned ; this is known as the *median disc* of Hensen, and is due to the substance of the sarcous elements being here thinner.

This form of muscular fibre composes the whole of the voluntary muscles,

all the muscles of the ear, those of the larynx, pharynx, tongue, the upper half of the œsophagus, and the walls of the large veins at the point where they open into the heart.

The *capillaries* of striped muscle are very abundant, and form a sort of rectangular network, the branches of which run longitudinally in the endomysium between the muscular fibres, and are joined at short intervals by transverse anastomosing branches. The larger vascular channels, arteries and veins, are found only in the perimysium, between the muscular fasciculi. The smaller vessels present peculiar saccular dilatations, which are supposed to act as receptacles for the blood during the contraction of the muscular fibres, when it is pressed out from some of the capillaries.

Nerves are profusely distributed to striped muscle. The mode of their termination will be described on a subsequent page.

The existence of *lymphatic* vessels in striped muscle has not been ascertained, though they have been found in tendons and in the sheath of the muscle.

The **unstriped muscle**, or **muscle of organic life**, is found in the walls of the hollow viscera—viz. the lower half of the œsophagus and the whole of the remainder of the gastro-intestinal tube; in the trachea and bronchi, and the alveoli and infundibula of the lungs; in the gall-bladder and ductus communis choledochus; in the large ducts of the salivary and pancreatic glands; in the pelvis and calices of the kidney, the ureter, bladder and urethra; in the female sexual organs—viz. the ovary, the Fallopian tubes, the uterus (enormously developed in pregnancy), the vagina, the broad ligaments, and the erectile tissue of the clitoris; in the male sexual organs—viz. the dartos of the scrotum, the vas deferens and epididymis, the vesiculæ seminales, the prostate gland, and the corpora cavernosa and corpus spongiosum; in the ducts of certain glands, as in Wharton's duct; in the capsule and trabeculæ of the spleen; in the mucous membranes, forming the muscularis mucosæ; in the skin, forming the arrectores pilorum, and also in the sweat-glands; in the arteries, veins, and lymphatics; in the iris and the ciliary muscle.

Fig. 44.—Non-striated elementary fibres from the human colon.

a. Treated with acetic acid, showing the corpuscles. *b*. Fragment of a detached fibre, not touched with acid.

Plain or unstriped muscular fibre is made up of spindle-shaped cells, called *contractile fibre-cells*, collected into bundles and held together by a cement-substance in which are contained some connective-tissue corpuscles (fig. 44). These bundles are further aggregated into larger bundles, or flattened bands, and bound together by ordinary connective tissue.

The *contractile fibre-cells* (fig. 45) are elongated, spindle-shaped, nucleated cells of various lengths, averaging from $\frac{1}{600}$ to $\frac{1}{300}$ of an inch in length, and $\frac{1}{4500}$ to $\frac{1}{3500}$ of an inch in breadth. On transverse section they are more or less polyhedral in shape, from mutual pressure. They present a faintly longitudinal striated appearance, and consist of an elastic cell-wall containing a central bundle of fibrillæ, representing the contractile substance, and an oval or rod-like nucleus, which includes, within a membrane, a fine network communicating at the poles of the nucleus with the contractile fibres (Klein). The adhesive interstitial substance, which connects the fibre-cells together, represents the endomysium, or delicate connective tissue which binds the fibres of striped muscular tissue into fasciculi; while the tissue connecting the individual bundles together represents the perimysium. The unstriped muscle, as a rule, is not under the control of the will, nor is the contraction rapid and involving the whole muscle, as is the case with the muscles of animal life. The membranes

which are composed of the unstriped muscle slowly contract in a part of their extent, generally under the influence of a mechanical stimulus, as that of distension or of cold; and then the contracted part slowly relaxes while another portion of the membrane takes up the contraction. This peculiarity of action is most strongly marked in the intestines, constituting their *vermicular motion*.

Cardiac Muscular Tissue.—The fibres of the heart differ very remarkably from those of other striped muscles. They are smaller by one-third, and their transverse striæ are by no means so distinct. The fibres are made up of distinct quadrangular cells joined end to end (fig. 46). Each cell contains a clear oval nucleus, situated near the centre of the cell. The extremities of the cells have a tendency to branch or divide, the subdivisions uniting with offsets from other

cells, and thus producing an anastomosis of the fibres. The connective tissue between the bundles of fibres is much less than in ordinary striped muscle, and no sarcolemma has been proved to exist.

Chemical Composition of Muscle.—In chemical composition the muscular fibres of both forms consist mainly of a proteid substance—myosin—which Dr. M. Foster speaks of as intermediate between fibrin and globulin. It is readily converted by the action of dilute acids into syntonin or acid-albumen, and by the action of dilute alkalies into alkali-albumen. Muscle, which is neutral or slightly alkaline in reaction when at rest, is rendered acid by contraction, from the development probably of sarcolactic acid. After death, muscle also exhibits an acid reaction, but this appears to be due to post-mortem change.

NERVOUS TISSUE

The **nervous tissues** of the body are comprised in two great systems—the *cerebro-spinal* and the *sympathetic*; and each of these systems consists of a *central organ*, or series of central organs, and of *nerves*.

The *cerebro-spinal* system comprises the brain (including the medulla oblongata), the spinal cord, the cranial nerves, the spinal nerves, and the ganglia connected with both these classes of nerves. The *sympathetic* system consists of a double chain of ganglia, with the nerves which go to and come from them. It is not directly connected with the brain or spinal cord, though it is so indirectly by means of its numerous communications with the cranial and spinal nerves.

All these nervous tissues are composed chiefly of two different structures—the *grey* or *vesicular*, and the *white* or *fibrous*. It is in the former, as is generally supposed, that nervous impressions and impulses originate, and by the latter that they are conducted. Hence the grey matter forms the essential constituent of all the ganglionic centres, both those in the isolated ganglia and those aggregated in the cerebro-spinal axis; while the white matter is found in all the commissural portions of the nerve-centres and in all the cerebro-spinal nerves. The nerves of the sympathetic system are chiefly composed of a somewhat different material in structure, which is named *grey* or *gelatinous* nerve-fibre. This form of nerve-fibre is also found in some of the cerebro-spinal nerves.

The **grey** or **vesicular nervous substance** is distinguished by its dark reddish-grey colour and soft consistence. It is found in the brain, spinal cord, and various ganglia intermingled with the fibrous nervous substance, and also in some of the nerves of special sense, and in gangliform enlargements which are found here and there in the course of certain cerebro-spinal nerves. It is composed, as its name implies, of vesicles, or corpuscles, commonly called *nerve-cells* or *ganglion-corpuscles*, containing nuclei and nucleoli; the vesicles, together with the blood-vessels, in the vesicular nerve-substance, and the nerve-fibres and vessels in the white nerve-substance, are embedded in a peculiar ground-substance, which was regarded by Kölliker as a modified form of retiform connective tissue. It was named by Virchow *neuroglia*, and consists of large branched cells, the branches passing in every direction amongst the nerve-tissue, thus holding it and binding it together. It is developed from the epiblast, and contains neither the characteristic fibres nor cells of connective tissue, and therefore cannot be regarded as belonging to the true connective tissues. Each nerve-cell consists of a finely granular protoplasmic material, of a reddish or yellowish-brown colour, which occasionally presents patches of a deeper tint, caused by the aggregation of pigment-granules (fig. 47). No distinct limiting membrane or cell-wall has been ascertained to exist. The nucleus is, as a rule, a large, well-defined, round, vesicular body, often presenting an intra-nuclear network, and containing a nucleolus which is peculiarly clear and brilliant. The nerve-corpuscles vary in shape and size; some are small, spherical or ovoid, with generally an even outline, such as those frequently found in the spinal ganglia; others are more or less angular, as in the ganglia of the sympathetic; others, again, are caudate or stellate in shape, and are characterised by their large size and by their having one or more tail-like processes issuing from them, which occasionally divide and subdivide into numerous branches (fig. 48). These are found in greatest number in the grey matter of the spinal cord. Still others are flask-shaped, as in the cortex of the cerebellum; or conical, as in the cerebral convolutions. For the most part nerve-cells have one or more processes, and they are distinguished, by the number of these processes, as unipolar, bipolar, or multipolar cells. These processes are very delicate, apparently tubular, and contain a granular material similar to that found within the corpuscle. Some of the processes terminate in fine, transparent fibres, which become lost among the other elements of the nervous tissue; others may be traced until, after losing their granular appearance, they become continuous with an ordinary nerve-fibre.

The **white** or **fibrous** nerve-substance or *nerve-fibre* is found universally in

the nervous cords, and also constitutes a great part of the brain and spinal cord. The fibres of which it consists are of two kinds, the *medullated* or *white* fibres, and the *non-medullated* or *grey* fibres.

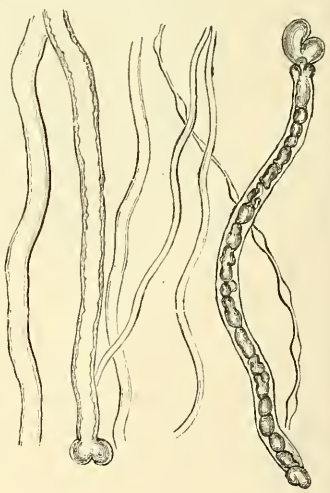
The **medullated** fibres form the white part of the brain and spinal cord, and also the greater part of the cerebro-spinal nerves, and give to these structures their opaque, white aspect. When perfectly fresh they appear to be homogeneous; but soon after removal from the body they present, when examined by transmitted light, a double outline or contour, as if consisting of two parts. The central portion is named the *axis-cylinder of Purkinje*; around this is a sort of sheath of fatty material, named the *white substance of Schwann*, which gives to the fibre its double contour, and the whole is enclosed in a delicate membrane, the *neurilemma*,* *primitive sheath*, or *nucleated sheath of Schwann* (fig. 49).

The *axis-cylinder* is the essential part of the nerve-fibre, and is always present; the other parts, the medullary sheath and the neurilemma, being occasionally absent, especially at the origin and termination of the nerve-fibre.

Fig. 48.—Nerve-vesicles from the inner part of the grey matter of the convolutions of the human brain. Magnified 350 times.

Nerve-cells: *a*. Larger. *b*. Smaller. *c*. Nerve-fibre with axis-cylinder.

Fig. 49.—Human nerve-tubes. Magnified 350 times. Three of them are fine, one of which is varicose, one of middling thickness, and with a simple contour; and three thick, two of which are double-contoured, and one with grumous contents.



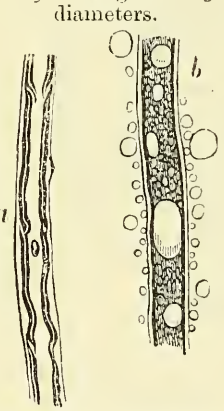
It undergoes no interruption from its origin in the nerve-centre to its peripheral termination, and must be regarded as a direct prolongation of a nerve-cell. It constitutes about one-half or one-third of the nerve-tube, the white substance being greater in proportion in the nerves than in the central organs. It is perfectly transparent, and is therefore indistinguishable in a perfectly fresh and natural state of the nerve. It is described by Kölliker as being distinguished from the white substance by the fact that, though soft and flexible, it is not fluid and viscid, but firm and elastic, somewhat like coagulated albumen, with which it appears for the most part also to agree in its chemical characters. When examined under a high power it presents the appearance of longitudinal striation, as if composed of very fine, homogeneous fibrillæ, held together in a faintly granular interstitial material. Occasionally at its termination the axis-cylinder of a fibre may be seen to break up into exceedingly fine fibrillæ, confirming the

* In older histological works the term 'neurilemma' is used to designate the fibrous envelope of the whole nerve, now called 'perineurium.'

view of its fibrillar structure. These fibrillæ have been termed the *primitive fibrillæ* of Schultze. The axis-cylinder is said by some to be enveloped in a very delicate, hyaline sheath, which separates it from the white matter of Schwann, but it is doubtful whether this really exists. The *medullary sheath* or *white matter of Schwann* is regarded as being a fatty matter in a fluid state, which insulates and protects the essential part of the nerve—the axis-cylinder. The white matter varies in thickness to a very considerable extent, in some forming a layer of extreme thinness, so as to be scarcely distinguishable, in others forming about one-half the nerve-tube. The size of the nerve-fibres, which varies from $\frac{1}{1200}$ to $\frac{1}{2000}$ of an inch, depends mainly upon the amount of the white substance, though the axis-cylinder also varies in size within certain limits. The white matter of Schwann does not always form a continuous sheath to the axis-cylinder, but undergoes interruptions in its continuity at regular intervals, giving to the fibre the appearance of constriction at these points. These were first described by Ranvier, and are known as the *nodes of Ranvier* (fig. 50). The portion of nerve-fibre between two nodes is called an *internodal segment*. The neurilemma or primitive sheath is not interrupted at the nodes, but passes over them as a continuous membrane. Each internodal segment contains an oval nucleus embedded in the medullary sheath. Medullated nerve-fibres, when examined, frequently present a beaded or varicose appearance: this is due to manipulation and pressure causing the oily matter to collect into drops, and in consequence of the extreme delicacy of the primitive sheath, even slight pressure will cause the transudation of the fatty matter, which collects as drops of oil outside the membrane. This is, of course, promoted by the action of ether (fig. 51).

FIG. 50.—A node of Ranvier of a medullated nerve-fibre, viewed from above, magnified about 750 diameters. The medullary sheath is discontinuous at the node, whereas the axis-cylinder passes from one segment into the other. At the node the sheath of Schwann appears thickened. (Klein and Noble Smith.)

FIG. 51.—Magnified 300 diameters.



a. Nerve-tube of the common eel in water. The delicate line on its exterior indicates the tubular membrane. The dark double-edged inner one is the white matter of Schwann, slightly wrinkled. *b*. The same in ether. Several oil-globules have coalesced in the interior, and others have accumulated around the exterior of the tube. The white matter has in part disappeared.

FIG. 52.—A small nervous branch from the sympathetic of a mammal.

a. Two dark-bordered nerve-tubes among a number of Remak's fibres, *b*.

The *neurilemma* or *primitive sheath* (sometimes called the *tubular membrane* or *sheath of Schwann*) presents the appearance of a delicate, structureless membrane. Here and there beneath it, and situated in depressions in the white matter of Schwann, are nuclei surrounded by a small amount of protoplasm. The nuclei are oval and somewhat flattened, and bear a definite relation to the nodes of Ranvier; one nucleus generally lying in the centre of each node.

Non-medullated Fibres.—Most of the nerves of the sympathetic system, and some of the cerebro-spinal, consist of another variety of nervous fibres, which are called the *grey* or *gelatinous* nerve-fibres—*fibres of Remak* (fig. 52). These consist of finely striated fibres enclosed in a delicate, homogeneous sheath,

similar to the neurilemma of the medullated nerve-fibres. Nuclei may be detected at intervals in each fibre, situated between the axis-cylinder and the neurilemma. In external appearance the gelatinous nerves are semi-transparent and grey or yellowish-grey. The individual fibres vary in size, generally averaging about half the size of the medullated fibres; they are often branched; the branches uniting with other neighbouring branches, so as to form a network. The olfactory nerve is made up of these gelatinous nerve-fibres, but they are of large size, and possess a distinct nucleated sheath.

Chemical Composition.—The different portions of the nervous system are composed of the two above-described kinds of nervous structure, the chemical composition of which is shown by the following analysis, by Lassaigne, which represents the relative proportion of the different constituents composing the grey and white matter of the brain.

	Grey	White
Water	85·2	73·0
Albuminous matter	7·5	9·9
Colourless fat	1·0	13·9
Red fat	3·7	0·9
Osmazome and lactates	1·4	1·0
Phosphates	1·2	1·3

It appears from this analysis that the cerebral substance consists of albumen, dissolved in water, combined with fatty matter and salts. The fatty matters consist of cerebrin, neurin, and lecithin. The two latter were first described by Liebreich as a crystalline phosphuretted fat, which he termed *protagon*. It seems probable, however, that it is simply a mixture of neurin and lecithin. Cholesterine is also described as one of the chemical constituents of the nervous tissues, being found in conjunction with lecithin. The salts are the phosphates of potash, soda, lime, magnesia, and iron, sulphate of potash, and chloride of sodium, with traces of silica. According to Vauquelin, the cord contains a larger proportion of fat than the brain; and according to L'Héritier, the nerves contain more albumen and more soft fat than the brain.

The nervous structures are divided, as before mentioned, into two great systems—viz. the *cerebro-spinal*, comprising the brain and spinal cord, the nerves connected with these structures, and the ganglia situated on them; and the *sympathetic*, consisting of a double chain of ganglia and the nerves connected with them. All these structures require separate consideration; they are composed of the two kinds of nervous tissue above described, intermingled in various proportions and having, in some parts, a very intricate arrangement.

The **brain** or **encephalon** is that part of the cerebro-spinal system which is contained in the cavity of the skull. It is divided into several parts, named the medulla oblongata, pons Varolii, cerebellum, and cerebrum. In these parts the grey or vesicular nervous matter is found partly on the surface of the brain, forming the convolutions of the cerebrum, and partly in the laminæ of the cerebellum. Again, grey matter is found in the interior of the brain, collected into large and distinct masses or ganglionic bodies, such as the corpus striatum, optic thalamus, and corpora quadrigemina. Finally, grey matter is found intermingled intimately with the white, but without definite arrangement, as in the corpora dentata of the medulla and cerebellum, or the grey matter in the pons Varolii and the floor of the fourth ventricle.

The white matter of the brain is divisible into three distinct classes of fibres. These are, in the first place, the nerves which arise in the grey matter and pass out through the cranial foramina. Next, the fibres which connect the brain with the spinal cord; that is to say, those which are usually traced upwards from the columns of the spinal cord, through the medulla oblongata into the encephalon, chiefly by means of the anterior pyramids, lateral tract, and restiform bodies, passing through the pons Varolii and crura cerebri to ex-

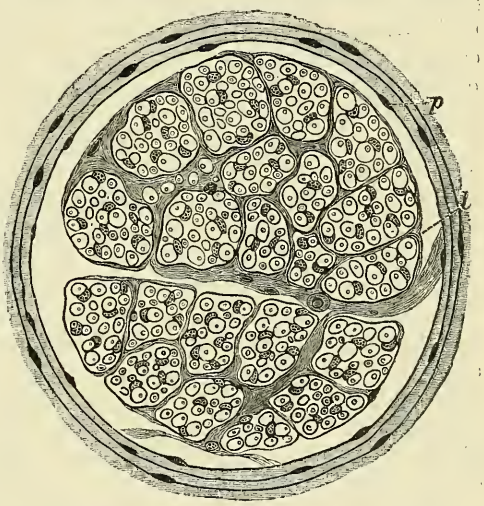
pand into the corpora striata, optic thalamus, and convolutions (*corona radiata*), and by means of the restiform bodies into the cerebellum. The other class of white fibres in the brain are commissural, some of the commissures serving to connect different parts of the same hemisphere together (as the fornix, processus e cerebello ad testes, &c.), or even different parts of the same section, as the arciform fibres of the medulla. Most of these commissures are longitudinal; while others, as the corpus callosum and the transverse fibres of the pons Varolii, are transverse, serving to connect opposite hemispheres, and thus probably securing the single action of a double organ.

The manner in which the grey and white matter are intermingled in the brain and spinal cord is very intricate, and can only be fully understood by a careful study of the details of its descriptive anatomy in the sequel. The further consideration of this subject will therefore be deferred until after the description of the various divisions of which the cerebro-spinal system is made up.

The **nerves** are round or flattened cords, formed of the nerve-fibres already described. They are connected at one end with the cerebro-spinal centre or with the ganglia, and are distributed at the other end to the various textures of the body; they are subdivided into two great classes—the *cerebro-spinal*, which proceed from the cerebro-spinal axis, and the *sympathetic* or *ganglionic* nerves, which proceed from the ganglia of the sympathetic. The **cerebro-spinal nerves** consist of numerous nerve-fibres collected together and enclosed in a membranous sheath (fig. 53). A small bundle of primitive fibres, enclosed in a tubular sheath, is called a *funiculus*; if the nerve is of small size, it may consist only of a single funiculus; but if large, the funiculi are collected together into larger bundles or fasciculi, which are bound together in a common membranous investment, and constitute the nerve.

FIG. 53.—Transverse section through a microscopic nerve, representing a compound nerve-bundle, surrounded by perineurium. Magnified 120 diameters.

The medullated fibres are seen as circles with a central dot, viz. medullary sheath and axis-cylinder, in transverse section. They are embedded in endoneurium, containing numerous nuclei, which belong to the connective-tissue cells of the latter. (Klein and Noble Smith.)



p. Perineurium, consisting of laminæ of fibrous connective tissues, alternating with flattened nucleated connective-tissue cells. *l*. Lymph-space between perineurium and surface of nerve-bundle.

In structure, the common membranous investment, or sheath of the whole nerve, which is called the *epineurium*, as well as the septa given off from it, and which separate the fasciculi, consists of connective tissue, composed of white and yellow elastic fibres, the latter existing in great abundance. The tubular sheath of the funiculi, called the *perineurium*, consists of a fine, smooth, transparent membrane, which may be easily separated, in the form of a tube, from the fibres it encloses; in structure it consists of connective tissue, which has a distinctly lamellar arrangement, consisting of several lamellæ, separated from each other by spaces containing lymph. The nerve-fibres are held together and supported within the funiculus by delicate connective tissue, called the *endoneurium*. It is continuous with septa which pass inwards from the innermost layer of the perineurium, and consists of a ground-substance in which are embedded fine bundles of fibrous connective tissue which run for the most part longitudinally.

It serves to support the capillary vessels, which are arranged so as to form a network with the elongated meshes. The cerebro-spinal nerves consist almost exclusively of the medullated nerve-fibres, the non-medullated existing in very small proportions.

The blood-vessels supplying a nerve terminate in a minute capillary plexus, the vessels composing which pierce the perineurium and run, for the most part, parallel with the fibres; they are connected together by short, transverse vessels, forming narrow, oblong meshes, similar to the capillary system of muscle. Fine non-medullated nerve-fibres accompany these capillary vessels, *vaso-motor fibres*, and break up into elementary fibrils, which form a network around the vessel. Horsley has also recently demonstrated certain medullated fibres as running in the epineurium and terminating in small spheroidal tactile corpuscles or end-bulbs of Krause. These nerve-fibres, which Professor Marshall believes to be sensory, and which he has termed *nervi nervorum*, are considered by him to have an important bearing upon certain neuralgic pains.

The nerve-fibres, as far as is at present known, do not coalesce, but pursue an uninterrupted course from the centre to the periphery. In separating a nerve, however, into its component funiculi, it may be seen that these do not pursue a perfectly insulated course, but occasionally join at a very acute angle with other funiculi proceeding in the same direction; from this, branches are given off, to join again in like manner with other funiculi. It must be distinctly understood, however, that in these communications the nerve-fibres do not coalesce, but merely pass into the sheath of the adjacent nerve, become intermixed with its nerve-fibres, and again pass on, to become blended with the nerve-fibres in some adjoining funiculus.

Nerves, in their course, subdivide into branches, and these frequently communicate with branches of a neighbouring nerve. The communications which thus take place form what is called a *plexus*. Sometimes a plexus is formed by the primary branches of the trunks of the nerves as the cervical, brachial, lumbar, and sacral plexuses—and occasionally by the terminal funiculi, as in the plexuses formed at the periphery of the body. In the formation of a plexus, the component nerves divide, then join, and again subdivide in such a complex manner that the individual funiculi become interlaced most intricately; so that each branch leaving a plexus may contain filaments from each of the primary nervous trunks which form it. In the formation also of smaller plexuses at the periphery of the body there is a free interchange of the funiculi and primitive fibres. In each case, however, the individual filaments remain separate and distinct, and do not inosculate with one another.

It is probable that through this interchange of fibres the different branches passing off from a plexus have a more extensive connection with the spinal cord than if they each had proceeded to be distributed without such connection with other nerves. Consequently, the parts supplied by these nerves have more extended relations with the nervous centres; by this means, also, groups of muscles may be associated for combined action.

The **sympathetic** nerves are constructed in the same manner as the cerebro-spinal nerves, but consist mainly of non-medullated fibres, collected into funiculi, and enclosed in a sheath of connective tissue. There is, however, in these nerves, a certain admixture of medullated fibres, and the amount varies in different nerves, and may be known by its colour. Those branches of the sympathetic which present a well-marked grey colour are composed more especially of gelatinous nerve-fibres, intermixed with a few medullated fibres; whilst those of a white colour contain more of the latter fibres, and a few of the former. Occasionally, the grey and white cords run together in a single nerve, without any intermixture, as in the branches of communication between the sympathetic ganglia and the spinal nerves, or in the communicating cords between the ganglia.

The nerve-fibres, both of the cerebro-spinal and sympathetic system, convey

impressions of a twofold kind. The sensory nerves, called also *centripetal* or *afferent* nerves, transmit to the nervous centres impressions made upon the peripheral extremities of the nerves, and in this way the mind, through the medium of the brain, becomes conscious of external objects. The *motor* nerves, called also *centrifugal* or *efferent* nerves, transmit impressions from the nervous centres to the parts to which the nerves are distributed, these impressions either exciting muscular contraction, or influencing the processes of nutrition, growth, and secretion.

Origin and Termination of Nerves.—By the expression 'the termination of nerve-fibres' is signified their connections with the nerve-centres, and with the parts they supply. The former are sometimes called their *origin*, or *central* termination; the latter their *peripheral* termination. The origin in some cases is single—that is to say, the whole nerve emerges from the nervous centre by a single root; in other instances the nerve arises by two or more roots, which come off from different parts of the nerve-centre, sometimes widely apart from each other, and it often happens, when a nerve arises in this way by two roots, that the functions of these two roots are different; as, for example, in the spinal nerves, each of which arises by two roots, the anterior of which is motor, and the posterior sensory. The point where the nerve root or roots emerge from the nervous centre is named the *superficial* or *apparent* origin, but the fibres of which the nerve consists can be traced for a certain distance into the nervous centre to some portion of the grey substance, which constitutes the *deep* or *real* origin of the nerve. The exact manner in which these fibres arise at their deep origin is still open to some doubt, but it would appear to be probable that the centrifugal or efferent nerve-fibres are directly continuous with one of the processes of the multipolar nerve-cells, and may therefore be said to be prolongations from the nerve-cells of the grey substance. The centripetal or afferent fibres, on the other hand, do not appear to be continuous with the nerve-cells. If traced from their apparent origin into the nerve-centre, they may be seen to bifurcate, assume a straight course, and send off lateral branches, which become lost in the grey matter.

Peripheral Terminations of Nerves.—The manner in which nerve-fibres terminate peripherally are several, and may be conveniently studied in the sensory and motor nerves respectively. **Sensory** nerves would appear to terminate either in *minute primitive fibrillæ* or networks of these; or else in special terminal organs, which have been termed *peripheral end-organs*, and of which there are three principal varieties, viz. the end-bulbs of Krause, the tactile corpuscles of Wagner, and the Pacinian corpuscles.

Termination in Fibrillæ.—When a medullated nerve-fibre approaches its termination, the white matter of Schwann suddenly disappears, leaving only the axis-cylinder, surrounded by the neurilemma, and we have now a non-medullated fibre. This, after a time, loses its neurilemma, and consists only of an axis-cylinder, which can be seen, in preparations stained with chloride of gold, to be made up of fine varicose fibrils. Finally, the axis-cylinder breaks up into its constituent primitive nerve-fibrillæ, which anastomose with one another, thus forming a network, and often present regular varicosities. This network passes between the elements of the tissue to which the nerves are distributed, which is always epithelial, the nerve-fibrils lying in the interstitial substance between the epithelial cells, and, as is believed by some, actually terminating *within* the cells, as minute swellings close to the nucleus. In this way nerve-fibres have been found to terminate in the epithelium of the skin and mucous membranes, and in the anterior epithelium of the cornea.

The **end-bulbs of Krause** (fig. 54) are of two kinds: 1. The *cylindrical end-bulbs*, found principally in the lower animals, are oblong or cylindrical corpuscles, into the interior of which the axis-cylinder of the nerve-fibres passes and terminates in a bulbous extremity. The corpuscle consists of a simple nucleated capsule, containing a soft, homogeneous core, in which the termination of the

axis-cylinder is contained. The white matter of Schwann ceases abruptly as the axis-cylinder enters the corpuscle, but the neurilemma is continued inwards with the axis-cylinder, and forms an investment of the core, lining the interior of the capsule. 2. The small *spheroidal end-bulb*, found only in men and monkeys, consists of a capsule of connective tissue, enclosing a number of polygonal cells, amongst which the axis-cylinder terminates. These spheroidal end-bulbs are found in the conjunctiva of man, in the mucous membrane of the mouth, nasal cavities and rectum, and also in the mucous membrane of the glans penis and clitoris. In this latter situation they have a mulberry-like appearance, from being constricted by connective-tissue septa into from two to six knob-like masses, and have received the name of *genital corpuscles*. Very similar corpuscles are found in the epineurium of nerve-trunks (see p. 45). In the synovial membrane of certain joints (e.g. those of the fingers), rounded or oval end-bulbs have been found; these are designated *articular end-bulbs*.

The **tactile corpuscles** (fig. 55), described by Wagner and Meissner, are oval-shaped bodies, made up of connective tissue, and consisting of a capsule, and im-

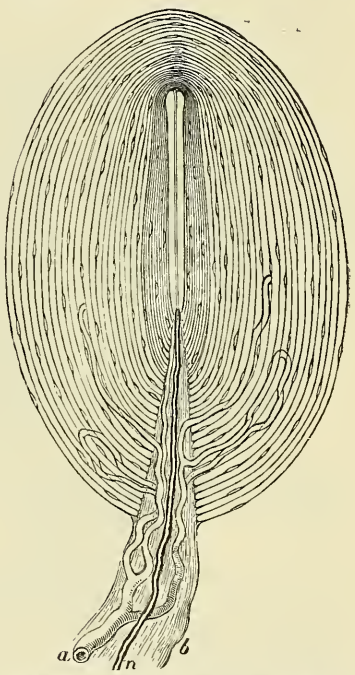
perfect membranous septa, derived from it, which penetrate its interior. One or more medullated nerve-fibres pass to each corpuscle, and sometimes pass at once into its interior, at other times wind round it two or three times; then lose their medullary sheath, and the axis-cylinders, entering the capsule, pursue a convoluted course, supported by the septa, and terminate in small globular or pyriform enlargements, near the inner surface of the capsule. These tactile corpuscles have been described as occurring in the papillæ of the corium of the hand and foot, the front of the fore-arm, the skin of the lips, and the mucous membrane of the tip of the tongue, the palpebral conjunctiva, and the skin of the nipple. They are not found in all the papillæ; but from their existence in those parts in which the skin is highly sensitive, it is probable that they are specially concerned in the sense of touch, though their absence from the papillæ of other tactile parts shows that they are not essential to this sense.

The **Pacinian corpuscles** * (fig. 56) are found in the human subject chiefly on the nerves of the palm of the hand and sole of the foot and in the genital organs of both sexes lying in the subcutaneous tissue; but they have also

* Often called in German anatomical works 'corpuscles of Vater.'

been described as connected with the nerves of the joints, and in some other situations, as the mesentery of the cat and along the tibia of the rabbit. Each of these corpuscles is attached to and encloses the termination of a single nerve-fibre. The corpuscle, which is perfectly visible to the naked eye (and which can be most easily demonstrated in the mesentery of a cat), consists of a number of lamellæ or capsules, arranged more or less concentrically around a central clear space, in which the nerve-fibre is contained. Each lamella is composed of bundles of fine connective-tissue fibres, and is lined on its inner surface by a single layer of nucleated endothelial cells. The central clear space, which is elongated or cylindrical in shape, is filled with a transparent material, in the middle of which is the single medullated fibre, which traverses the space to near its distal extremity. Here it terminates in a rounded knob or end, sometimes bifurcating previously, in which case each branch has a similar arrangement. Todd and Bowman have described minute arteries as entering by the sides of the nerves and forming capillary loops in the intercapsular spaces, and even penetrating into the central space. Other authors describe the artery as entering the corpuscle at the pole opposite to the nerve-fibre.

Fig. 56.—Pacinian corpuscle, with its system of capsules and central cavity.



a. Arterial twig, ending in capillaries, which form loops in some of the intercapsular spaces, and one penetrates to the central capsule. *b*. The fibrous tissue of the stalk prolonged from the neurilemma. *n*. Nerve-tube advancing to the central capsule, there losing its white matter, and stretching along the axis to the opposite end, where it is fixed by a tubercular enlargement.

Herbst has described a somewhat similar 'nerve-ending' to the Pacinian corpuscle, as being found in the mucous membrane of the tongue of the duck, and in some other situations. It differs, however, from the Pacinian corpuscles, in being smaller, its capsule thinner and more closely approximated, and especially in the fact that the axis-cylinder in the central clear space is coated with a continuous row of nuclei. These bodies are known as the *corpuscles of Herbst*.

Tactile corpuscles have been described by Grandry as occurring in the papillæ of the beak and tongue of birds, and by Merkel as occurring in the papillæ and epithelium of the skin of man and animals, especially in those parts of the skin devoid of hair. They consist of a capsule composed of a very delicate, nucleated membrane, and contain two or more granular, somewhat flattened cells, between which the medullated nerve-fibre, which enters the capsule by piercing its investing membrane, is supposed to terminate.

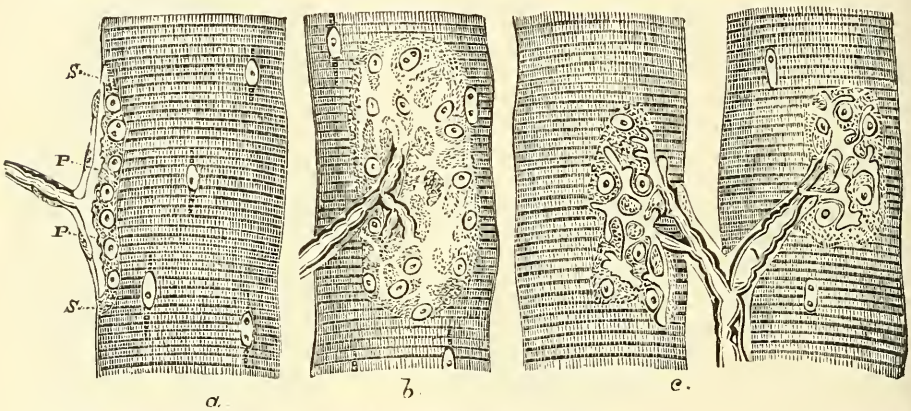
In the organs of **special sense** the nerves terminate in cells, which belong to the epithelial class, and have received the name of *sensory* or *nerve-epithelium* cells. The axis-cylinders terminate in these epithelial cells, which are variously modified and to the peripheral extremity of which are often connected peculiar styliform processes. These cells will be more particularly described in the sequel, in connection with the description of the organs of special sense.

Motor nerves are to be traced either into unstriped or striped muscular fibres. In the **unstriped** or **involuntary** muscles the nerves are derived from the sympathetic, and are composed mainly of the non-medullated fibres. Near their termination they divide into a number of branches, which communicate and form an intimate plexus. At the junction of the branches small triangular nuclear bodies

(ganglion-cells) are situated. From these plexuses minute branches are given off, which divide and break up into the ultimate fibrillæ of which the nerve is composed. These fibrillæ course between the involuntary muscle-cells, and, according to Elischer, terminate on the surface of the cell, opposite the nucleus, in a minute swelling. Arnold and Frankenhäuser believed that these ultimate fibrillæ penetrated the muscular cell, and ended in the nucleus. More recent observation has, however, tended to disprove this.

In the **striped** or **voluntary** muscle, the nerves supplying the muscular fibres are derived from the cerebro-spinal nerves, and are composed mainly of medullated fibres. The nerve, after entering the sheath of the muscle, breaks up into fibres, or bundles of fibres, which form plexuses, and gradually divide until, as a rule, a single nerve-fibre enters a single muscular fibre. Sometimes, however, if the muscular fibre is long, more than one nerve-fibre enters it. Within the muscular fibre the nerve terminates in a special expansion, called by Kühne, who first accurately described them, *motorial end-plates* (fig. 57).* The nerve-

Fig. 57.—Muscular fibres of *Lacerta viridis* with the terminations of nerves.



a. Seen in profile. P P. The nerve end-plates. S S. The base of the plate, consisting of a granular mass with nuclei. *b*. The same as seen in looking at a perfectly fresh fibre, the nervous ends being probably still excitable. (The forms of the variously divided plate can hardly be represented in a woodcut by sufficiently delicate and pale contours to reproduce correctly what is seen in nature.) *c*. The same as seen two hours after death from poisoning by curare.

fibre, on approaching the muscular fibre, suddenly loses its white matter of Schwann, which abruptly terminates; the neurilemma becomes continuous with the sarcolemma of the muscle, and only the axis-cylinder enters the muscular fibre, where it immediately spreads out, ramifying like the roots of a tree, immediately beneath the sarcolemma, and is embedded in a layer of granular matter, containing a number of clear, oblong nuclei, the whole constituting an end-plate from which the contractile wave of the muscular fibre is said to start.

The nerves supplying tendons have peculiar nerve-endings, and are especially numerous near the point where the tendon becomes muscular. In this situation spindle-shaped bodies are found, and are known as the *organs of Golgi*. They are apparently composed of several tendinous bundles, fused into one, into which one or more nerve-fibres pass, and, dividing, spread out between the tendon-bundles and form a branched expansion. Nerve-fibres occasionally terminate in tendons as end-bulbs or as small Pacinian corpuscles.

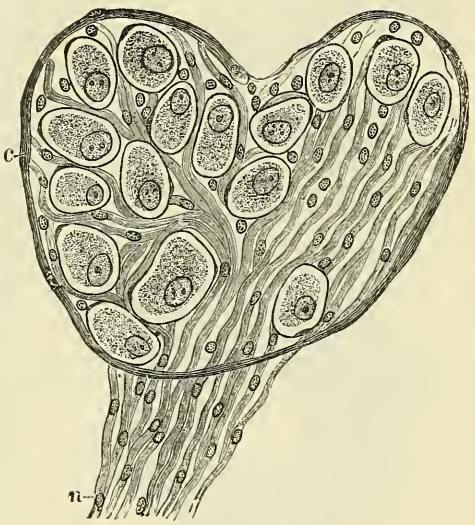
The **Ganglia** may be regarded as separate and independent nervous centres, of smaller size and less complex structure than the brain, connected with each other, with the cerebro-spinal axis, and with the nerves in various situations. They are found on the posterior root of each of the spinal nerves; on the posterior or sensory root of the fifth cranial nerve; on the facial and auditory nerves;

* They had, however, previously been noticed, though not accurately described, by Doyère, who named them 'nerve-hillocks.'

on the glosso-pharyngeal and pneumogastric nerves; and on the branches of certain spinal nerves. They are also found in a connected series along each side of the vertebral column, forming the trunk of the sympathetic; and on the branches of that nerve, generally in the plexuses or at the point of junction of two or more nerves with each other, or with branches of the cerebro-spinal system. On section they are seen to consist of a reddish-grey substance, traversed by numerous white nerve-fibres; they vary considerably in form and size; the largest are found in the cavity of the abdomen; the smallest, not visible to the naked eye, exist in considerable numbers upon the nerves distributed to the different viscera. The ganglia are invested by a smooth and firm, closely adhering, membranous envelope, consisting of dense areolar tissue; this sheath is continuous with the perineurium of the nerves, and sends numerous processes into the interior of the ganglion, which support the blood-vessels supplying its substance.

In structure all ganglia are essentially similar (fig. 58), consisting of the same structural elements as the other nervous centres—viz. a collection of *vesicular nervous matter* traversed by tubular and gelatinous *nerve-fibres*. The vesicular nervous matter consists of nerve or ganglion cells, most of which appear to be free and of a round or oval form; these are more especially seated near the surface of the ganglion; others are unipolar, bipolar, or multipolar, and their caudate processes give origin to nerve-fibres. In the ganglion the nerve-cells are enclosed in a transparent capsule with nuclei on its inner surface. The nerve-fibres on entering the ganglion lay aside their perineurium, which becomes continuous with the capsule. Some of the fibres run through the ganglion without being connected with the cells, others arise from the caudate processes of the cells.

FIG. 58.—Section through a microscopic ganglion. Magnified 300 diameters. (Klein and Noble Smith.)



c. Capsule of the ganglion. *n*. Nerve-fibres passing out of the ganglion. The nerve-fibres which entered the ganglion are not represented. The nerve-fibres are ordinary medullated fibres, but the details of their structure are not shown, owing to the low magnifying power. The ganglion-cells are invested by a special capsule, lined by a few nuclei, which are here represented as if contained *in* the capsule.

A remarkable modification of the bipolar nerve-cell is found in the sympathetic ganglia, especially in the frog, but also in some few instances in the mammal. The cells are pear-shaped, and from the narrow end two processes arise: one a straight axis-cylinder process, into which the substance of the ganglion is prolonged; the other, a thin fibre, winds spirally round the straight fibre, and then passes away from the cell in the opposite direction and becomes invested with a medullary sheath and neurilemma of its own, and constitutes a medullated fibre, while the straight axis-cylinder process forms a non-medullated fibre.

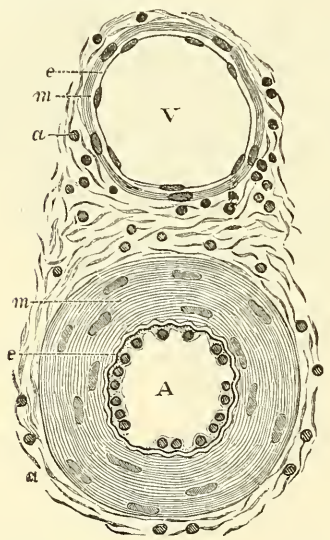
THE VASCULAR SYSTEM

The **Vascular System,** exclusive of its central organ, the heart, is divided into four classes of vessels: the arteries, capillaries, veins, and lymphatics; the minute structure of which we will now proceed briefly to describe, referring the reader to the body of the work for all that is necessary in the details of their ordinary anatomy.

Structure of Arteries (fig. 59).—The arteries are composed of three coats: internal or endothelial coat (*tunica intima* of Kölliker); middle muscular coat (*tunica media*); and external cellular coat (*tunica adventitia*).

The two inner coats together are very easily separated from the external, as by the ordinary operation of tying a ligature on an artery. If a fine string be tied forcibly upon an artery and then taken off, the external coat will be found undivided, but the internal coats are divided in the track of the ligature and can easily be further dissected from the outer coat. The *inner coat* can be separated from the middle by a little maceration, or it may be stripped off in small pieces; but, on account of its friability, it cannot be separated as a complete membrane. It is a fine, transparent, colourless structure which is highly elastic, and is commonly corrugated into longitudinal wrinkles. The inner coat consists of 1. A layer of pavement-epithelium, the cells of which are polygonal, oval, or fusiform, and have very distinct round or oval nuclei. This endothelium, as it is (sometimes) called, is brought into view most distinctly by staining with nitrate of silver. 2. A sub-epithelial layer, consisting of delicate connective tissue with branched cells lying in the interspaces of the tissue. 3. An elastic or fenestrated layer, which consists of an elastic membrane containing a network of elastic fibres, having principally a longitudinal direction and in which, under the microscope, small, elongated apertures or perforations may be seen, giving it a fenestrated appearance. It was therefore called by Henle the *fenestrated membrane*. This membrane forms the chief thickness of the inner coat, and can be separated into several layers, some of which present the appearance of a network of longitudinal elastic fibres, and others present a more membranous character, marked by pale lines having a longitudinal direction. In arteries of less than a line in diameter the sub-epithelial layer consists of a single layer of stellate cells, and the connective tissue is only largely developed in the large-sized vessels. The fenestrated membrane in microscopic arteries is a very thin layer, but in the larger arteries, and especially in the aorta, it has a very considerable thickness.

Fig. 59.—Transverse section through a small artery and vein of the mucous membrane of the epiglottis of a child. Magnified about 350 diameters. (Klein and Noble Smith.)



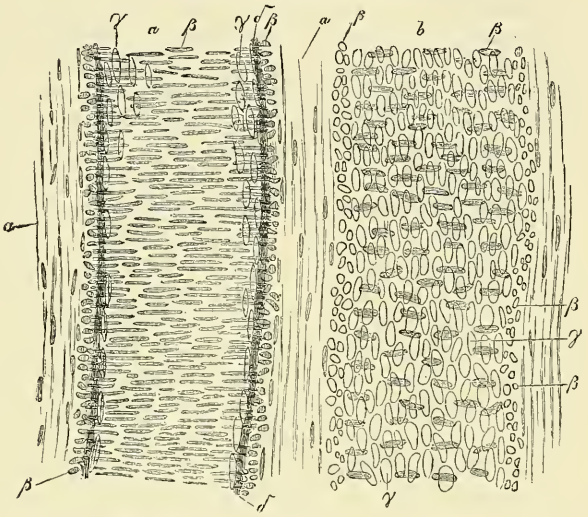
A. Artery, showing the nucleated endothelium, *e*, which lines it: the vessel being contracted, the endothelial cells appear very thick. Underneath the endothelium is the wavy elastic intima. The chief part of the wall of the vessel is occupied by the circular muscle-coat *m*: the staff-shaped nuclei of the muscle-cells are well seen. Outside this is *a*, part of the adventitia. This is composed of bundles of connective-tissue fibres, shown in section, with the nuclei of the connective-tissue corpuscles. The adventitia gradually merges into the surrounding connective tissue. V. Vein showing a thin endothelial membrane, *e*, raised accidentally from the intima, which on account of its delicacy is seen as a mere line on the media *m*. This latter is composed of a few circular unstriped muscle-cells. *a*. The adventitia, similar in structure to that of an artery.

The *middle* coat (*tunica media*) is distinguished from the inner by its colour and by the transverse arrangement of its fibres, in contradistinction to the longitudinal direction of those of the inner coat. It consists principally of muscular tissue, being made up of muscle-fibre cells in fine bundles, arranged in lamellæ and disposed circularly around the vessel. These lamellæ vary in number according to the size of the vessel; the very small arteries having only a single layer, and those not larger than one-tenth of a line in diameter three or four layers. It is to this coat that the great thickness of the walls of the artery is mainly due (fig. 59 A *m*). In the larger vessels, as the iliac, femoral, and

carotid, elastic fibres unite to form lamellæ, which alternate with the layers of muscular fibre and are united by elastic fibres which pass between the muscular bundles. In the largest arteries, as the aorta and innominate, the amount of elastic tissue is very considerable. In these vessels also bundles of white connective tissue have been found in small quantities in the middle coat. The muscle-fibre cells of which the middle coat is made up are about $\frac{1}{500}$ of an inch in length and contain well-marked, rod-shaped nuclei, which are often slightly curved.

The *external* coat (*tunica adventitia*) consists mainly of fine and closely felted bundles of white connective tissue, but also contains elastic fibres in all but the smallest arteries. The elastic tissue is much more abundant next the tunica media, and it is sometimes described as forming here, between the adventitia and media, a special layer, the *tunica elastica externa* of Henle. This layer is most marked in arteries of medium size. In the largest vessels the external coat is relatively thin; but in small arteries it is of greater proportionate thickness. In the smaller arteries it consists of a single layer of white connective tissue and elastic fibres; while in the smallest arteries, just above the capillaries, the elastic fibres are wanting, and the connective tissue, of which the coat is composed, becomes more homogeneous the nearer it approaches the capillaries, and is gradually reduced to a thin membranous envelope, which finally disappears.

FIG. 60.—Longitudinal section of artery and vein.



An artery from the mesentery of a child, ·062‴, and *b*, vein ·067‴ in diameter, treated with acetic acid and magnified 350 times. *a*. Tunica adventitia, with elongated nuclei. *β*. Nuclei of the contractile fibre cells of the tunica media, seen partly from the surface, partly apparent in transverse section. *γ*. Nuclei of the endothelial cells. *δ*. Elastic longitudinal fibrous coat.

Some arteries have extremely thin coats in proportion to their size; this is especially the case in those situated in the cavity of the cranium and spinal canal, the difference depending on the greater thinness of the external and middle coats.

The arteries, in their distribution throughout the body, are included in a thin fibro-areolar investment, which forms what is called their *sheath*. In the limbs this is usually formed by a prolongation of the deep fascia; in the upper part of the thigh it consists of a continuation downwards of the transversalis and iliac fasciæ of the abdomen; in the neck, of a prolongation of the deep cervical fascia. The included vessel is loosely connected with its sheath by a delicate areolar tissue; and the sheath usually encloses the accompanying veins, and sometimes a nerve. Some arteries, as those in the cranium, are not included in sheaths.

All the larger arteries are supplied with blood-vessels like the other organs of the body; they are called the *vasa vasorum*. These nutrient vessels arise from a branch of the artery or from a neighbouring vessel, at some considerable distance from the point at which they are distributed; they ramify in the loose areolar tissue connecting the artery with its sheath, and are distributed to the external coat, but do not, in man, penetrate the other coats; though in some of

the larger mammals some few vessels have been traced into the middle coat. Minute veins serve to return the blood from these vessels; they empty themselves into the venæ comites in connection with the artery. Lymphatic vessels and lymphatic spaces are also present in the outer coat.

Arteries are also supplied with nerves, which are derived chiefly from the sympathetic, but partly from the cerebro-spinal system. They form intricate plexuses upon the surfaces of the larger trunks, and run along the smaller branches as single filaments or bundles of filaments, which twist around the vessel and unite with each other in a plexiform manner. The branches derived from these plexuses penetrate the external coat and are principally distributed to the muscular tissue of the middle coat, and thus regulate, by causing the contraction and relaxation of this tissue, the amount of blood sent to any part.

The Capillaries.—The smaller arterial branches (excepting those of the cavernous structure of the sexual organs, of the spleen, and in the uterine placenta) terminate in a network of vessels which pervade nearly every tissue of the body. These vessels, from their minute size, are termed capillaries (*capillus*, a 'hair'). They are interposed between the smallest branches of the arteries and the commencing veins, constituting a network, the branches of which maintain the same diameter throughout; the meshes of the network being more uniform in shape and size than those formed by the anastomoses of the small arteries and veins.

The *diameter* of the capillaries varies in the different tissues of the body, their usual size being about $\frac{1}{3000}$ of an inch. The smallest are those of the brain, and the mucous membrane of the intestines; and the largest those of the skin and the marrow of bone, where they are stated to be as large as $\frac{1}{1200}$ of an inch. The *form* of the capillary net varies in the different tissues, the meshes being generally rounded or elongated. The *rounded form of mesh* is most common, and prevails where there is a dense network, as in the lungs, in most glands and mucous membranes, and in the cutis; here the meshes are more or less angular, sometimes nearly quadrangular, or polygonal; more frequently irregular.

Elongated meshes are observed in the bundles of fibres and tubes composing muscles and nerves, the meshes being usually of a parallelogram form, the long axis of the mesh running parallel with the long axis of the nerve and fibre. Sometimes the capillaries have a *looped* arrangement; a single vessel projecting from the common network and returning after forming one or more loops, as in the papillæ of the tongue and skin. The number of the capillaries, and the size of the meshes, determine the degree of vascularity of a part. The closest network and the smallest interspaces are found in the lungs and in the choroid coat of the eye. In these situations the interspaces are smaller than the capillary vessels themselves. In the kidney, in the conjunctiva, and in the cutis the interspaces are from three to four times as large as the capillaries which form them; and in the brain from eight to ten times as large as the capillaries in their long diameter, and from four to six times as large in their transverse diameter. In the adventitia of arteries the width of the meshes is ten times that of the capillary vessels. As a general rule, the more active the function of the organ, the closer is its capillary net and the larger its supply of blood; the meshes of the network being very narrow in all growing parts, in the glands and in the mucous membranes; wider in bones and ligaments, which are comparatively inactive; and nearly altogether absent in tendons, in which very little organic change occurs after their formation.

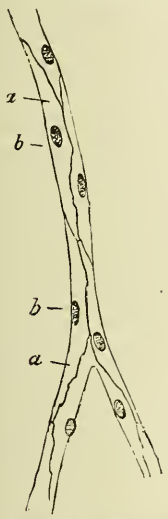
Structure.—The walls of the capillaries consist of a fine, transparent, epithelial layer, composed of cells joined edge to edge by an interstitial cement-substance, and continuous with the endothelial cells which line the arteries and veins. When stained with nitrate of silver the edges which bound the epithelial cells are brought into view (fig. 61). These cells are of large size and of an irregular polygonal or lanceolate shape, each containing an oval nucleus which may be brought into view by carmine or logwood. Between their edges, at various points of their meeting, roundish dark spots are sometimes seen, which have

been described as stomata, though they are closed by intercellular substance. They have been believed to be the situation through which the white corpuscles of the blood, when migrating from the blood-vessels, emerge ; but this view, though probable, is not universally accepted.

Kolossow, a Russian observer, describes these cells as having a rather more complex structure. He states that they consist of two parts : of hyaline ground-plates and of a protoplasmic granular part, in which is embedded the nucleus, on the outside of the ground-plates. This hyaline internal coat of the capillaries does not form a complete membrane, but consists of 'plates' which are inelastic, and though in contact with each other, are not continuous ; when therefore the capillaries are subjected to intra-vascular pressure, the plates become separated from each other ; the protoplasmic portions of the cells, on the other hand, are united together.

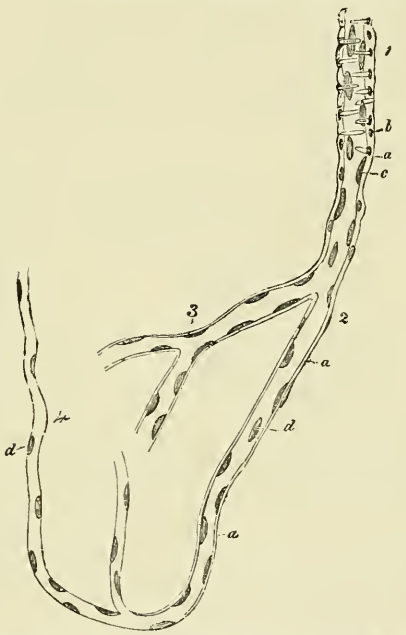
In many situations a delicate sheath or envelope of branched nucleated connective-tissue cells is found around the simple capillary tube, particularly in the

Fig. 61.—Capillaries from the mesentery of a guinea-pig after treatment with solution of nitrate of silver.



a. Cells. *b*. Their nuclei.

Fig. 62.—Finest vessels on the arterial side. From the human brain. Magnified 300 times.



1. Smallest artery. 2. Transition vessel. 3. Coarser capillaries. 4. Finer capillaries. *a*. Structureless membrane still with some nuclei, representative of the tunica adventitia. *b*. larger ones ; and in other places, especially in the glands, the capillaries are invested with retiform lymphatic tissue ; and again, in other situations, as the pia mater of the brain and cord, and in the retina, the capillaries are invested with a sheath composed of a delicate epithelial membrane.

In the largest capillaries (which ought, perhaps, to be described rather as the smallest arteries) there is, outside the epithelial layer, a muscular layer, consisting of contractile fibre-cells, arranged transversely, as in the tunica media of the larger arteries (fig. 62).

The **veins**, like the arteries, are composed of three coats—internal, middle, and external ; and these coats are, with the necessary modifications, analogous to the coats of the arteries ; the internal being the epithelial, the middle the muscular, and the external the connective or areolar. The main difference

between the veins and the arteries is in the comparative weakness of the middle coat of the former, and to this it is due that the veins do not stand open when divided, as the arteries do, and that they are passive rather than active organs of the circulation.

In the veins immediately above the capillaries the three coats are hardly to be distinguished. The epithelium is supported on an outer membrane separable into two layers, the outer of which is the thicker, and consists of a delicate, nucleated membrane (adventitia), while the inner is composed of a network of longitudinal elastic fibres (media). In the veins next above these in size (one-fifth of a line according to Kölliker) a muscular layer and a layer of circular fibres can be traced, forming the middle coat, while the elastic and connective elements of the outer coat become more distinctly perceptible. In the middle-sized veins the typical structure of these vessels becomes clear. The epithelium is of the same character as in the arteries, but its cells are more oval and less fusiform. It is supported by a connective-tissue layer, consisting of a delicate network of branched cells, and external to this is a layer of longitudinal elastic fibres, but seldom any appearance of a fenestrated membrane. This constitutes the *internal* coat. The *middle* coat is composed of a thick layer of connective tissue with elastic fibres, intermixed, in some veins, with a transverse layer of muscular fibres. The white fibrous element is in considerable excess, and the elastic fibres are in much smaller proportion in the veins than in the arteries. The *outer* coat consists of areolar tissue, as in the arteries, with longitudinal elastic fibres. In the largest veins the outer coat is from two to five times thicker than the middle coat, and contains a large number of longitudinal muscular fibres. This is most distinct in the inferior vena cava, especially at the termination of this vein in the heart, in the trunks of the hepatic veins, in all the large trunks of the vena portæ, in the splenic, superior mesenteric, external iliac, renal and azygos veins. In the renal and portal veins it extends through the whole thickness of the outer coat, but in the other veins mentioned a layer of connective and elastic tissue is found external to the muscular fibres. All the large veins which open into the heart are covered for a short distance with a layer of striped muscular tissue continued on to them from the heart. Muscular tissue is wanting—(1) in the veins of the maternal part of the placenta; (2) in the venous sinuses of the dura mater and the veins of the pia mater of the brain and spinal cord; (3) in the veins of the retina; (4) in the veins of the cancellous tissue of bones; (5) in the venous spaces of the corpora cavernosa. The veins of the above-mentioned parts consist of an internal epithelial lining supported on one or more layers of areolar tissue. The internal and external jugular veins and the subclavian vein are said to contain either no muscular fibres at all, or at all events only a slight amount in their middle coat.

Most veins are provided with valves, which serve to prevent the reflux of the blood. They are formed by a reduplication of the inner coat, strengthened by connective tissue and elastic fibres, and are covered on both surfaces with epithelium, the arrangement of which differs on the two surfaces. On the surface of the valve next the wall of the vein, the cells are arranged transversely; whilst on the other surface, over which the current of blood flows, the cells are arranged vertically in the direction of the current. Their form is semilunar. They are attached by their convex edge to the wall of the vein; the concave margin is free, directed in the course of the venous current, and lies in close apposition with the wall of the vein as long as the current of blood takes its natural course; if, however, any regurgitation takes place, the valves become distended, their opposed edges are brought into contact, and the current is interrupted. Most commonly two such valves are found placed opposite one another, more especially in the smaller veins or in the larger trunks at the point where they are joined by smaller branches; occasionally there are three and sometimes only one. The wall of the vein on the cardiac side of the point of attachment of each segment of the valve is expanded into a pouch or sinus, which gives to the vessel, when

injected or distended with blood, a knotted appearance. The valves are very numerous in the veins of the extremities, especially of the lower extremities, these vessels having to conduct the blood against the force of gravity. They are absent in the very small veins, i.e. those less than $\frac{1}{12}$ of an inch in diameter, also in the venæ cavæ, the hepatic veins, portal vein and its branches, the renal, uterine, and ovarian veins. A few valves are found in the spermatic veins, and one also at their point of junction with the renal vein and inferior vena cava respectively. The cerebral and spinal veins, the veins of the cancellated tissue of bone, the pulmonary veins, and the umbilical vein and its branches, are also destitute of valves. They are occasionally found, few in number, in the venæ azygos and intercostal veins.

The veins are supplied with nutrient vessels, *vasa vasorum*, like the arteries. Nerves also are distributed to them in the same manner as to the arteries, but in much less abundance.

The **lymphatic** vessels, including in this term the lacteal vessels, which are identical in structure with them, are composed of three coats. The *internal* is an epithelial and elastic coat. It is thin, transparent, slightly elastic, and ruptures sooner than the other coats. It is composed of a layer of elongated epithelial cells with serrated margins, by which the adjacent cells are dovetailed into one another. These are supported on a single layer of longitudinal elastic fibres. The *middle* coat is composed of smooth muscular and fine elastic fibres, disposed in a transverse direction. The *external*, or fibro-areolar, coat consists of filaments of connective tissue, intermixed with smooth muscular fibres, longitudinally or obliquely disposed. It forms a protective covering to the other coats, and serves to connect the vessel with the neighbouring structures. The above description applies only to the larger lymphatics; in the smaller vessels there is no muscular or elastic coat, and their structure consists only of a connective-tissue coat, lined by epithelium. The thoracic duct (fig. 63) is a somewhat more complex structure than the other lymphatics; it presents a distinct sub-epithelial layer of branched corpuscles, similar to that found in the arteries, and in the middle coat is a layer of connective tissue with its fibres arranged longitudinally. The lymphatics are supplied by nutrient vessels, which are distributed to their outer and middle coats; but no nerves have at present been traced into them.

Fig. 63. Transverse section through the coats of the thoracic duct of man. Magnified 30 times.

a. Epithelium, striated lamellæ, and inner elastic coat. *b*. Longitudinal connective tissue of the middle coat. *c*. Transverse muscles of the same. *d*. Tunica adventitia, with *e*, the longitudinal muscular fibres.

The lymphatics are very generally provided with valves, which assist materially in effecting the circulation of the fluid they contain. These valves are formed of a thin layer of fibrous tissue, lined on both surfaces by epithelium, which presents the same arrangement upon the two surfaces as was described in connection with the valves of veins. Their form is semilunar; they are attached by their convex edge to the sides of the vessel, the concave edge being free and directed along the course of the contained current. Usually two such valves, of equal size, are found opposite one another; but occasionally exceptions occur, especially at or near the anastomoses of lymphatic vessels. Thus, one valve may be of very rudimentary size and the other increased in proportion.

The valves in the lymphatic vessels are placed at much shorter intervals than in the veins. They are most numerous near the lymphatic glands, and they are found more frequently in the lymphatics of the neck and upper extremity than in the lower. The wall of the lymphatics immediately above the point of attachment of each segment of a valve is expanded into a pouch or sinus, which gives to these vessels, when distended, the knotted or beaded appearance which they

present. Valves are wanting in the vessels composing the plexiform network in which the lymphatics usually originate on the surface of the body.

Origin of Lymphatics.—The finest visible lymphatic vessels (lymphatic capillaries) form a plexiform network in the tissues and organs, and they consist of a single layer of epithelial plates, with more or less sinuous margins. These vessels commence in an intercommunicating system of clefts or spaces in the connective tissue of the different organs, which have no complete epithelial lining. They have been named the *rootlets* of the lymphatics, and are identical with the spaces in which the connective-tissue corpuscles are contained. This then is properly regarded as one method of their commencement, where the lymphatic vessels are apparently continuous with spaces in the connective tissue, and Klein has described and figured a direct communication between these spaces and the lymphatic vessel.* But the lymphatics have also other modes of origin, for the intestinal lacteals commence by closed extremities, though some observers believe that the closed extremity is continuous with a minute network contained in the substance of the villus, through which the lacteal is connected with the epithelial cells covering it. Again, it seems now to be conclusively proved that the serous membranes present stomata or openings between the epithelial cells (fig. 64), by which there is an open communication with the lymphatic system and through which the lymph is thought to be pumped by the alternate dilatation and contraction of the serous surface, due to the movements of respiration and circulation, so that the serous and synovial sacs may be regarded, in a certain sense, as large lymph cavities or sinuses.† Von Recklinghausen was the first to observe the passage of milk and other coloured fluids through these stomata on the peritoneal surface of the central tendon of the diaphragm. Again, in most glandular structures the lymphatic capillaries have a lacunar origin. Here they begin in irregular clefts or spaces in the tissue of the part; occupying the penetrating connective tissue and surrounding the lacunæ or tubules of the gland, and in many places separating the capillary network from the alveolus or tubule, so that the interchange between the blood and the secreting cells of the part must be carried on through this lymph-space or lacuna. Closely allied to this is the mode of origin of lymphatics in perivascular and perineural spaces. Sometimes a minute artery may be seen to be ensheathed for a certain distance by a lymphatic capillary vessel, which is often many times wider than a blood capillary. These are known as perivascular lymphatics.

Terminations of Lymphatics.—The lymphatics, including the lacteals, discharge their contents into the veins at two points; namely, at the angles of junction of the subclavian and internal jugular veins: on the left side by means of the thoracic duct, and on the right side by the right lymphatic duct. (See description of lymphatics on a subsequent page.)

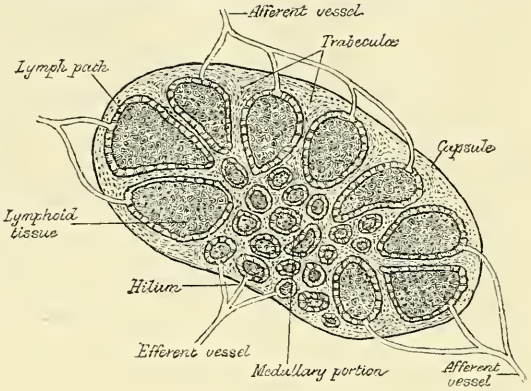
Lymphatic glands (*conglobate glands*) are small oval or bean-shaped bodies,

* *Atlas of Histology*, pl. viii. fig. xiv.

† The resemblance between lymph and serum led Hewson long ago to regard the serous cavities as sacs into which the lymphatics open. Recent microscopic discoveries confirm this opinion in a very interesting manner.

situated in the course of lymphatic and lacteal vessels so that the lymph and chyle pass through them on their way to the blood. They generally present on one side a slight depression—the *hilum*—through which the blood-vessels enter and leave the interior. The efferent lymphatic vessel also emerges from the gland at this spot, while the afferent vessels enter the organ at different parts of the periphery. On section (fig. 65), a lymphatic gland displays two different structures: an external, of lighter colour—the *cortical*; and an internal, darker—the *medullary*. The cortical structure does not form a complete investment, but is deficient at the hilum, where the medullary portion reaches the surface of the gland; so that the efferent vessel is derived directly from the medullary structure, while the afferent vessels empty themselves into the cortical substance.

Fig. 65.—Diagrammatic section of lymphatic gland, showing the course of the lymph.



Lymphatic glands consist of (1) a fibrous envelope, or *capsule*, from which a framework of processes (*trabeculæ*) proceed inwards, dividing the gland into open spaces (*alveoli*) freely communicating with each other; (2) a quantity of adenoid tissue occupying these spaces without completely filling them; (3) a free supply of blood-vessels, which are supported on the trabeculæ; and (4) the *afferent* and *efferent* vessels. Little is known of the nerves, though Kölliker describes some fine nervous filaments passing into the hilum.

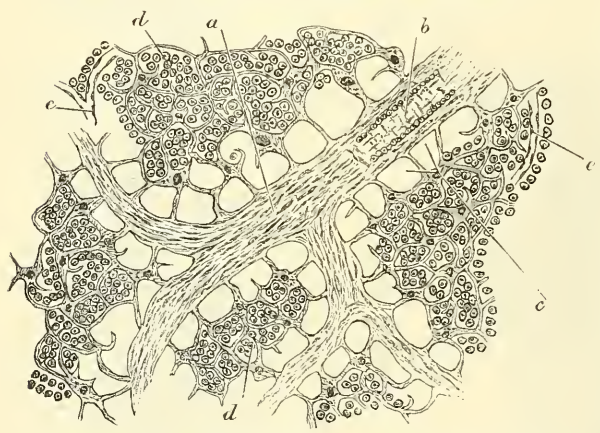
a. Lymph-tube, with its complicated system of vessels. *b*. Retinacula stretched between the tube and the septa. *c*. Portion of another lymph-tube. *d*. Septa.

The *capsule* is composed of a layer of connective tissue, and from its internal surface are given off a number of membranous septa or lamellæ, consisting, in

man, of connective tissue, with a small admixture of muscular fibre-cells; but in many of the lower animals composed almost entirely of involuntary muscular fibre. They pass inwards, radiating towards the centre of the gland, for a certain distance, that is to say, for about one-third or one-fourth of the space between the circumference and the centre of the gland They thus divide the outer part of its interior into a number of oval compartments or *alveoli* (fig. 65). This is the cortical portion of the gland. After having penetrated into the gland for some distance, these septa break up into a number of smaller trabeculæ, which form flattened bands or cords, interlacing with each other in all directions, forming in the central part of the organ a number of intercommunicating spaces, also called *alveoli*. This is the medullary portion of the gland, and the spaces or alveoli in it not only freely communicate with each other, but also with the alveoli of the cortical portion. In these alveoli or spaces (fig. 66) is contained the proper gland-substance or lymphoid tissue. The gland-pulp does not, however, completely fill the alveolar spaces, but leaves, between its outer margin and the trabeculæ forming the alveoli, a channel or space of uniform width throughout. This is termed the *lymph-path* or *lymph-sinus* (fig. 68). Running across it are a number of trabeculæ of retiform connective tissue, the fibres of which are, for the most part, covered by ramified cells. This tissue appears to serve the purpose of maintaining the gland-pulp in the centre of the space in its proper position.

On account of the peculiar arrangement of the framework of the organ, the gland-pulp in the cortical portion is disposed in the form of nodules, and in the medullary part in the form of rounded cords. It consists of ordinary lymphoid tissue, being made up of a delicate reticulum of retiform tissue, which is continuous with that in the lymph-paths, but marked off from it by a closer reticulation; in its meshes are closely packed lymph-corpuscles, traversed by a dense plexus of capillary blood-vessels.

Fig. 68.—Section of lymphatic-gland tissue.



a. Trabeculæ. *b*. Small artery in substance of same. *c*. Lymph-paths. *d*. Lymph-corpuscles. *e*. Capillary plexus.

The *afferent vessels*, as above stated, enter at all parts of the periphery of the gland, and after branching and forming a dense plexus in the substance of the capsule open into the lymph-sinuses of the cortical part. In doing this, they lose all their coats except their epithelial lining, which is continuous with a layer of similar cells lining the lymph-paths. In like manner the *efferent* vessel commences from the lymph-sinuses of the medullary portion. The stream of lymph carried to the gland by the afferent vessel thus passes through the plexus in the capsule to the lymph-paths of the cortical portion, where it is exposed to the action of the gland-pulp; flowing through these it enters the paths or sinuses of the medullary portion, and finally emerges from the hilum by means of the efferent vessel. The stream of lymph in its passage through the lymph-sinuses is much retarded by the presence of the reticulum. Hence morphological elements, either normal or morbid, are easily arrested and deposited in the sinuses. This is a matter of considerable importance in connection with the subject of poisoned wounds and the absorption of the poison by the lymphatic system, since by this means septic organisms carried along the lymphatic

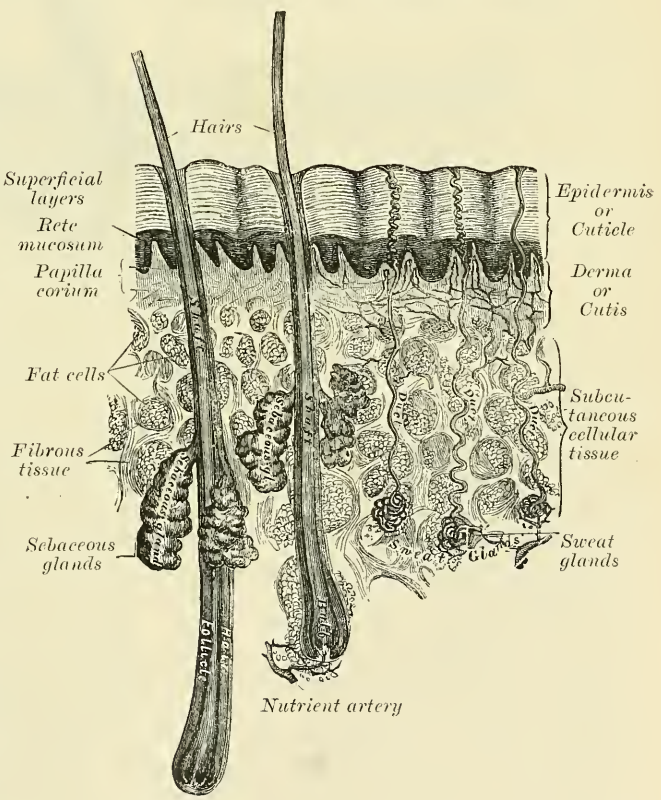
vessels may be arrested in the lymph-sinuses of the gland tissue, and thus be prevented from entering the general circulation. The arteries of the gland enter at the hilum and either pass at once to the gland-pulp, to break up into a capillary plexus, or else run along the trabeculæ, partly to supply them and partly running across the lymph-paths to assist in forming the capillary plexus of the gland-pulp. This plexus traverses the lymphoid tissue, but does not pass into the lymph-sinuses. From it the veins commence and emerge from the organ at the same place as that at which the artery enters.

THE SKIN AND ITS APPENDAGES

The **skin** (fig. 69) is the principal seat of the sense of touch, and may be regarded as a covering for the protection of the deeper tissues; it is also an important excretory and absorbing organ. It consists principally of a layer of vascular tissue, named the *derma*, *corium*, or *cutis vera*, and an external covering of epithelium, termed the *epidermis* or *cuticle*. On the surface of the former layer are the sensitive *papillæ*; and within, or embedded beneath it, are certain organs with special functions, namely, the *sweat-glands*, *hair-follicles*, and *sebaceous glands*.

The **epidermis** or **cuticle** (*scarf-skin*) is an epithelial structure belonging to the class of stratified epithelium (fig. 70). It is accurately moulded on the papillary layer of the derma. It forms a defensive covering to the surface of the true skin, and limits the evaporation of watery vapour from its free surface. It varies in thickness in different parts. In some situations, as in the palms of the hands and soles of the feet, it is thick, hard, and horny in texture. This may be partly due to the fact that these parts are exposed to intermittent pressure, but that this is not the only cause is proved by the fact that the condition exists to a very considerable extent at birth. The more superficial layer of cells, called the *horny* layer (*stratum corneum*) may be separated by maceration from the deeper layers, which are called the *rete mucosum*, and which consist of several layers of differently shaped cells. The free surface of the epidermis is marked by a network of linear furrows of variable size, marking out the surface into a number of spaces of polygonal or lozenge-shaped form. Some of these furrows are large, as opposite the flexures of the joints, and correspond to

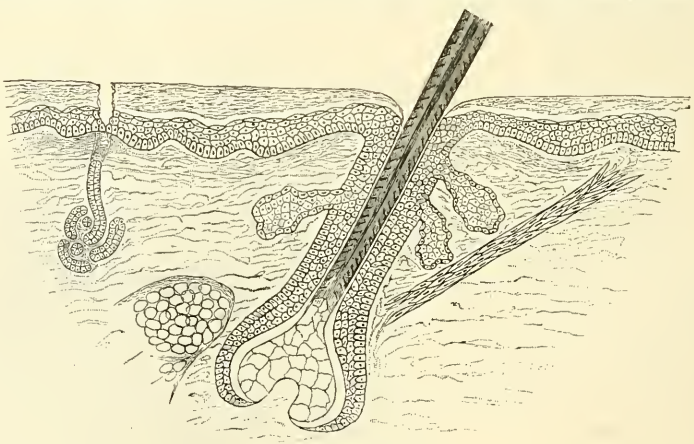
Fig. 69.—A sectional view of the skin (magnified).



the folds in the derma produced by their movements. In other situations, as upon the back of the hand, they are exceedingly fine, and intersect one another at various angles; upon the palmar surface of the hand and fingers, and upon the sole of the foot, these lines are very distinct, and are disposed in curves. They depend upon the large size and peculiar arrangement of the papillæ upon which the epidermis is placed. The deep surface of the epidermis is accurately moulded upon the papillary layer of the derma, each papilla being invested by its epidermic sheath; so that when this layer is removed by maceration, it presents on its under surface a number of pits or depressions corresponding to the elevations in the papillæ, as well as the ridges left in the intervals between them. Fine tubular prolongations are continued from this layer into the ducts of the sudoriferous and sebaceous glands.

In structure, the epidermis consists of several layers of epithelial cells, agglutinated together and having a laminated arrangement. These several layers may be described as composed of four different strata from within outwards: (1) the *rete Malpighii*, composed of several layers of epithelial cells, of which the deepest layer is elongated in figure and placed perpendicularly on the surface of the corium, their lower ends being denticulate, to fit into corresponding denticulations of the true skin; while the succeeding laminæ consist of cells of a more rounded or polyhedral form, the contents of which

FIG. 70.—Microscopic section of skin, showing the epidermis and derma: a hair in its follicle: the arrector pili muscle: sebaceous and sudoriferous glands.



are soft, opaque, granular, and soluble in acetic acid. They are often marked on their surfaces with ridges and furrows, and are covered with numerous fibrils, which connect the surfaces of the cells: these are known as *prickle* cells (see page 14). (2) Immediately superficial to these is a single layer of flattened, spindle-shaped cells, the *granular layer*, which contain granules that become deeply stained in hæmatoxylin. They are supposed to be cells in a transitional stage between the protoplasmic cells of the rete Malpighii and the horny cells of the superficial layers. (3) Above this layer, the cells become indistinct, and appear, in sections, to form a homogeneous or dimly striated membrane, composed of closely packed scales, in which traces of a flattened nucleus may be found. It is called the *stratum lucidum*. (4) As these cells successively approach the surface by the development of fresh layers from beneath, they assume a flattened form, from the evaporation of their fluid contents, and consist of many layers of horny epithelial scales in which no nucleus is discernible, forming the *stratum corneum*. These cells apparently become changed in their chemical composition, as they are now unaffected by acetic acid. The deepest layer of the rete Malpighii is separated from the papillæ by an apparently homogeneous basement-membrane, which is most distinctly brought into view in specimens prepared with chloride of gold. This, according to Klein, is merely the deepest portion of the epithelium, and is

'made up of the basis of the individual cells, which have undergone a chemical and morphological alteration.' The black colour of the skin in the negro, and the tawny colour among some of the white races, is due to the presence of pigment in the cells of the cuticle. This pigment is more especially distinct in the cells of the deeper layer, or rete mucosum, and is similar to that found in the cells of the pigmentary layer of the retina. As the cells approach the surface and desiccate, the colour becomes partially lost.

The **derma, corium,** or **cutis vera,** is tough, flexible, and highly elastic, in order to defend the parts beneath from violence.

It varies in thickness, from a quarter of a line to a line and a half, in different parts of the body. Thus it is very thick in the palms of the hands and soles of the feet; thicker on the posterior aspect of the body than the front, and on the outer than the inner side of the limbs. In the eyelids, scrotum, and penis it is exceedingly thin and delicate. The skin generally is thicker in the male than in the female, and in the adult than in the child.

The corium consists of fibrous connective tissue, with a varying amount of elastic fibres and numerous blood-vessels, lymphatics, and nerves. The fibro-areolar tissue forms the framework of the cutis, and is differently arranged in different parts, so that it is usual to describe it as consisting of two layers: the deeper or *reticular* layer, and the superficial or *papillary* layer. Unstriped muscular fibres are found in the superficial layers of the corium, wherever hairs are found; and in the subcutaneous areolar tissue of the scrotum, penis, labia majora of the female, and the nipples. In the latter situation the fibres are arranged in bands, closely reticulated and disposed in superimposed laminæ.

The *reticular* layer consists of strong interlacing fibrous bands, composed chiefly of the white variety of fibrous tissue, but containing, also, some fibres of the yellow elastic tissue, which vary in amount in different parts, and connective-tissue corpuscles, which are often to be found flattened against the white fibrous tissue bundles. Towards the attached surface the fasciculi are large and coarse, and the areolæ which are left by their interlacement are large, and occupied by adipose tissue and sweat-glands. Below this the elements of the skin become gradually blended with the subcutaneous areolar tissue, which, except in a few situations, contains fat. Towards the free surface the fasciculi are much finer, and their mode of interlacing close and intricate.

The *papillary layer* is situated upon the free surface of the *reticular layer*; it consists of numerous small, highly sensitive, and vascular eminences, the *papillæ*, which rise perpendicularly from its surface, and form the essential element of the organ of touch. The papillæ are conical-shaped eminences, having a round or blunted extremity, occasionally divided into two or more parts and connected by a thin base with the free surface of the corium. Their average length is about $\frac{1}{100}$ of an inch, and they measure at their base $\frac{1}{250}$ of an inch in diameter. On the general surface of the body, more especially in those parts which are endowed with slight sensibility, they are few in number, short, exceedingly minute, and irregularly scattered over the surface; but in some situations, as upon the palmar surface of the hands and fingers, upon the plantar surface of the feet and toes, and around the nipple, they are long, of large size, closely aggregated together, and arranged in parallel curved lines, forming the elevated ridges seen on the free surface of the epidermis. In these ridges the larger papillæ are arranged in a double row, with smaller papillæ between them; and these rows are subdivided into small square-shaped spaces by short transverse furrows, regularly disposed; in the centre of each of these transverse furrows is the minute orifice of the duct of a sweat-gland. No papillæ exist in the grooves between the ridges. In structure the papillæ consist of very small and closely interlacing bundles of finely fibrillated tissue, with a few elastic fibres.

The *arteries* supplying the skin form a network in the subcutaneous tissue, from which branches are given off to supply the sweat-glands, the hair-follicles, and the fat. Other branches are given off which form a plexus immediately beneath the corium; from this, fine capillary vessels pass into the papillæ,

forming, in the smaller papillæ, a single capillary loop, but in the larger, a more or less convoluted vessel. There are numerous *lymphatics* supplied to the skin, which form two networks, superficial and deep, communicating with each other and with those of the subcutaneous tissue by oblique branches. They originate in the cell-spaces of the tissue.

The *nerves* of the skin terminate partly in the epidermis and partly in the cutis vera. The former form a dense plexus in the superficial layer of the corium, which extends horizontally and gives off numerous fibrils; these are prolonged into the epidermis and terminate between the cells in bulbous extremities; or, according to more recent observations, in the deep epithelial cells themselves. The latter terminate in end-bulbs, touch-corpuscles, or Pacinian bodies, in the manner already described; and, in addition to these, a considerable number of fibrils are distributed to the hair-follicles, which are said to entwine the follicle in a circular manner. Other nerve-fibres are supplied to the plain muscular tissues of the hair-muscles (arrectores pili) and to the muscular coat of the blood-vessels. These are probably non-medullated fibres.

The **appendages of the skin** are the nails, the hairs, the sudoriferous and sebaceous glands, and their ducts.

The nails and hairs are peculiar modifications of the epidermis, consisting essentially of the same cellular structure as that tissue.

The **nails** are flattened, elastic structures of a horny texture, placed upon the dorsal surface of the terminal phalanges of the fingers and toes. Each nail is convex on its outer surface, concave within, and is implanted by a portion, called the *root*, into a groove in the skin; the exposed portion is called the *body*, and the anterior extremity the *free edge*. The nail has a very firm adhesion to the cutis, being accurately moulded upon its surface, as the epidermis is in other parts. The part of the cutis beneath the body and root of the nail is called the *matrix*, because it is the part from which the nail is produced. Corresponding to the body of the nail, the matrix is thick, and covered with large, highly vascular papillæ, arranged in longitudinal rows, the colour of which is seen through the transparent tissue. Behind this, near the root of the nail, the papillæ are small, less vascular, and have no regular arrangement, and here the tissue of the nail is somewhat more opaque; hence this portion is of a whiter colour, and is called the *lunula* on account of its shape.

The cuticle, as it passes forwards on the dorsal surface of the finger or toe, is attached to the surface of the nail, a little in advance of its root; at the extremity of the finger it is connected with the under surface of the nail a little behind its free edge. The cuticle and horny substance of the nail (both epidermic structures) are thus directly continuous with each other. The nails, in structure, consist of cells having a laminated arrangement, and these are essentially similar to those composing the epidermis. The deepest layer of cells, which lie in contact with the papillæ of the matrix, are of elongated form, arranged perpendicularly to the surface and provided with nuclei; those which succeed them are of a rounded or polygonal form, the more superficial ones becoming broad, thin, and flattened, and so closely compacted as to make the limits of each cell very indistinct. It is by the successive growth of new cells at the root and under surface of the body of the nail that it advances forwards and maintains a due thickness, whilst, at the same time, the growth of the nail in the proper direction is secured. As these cells in their turn become displaced by the growth of new cells, they assume a flattened form, lose their nuclei, and finally become closely compacted together into a firm, dense, horny texture. In *chemical composition* the nails resemble epidermis. According to Mulder, they contain a somewhat larger proportion of carbon and sulphur.

The **hairs** are peculiar modifications of the epidermis, and consist essentially of the same structure as that membrane. They are found on nearly every part of the surface of the body, excepting the palms of the hands, soles of the feet, and

the penis. They vary much in length, thickness, and colour in different parts of the body and in different races of mankind. In some parts, as in the skin of the eyelids, they are so short as not to project beyond the follicles containing them; in other parts, as upon the scalp, they are of considerable length; again, in other parts, as the eyelashes, the hairs of the pubic region, and the male whiskers and beard, they are remarkable for their thickness. The hairs generally present a cylindrical or more or less flattened form and a reniform outline upon transverse section.

A hair consists of a *root*, the part implanted in the skin; the *shaft* or *stem*, the portion projecting from its surface; and the *point*.

The *root of the hair* presents at its extremity a bulbous enlargement, which is whiter in colour and softer in texture than the shaft, and is lodged in a follicular involution of the epidermis called the *hair-follicle*. When the hair is of considerable length the follicle extends into the subcutaneous cellular tissue. The hair-follicle commences on the surface of the skin with a funnel-shaped opening, and passes inwards in an oblique direction to become dilated at its deep extremity, to correspond with the bulbous condition of the hair which it contains. It has opening into it, near its free extremity, the orifices of the ducts of one or more sebaceous glands (fig. 70). At the bottom of each hair-follicle is a small conical vascular eminence or papilla, similar in every respect to those found upon the surface of the skin; it is continuous with the dermic layer of the follicle, is highly vascular, and probably supplied with nervous fibrils; this is the part through which material is supplied for the production and constant growth of the hair. In structure the hair-follicle consists of two coats—an outer or *dermic*, and an inner or *epidermic*.

The *outer* or *dermic* coat is formed mainly of fibrous tissue; it is continuous with the corium, is highly vascular, and supplied by numerous minute nervous filaments. It consists of three layers (fig. 71). The most internal, next the cuticular lining of the follicle, consists of a hyaline basement-membrane having a glassy, transparent appearance, which is well marked in the larger hair-follicles, but is not very distinct in the follicles of minute hairs. It is continuous with the basement-membrane of the surface of the corium. External to this is a layer of spindle-shaped cells, with oblong nuclei, arranged in a circular manner around the follicle, but reaching only as high as the entrance of the ducts of the sebaceous glands. Externally is a thick layer of connective tissue, arranged in longitudinal bundles, in which are contained the blood-vessels and nerves. This is continuous above with the corium.

FIG. 71.—Transverse section of hair-follicle.

Outer root-sheath. *f*, *g*. Inner root-sheath. *h*. Cuticle of root-sheath. *i*. Hair. (From Quain's 'Anatomy,' Biesiadecki.)

The *inner* or *epidermic* layer is closely adherent to the root of the hair, so that when the hair is plucked from its follicle this layer most commonly adheres to it and forms what is called the *root-sheath*. It consists of two strata named respectively the *outer* and *inner root-sheath*; the former of these corresponds with the Malpighian layer of the epidermis, and resembles it in the rounded form and soft character of its cells; at the bottom of the hair-follicle these cells become continuous with those of the root of the hair. The *inner* root-sheath consists of a delicate cuticle next the hair; then of one or two layers of horny, flattened, nucleated cells, known as *Huxley's layer*; and finally of a single layer of non-nucleated, horny, cubical cells, called *Henle's layer*.

The hair-follicle contains the root of the hair, which terminates in a bulbous

extremity, and is excavated so as to exactly fit the papilla from which it grows. The bulb is composed of polyhedral epithelial cells, which as they pass upwards into the root of the hair become elongated and spindle-shaped, except some in the centre which remain polyhedral. Some of these latter cells contain pigment-granules, which give rise to the colour of the hair. It occasionally happens that these pigment-granules completely fill the cells in the centre of the bulb; this gives rise to the dark tract of pigment often found, of greater or less length, in the axis of the hair.

The *shaft of the hair* consists of a central pith or medulla, the fibrous part of the hair, and the cortex externally. The *medulla* occupies the centre of the shaft and ceases towards the point of the hair. It is usually wanting in the fine hairs covering the surface of the body, and commonly in those of the head. It is more opaque and deeper coloured when viewed by transmitted light than the fibrous part; but when viewed by reflected light it is white. It is composed of rows of polyhedral cells, which contain air-bubbles. The *fibrous* portion of the hair constitutes the chief part of the shaft; its cells are elongated and unite to form flattened fusiform fibres. Between the fibres are found minute spaces which contain either pigment-granules in dark hair, or minute air-bubbles in white hair. In addition to this there is also a diffused pigment contained in the fibres. The cells which form the *cortex* of the hair consist of a single layer which surrounds those of the fibrous part; they are converted into thin, flat scales, having an imbricated arrangement.

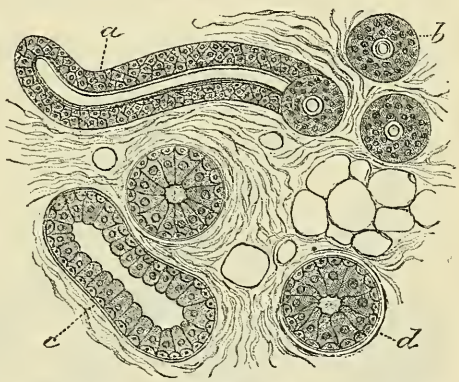
Connected with the hair-follicles are minute bundles of involuntary muscular fibres, termed the *arrectores pili*. They arise from the superficial layer of the corium, and are inserted into the outer surface of the hair-follicle, below the entrance of the duct of the sebaceous gland. They are placed on the side towards which the hair slopes, and by their action elevate the hair (fig. 70).

The **sebaceous glands** are small, sacculated, glandular organs, lodged in the substance of the corium. They are found in most parts of the skin, but are most abundant in the scalp and face: they are also very numerous around the apertures of the anus, nose, mouth, and external ear; but are wanting in the palms of the hands and soles of the feet. Each gland consists of a single duct, more or less capacious, which terminates in a cluster of small secreting pouches or saccules. The sacculi connected with each duct vary, as a rule, in number from two to five, but, in some instances, may be as many as twenty. They are composed of a transparent, colourless membrane, enclosing a number of cells. Of these, the outer layer or marginal cells are small, polyhedral, epithelial cells, continuous with the lining cells of the duct. The remainder of the sac is filled with larger cells, containing fat, except in the centre, where the cells have become broken up, leaving a cavity containing their débris and a mass of fatty matter, which constitutes the sebaceous secretion. The orifices of the ducts open most frequently into the hair-follicles, but occasionally upon the general surface, as in the labia minora and the free margin of the lips. On the nose and face the glands are of large size, distinctly lobulated, and often become much enlarged from the accumulation of pent-up secretion. The largest sebaceous glands are those found in the eyelids—the Meibomian glands.

The **sudoriferous** or **sweat glands** are the organs by which a large portion of the aqueous and gaseous materials are excreted by the skin. They are found in almost every part of this structure and are situated in small pits in the deep parts of the corium, or, more frequently, in the subcutaneous areolar tissue, surrounded by a quantity of adipose tissue. They are small, lobular, reddish bodies, consisting of a single convoluted tube, from which the efferent duct proceeds upwards through the corium and cuticle, becomes somewhat dilated at its extremity, and opens on the surface of the cuticle by an oblique valve-like aperture. The efferent duct, as it passes through the epidermis, presents a spiral arrangement, being twisted like a corkscrew, in those parts where the epidermis is thick; where, however, it is thin, the spiral arrangement does not

exist. In the superficial layers of the corium, the duct is straight, but in the deeper layers it is convoluted or even twisted. The spiral course of these ducts is especially distinct in the thick cuticle of the palm of the hand and sole of the foot. The size of the glands varies. They are especially large in those regions where the amount of perspiration is great, as in the axillæ, where they form a thin, mammillated layer of a reddish colour, which corresponds exactly to the situation of the hair in this region; they are large also in the groin. Their number varies. They are most numerous on the palm of the hand, presenting, according to Krause, 2,800 orifices on a square inch of the integument, and are rather less numerous on the sole of the foot. In both of these situations the orifices of the ducts are exceedingly regular, and correspond to the small transverse grooves which intersect the ridges of the papillæ. In other situations they are more irregularly scattered, but in nearly equal numbers, over parts including the same extent of surface. In the neck and back they are least numerous, their number amounting to 417 on the square inch (Krause). Their total number is estimated by the same writer at 2,381,248, and, supposing the aperture of each gland to represent a surface of $\frac{1}{50}$ of a line in diameter, he calculates that the whole of these glands would present an evaporating surface of about eight square inches. Each gland consists of a single tube intricately convoluted, terminating at one end by a blind extremity, and opening at the other end upon the surface of the skin. In the larger glands this single duct usually divides and subdivides dichotomously; the smaller ducts ultimately terminating in short cæcal pouches, rarely anastomosing. The wall of the duct is thick, the width of the canal rarely exceeding one third of its diameter. The tube, both in the gland and where it forms the excretory duct, consists of two layers—an outer, formed by fine areolar tissue, and an inner layer of epithelium. The external or fibro-cellular coat is thin, continuous with the superficial layer of the corium, and extends only as high as the surface of the true skin. The epithelial lining in the distal part of the coiled tube of the gland proper consists of a single layer of cubical epithelium, supported on a basement-membrane, and beneath it, between the epithelium and the fibro-cellular coat, a layer of plain muscular fibres, arranged longitudinally. In the duct and the proximal part of the coiled tube of the gland proper there are two or more layers of polyhedral cells, lined on their internal surface, i.e. next the lumen of the tube, by a delicate membrane or cuticle, and on their outer surface by a limiting membrana propria, but there are no muscular fibres. The epithelium is continuous with the epidermis and with the delicate internal cuticle which is all that is present in the epidermic portion of the tube. When the cuticle is carefully removed from the surface of the cutis, these convoluted tubes of epithelium may be drawn out and form short, thread-like processes on its under surface.

FIG. 72.—Coiled tube of a sweat-gland cut in various directions.



a. Longitudinal section of the proximal part of the coiled tube. *b*. Transverse section of the same. *c*. Longitudinal section of the distal part of the coiled tube. *d*. Transverse section of the same. (From Klein and Noble Smith's 'Atlas of Histology.')

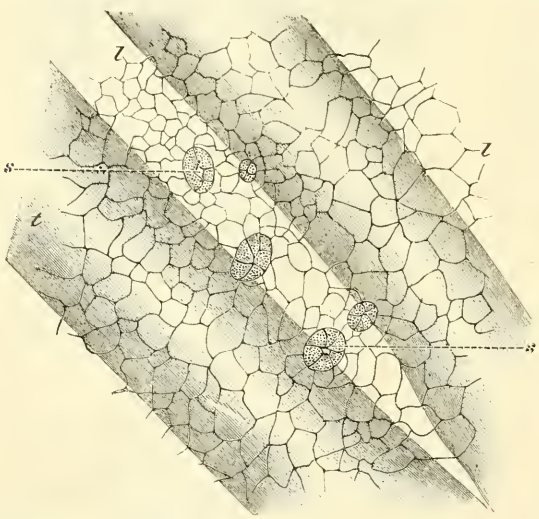
The contents of the smaller sweat-glands are quite fluid; but in the larger glands the contents are semi-fluid and opaque, and contain a number of coloured granules and cells which appear analogous to epithelial cells.

SEROUS MEMBRANES

The **serous membranes** form shut sacs and may be regarded as lymph-sacs, from which lymphatic vessels arise by stomata or openings between the epithelial cells (see page 58). The sac consists of one portion which is applied to the walls of the cavity which it lines—the *parietal* portion; and another reflected over the surface of the organ or organs contained in the cavity—the *visceral* portion. Sometimes the sac is arranged quite simply, as the tunica vaginalis testis; at others with numerous involutions or recesses, as the peritoneum, in which, nevertheless, the membrane can always be traced continuously around the whole circumference. The sac is completely closed, so that no communication exists between the serous cavity and the parts in its neighbourhood. An apparent exception exists in the peritoneum of the female; for the Fallopian tube opens freely into the peritoneal cavity in the dead subject so that a bristle can be passed from the one into the other. But this communication is closed during life, except at the moment of the passage of the ovum out of the ovary into the tube, as is proved by the fact that no interchange of fluids ever takes place between the two cavities in dropsy of the peritoneum, or in accumulation of fluid in the Fallopian tubes.* The serous membrane is often supported by a firm, fibrous layer, as is the case with the pericardium, and such membranes are sometimes spoken of as 'fibro-serous.'

The various serous membranes are the peritoneum, lining the cavity of the abdomen; the two pleuræ and the pericardium, lining the lungs and heart respectively; and the tunicæ vaginales, surrounding each testicle in the scrotum.† Serous membranes are thin, transparent, glistening structures, lined on their inner surface by a single layer of polygonal or pavement epithelial cells, supported on a matrix of fibrous connective tissue, with networks of fine elastic fibres, in which are contained numerous capillaries and lymphatics. On the surface of the epithelium between the cells numerous apertures or interruptions are to be seen. Some of these are stomata, surrounded by a ring of cubical epithelium (see fig. 73), and communicate with a lymphatic capillary; others (*pseudostomata*) are mere interruptions in the epithelial layer, and are occupied by processes of the branched connective-tissue corpuscle of the subjacent tissue or by accumulations of the intercellular cement-substance.

FIG. 73.—Part of peritoneal surface of the central tendon of diaphragm of rabbit, prepared with nitrate of silver.



s. Stomata. *l*. Lymph-channels. *t*. Tendon-bundles. The stomata are surrounded by germinating epithelial cells. (From 'Handbook for the Physiological Laboratory.' Klein.)

The secretion of these membranes is, in most cases, only sufficient in quantity to moisten the surface, but not to furnish any appreciable quantity of fluid. When a small quantity can

* The communication between the uterine cavity and the peritoneal sac is not only apparent in the dead subject, but is an anatomical fact, which is established by the continuity of its epithelium with that covering the uterus, Fallopian tubes, and fimbriæ.

† The arachnoid membrane lining the brain and spinal cord was formerly regarded as a serous membrane, but is now no longer classed with them, as it differs from them in structure, and does not form a shut sac as do the other serous membranes.

be collected, it appears to resemble in many respects the lymph, and like that fluid coagulates spontaneously; but when secreted in large quantities, as in dropsy, it is a watery fluid, which gives a precipitate of albumen on boiling.

SYNOVIAL MEMBRANES

Synovial membranes, like serous membranes, are connective-tissue membranes placed between two movable tissues, so as to diminish friction, as between the two articular ends of the bones forming a movable joint; between a tendon and a bone, where the former glides over the latter; and between the skin and various subcutaneous bony prominences.

The synovial membranes are composed essentially of connective tissue, with the cells and fibres of that structure, containing numerous vessels and nerves. It was formerly supposed that these membranes were analogous in structure to the serous membranes, and consisted of a layer of flattened cells on a basement-membrane. No such cells, however, exist, and the only ones found on the surface are irregularly branched connective-tissue corpuscles, similar to those found throughout the tissue. Here and there these cells are collected in patches and present the appearance of epithelium, but do not possess the true characters of an epithelial layer. They are surrounded and held together by an albuminous ground-substance. A further description of the synovial membranes will be found in the descriptive anatomy of the joints.

MUCOUS MEMBRANE

Mucous membranes line all those passages by which the internal parts communicate with the exterior, and are continuous with the skin at the various orifices of the surface of the body. They are soft and velvety, and very vascular, and their surface is coated over by their secretion, *mucus*, which is of a tenacious consistence, and serves to protect them from the foreign substances introduced into the body with which they are brought in contact.

They are described as lining the two tracts—the gastro-pulmonary and the genito-urinary; and all, or almost all, mucous membranes may be classed as belonging to and continuous with the one or the other of these tracts.

The external surfaces of these membranes are attached to the parts which they line by means of connective tissue, which is sometimes very abundant, forming a loose and lax bed, so as to allow considerable movement of the opposed surfaces on each other. It is then termed the *submucous tissue*. At other times it is exceedingly scanty, and the membrane is closely connected to the tissue beneath; sometimes, for example, to muscle, as in the tongue; sometimes to cartilage, as in the larynx; and sometimes to bone, as in the nasal fossæ and sinuses of the skull.

In structure a mucous membrane is composed of *corium* and *epithelium*. The epithelium is of various forms, including the squamous, columnar, and ciliated, and is often arranged in several layers (see fig. 11). This epithelial layer is supported by the corium, which is analogous to the derma of the skin, and consists of connective tissue, either simply areolar, or containing a greater or less quantity of lymphoid tissue. This tissue is usually covered on its external surface by a transparent structureless basement-membrane, and internally merges into the submucous areolar tissue. It is only in some situations that the basement-membrane can be demonstrated. The corium is an exceedingly vascular membrane, containing a dense network of capillaries, which lie immediately beneath the epithelium, and are derived from small arteries in the submucous tissue.

The fibro-vascular layer of the corium contains, besides the areolar tissue and vessels, unstriped muscle-cells, which form in many situations a definite

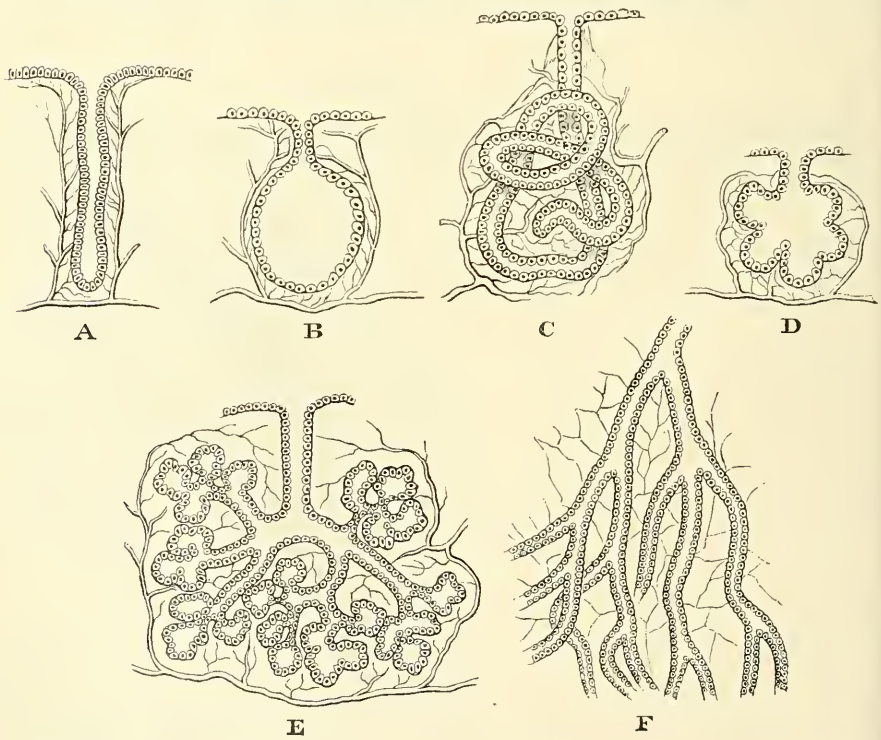
layer, called the *muscularis mucosæ*. These are situated in the deepest part of the membrane, and are plentifully supplied with nerves. Other nerves pass to the epithelium and terminate between the cells. Lymphatic vessels are found in great abundance, commencing either by cæcal extremities or in networks, and communicating with plexuses in the submucous tissue.

Embedded in the mucous membrane are found numerous glands, and projecting from it are processes (villi and papillæ) analogous to the papillæ of the skin. These glands and processes, however, exist only at certain parts, and it will be more convenient to defer their description to the sequel, where the parts are described as they occur.

SECRETING GLANDS

The **secreting glands** are organs in which the blood, circulating in capillary vessels, is brought into contact with epithelial cells, whereby certain elements are separated ('secreted') out of the blood. The essential parts therefore of a secreting gland are *cells*, which have the power of extracting from the blood certain matters, and in some cases converting them into new chemical compounds; and *blood-vessels*, by which the blood is brought into close relation-

Fig. 74.—Diagrammatic plan of varieties of secreting glands.



A. Simple gland. B. Sacculated simple gland. C. Simple convoluted tubular gland. D, E. Racemose gland. F. Compound tubular gland.

ship with these cells. The general arrangement in all secreting structures—that is to say, not only in secreting glands, but also in secreting membranes—is that the cells are arranged on one surface of an extra-vascular basement-membrane, which supports them, and a minute plexus of capillary vessels ramifies on the other surface of the membrane. The cells then extract from the blood certain constituents which pass through the membrane into the cells, where they are prepared and elaborated. The basement-membrane does not

however, always exist, and any free surface would appear to answer the same purpose in some cases.

By the various modifications of this secreting surface the different glands are formed. This is generally effected by an involution of the membrane in different ways, the object being to increase the extent of secreting surface within a given bulk.

In the simplest form a single involution takes place, constituting a *simple* gland; this may be either in the form of an open tube (fig. 74, A), or the walls of the tube may be dilated so as to form a saccule (fig. 74, B). These are named the *simple tubular* or *saccular* glands. Or, instead of a short tube, the involution may be lengthened to a considerable extent, and then coiled up to occupy less space. This constitutes the *simple convoluted tubular* gland, an example of which may be seen in the sweat-glands of the skin (fig. 74, C).

If, instead of a single involution, secondary involutions take place from the primary one, as in fig. 74, D and E, the gland is then termed a compound one. These secondary involutions may assume either a saccular or tubular form, and so constitute the two subdivisions—the *compound saccular* or *racemose* gland, and the *compound tubular*. The racemose gland in its simplest form consists of a primary involution which forms a sort of duct, upon the extremity of which are found a number of secondary involutions, called saccules or alveoli, as in Brunner's glands (fig. 74, D). But, again, in other instances, the duct, instead of being simple, may divide into branches, and these again into other branches, and so on; each ultimate ramification terminating in a dilated cluster of saccules, and thus we may have the secreting surface almost indefinitely extended, as in the salivary glands (fig. 74, E). In the *compound tubular* glands the division of the primary duct takes place in the same way as in the racemose glands, but the branches retain their tubular form, and do not terminate in saccular recesses, but become greatly lengthened out (fig. 74, F). The best examples of this form of gland are to be found in the kidney and testicle. All these varieties of glands are produced by a more or less complicated involution of a secreting membrane, and they are all identical in structure; that is to say, the saccules or tubes, as the case may be, are lined with cells, generally spheroidal or columnar in figure, and on their outer surface is an intimate plexus of capillary vessels. The secretion, whatever it may be, is eliminated by the cells from the blood, and is poured into the saccule or tube, and so finds its way out through the primary involution on to the free surface of the secreting membrane. In addition, however, to these glands, which are formed by an *involution* of the secreting membrane, there are some few others which are formed by a *protrusion* of the same structure, as in the vascular fringes of synovial membranes. This form of secreting structure is not nearly so frequently met with.

ORIGIN AND DEVELOPMENT OF THE BODY

THE OVUM

THE whole body is developed out of the **ovum** (fig. 75) when fertilised by the spermatozoa. The ovum is merely a simple nucleated cell, or collection of protoplasm, and the spermatozoa disappear when they have accomplished their mysterious function. All the complicated changes by which the various intricate organs of the whole body are formed from one simple cell may be reduced to two general processes, viz. the *segmentation* or *cleavage* of cells, and their *differentiation*. The former process consists in the splitting of the nucleus and its investing cell-wall, whereby the original cell is represented by two. The differentiation of cells is a term used to describe that unknown power or tendency impressed on cells which, to all methods of examination now known, seem absolutely identical, whereby they grow into different forms; so that (to take the first instance which occurs in the growth of the embryo) the indifferent cells of the

FIG. 75.—Ovum of the sow.

vascular area are differentiated, some of them into blood-globules, others into the solid tissue which forms the blood-vessels. The extreme complexity of the process of development renders it at all times difficult to describe intelligibly, and still more so in a work like this, where adequate space and illustration can hardly be afforded, having respect to the main purpose of the work. I can only hope to render the leading features of the process tolerably plain, and must refer the reader who wishes to follow the various changes more minutely to the special works on the subject, and especially the work of Foster and Balfour. Many of the statements which are accepted in human embryology are made only on the strength of experiments on the lower animals, direct observation on the human subject being impossible.

The **ovum** is a small spheroidal body situated in immature Graafian vesicles near their centre, but in the mature ones in contact with the membrana granulosa,* at that part of the vesicle which projects from the surface of the ovary. The cells of the membrana granulosa are accumulated round the ovum in greater number

* See the description of the ovary at a future page.

than at any other part of the vesicle, forming a kind of granular zone, the *discus proligerus*.

The **human ovum** (fig. 76) is extremely minute, measuring from $\frac{1}{240}$ to $\frac{1}{120}$ of an inch in diameter. It is a cell consisting externally of a transparent envelope, the *zona pellucida* or *vitelline membrane*. Within this, and in close contact with it, is the *yolk* or *vitellus*; embedded in the substance of the yolk is a small vesicular body, the *germinal vesicle* (*vesicle of Purkinje*), the nucleus of the cell; and this contains as its nucleolus a small spot, the *macula germinativa*, or *germinal spot* of Wagner.

The **zona pellucida**, or **vitelline membrane**, is a thick, colourless, transparent membrane, which appears under the microscope as a radially striated membrane, bounded externally and internally by a dark outline. The striæ are believed to be minute pores, and are regarded as the channels by which nutritive particles are admitted into the interior of the ovum and possibly the way by which the spermatozoa gain access into the interior of the ovum, after the rupture of the Graafian follicle. The presence of these striæ has given to the zona pellucida the name of *zona radiata*, or striated membrane of the ovum. The zona pellucida corresponds to the chorion of the impregnated ovum.

The **yolk** consists of granular protoplasm, i.e. granules or globules of various sizes, embedded in a finely reticulated matrix. The smaller granules resemble pigment; the larger granules, which are in the greatest number at the periphery of the yolk, resemble fat-globules. In the human ovum the number of granules is comparatively small. Before and immediately after fertilisation it shows distinct movements of contraction and expansion.

The **germinal vesicle** consists of a fine, transparent, structureless membrane containing a clear matrix, embedded in which is occasionally found a small amount of nucleo-plasm (see p. 8). It is about $\frac{1}{720}$ of an inch in diameter, and in immature ova lies nearly in the centre of the yolk; but as the ovum becomes developed it approaches the surface, and enlarges much less rapidly than the yolk.

The **germinal spot** occupies that part of the periphery of the germinal vesicle which is nearest to the periphery of the yolk. It is opaque, of a yellow colour, and finely granular in structure, measuring from $\frac{1}{3600}$ to $\frac{1}{2400}$ of an inch.

The phenomena attending the discharge of the ova from the Graafian vesicles, since they belong as much or more to the ordinary function of the ovary than to the general subject of the growth of the body, are described with the anatomy of the ovaries on a subsequent page.

Either before its escape from the Graafian follicle or immediately after, the ovum undergoes a peculiar change, which results in the formation of one or more peculiar bodies, the *polar globules* of Robin, the origin of which has not hitherto been known; and also with the formation of another body, which appears to take a remarkable part in fecundation, and is named the 'female pronucleus.' The manner in which these bodies are developed from the germinal vesicle is briefly as follows: usually before the rupture of the Graafian follicle, but after the ovum has become mature or ripe, a portion of the germinal vesicle is protruded outside the yolk, but still remains within the vitelline membrane; this forms a small globular mass and constitutes the first polar globule. After a time, generally not till the ovum has entered the tube, a second protrusion of a portion of the germinal vesicle takes place, and forms a second polar globule. We have thus about two-thirds of the germinal vesicle extruded from the yolk and about one-third remaining behind, and at the ejection of each of these bodies a visible shrinking of the yolk takes place. The portion of the germinal vesicle which remains behind recedes from the surface towards the centre of the yolk and assumes a spherical form, and is now termed the 'female pronucleus.' All these changes, it must be understood, occur at each expulsion of an ovum, and are quite independent of fecundation.

FERTILISATION AND EARLY CHANGES IN THE OVUM

The first changes in the ovum which take place at the time of conception appear to be as follows: One or more spermatozoa penetrate the ovum, and come into contact with the yolk, and with the portion of the germinal vesicle remaining in the yolk. It seems as if this normally occurs in the Fallopian tube,* but it is possible that it sometimes occurs before the ovum has entered the tube, or after it has passed through the tube and reached the cavity of the uterus; abnormally it may even take place in the peritoneal cavity. One spermatozoon, more advanced than the rest, becomes buried in the yolk, the tail disappears, and the head, a sort of nuclear body, constitutes the 'male pronucleus.' This gradually approaches the female pronucleus, which by this time is situated in the centre of the yolk. As soon as they come into contact they fuse into one, and form together a new nucleus, and thus fecundation is effected (fig. 77).† It is believed by most physiologists that one spermatozoon is sufficient for fecundation.

The first result of the fertilisation of the ovum is a cleavage or multiplication of the yolk, which is first cleft into two masses, the germinal vesicle having pre-

viously split up into two nuclei; so that it now consists of two separate masses of protoplasm, each containing a nucleus, situated within the original vitelline membrane, which takes no part in this process of division. Then, each of these two daughter elements divides in like manner, and thus four nucleated elements are formed, and so on, until at length a mulberry-like agglomeration of nucleated masses of protoplasm results (fig. 78). These masses are sometimes termed *vitelline spheres*.

The manner in which segmentation occurs is somewhat peculiar. The two spheres resulting from the first cleavage are of unequal size. One, which for the sake of distinction we will call the *upper* or epiblastic cell, is larger than the other, the *lower* or hypoblastic cell. And after they have divided three or four times, the rate of cleavage in the spheres derived from the upper or epiblastic segment becomes more rapid than in those derived from the lower or hypo-

* Many physiologists, as Bischoff and Dr. M. Barry, taught that the ovum is fecundated in the ovary, but the reasoning of Dr. Allen Thomson appears very cogent in proving that the usual spot at which the spermatozoa meet the ovum is in the tube, down which it slowly travels to the uterus, in its course becoming surrounded by an albuminous envelope derived from the walls of the tube.

† If the student refers to the development of the generative organs, he will find that the ovum of the female and the spermatozoon of the male are derived from fundamentally the same structures, and therefore their fusion is the union of two elements of very similar morphological value.

blastic segment. In addition to this, the spheres derived from the upper segment have a tendency to spread over and enclose those from the lower segment; so that by about the ninth or tenth division there is an external layer of spheres derived from the primary upper or epiblastic segment surrounding and almost enclosing a mass of spheres, which in consequence of their diminished rate of

cleavage are fewer in number and larger in size, derived from the primary lower or hypoblastic segment (fig. 79, A). Fluid collects between the two sets of spheres, except at one part, where they remain in contact, and the ovum is converted into a sac, formed by a layer of spheres derived from the upper primary

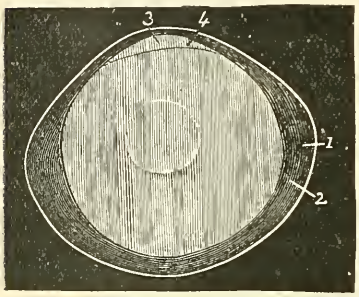
ep. Epiblast. *hy.* Primitive hypoblast. *bp.* Place where the epiblast has not yet grown over the hypoblast. (From Balfour, after Ed. van Beneden.)

segment and containing at one part another mass of spheres derived from the lower primary segment (fig. 79, B). The inner cells are rather more granular than the outer, beneath which they gradually spread, becoming applied over a part of their inner surface in a single layer; so that the cavity is afterwards enclosed in a double layer of cells. This complete investment does not, however,

take place for some time, being generally not completed until after the mesoblast has begun to form.

The ultimate destination of the outermost complete layer of spheres is, at present, doubtful. By some they are believed to be transitory and to gradually disappear in the course of the formation of the various layers of the blastodermic membrane; by others it is thought that they form the outer layer (epiblast) of this membrane. Adopting the latter and more general view, the ovum would consist of a cavity surrounded by (1) a layer of cells completely lining the interior of the vitelline membrane, and (2) by a second layer internal to these and partially lining the interior of the outer layer, both sets of cells derived from the segmentation of the yolk. The double layer of cells is called the 'blastodermic membrane,' the outer layer being termed the 'epiblast,' and the inner the 'hypoblast.'

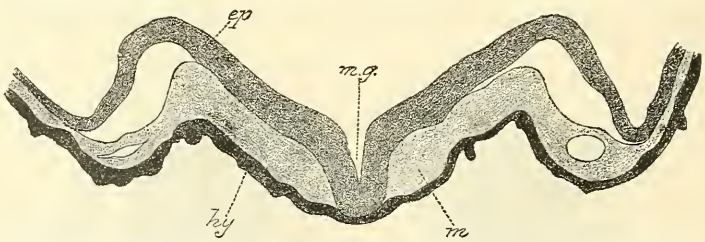
Fig. 80.—Ovum with the germinal area, seen in profile to show the division of the blastodermic membrane.



1. Vitelline membrane. 2. Blastoderm. 3. Germinal area. 4. Place where the blastoderm is just divided into its two layers.

Blastodermic membrane.—At first the area of the blastodermic membrane, which consists of both the inner and outer layers of cells, is a small disc; that is to say, when the inner or more granular cells have only spread for a short distance over the outer ones. This disc is called the *germinal disc* or *area germinativa*, because in it the first traces of the embryo are seen (fig. 80). The first trace of the embryo appears as a faint streak at the posterior end of the area germinativa, called the *primitive trace*. After the formation of the primitive trace, but previous to the appearance of the next parts of the embryo, presently to be described, viz. the laminæ dorsales and the notochord, the blastodermic membrane consists of only two layers, the *epiblast* and *hypoblast*, but after the formation of these structures a third layer makes its appearance. This is the *mesoblast*, and is situated between the other two (fig. 81). As to the precise origin

Fig. 81.—Section across the anterior part of the medullary groove of an early embryo of the guinea-pig. (By Schäfer. From Quain's 'Anatomy,' 1890.)



ep. Folds of epiblast rising up on either side of the middle line, and thus bounding the medullary groove. *mg.* Middle of medullary groove. *hy.* Hypoblast, which is in contact with the medullary epiblast at the middle of the groove, but is elsewhere separated from it by mesoblast, *m*, which has burrowed forwards between the two primary layers. A cleft is seen in the mesoblast on either side; this is the commencement of the anterior part of the body-cavity.

of this third layer considerable difference of opinion exists. According to some embryologists it is formed entirely by proliferation of cells belonging to the epiblastic layer; according to others it is formed by a splitting of the hypoblast, or, at all events, a differentiation of it into a central layer of mesoblastic cells and a lower layer of hypoblastic cells. Or, what seems most probable, it is derived mainly from the epiblast, the hypoblast taking a smaller and more subordinate share in its formation. But in whichever way this third stratum may be formed, the blastodermic membrane eventually consists of three layers. The external, which used to be called the serous layer, but is now more commonly termed the

epiblast, or *ectoderm*; the internal, the mucous layer, the *hypoblast*, or *entoderm*; and the middle, which is now usually called the *mesoblast*, or *mesoderm*, but which was formerly named the 'vascular layer.'

The *epiblast* is mainly concerned in the formation of the external cuticle and the whole of the nervous system. It consists of cells of an epithelial character; that is to say, cells of an irregular columnar shape, forming, for the most part, a single stratum, but becoming more numerous and flattened at the germinal disc. The epidermis of the body and all the involutions of the epidermis in the ducts of superficial glands, as the mammæ, as well as the brain, the spinal cord, the nerves, and the portions of the nose, eye, and ear, which are directly formed from the brain, are developed from it. The external layer of the amnion is also formed from the epiblast, and probably also a portion of the chorion.

The *hypoblast* is mainly concerned in forming the internal epithelium, viz. that of the whole alimentary passages except the mouth and the anus (which are formed by involutions of the epiblast); and the epithelium of all the glandular organs which open into the intestinal tract, the epithelium of the trachea, bronchial tubes and air sacs of the lungs; the epithelium of the urinary organs and of the thyroid and thymus glands. The hypoblast forms also the deeper layer of the umbilical vesicle and allantois. Its cells are epithelial and are at first flattened, but subsequently become columnar and larger than those of the epiblast.

All the rest of the embryo is formed from the mesoblast, viz. all the vascular and locomotive system, the cutis, all the connective tissues, and the genito-urinary organs, with the exception of the epithelium of the bladder and urethra, which is developed from the hypoblast. The vascular system of the fœtus extends to the yolk and the maternal parts along the umbilical vesicle and allantois, so that the greater part of these bodies and the outer layer of the amnion are also formed out of the mesoblast. The fœtal portion of the placenta, being essentially a vascular structure, is also developed from the mesoblast. Its cells are irregular and branched and surrounded by a considerable amount of intercellular fluid. It may therefore be regarded as resembling more closely embryonic connective tissue.

FIRST RUDIMENTS OF THE EMBRYO

The *primitive trace* alluded to above as appearing in the *area germinativa*, is a very transitory structure, which marks the direction of the embryonic axis, and is gradually lost in consequence of its place becoming occupied by the rudimentary spinal column (figs. 82 and 83).

The first real approach towards a definite form in the embryo is made (1) by the development of the rudimentary spinal column; (2) by the cleavage of the middle layer of the blastodermic membrane from which a part of that column is derived; and (3) by the incurvation of the column at its cephalic end to form the brain and brain-case.

First, a folding up of the cells of the epiblast or outer layer takes place. This commences in the anterior part of the area germinativa and extends in the same direction as the primitive trace, gradually occupying its position until this latter is lost at the caudal extremity of the embryo (fig. 84). This folding up of the epiblast gives rise to a longitudinal groove down its centre, in consequence of the manner in which the cells of the epiblast are heaped up into two longitudinal ridges, with a furrow between them, so that the sides and base of the groove are formed of epiblastic cells (fig. 85, A). The mesoblast, lying between the epiblast and hypoblast, fills up the space thus caused between these two layers, so that the sides of the groove are occupied by a longitudinal thickening of mesoblast; the two masses being separated at the bottom of the groove by the junction of the epiblast and hypoblast at the situation of the primitive trace. The groove becomes deeper and deeper in consequence of the further growing up of the cells

to form the ridge on either side. In this way the ridges eventually become two plates, the *laminæ dorsales* or *medullary plates*, which finally, bending over the groove, coalesce and thus form a closed tube, the *neural canal*, lined by epiblast and having a covering of the same membrane (fig. 85). These layers of epiblast are at first in contact with one another, but eventually become separated, mesoblastic structures growing up between them and the line of coalescence becomes obliterated. The coalescence first takes place in the middle of the embryo, then towards the cephalic end, and lastly at the caudal extremity. The lining of this tube is developed into the nervous centres, the covering into the epidermis of the back and head. The cephalic extremity of the neural canal is soon seen to be more dilated than the rest, and to present constrictions dividing it imperfectly

into three chambers : the brain is developed from this dilated portion ; the spinal cord takes its origin from the remainder of the tube. Below the neural canal, the hypoblast and epiblast are in contact, separating the two longitudinal thickenings of mesoblast on either side of the canal. Here a thickening of the hypoblast, commencing from the anterior end of the primitive trace, takes place and gradually separates itself off from the hypoblast, so as to form a rod-like column, lying between the hypoblast and the epiblast, beneath the neural canal. This is known as the *notochord* or *chorda dorsalis*. This, when fully developed, is composed of clear epithelium-like cells enclosed in a sheath of homogeneous substance. It is essentially an embryonic structure, though traces of it remain in the centre of the intervertebral discs throughout life. The collection of mesoblastic cells, which forms a thick longitudinal column on either side

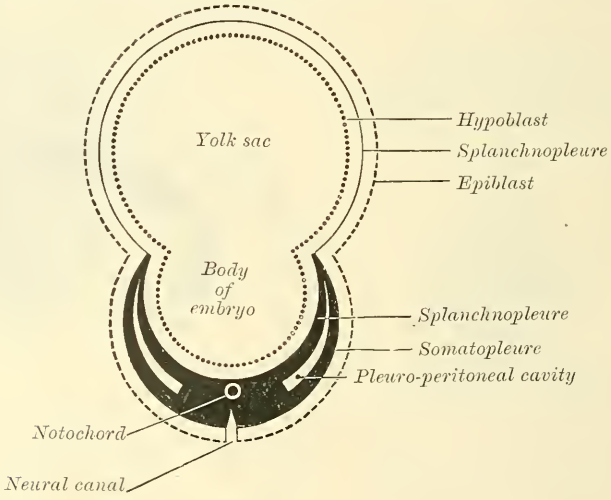
of the neural canal, becomes separated from the rest of the mesoblastic layer. It undergoes a series of transverse segmentations and becomes converted into a row of well-defined, dark, square segments or masses, separated by clear, transverse intervals, called the *protovertebræ* or *mesoblastic somites*. They first make their appearance in the region which afterwards becomes the neck, then further forwards towards the head, and afterwards extend along the body. These bodies, as will be explained hereafter, are not the same as the permanent vertebræ, but they are differentiated, partly into the vertebræ and partly into the muscles and true skin. On either side of the protovertebræ the mesoblast splits into two layers, the upper, or that covered by epiblast, is called *somatopleure*, and the lower, lined by hypoblast, the *splanchnopleure* (fig. 85, B, 5–5′). From the former the skeleton muscles and true skin of the external parts of the body are derived, from the latter the muscular and other mesoblastic portions of the viscera. The space between them is the common pleuro-peritoneal cavity. Whilst the parietes of the body are still unclosed, this common pleuro-peritoneal cavity is continuous with the space between the amnion and chorion, as seen in fig. 82, F. The embryo, which at first seems to be a mere streak, extends longitudinally and laterally. As it grows forward the cephalic end becomes remarkably curved on itself (cephalic flexure), owing to the growth forwards of the anterior extremity of the embryo over the blastodermic membrane in front of it, thus causing a dipping down of the blastoderm in front of the neural canal. A smaller but similar folding-over takes place at its hinder end (caudal flexure). At the same time the sides of the embryo grow and curve towards each other; so that the embryo is aptly compared to a canoe turned over (fig. 86). In consequence of this incurving of the embryo, both in an antero-posterior and a lateral direction, the original yolk, with the three layers derived from the cleavage of the blastodermic membrane which cover it, is converted into a sort of hour-glass shape with two unequal globes. The smaller globe is formed by the part of the blastodermic membrane (area germinativa) which has already undergone certain changes in the formation of the embryo, and constitutes the part which has been compared to a canoe. The larger globe is called the *yolk-sac* or *umbilical vesicle*, and is formed by the rest of the blastodermic membrane, i.e. that part which is not concerned in the formation of the area germinativa. The two freely communicate through the constriction which is the site of the future umbilicus, and through this constriction the internal layer of the blastodermic membrane (the hypoblast) and the innermost of the two layers into which the mesoblast divides, viz. the splanchnopleure, pass out; the incurving having only involved the somatopleural layer of the mesoblast and the epiblast

Fig. 86.—Diagrammatic section through the ovum of a mammal in the long axis of the embryo.

Yolk-sac, communicating with the middle part of the intestine by *v i*, the vitello-intestinal duct. *u*. The allantois. The ovum is surrounded externally by the villous chorion.

(fig. 87). The umbilical vesicle is, therefore, at first a mere part of the general cavity of the yolk, partly enclosed by the embryo; but as the latter grows round on all sides towards the umbilical aperture, the yolk becomes distinguished into two portions. One lies inside the embryo and eventually forms a part of the intestinal cavity (out of which also, as will hereafter be seen, the bladder is developed). The other lies external to the embryo and remains therefore for a time a part of what is, in a more restricted sense, the ovum. The two parts are almost separated from each other by the meeting of the abdominal walls of the embryo at the umbilicus, through which they still communicate by a passage, the *omphalo-mesenteric duct*, the destination of which will be pointed out presently. The extra-embryonic portion is of small importance and very temporary duration in the human subject. It is for the purpose of supplying nutrition to the embryo during the very earliest period, before it can obtain it from the uterine sinuses of the mother. In the oviparous animals, however, where no supply of nutrition can be obtained from the mother,

Fig. 87.—Diagrammatic section of embryo, showing the formation of the umbilical vesicle.



since the egg is entirely separated from her, the yolk-sac is large and of great importance, as it supplies nutrition to the chick during the whole of fœtation. Vessels developed in the middle blastodermic layer soon cover the umbilical vesicle, forming the *vascular* area, the chief vessels of which are the *omphalo-mesenteric*, two in number (fig. 88). The vessels of this area appear to absorb the fluid of the umbilical vesicle, which as the fluid is absorbed dries up and has no further function. The activity of the umbilical vesicle ceases about the fifth or sixth week, at the same time that the allantois, which is the great bond of vascular connection between the embryo and the uterine tissues, is formed. In fact, the umbilical vesicle provides for the nutrition of the fœtus from the ovum itself, while the allantois is the channel whereby it is nourished from the uterine tissues. The umbilical vesicle, containing fluid, remains visible, however, up to the fourth or fifth month, with its pedicle and the omphalo-mesenteric vessels. The latter vessels become atrophied as the functional activity of the body with which they are connected ceases.

So far we have traced—(1) the segmentation or cleavage of the yolk into a number of nucleated cells—'vitelline spheres.' (2) The accumulation of fluid within the ovum, and the arrangement of the vitelline spheres around the fluid on the internal surface of the vitelline membrane, forming a second membrane, the 'blastodermic membrane.' (3) The separation of the blastodermic membrane

into three layers, named, from within outwards, the 'hypoblast,' the mesoblast,' and the 'epiblast.' (4) The formation of an elongated, oval-shaped disc, called the 'area germinativa.' (5) The appearance in the centre of the area germinativa of a delicate line or furrow, running longitudinally, and called the 'primitive trace.' (6) The formation of a distinct groove in the situation of this primitive trace, caused by the growing-up of the cells on either side of it, so as to form two longitudinal ridges, called the 'laminæ dorsales.' (7) The increase and incurvation of these laminæ dorsales, until they meet behind, enclosing a canal, lined by epiblast. The canal is the neural canal, and from the epiblast which lines it the nervous centres are developed. (8) The formation, in the hypoblast immediately under this canal, of a continuous rod-shaped body, the

y, The umbilical vesicle with the omphalo-mesenteric vessels, *v*, and its long tubular attachment to the intestine. *c*, The villi of the chorion. *m*, The amnion opened. *u*, Cul-de-sac of the allantois, and on each side of this the umbilical vessels passing out to the chorion. In the embryo : *a*, The eye. *e*, The ear-vesicle. *h*, The heart. *l*, The liver. *o*, The upper ; *p*, the lower limb. *w*, Wolffian body, in front of which are the mesentery and fold of intestine. The Wolffian duct and tubes are not represented.

'chorda dorsalis' or 'notochord.' (9) The formation from the mesoblast, on either side of the notochord, of a longitudinal column, divided into a number of square segments, the 'protovertebræ.' (10) The splitting of the mesoblast, external to the protovertebræ, into two layers—the outer, called the 'somatopleure,' lined externally by the epiblast ; the inner, called the 'splanchnopleure,' lined internally by the hypoblast, a space being left between the two, which forms the 'pleuro-peritoneal cavity.' (11) The curving of the embryo on itself, both longitudinally and laterally, so as to be comparable to a canoe ; the walls being formed of all three layers of the blastodermic membrane and the well of the canoe—that is, the body-cavity of the embryo, opening into the cavity of the yolk-sac. (12) A portion of the yolk-sac lying in the body-cavity of the embryo, and a portion outside it ; the two communicating by a duct, the 'omphalo-

mesenteric ' duct. The portion of the yolk-sac external to the body-cavity is termed the umbilical vesicle, and provides nutrition to the embryo until such time as the allantois is formed ; vessels, developed from the middle blastodermic layer, ramifying over it, and gradually absorbing its contents.*

FORMATION OF MEMBRANES

The **membranes** investing the fœtus are the amnion, the chorion, and the decidua. The two former are developed from fœtal structures, and are proper to the fœtus ; the latter is formed in the uterus, and is derived from the maternal structures.

The Amnion.—The amnion is the membrane which immediately surrounds the embryo. It is of small size at first, but increases considerably towards the middle of pregnancy, as the fœtus acquires the power of independent movement. It exists only in reptiles, birds, and mammals, which are hence called ' Amniota,' but is absent in amphibia and fishes. It is formed thus. At or near the

FIG. 89.—Diagram of a transverse section of a mammalian embryo, showing the mode of formation of the amnion. The amniotic folds have nearly united in the middle line. (From Quain's ' Anatomy,' vol. i. pt. 1. 1890.)

extremities of the incurved fœtus—that is to say, at the point of constriction of the blastodermic membrane, where the portion which has undergone changes to form the body of the embryo joins the part devoted to the formation of the umbilical vesicle—an inflection of the epiblast and outer layer of the mesoblast, which have become separated from the inner layer of the mesoblast and hypoblast by the formation of the pleuro-peritoneal cavity, takes place (fig. 82, D 7). These inflections or backward folds commence first at the cephalic extremity, and subsequently at the caudal end and sides, and deepen more and more, in consequence of the sinking of the embryo into the blastodermic vesicle, until, gradually approaching, they meet one another (fig. 82, E 7, and 89). After they come in contact they fuse together, and the septum between them disappears ; so that the inner layer of the cephalic fold becomes continuous with the inner layer of the caudal fold, and the outer with the outer (fig. 82, F 7'). Thus we have two membranes, one formed by the inner layer of the fold—*the true amnion* —which encloses a space over the back of the embryo—the *amniotic cavity*

* According to Professor John A. Ryder, it is ' very doubtful if any considerable amount of nutriment is supplied to the embryo from the yolk-sac at any time.'

(fig. 82, F and G, *a*)—containing a clear fluid, the *liquor amnii*.* The other, the outer layer of the fold—the *false amnion*—lines the internal surface of the original vitelline membrane. Between the two is an interval, which of course communicates with the pleuro-peritoneal cavity. This it continues to do until the body-walls of the embryo have grown up and coalesced at the umbilicus. Then the amniotic fold is carried downwards, and encloses the umbilical cord, by which the fœtus is attached to the placenta. The true amnion—or, as it is usually called, the amnion—is formed of two layers, derived respectively from the epiblast and from the parietal layer of the mesoblast. The one from the epiblast consists of nucleated cells; the other, from the mesoblast, has a fibrous and, according to some embryologists, a muscular structure; at all events, it possesses the power of rhythmic contraction during life. In some animals this layer is vascular.

The amnion is at first in close contact with the surface of the body of the embryo, but about the fourth or fifth week fluid begins to accumulate, and thus separates the two. The quantity steadily increases up to about the sixth month of pregnancy, after which it diminishes somewhat. The use of the liquor amnii is believed to be chiefly to allow of the movements of the fœtus in the later stages of pregnancy, though it no doubt serves other purposes also. It contains about one per cent. of solid matter, chiefly albumen, with traces of urea, the latter probably derived from the urinary secretion of the fœtus.

The Chorion.—The chorion is rather a complex membrane made up essentially of two parts:—first, of the membranes of the ovum external to the pleuro-peritoneal cavity—that is to say, of the vitelline membrane and false amnion; and, secondly, of a diverticulum of those layers of the original blastodermic membrane which are internal to the pleuro-peritoneal cavity. This diverticulum is called the *allantois*.

1. *The portion of the chorion which is formed from the membranes of the ovum external to the pleuro-peritoneal cavity.* We have seen that in the formation of the amnion we had two layers formed out of a reduplication of the epiblast and outer layer of the mesoblast: one—the *true* amnion—which surrounds the embryo and encloses a cavity between it and the embryo—the *amniotic cavity*; and secondly, the *false* amnion, which lies in apposition with the internal surface of the vitelline membrane, and forms a complete covering to the ovum and its contents; and that between these two layers there is a space (which must not be confounded with the amniotic cavity) which communicates with the pleuro-peritoneal space, and, according to Dalton, contains a semi-fluid, gelatinous material. At a very early period of gestation cellular processes or fringes grow outwards from the external surface of the false amnion, which have been likened by Dalton to tufts of seaweed. They are at first destitute of vessels, and are of simple cellular structure. These fringes, or villi, as they subsequently become, cover at first the whole surface of the chorion; but as development progresses and the placenta, by which the extent of the attachment of the ovum to the uterine walls is to be limited, is about to be formed, the villi are not further developed over the rest of the chorion, but are confined to that part only which is to form the fœtal portion of the placenta. They may, however, be recognised all over the chorion, as abortive processes, during the whole of fœtal gestation.

2. *The Allantois.*—This structure is derived from the layers of the blastodermic membrane which are internal to the pleuro-peritoneal space, being formed by the projection of a hollow bud of that part of the hypoblast and splanchno-

* The student should be careful not to confound this cavity with that formed between the true and false amnion, which communicates with the pleuro-peritoneal cavity of the embryo. This latter space ought with more propriety to be called the 'amniotic cavity,' since it is contained between the layers of the amnion; whereas the so-called amniotic cavity is not really between the layers of the amnion at all, but between the inner layer of the amnion and the body of the embryo.

pleure which is contained in the body-cavity of the embryo, and which, as we have before stated, is intended for the formation of the intestinal canal (fig. 86, *u*). It extends into and through the pleuro-peritoneal space, into the cavity between the true and false amnion, until it meets the latter, over the internal surface of which it spreads. In this diverticulum two arteries and two veins, the *allantoic vessels*, are developed. The arteries are in the first instance branches of the two primary divisions of the abdominal aorta, but subsequently, when the two aortas coalesce, they become branches of the hypogastric arteries. The veins join the veins of the yolk-sac, and form the umbilical veins. When the allantois meets the chorion, branches from these allantoic vessels permeate the cellular tufts or fringes which have been described as growing from the outer surface of the false amnion and convert them into villi, and these eventually form the fœtal portion of the placenta * (fig. 88, *c*). The allantois is the chief agent of the early circulation, for it is the duct or tract along which the vessels extend which convey the blood of the embryo to the fœtal chorion, where it is exposed to the influence of the maternal blood circulating in the decidua or uterine portion of the placenta, from which it imbibes the materials of nutrition, and to which it gives up effete materials, the removal of which is necessary for its purification. In some animals the allantois is a hollow projection and is usually styled the *allantoic vesicle*; but in most mammals, and especially in man, the external or mesoblastic element undergoes great development, while the internal or hypoblastic element undergoes little increase beyond the body of the embryo, so that it is very doubtful whether any cavity exists in the allantois beyond the limits of the umbilicus, or whether it does not rather consist of a solid mass of material derived from the mesoblastic tissue.† A portion of the allantoic vesicle *within* the body-cavity is eventually destined to form the bladder, while the remainder forms an impervious cord, the *urachus*, stretching from the summit of the bladder to the umbilicus. The part external to the fœtus forms the umbilical cord, by which the fœtus is connected with the villi of the chorion, and which eventually form the fœtal portion of the placenta.

The Decidua.—The growth of the chorion and placenta can only be understood by tracing the formation of the decidua.

The decidua (figs. 83 G, 90) is formed from the mucous membrane of the uterus. Even before the arrival of the fecundated ovum in the uterus, the mucous membrane of the latter becomes vascular and tumid, and when the ovum has reached the uterus it becomes embedded in the folds of the mucous membrane, which grow up around it and finally completely encircle it, so as to cover it in entirely and exclude it from the uterine cavity. Thus two portions of the uterine mucous membrane (decidua) are formed, viz. that which coats the muscular wall of the uterus, *decidua vera*, and that which is in contact with the ovum, *decidua reflexa*. The decidua vera at the os internum and at the openings of the Fallopian tubes is continuous with the lining membrane of these canals, the thickening of the original mucous membrane of the uterus which converts it into decidua abruptly ceasing at these points. The neck of the uterus after conception is closed by a plug of mucus. The decidua vera is perforated by the openings formed by the enlarged uterine glands, which become much hypertrophied and developed into tortuous tubes. It contains at a later period numerous arteries and venous channels, continuous with the uterine sinuses, and it is from it that the uterine part of the placenta is developed. The portion of

* In some animals, some of the vessels of the villi of the chorion are derived from the yolk-sac, that is from the omphalo-mesenteric vessels.

† Indeed, it would appear, from the researches of His, that in the human embryo not only is the allantois formed unusually early, as is admitted by all, but in an altogether exceptional manner, not consisting of an outgrowth from the portion of the splanchnopleure engaged in the formation of the alimentary canal, but being present from the very earliest period as a stalk connecting the posterior extremity of the embryo with the chorion.

the decidua vera which takes part in the formation of the placenta is called the *decidua serotina* (fig. 90, *f*).

Here the greater part of the glands disappear, only a small portion of the deeper part of the tubes which are imbedded in the uterine muscular coat remaining, and the whole of this portion of the decidua, except a thin layer next the uterine wall, becomes converted into a series of vascular spaces or sinuses, which freely communicate with each other. This constitutes the maternal portion of the placenta.

The decidua reflexa is shaggy on its outer aspect, but smooth within. The vessels, which it contains at first, disappear after about the third month. About the fifth or six month the space between the two layers of the decidua disappears, and towards the end of pregnancy the decidua reflexa is transformed into a thin yellowish membrane, which constitutes the external envelope of the ovum.

Much additional interest has been given to the physiology of the decidua by the fact, which seems to be now established by the researches of Sir John Williams, that every discharge of an ovum, whether impregnated or not, is, as a rule, accompanied by the formation of a decidua, and that the essence of menstruation consists in the separation of a decidual layer of the mucous membrane from the uterus ; while in the case of pregnancy there is no exfoliation of the membrane, but, on the contrary, it undergoes further development in the manner described above.

Fig. 90.—Sectional plan of the gravid uterus in the third and fourth month. (From Wagner.)

The **Placenta** is the organ by which the connection between the fœtus and mother is maintained. It subserves the purposes both of circulation and respiration. It is formed of two parts, as already shown—viz. the maternal portion, which is developed out of the decidua vera (serotina), and the fœtal portion formed out of the villi of the chorion. Its shape in the human subject is that of a disc, one side of which adheres to the uterine wall, while the other is covered by the amnion. The villi of the chorion gradually enlarge, forming large projections—' cotyledons '—which each contain the ramifications of vessels communicating with the umbilical (allantoic) arteries and veins of the fœtus. These vascular tufts are covered with epithelium, and project into the vascular spaces or sinuses above mentioned, which constitute the maternal portion of the organ. In these sinuses the uterine blood is brought into close proximity with the villi of the fœtal placenta, which lie in the sinuses. The interchange of fluids necessary for the growth of the fœtus and for the depuration of the blood takes place through the walls of the villi, but there is no direct continuity between the maternal and fœtal vessels. The fœtal vessels form tufts of

capillaries, the blood from which is returned by small veins, which end in tributaries of the umbilical vein. The maternal arteries open into the sinuses somewhat after the manner of the arteries of erectile tissues. These spaces communicate with a plexus of veins which anastomose freely with one another and give rise, at the edge of the placenta, to a venous channel which runs around its whole circumference—the *placental sinus*.

The **umbilical cord** appears about the end of the fifth week after conception. It consists of the coils of two arteries (*umbilical*, originally *allantoic*) and a single vein, united together by a gelatinous tissue (*jelly of Wharton*). There are originally two umbilical veins, but one of these vessels becomes obliterated, as do also the two omphalo-mesenteric arteries and veins and the duct of the umbilical vesicle, all of which are originally contained in the rudimentary cord. The permanent structures of the cord are, therefore, furnished by the allantois.

In this manner the human embryo eventually becomes surrounded by three membranes: (1) the *amnion*, derived from the outer layer of the mesoblast and the epiblast; (2) the *chorion*, formed most probably by three layers—the allantois (which is derived from the inner layer of the mesoblast and hypoblast), the false amnion, and perhaps the vitelline membrane; and (3) the *decidua*, derived from the mucous membrane of the uterus.

DEVELOPMENT OF THE EMBRYO

The further development of the embryo will, perhaps, be better understood if we follow as briefly as possible the principal facts relating to the chief parts of which the body consists—viz. the spine, the cranium, the pharyngeal cavity, mouth, &c., the nervous centres, the organs of the senses, the circulatory system, the alimentary canal and its appendages, the organs of respiration, and the genito-urinary organs.* The reader is also referred to the chronological table of the development of the fœtus at the end of this section.

Development of the Spine.—We have already traced the first steps in the formation of the spine.—(1) The looping up of two longitudinal folds from the cells of the epiblast on either side of the primitive streak, so as to form a groove, and the gradual growing together of these ridges (*laminæ dorsales*) so as to convert the groove into a canal, which is lined by epiblast, and out of which the spinal cord is developed. (2) The formation in front of this groove of a continuous cellular cord, enclosed in a structureless sheath, the *notochord* or *chorda dorsalis* (fig. 91). The notochord extends from the cephalic to the caudal extremity of the embryo, and lies in the place which is afterwards occupied by the bodies of the vertebræ. (3) On either side of the neural canal, a portion of the mesoblastic layer is divided longitudinally from the rest of the mesoblast, so as to form a thick column, which extends from the cephalic to the caudal extremity of the embryo on either side of the spinal canal and notochord (fig. 85, A 7); this is the *protovertebral column*. From the greater part of it is derived the vertebral column, a small portion at the upper and outer part being differentiated from it and eventually forming the muscles of the back. (4) This column undergoes a process of transverse segmentation and becomes converted into a number of quadrilateral blocks, the *protovertebral somites* (fig. 92). The process of segmentation commences in the cervical region and proceeds successively through the other regions of the spine until a number of segments are formed, which correspond very closely to the number of the permanent vertebræ. (5) These protovertebral somites extend laterally; they grow forwards and inwards until they meet in front of the notochord in the middle line, which they thus enclose; and backwards and inwards, around the spinal canal, which they also enclose.

* The scope of this work only permits the briefest possible reference to these subjects. Those who wish to study the subject of embryology in more detail are referred to Kölliker's *Entwickelungsgeschichte*; to vol. i. pt. 1, of the tenth edition of Quain's *Anatomy*; or to the works of Professor Dalton and of Foster and Balfour.

The notochord and the spinal canal are thus surrounded by a cellular mass derived from the mesoblastic layer, which constitutes the *membranous matrix* of the vertebræ. This structure is covered on its internal surface by hypoblast, and on its outer by epiblast, and presents the transverse segmentation already described (page 81). (6) The next step is the conversion of this primitive membranous matrix into cartilage. This takes place probably about the fourth or fifth week in the human embryo (Kölliker). The part of the protovertebral somites which has extended backwards to enclose the spinal foramen, and which eventually forms the arches of the vertebræ, simply undergoes a process of chondrification, so that the permanent arches correspond to the primary segments of the protovertebral somites, spaces being left between them for the spinal nerves and ganglia to grow out from the spinal chord. But a somewhat

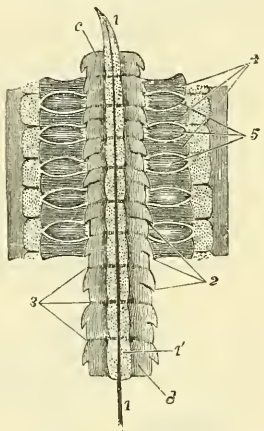
Fig. 92.—Cervical part of the primitive vertebral column and adjacent parts of an embryo of the sixth day, showing the division of the primitive vertebral segments. (From Kölliker, after Remak.)



1, 1. Chorda dorsalis in its sheath, pointed at its upper end. 2, points by three lines to the original intervals of the primitive vertebræ. 3, in a similar manner, indicates the places of new division into permanent bodies of vertebræ. *c* indicates the body of the first cervical vertebra; in this and the next the primitive division has disappeared, as also in the two lowest represented, viz. *d* and the one above; in those intermediate the line of division is shown. 4, points in three places to the vertebral arches; and 5, similarly, to three commencing ganglia of the spinal nerves: the dotted segments outside these parts are the muscular plates.

more complex change goes on in the portion of the protovertebral somites which encloses the notochord and which is destined to form the bodies of the vertebræ. Here each one of the protovertebral segments undergoes a second transverse division through its centre, and in the interval which is left between these secondary segmentations the fibrous structure of the intervertebral discs is formed. The half-segment of the original protovertebral somites on either side of this secondary segmentation joins with the segment above and below, and undergoes chondrification, and thus forms the basis of the body of a future vertebra. Each cartilaginous body of a vertebra is formed therefore out of half an original protovertebral plate joined to the half of another plate above or below it, as the case may be. (7) The notochord contained in the centre of this

chondrifying mass does not continue to grow, but becomes in the human subject relatively smaller, so as, at last, to form a mere slender thread, except opposite the secondary segmentations; that is to say, corresponding to the intervals between the bodies of the permanent vertebræ. Here it presents thickenings, and forms an irregular network, the remains of which are to be found at all periods of life in the central pulp of the intervertebral discs.

Development of the Ribs and Sternum.—The ribs are formed by extensions of the protovertebral mesoblast between the muscle-plates, growing out from the cartilaginous vertebræ. These speedily undergo chondrification, and appear as cartilaginous bars, and become separated from the vertebræ at their posterior extremities. At their anterior ends the costal bars, which are to form the nine upper ribs, turn upwards and fuse together so as to form a cartilaginous strip bounding a central median fissure. The strips on either side then join in the middle line from before backwards, and so give rise to a longitudinal piece of cartilage, which represents the manubrium and gladiolus of the sternum. In the process of development the sternal attachment of the eighth rib disappears, while that of the ninth subdivides, one portion remaining attached to the inferior extremity of the cartilaginous sternum and becoming developed into the ensiform cartilage, the other portion receding from the sternum and becoming attached to the rib above.

The further development of the vertebræ, ribs, and sternum, and the ossification of their cartilaginous structure, are described in the body of the work.

Development of the Cranium in general and the Face.—We have seen that the first trace of the embryo consists in the formation of a longitudinal fold of the epiblast on either side of a median groove, and that these folds or ridges grow backwards and meet in the median line, thus forming a canal. This canal, at the cephalic extremity of the embryo, is dilated and forms a bulbous enlargement. The bulbous enlargement soon expands into three vesicular dilatations, which are known as the three *primary cerebral vesicles*, from which all the different parts of the encephalon are presently to be developed. The most anterior of the three forms the optic thalamus, whilst a hollow projection from it forms the corpus striatum and the cerebral hemispheres; the middle one forms the tubercula quadrigemina; the posterior the medulla oblongata. The primary cerebral vesicles are at this time, of course, hollow, and their cavities freely communicate with each other at the points of constriction. As the embryo grows, the cerebral vesicles become twice bent forward on their own axis (figs. 93, 94, A and B). The upper or posterior curvature is called the cerebral; the lower or anterior, the frontal protuberance.

FIG. 93.—Longitudinal section of the head of an embryo four weeks old, seen from the inside.

Thus, we have a triple cavity (see fig. 94, A, where the three cavities are marked *c*, *mc*, and *mo*), lined by epiblast and covered by the same structure. Between these two layers of epiblast, a layer of mesoblast, derived from the protovertebral plates of the trunk, is prolonged and spreads over the whole surface of the cerebral vesicles. From these structures the cranium and its contents are developed. The external layer of the epiblast forms the superficial epithelium of the scalp. The mesoblastic layer forms the true skin, the blood-vessels, muscles, connective tissue, bones of the skull and membranes of the brain. The layer of epiblast lining the cavity forms the nervous substance of the encephalon, while the cavity itself constitutes the ventricles.

The upper end of the notochord terminates at its cephalic end in a pointed

extremity which extends as far forwards as the situation of the body of the future sphenoid bone, and is there embedded in a mass of tissue, the 'investing mass of Rathke.' This mass, derived from mesoblastic tissue, becomes cartilaginous, and from it is developed the basi-occipital and basi-sphenoid bones; and by lateral expansions from it the occipitals, the greater wings of the sphenoid, and the periotic mass of cartilage surrounding the primary auditory vesicles.

From the front of the investing mass of Rathke, which corresponds in position to the future dorsum sellæ, two lateral bars are directed forwards enclosing a space, which forms the pituitary fossa, in which the pituitary body is eventually developed. These bars are named the *trabeculæ cranii*, and extend as far forwards as the anterior extremity of the head, where they coalesce with each other. From them the pre-sphenoid and lateral masses of the ethmoid are developed; and from their coalescence a process, the *fronto-nasal process*, is prolonged downwards to form a portion of the framework of the face, hereafter to be described. From the pre-sphenoids, which are developed from these trabeculæ, a lateral expansion takes place, which forms the orbito-sphenoid or lesser wings of the sphenoid, enclosing the optic foramen.

Vertical section of the anterior end of the notochord and pituitary body, &c., from an embryo sixteen millimètres long. In A, the faucial opening is still closed. In B, it is formed. *c.* Anterior cerebral vesicle. *mc.* Meso-cerebrum. *mo.* Medulla oblongata. *co.* Corneous layer. *m.* Medullary layer. *if.* Infundibulum. *am.* Amnion. *spe.* Spheno-ethmoidal. *bc.* Central (dorsum sellæ), and *spo*, spheno-occipital parts of the basis cranii. *h.* Heart. *f.* Anterior extremity of primitive alimentary canal and opening (later) of the fauces. *i.* Cephalic portion of primitive intestine. *tha.* Thalamus. *p'.* Closed opening or the involuted part of the pituitary body (*py*). *ch.* Notochord. *ph.* Pharynx.

The portions of the base of the skull above enumerated are formed from cartilage; the remaining parts, comprising the vault of the skull, are of membranous formation.

The head at first consists simply of a cranial cavity, the face being subsequently developed in the manner now to be described by a series of arches with clefts between them (fig. 95). It is usual in our text-books to describe the arches as a series of processes which jut out and grow downwards, inclining towards each other until they meet in the middle line and thus form a series of inverted arches; whilst the clefts are the spaces left between each pair of processes. This, however, is scarcely the true description, and leads rather to the false impression that the arches are formed by processes budding out from the embryo, much in the same way as the extremities do, and that they are free on every

side. The more correct description is that the clefts are first formed, and that the arches consist of a thickening of the tissue on either side of the cleft. The arches thus formed may be divided into two sets, according as they are placed in front or behind the buccal cavity or mouth, the former being known as the *pre-oral*, and the latter as the *post-oral* or *visceral* arches. Four clefts on each side appear laterally in the undifferentiated somato-splanchno-pleural wall of the fore-gut, and between them thickenings occur which ultimately meet and fuse in the middle line, and above are connected with the investing mass. These are the so-called post-oral visceral arches. Differentiation of tissue occurs from above downwards, and cartilage is formed in them in connection with the investing mass. The first post-oral arch has no cleft in front of it, but forms a rim in front of the fore-gut. The pre-oral arches are formed in much the same way by local thickening, in which differentiation of tissue and formation of cartilage proceeds in a direction forwards and downwards from the investing mass.

The *pre-oral* or *maxillary arch* unites with the *fronto-nasal* process. The latter, which is derived, as stated above, from the coalescence of the trabeculæ cranii, consists of three plates, a central single one and two lateral ones. The *central* is called the '*mid-frontal*' process. It is prolonged downwards and forwards from the middle of the base of the skull, from the point of coalescence of the two trabeculæ cranii, and from it the septum of the nose is developed. It is free in front and below, but behind it is united with the coalesced portion of the trabeculæ, which therefore probably assists in the formation of the septum nasi, and, in addition, of the prominent part of the future nose. The *lateral* plates of the fronto-nasal process are separated from the central one by a depression or furrow on either side; these furrows form the primary nasal pits or fossæ. The lateral plates project downwards parallel to the mid-process for a certain distance, and then, curving inwards, unite with it, thus shutting off the nasal fossæ from the rest of the face. The lateral masses of the ethmoid and lachrymal bones are developed in the lateral plates, and by their union with the mid-frontal process form the intermaxillary bone and the *lunula*, or central part of the upper lip.

Fig. 95.—Face of an embryo of 25 to 28 days. Magnified 15 times.

The *maxillary* processes spring from the base of the skull further back than the fronto-nasal process, and at their origin are closely connected with the first post-oral or visceral arch. They descend for a short distance, forming the outer wall of the orbit, in which the malar bone is developed; they then incline inwards, and, meeting the lateral plate of the fronto-nasal process, form the floor of the orbit, and shut it off from the rest of the face; then, continuing their course downwards and inwards, they join the mid-frontal process, and with it complete the alveolar arch and the superior maxillary bone. Finally, palatal processes are formed by an extension of the inner sides of this arch; these coalesce with each other in the median line, thus separating the cavity of the mouth from the nasal fossæ, and completing the palate. In front, however, the palatal processes do not join with the mid-frontal process, but a cleft is left which constitutes the naso-palatine canal.

The *post-oral* arches are five in number in the amniota, and of these the

first only is concerned in the formation of the face proper, for the lower jaw or mandible is in part developed from it, and hence it is called the *mandibular* arch. The second is named the *hyoid* arch : from it are formed the styloid process, the stylo-hyoid ligament, and the lesser cornu of the hyoid bone. The third, or *thyro-hyoid* arch, gives origin to the great cornu of the hyoid bone, while the body of this bone is formed between the second and third arches. This third arch, together with the fourth and fifth, correspond to the arches which, in fishes and amphibia, form the gill-plates, but which, in the amniota, never do so. They are appropriately named *branchial*, a name which was primarily given to the whole series by Rathke, who first described them.

The deeper part of the first or mandibular arch contains a transitory cartilaginous rod, which has long been known as the 'cartilage of Meckel,' the proximal end of which is at first attached to the basis cranii, and afterwards to the periotic capsule. It is, during some part of fœtal life, directly continuous with the malleus, which by some is believed to be developed from it. The median end of the lower jaw-bone is developed from this cartilage ; the greater part of the rest of the bone being developed from membrane.

Between the mandibular arch and the pre-oral arch the buccal cavity or mouth is formed ; this therefore owes its origin to the formation of the pre-oral and post-oral arches, and consists of mesoblastic tissue lined by epiblast. As has been already stated (page 81) the cephalic end of the embryo becomes remarkably curved on itself, the fore- and mid-brain bending downwards over the anterior portion of the original blastodermic membrane which remains within the body of the embryo and from which the fore-gut is to be developed. This fore-gut terminates as a blind extremity beneath the head (fig. 94, A, *f*). Another prominence forms on the ventral surface of the fore-gut, which represents the rudimentary heart (fig. 94, A, *h*). Between these two prominences, caused by the projection of the fore-brain and the heart, an involution of the epiblast takes place, gradually deepening until it comes in contact with the upper part of the alimentary canal. This is the *stomodæum* or *mouth*, which becomes bounded by prominences, constituting the pre-oral and mandibular arches. It is at first quite distinct from the upper part of the alimentary canal, which, as we shall hereafter see, is formed by the inner or splanchno-pleural layer of the mesoblast and the hypoblast, the two cavities being separated by all the layers of the blastodermic membrane. A communication between the two is, however, gradually effected by the absorption of these layers at the anterior extremity of the primitive alimentary cavity and the hinder portion of the epiblastic involution from which the mouth is formed.

Between each of these visceral arches are clefts, four in number, which run through the tissues of the neck to the cavity of the pharynx ; the first persists, though only in a portion of its extent, forming the Eustachian tube, the meatus auditorius, and the tympanic cavity. The other fissures are wholly closed by the sixth week.

Development of the Nervous Centres and the Nerves.—The medullary groove above described (page 80) presents, about the third week, three dilatations at its upper end, separated from one another by two constrictions, and at its posterior part another dilatation, called the *rhomboidal sinus*. Soon afterwards the groove becomes a closed canal (*medullary canal*) and a soft blastema lines it, exhibiting corresponding dilatations. This is the rudiment of the cerebro-spinal axis. As the embryo grows, its cephalic part becomes more curved, and the three dilatations at the anterior end of the primitive cerebro-spinal axis become vesicles distinctly differentiated from each other (fig. 93). These are the primary cerebral vesicles—anterior, middle, and posterior. Subsequently the anterior and posterior vesicles become subdivided and each forms two vesicles, whilst the middle one remains permanently undivided. It will thus be seen that at the anterior extremity of the medullary groove are five dilatations, separated from each other by constrictions, from which the five fundamental divisions of the

brain are formed. These five permanent rudiments of the brain and medulla have received the names, from before backwards, of prosencephalon, thalamencephalon, mesencephalon, epencephalon, and metencephalon. The first two of these are formed from the anterior primary vesicle, the last two from the posterior primary vesicle, and the mesencephalon from the middle primary vesicle. In addition to this a hollow protrusion takes place from the anterior primary vesicle, which constitutes the rudiment of the optic nerve and retina, as will be explained in the sequel (fig. 96, A). Subsequently another protrusion takes place from the anterior vesicle (prosencephalon), which is at first simple, but soon becomes divided into two parts by an antero-posterior fissure. These expand forwards, backwards, and laterally, and form the cerebral hemispheres (fig. 96 H).

These vesicles do not, however, remain in the same line as the cord, but certain definite flexures take place, which result in an alteration of the position of the vesicles to one another. The first of these flexures takes place opposite the base of the middle vesicle, which becomes sharply bent on itself over the end of the notochord. This has the effect of causing the mid-brain to become the most prominent part of the encephalon on the convexity of the curve (fig. 96, M). A second flexure, with its curve in the opposite direction, takes place in the epencephalon and is very abrupt. A third, but less marked, flexure, takes place in the metencephalon at its junction with the cord and has its concavity forwards, in the same direction as the first curve. The first of these curves or flexures remains permanently, but the second and third almost entirely disappear in the further development of the brain.

The different parts of the brain are formed on the walls of the vesicles as local thickenings in different positions. These thickenings, as they increase, gradually encroach upon the interior of the vesicles; a permanent cavity, however, remains, which constitutes the cavity of the ventricles.

The parts of the brain formed from the prosencephalon, or first secondary vesicle, are first of all the cerebral hemispheres, which, as has been stated, are formed as hollow outgrowths from this vesicle, on the interior of which thickening takes place. They are at first covered and concealed by the middle primary vesicle, in consequence of the flexure which takes place, but by the third month they have risen above the optic thalami, and by the sixth month above the cerebellum. The other parts formed from the prosencephalon are the corpora striata, the corpus callosum, the fornix, and the olfactory bulbs and tract. The cavity of this vesicle forms the lateral ventricles, the foramen of Monro, and the anterior part of the third ventricle. The portions of the encephalon developed from the thalamencephalon, or second secondary vesicle, are the optic thalami, the pineal gland, a part of the pituitary body, and, by a special prolongation, the optic nerve and retina. The cavity of this vesicle constitutes that part of the third ventricle which is not formed by the first secondary vesicle. The mesencephalon, or third secondary vesicle, corresponding to the middle primary vesicle, is developed into the corpora quadrigemina and the crura cerebri. This vesicle is at first situated at the summit of the angle caused by the first flexure (fig. 96, A). Its smooth surface is soon divided by a median and transverse groove into four tubercles (tubercula quadrigemina), which are gradually covered in by the growth of the cerebral hemispheres. Its cavity diminishes as its walls thicken, and contracts to form the aqueduct of Sylvius.

The epencephalon, or fourth secondary vesicle, is developed into the pons Varolii and the cerebellum, and the metencephalon, or fifth secondary vesicle, forms the medulla. The cavity of these two secondary vesicles, which it will be remembered constituted the third primary vesicle, forms the fourth ventricle.

The development of the pituitary body has of late received much attention. It is mainly formed by a diverticulum from the buccal involution of epiblast. At its upper and front part this involution, from which the mouth or stomodæum is developed, forms a hollow saccular protrusion, which extends into the angle formed by the bend of the mid-brain. Here it comes in contact with a median

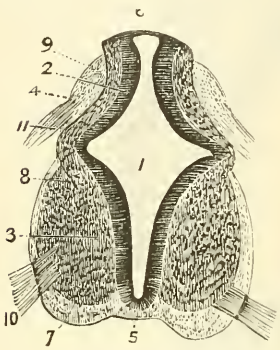
hollow protrusion, which passes downwards and backwards from the posterior portion of the anterior cerebral vesicle (fig. 94, c, *if*). They become intimately connected, and together form the pituitary body or hypophysis.

When the medullary groove is first closed, the fœtal spinal marrow occupies its whole length, and presents a large central canal, which gradually contracts in consequence of the thickening and rapid growth of the epiblast around it. This increase in thickness takes place principally at the sides, so that eventually the central canal acquires on section the appearance of a slit. According to some investigators, the two sides of this slit eventually join in the middle, and the original canal is divided into two: an *anterior*, which becomes the central permanent canal, which in after-life is no longer perceptible to the eye, though it is still visible on microscopic section; and a *posterior*, which becomes filled about the ninth week with a septum of connective tissue from the pia mater, and forms the posterior fissure of the cord. According to other observers, the posterior fissure is formed independently of the central canal, as a cleft formed by the enlarging lateral halves of the cord, into which an ingrowth of connective tissue from the pia mater takes place. The anterior fissure is apparently formed in this latter manner, simply as a cleft left between the lateral halves of the cord.

FIG. 97.—Section of the medulla in the cervical region, at six weeks. Magnified 50 diameters.



1. Central canal. 2. Its epithelium. 3. Anterior grey matter. 4. Posterior grey matter. 5. Anterior commissure. 6. Posterior portion of the canal, closed by the epithelium only. 7. Anterior column. 8. Lateral column. 9. Posterior column. 10. Anterior roots. 11. Posterior roots.

After the fourth month the spinal column begins to grow in length more rapidly than the medulla spinalis, so that the latter no longer occupies the whole canal. The cord is composed at first entirely of uniform-looking cells, which soon separate into two layers, the inner of which forms the epithelium of the central canal, while the outer forms the central grey substance of the cord (fig. 97). The white columns are formed later; their rudiments can be detected about the fourth week, and some embryologists believe that they are developed from the mesoblast.

The cerebral and spinal membranes are, according to Kölliker, a production from the protovertebral discs, and are recognisable about the sixth week. As the fissures separating the segments of the cerebro-spinal axis appear, the membranes extend through them, and the pia mater passes into the cerebral ventricles. Bischoff, however, describes the pia mater and arachnoid as developed from the cerebral vesicles, so that they are, according to him, formed in the position which they permanently occupy.

The Nerves.—The nerves are developed, like the rest of the nervous system, from epiblast. The spinal nerves are developed as follows:—Close to the point of involution of the epiblast in the median line, that is to say, in the angle of junction of the neural and general epiblast, a cellular swelling constituting the *neural crest* appears and forms a continuous ridge on the dorsal aspect of the neural canal. On this crest enlargements occur, corresponding with the middle of each protovertebral segment. These grow downwards between the neural canal and the mesoblastic tissue forming the protovertebræ, and occupy a position on the lateral wall of the canal. These enlargements are the rudiments of the ganglia of the posterior roots; they are at first attached to the neural crest from which they spring, but subsequently this attachment becomes lost, and they then form isolated masses on either side of the neural canal, which now contains the rudimentary cord. They consist of oval cells, from either end of which a process eventually springs; one, passing centrally, grows into the embryonic cord and constitutes the posterior root of the nerve; the other, growing peripherally, joins the fibres of the anterior root to form the spinal nerve.

The anterior root is, according to the recent researches of His, a direct outgrowth of certain cells which are found in the rudimentary cord and which are named *neuroblasts*. These cells, like those mentioned above, are oval, and have a prolongation directed outwards towards the surface of the cord. These processes pass out of the cord in bundles and penetrate the mesoblast and join with fibres of the posterior root, and from the point of union the nerve grows towards its peripheral termination.

Most of the cranial nerves are developed in the same manner as the posterior roots of the spinal nerves. That is to say, the neural crest, developed from the epiblast, is continued onwards, along the dorsal surface of the cephalic portion of the neural tube, as far as the mid-brain. From this a series of swellings at irregular intervals form the rudimentary ganglia, from the polar cells of which the nerve is formed and its connection with the brain established. This appears to be the case with the third, fifth, the facial, the auditory, the glosso-pharyngeal, and the pneumogastric and probably the fourth. With regard to the mode of origin of the sixth, the spinal accessory and the hypoglossal, our knowledge is not so exact, but they would appear to arise, like the anterior roots of the spinal nerves, from groups of oval cells (neuroblasts) in the basal laminæ.

The olfactory tract and bulb is a protrusion of the antero-ventral part of each cerebral hemisphere. This protrusion comes in contact with the thickened epiblast of the olfactory area (see page 100), from which neuroblastic cells, which are formed within the area, pass out and form a ganglion between the area and the olfactory bulb. From this ganglion cell-processes grow centripetally to form the nerve-roots, and centrifugally to form the olfactory nerves which ramify on the Schneiderian membrane.

The optic nerve arises in a manner entirely different from any of the other cranial nerves, as a hollow outgrowth of the brain, which subsequently becomes solid. It will be considered in connection with the development of the eye.

The sympathetic nerves are developed as outgrowths from the gangliated roots of the spinal and cranial nerves.

Development of the Eye.—The nervous elements and non-vascular parts of the eye are formed from the epiblast, and the vascular portions from the mesoblast; but the method of development is somewhat complicated. The essential portion of the eye—i.e. the retina and the parts immediately connected with it—is an outgrowth from the rudimentary brain (primitive ocular vesicle), and this outgrowth is met by an ingrowth from the common epidermic or corneous layer of the epiblast, out of which the lens and the conjunctival and corneal epithelium are developed.

The first appearance of the eye consists in the protrusion or evolution from the medullary wall of the thalamencephalon of a vesicle, called the *primitive ocular vesicle*. This is at first an open cavity communicating by a hollow stalk with the general cavity of the cerebral vesicle. As development advances the hollow stalk becomes solid, and thus the optic nerve is formed, receiving, however, in a way presently to be explained, mesoblastic elements for the formation of its central artery and connective tissue. As the primitive ocular vesicle is prolonged forwards, it meets the epidermic layer of the epiblast, which at the point of contact becomes thickened, and then forms a depression which gradually encroaches on the most prominent part of the primitive ocular vesicle, which in its turn appears to recede before it, so as to become at first depressed and then inverted in the manner indicated in fig. 98, so that the cavity is finally almost obliterated by the folding back of its anterior half, and the original sac converted into a cup-shaped cavity, the *ocular cup*, in which the involuted epiblastic layer, the rudiment of the lens, is received (fig. 98, B). This cup-shaped cavity consists therefore of two layers: one, the outer, originally the posterior half of the primitive ocular vesicle, is thin, and eventually forms

the pigmental layer of the retina; * the other layer, the inner, originally the anterior or more prominent half, which has become folded back, and is much thicker, is converted into the nervous layers of the retina. Between the two are the remains of the cavity of the original primary vesicle, which finally becomes obliterated by the union of its two layers. As development proceeds the cup-shaped cavity or ocular cup increases in size, and thus a space is formed between it and the rudimentary lens which it contains; this is the *secondary ocular vesicle,* and in it the vitreous humour is developed (fig. 98, c). The folding in of the primary optic vesicle to produce the optic cup not only takes place in front, at its most prominent part, opposite the lens, but also below, where a cleft or fissure is formed, the *choroidal fissure* or *ocular cleft,* through which vascular elements, within the vesicle and derived from the mesoblast, retain their connection with the rest of the mesoblast. This gap or cleft is continued for some distance into the stalk of the optic vesicle and thus allows a process of the mesoblast to extend down the stalk to form the arteria centralis retinæ and its accompanying vein. After a time the gap or fissure becomes closed, by a coalescence of its margins, but the line of union remains apparent for some considerable period. The lens is at first a thickening of the epiblast, then a depression or involution takes place, thus forming an open follicle, the margins

of which gradually approach each other and coalesce, forming an enclosed cavity of epiblastic cells (fig. 98). At the point of involution the external layer of epiblast separates from the ball of the lens and passes freely over the surface, so that the lens becomes disconnected from the epiblastic layer from which it was developed, and recedes into the ocular cup, while the cuticular layer covering it is developed into the corneal epithelium. The cells forming the posterior or inner wall of the cavity, which is to form the lens, rapidly increase in size, becoming elongated and developed into fibres, and, filling up the cavity, convert it into a solid body. The cells on the anterior wall undergo no change and retain their cellular character. The secondary ocular vesicle, or space between the lens and the hollow of the ocular cup (figs. 98, c, 7, and 99), contains a quantity of mesoblastic tissue continuous through the ocular cleft with the rest of the mesoblast, and into this blood-vessels project themselves through the ocular cleft. The iris and ciliary processes are formed from this vascular tissue, and the choroid is developed in the mesoblast surrounding the ocular vesicle.

* This layer forms functionally part of the choroid, and was formerly described as belonging to this membrane; it is now described as part of the retina, on account of its method of development.

A portion of this tissue also becomes converted into the vitreous humour, and surrounds the lens with a vascular membrane—the *vascular capsule of the lens*, which is connected with the termination of the temporary artery (hyaloid) that forms the continuation of the central artery of the retina through the vitreous chamber. This vascular capsule of the crystalline lens forms the membrana pupillaris (described on a subsequent page), and also attaches the borders of the iris to the capsule of the lens. It disappears about the seventh month.

The eyelids are formed at the end of the third month, as small cutaneous folds, which come together and unite in front of the globe and cornea. This union is broken up and the eyelids separate before the end of fœtal life.

The lachrymal canal appears to result from the non-closure of a fissure which exists between the lateral plates of the fronto-nasal and maxillary processes. Born, however, considers that it is formed by a thickening of the deeper layer of the epidermis which sinks into the corium and subsequently becomes hollowed out into a tube.

Development of the Ear.—The first rudiment of the ear appears shortly after that of the eye, in the form of a thickening of the epiblast, on the outside of that part of the third primary cerebral vesicle which eventually forms the medulla oblongata, opposite the dorsal end of the first post-oral visceral cleft. The thickening is then followed by an involution of the epiblast, which becomes deeper and deeper, sinking towards the base of the skull, and a flask-shaped cavity is formed; by the narrowing of the external aperture the neck of the flask constitutes the *recessus labyrinthi*. The mouth of the flask then becomes closed, and thus a shut sac is formed, the *primitive auditory* or *otic vesicle*, which by its sinking inwards comes to be placed between the ali-sphenoid and basi-occipital matrices. From it the internal ear is formed. The middle ear and the Eustachian tube are developed from the remains of the first branchial cleft, while the pinna and external meatus are developed from the soft parts overhanging the posterior margin of the same cleft. The primary otic vesicle becomes embedded in a mass of mesoblastic tissue, which rapidly undergoes chondrification and ossification. It, as before stated, is at first flask- or pear-shaped; the neck of the flask, or *recessus labyrinthi*, prolonged backwards, forms the aquæductus vestibuli. From it are given off certain prolongations or diverticula, from which the various parts of the labyrinth are formed. One from the anterior end gradually elongates, and, forming a tube, bends on itself from left to right and becomes the cochlea. Three others, which appear on the surface of the vesicle, form the semicircular canals. Of these, the one which is to constitute the external semicircular canal does not appear at such an early date as the other two. Subsequently, a constriction takes place in the original vesicle, which, gradually increasing, divides it into two, and from these are formed the utricle and saccule. Finally, the auditory nerve, which has been developed from the 'neural crest' in the manner above described (page 97), pierces the auditory capsule in two main divisions—one for the vestibule, the other for the cochlea. The middle ear and Eustachian tube are the remains of the first pharyngeal or branchial cleft (hyo-mandibular), and are, from an early period, closed by the formation of the membrana tympani, which consists of a layer of epiblast externally, a layer of hypoblast internally, and between the two of mesoblastic tissue constituting its fibrous and vascular layer. With regard to the exact mode of development of the ossicles of the middle ear there is considerable difference of opinion. By some the *malleus* is believed to be developed from the proximal end of the mandibular (Meckel's) cartilage, and the *incus* from the proximal end of the hyoidean cartilage. Others, again, believe that they are both developed from the mandibular cartilage. A third group of observers believe that they are developed from a hyo-mandibular cartilage, similar to that which in some of the lower animals forms a suspensory apparatus for both mandibular and hyoidean arches. The *stapes* is believed by some to be formed

by a deposit of cartilaginous cells around the fenestra ovalis; by others it is supposed to be developed from the proximal end of the hyoidean arch.

The external auditory meatus is developed, like the pinna, from the soft parts on the posterior margin of the first visceral cleft by an outgrowth of the tissues in this situation.

Development of the Nose.—The olfactory fossæ, like the primary auditory vesicles, are formed in the first instance by a thickening and involution of the epiblast, which takes place at a point below and in front of the ocular vesicle (fig. 95, 2, 3). The thickening appears at a very early period, about the fourth week. The borders of the involuted portion very soon become prominent, in consequence of the development of the mid-frontal and lateral naso-frontal plates above spoken of (page 92), which are formed on either side of the rudimentary fossæ. As these processes increase, the fossæ deepen and become converted into a deep channel, which eventually forms the upper part of the nasal fossæ—that is, the two superior meatuses, the part to which the olfactory nerves are distributed. At this time they are continuous with the buccal cavity, a portion of which forms the lower part, or inferior meatus of the nasal fossæ. For as the palatine septum is formed, the buccal cavity is divided into two parts, the upper of which forms the lower part of the nasal fossæ, while the remainder forms the permanent mouth.

The soft parts of the nose are formed from the coverings of the frontal projections and of the olfactory fossæ. The nose is perceptible about the end of the second month. The nostrils are at first closed by epithelium, but this disappears about the fifth month.

The olfactory nerve, as above pointed out, is formed from the anterior cerebral vesicle, as a secondary vesicle on its under surface, and it lies upon the involuted epiblast, which subsequently forms the nasal fossæ.

Development of the Skin, Glands, and Soft Parts.—The epidermis is produced from the external, the true skin from the middle, blastodermic layer (fig. 82, 19, 20). About the fifth week the epidermis presents two layers, the deeper one corresponding to the rete mucosum. The subcutaneous fat forms about the fourth month, and the papillæ of the true skin about the sixth. A considerable desquamation of epidermis takes place during fœtal life, and this desquamated epidermis, mixed with a sebaceous secretion, constitutes the *vernix caseosa*, with which the skin is smeared during the last three months of fœtal life. The nails are formed at the third month, and begin to project from the epidermis about the sixth. The hairs appear between the third and fourth month in the form of depressions of the deeper layer of the epithelium, which then become inverted by a projection from the papillary layer of the skin. The papillæ grow into the interior of the epithelial layer; and finally, about the fifth month, the fœtal hairs (*lanugo*) appear first on the head and then on the other parts. These hairs drop off after birth, and give place to the permanent hairs. The cellular structure of the sudoriferous and sebaceous glands is formed from the epithelial layer, while the connective tissue and blood-vessels are derived from the mesoblast about the fifth or sixth month. The mammary gland is also formed: partly from mesoblast—its blood-vessels and connective tissue; and partly from epiblast—its cellular elements. Its first rudiment is seen about the third month, in the form of a small projection inwards of epithelial elements, which invade the mesoblast; from this, similar tracts of cellular elements radiate; these subsequently give rise to the glandular follicles and ducts. The development of the former, however, remains imperfect, except in the adult female, and especially after pregnancy.

Development of the Limbs.—The upper and lower limbs begin to project, as buds, from the anterior and posterior part of the embryo about the fourth week. These buds are formed by a projection of the somatopleure (i.e. the outer layer of the mesoblast and the epiblast) from the point where the mesoblast splits into its parietal and visceral layers, just external to the vertebral somites, of which

they may be regarded as lateral extensions. The division of the terminal portion of the bud into fingers and toes is early indicated, and soon a notch or constriction marks the future separation of the hand or foot from the fore-arm or leg. Next, a similar groove appears at the site of the elbow or knee. The indifferent tissue or blastema, of which the whole projection is at first composed, is differentiated into muscle and cartilage, before the appearance of any internal cleft for the joints between the chief bones.

The **muscles** become visible about the seventh or eighth week. The vertebral muscles appear to be developed from the 'muscle-plates' of the protovertebræ. These bodies (page 81, and fig. 82, c, 13) consist of a compact mass of cells for the most part irregularly arranged, but externally—that is to say, next the cutaneous epiblast—they become arranged in the form of a single layer of columnar cells. This is known as the *muscle-plate*. On the inner surface of this a second layer of cells makes its appearance, and these begin to elongate in an antero-posterior direction and become developed into longitudinal groups of muscle-fibres. The muscles of the neck and jaws, as well as those which enclose the cavities of the thorax and abdomen, and probably also those of the limbs, are also formed from the same source. The cutaneous muscles are developed from the cutaneous portion of the middle blastodermic layer.

Development of the Blood-vascular System.—There are three distinct stages in the development of the circulatory system before it arrives at its complete or adult condition, in accordance with the manner in which nourishment is provided for at different periods of the existence of the individual. In the first stage there is the *vitelline circulation*, during which nutriment is extracted from the yolk or contents of the vitelline membrane. In the second stage there is the *placental circulation*, which commences after the formation of the placenta, and during which nutrition is obtained by means of this organ from the blood of the mother. In the third stage there is the *complete circulation of the adult*, commencing at birth, and during which nutrition is provided for by the organs of the individual itself.

1. The **vitelline circulation** is carried on partly within the body of the embryo and partly external to it in the vascular area of the yolk. It consists of a median tubular heart, from which two vessels (arteries) project anteriorly. These carry the blood to a plexus of capillaries spread over the area vasculosa, and also, though to a less extent, in the body of the embryo. From this plexus the blood is returned by two vessels (veins) which enter the heart posteriorly, and thus a complete circulation is formed.

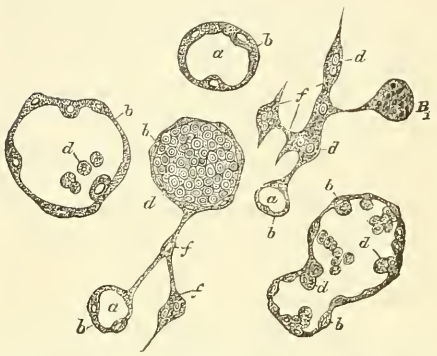
In these vessels and the heart a fluid (*blood*) is contained, in which rudimentary corpuscles are found. The mode of formation of these elementary parts will have first to be considered.

In mammalia the heart is formed by a dilatation of the body cavity on either side of the median line in front of the anterior extremity of the rudimentary pharynx, at about the level of the posterior primary cerebral vesicle. This dilatation is the rudiment of the future pericardium. Into it an invagination of the splanchnopleure takes place on either side of the embryo; this invagination speedily becomes separated from the rest of the splanchnopleure and the aperture of invagination becomes closed. In this manner two closed tubes are formed which present two distinct strata of cells; the inner and thinner layer, derived from the hypoblast, forms the endocardium, the outer and thicker, derived from the visceral mesoblast, forms the muscular wall of the heart. In its very earliest and primitive condition, the heart consists therefore of a pair of tubes, one on either side of the body. These, however, soon coalesce in the median line, and, fusing together, form a single central tube.* Each of the two primary tubes receives posteriorly a large vessel (a vein), and is prolonged anteriorly into a second vessel (an artery). So that after fusion of the heart-tubes has taken place, there is, in the primitive vitelline

* In most fishes and in amphibia the heart originates as a single median tube.

circulation, as above mentioned, a single tubular heart, with two arteries proceeding from it and two veins emptying themselves into it. The earliest *vessels* are also formed in the visceral layer of the mesoblast. They are developed from that part of the mesoblast which surrounds the portion of blastoderm which is occupied by the developing body of the embryo and which is known as the 'vascular area.' So that the first blood-vessels are developed outside the body of the embryo. The indifferent cells of which this layer is composed become enlarged and give off processes, which grow out from the cells in two or more directions. The cells or their processes fuse together, so that an irregular network is formed, consisting of tubes derived from the enlarged cells and their processes (fig. 100). The nuclei of these enlarged cells multiply; some few of the proliferated nuclei remain embedded in the walls of the cell, but the greater number of them are free and are converted into blood-corpuscles. The tubes or primary vessels consist in the first instance of the original protoplasm of the cell, with here and there nuclei, derived from the original divided nucleus embedded in it.

Fig. 100.—Various forms of mother-cells undergoing development into blood-vessels, from the middle layer of the chick's blastoderm. (Klein.)



a. Large mother-cell vacuolated, forming the rudimentary vessel. *b*. The wall of this cell formed of protoplasm, with nuclei embedded, and in some cases more or less detached and projecting. *c*. Processes connected with neighbouring cells, formed of the common cellular substance of the germinal area. *d*. Blood-corpuscles. *f*. Small mother-cells—vacuolation commencing. *B*. Mother-cell in which only obscure granular matter is found.

Then differentiation of the protoplasm into flattened cells around these nuclei takes place and constitutes the wall of the capillary or the lining membrane of the larger vessel. In these latter, other cells, derived from the mesoblast, apply themselves externally and form the other coats of the vessel at a later period.

The *blood-discs* are formed from the original divided nucleus of the vacuolated mesoblastic cells. They are free, and accumulate, each one around itself, a small quantity of the protoplasm of the cell, which rapidly acquires a tinge of colour. The earliest blood-corpuscles are therefore at first nucleated, and in this and other respects—that is, in their possession of amœboid movements and in their capability of undergoing multiplication by division—resemble the white corpuscles. As soon, however, as the liver is formed, true white corpuscles make their appearance, and it seems that the chief source from which they are derived is the embryonic liver, though later on the spleen and lymphatic glands take up this function and continue it after birth. The nucleated condition of the red globules ceases before birth. The vitelline circulation commences about the fifteenth day and lasts till the fifth week. When fully established it is carried on as follows:—Proceeding from the tubular heart are two arteries, the first aortic arteries (fig. 101), which unite at some distance from the heart into a single artery. This runs down in front of the primitive vertebræ and in the walls of the intestinal cavity, and again divides into two *primitive aortæ* or *vertebral* arteries, and these give off five or six *omphalo-mesenteric* arteries, which ramify

Fig. 101.—Heart at the fifth week.

in that part of the blastoderm which surrounds the developing body of the embryo and which is known as the *vascular area*. They terminate peripherally in a circular vessel—the *terminal sinus*. This vessel surrounds the vascular portion of the germinal area, but does not extend up to the anterior end of the embryo. It terminates on either side in a vein called the *omphalo-mesenteric*. The two omphalo-mesenteric veins open into the opposite extremity of the heart to that from which the arteries proceeded.

2. **The Placental Circulation.**—As the umbilical vesicle diminishes, the allantois, which is formed by a protrusion from the lower part of the intestine, enlarges and becomes converted into a vascular chorion, a part of which forms the placenta. When the umbilical vesicle disappears this becomes the only source of nutrition for the embryo. The allantois carries with it two arteries, derived from branches of the primitive aorta, and two veins; these vessels become much enlarged as the placental circulation is established, but subsequently one of the veins disappears, and in the later stages of uterine life the circulation is carried on between the fœtus and the placenta by two arteries and one vein (*umbilical*).

During the occurrence of these changes great alterations take place in the primitive heart and blood-vessels, above alluded to, which will now require description.

Further Development of the Heart.—The simple median tube, formed by the coalescence of the pair of tubes of which the primitive heart consists, becomes elongated and bent on itself, so as to form an S-shaped tube, the anterior part of the tube bending over to the right, and the posterior to the left. At the same time the middle portion is protruded forwards and arches transversely from right to left, and at the same time becomes twisted on itself so that the extremity from which the arteries are prolonged is situated in front and to the right, and that into which the veins enter is behind and to the left. The bent tube then becomes divided by two transverse constrictions into three parts. One, the posterior, becomes the auricles, the middle one forms the two ventricular cavities, while the anterior forms the aortic bulb, from which the commencement of the aorta and pulmonary artery is developed. A division of each of these cavities now takes place, so as to convert them into right and left ventricle, right and left auricle, and aorta and pulmonary artery respectively. This division first takes place in the middle portion of the tubular heart, the rudimentary ventricular cavities (fig. 101, A, 5). A partition rises up from the lower part of the right wall of this cavity, and gradually grows until it reaches the constrictions which separate it from the other two, and thus the interventricular septum is completed. At the same time a cleft appears on the outside, a little to the right of the most prominent point, which ultimately becomes the apex of the heart. The cleft becomes less marked as development progresses, but remains, to some extent, persistent throughout life, as the interventricular groove.

The first appearance of a division in the posterior or auricular portion of the tubular heart makes its appearance, at a very early period of development, in the shape of two projecting pouches, one on either side; these are the rudiments of the auricular appendages, but the actual division of the cavity by a septum does not occur until some time after the appearance of the ventricular septum. This is formed by the growth of a partition from the anterior wall of the auricular cavity, which grows backwards, and partially separates the cavity into two. The partition, however, is not completed until after birth, a part remaining undeveloped, and thus permitting of a communication (*foramen ovale*) between the two auricles during the whole of fœtal life. In a like manner, the aortic bulb is divided into two by the growth of a septum downwards, from the distal end of the bulb, which divides the cavity into the permanent aorta and the pulmonary artery. Very soon a superficial furrow appears on the external surface of this portion of the heart corresponding to the septum internally, and, becoming deeper, the two vessels are gradually separated from each other through the septum, in the immediate neighbourhood of the ventricular portion

of the heart, whilst beyond this they still remain joined together, and give origin to the fourth and fifth aortic arches, presently to be described.

Further Development of the Arteries.—In the vitelline circulation, two arteries were described as coming off from the primitive heart, and running down in front of the developing vertebræ. The first change consists in the fusion of these arteries into one at some distance from the heart, thus forming the descending thoracic and abdominal aorta. In consequence of the heart falling backwards to the lower part of the neck and then into the thorax, as the head is developed, the two original arteries, proceeding from the heart to the point of fusion in the common descending aorta, become elongated, and assume an arched form, curving backwards on each side, from the front of the body towards the vertebral column (fig. 102, A). These are the first or primitive aortic arches. As the heart recedes into the thorax, and these arches, which correspond in position to the first pharyngeal or mandibular arch, become elongated, four pairs of arches are formed behind them around the pharynx (fig. 102). The arches, five in number, remain permanent in fishes, giving off from their convex borders the branchial arteries to supply the gills. In many animals the five pairs do not exist together, for the first two have disappeared before the others are formed; but this is not so in man, where all five arches are present and pervious during a certain period of embryonic existence. Only some of the arches in mammalia remain as permanent structures; other arches, or portions of them, become obliterated or disappear. The first two arches entirely disappear. The third remains as a part of the internal carotid artery, the remainder being formed by the upper part of the posterior aortic root, i.e. the descending part of the original vessel which proceeded from the rudimentary tubular heart. The common and external carotid are formed from the anterior aortic root, that is, the ascending portion of the same primitive vessel. The fourth arch on the left side becomes developed into the permanent arch of the aorta in mammals; but in birds it is the fourth arch on the right side which forms the aortic arch; while in reptiles the fourth arch on both sides persists, as there is a permanent double aortic arch. The fourth arch on the right side forms the subclavian artery, and by the junction of its commencement with the anterior aortic root, from which the common carotid is developed, it forms the innominate artery.* The fifth arch on the left side forms the pulmonary artery and the ductus arteriosus; that on the right side becomes atrophied and disappears. The first part of the fifth left arch remains connected with that part of the bulbous aorta which is separated as the pulmonary stem, and with it forms the common pulmonary artery. From about the middle of this arch two branches are given off, which form the right and left pulmonary arteries respectively, and the remaining portion, i.e. the part beyond the origin of the branches, communicating with the left fourth arch—that is, the descending part of the arch of the aorta—constitutes the ductus arteriosus. This duct remains pervious during the whole of fœtal life, and after birth becomes obliterated.

The development of the arteries in the lower part of the body is going on during the same time. We have seen that originally there were two primitive arteries coming off from the primary tubular heart, and that these two vessels, at some distance from the heart, became fused together to form a single median artery, which coursed down in front of the vertebræ to the bottom of the spinal column, forming the permanent descending aorta. From the extremity of this the two vitelline arteries, which were originally parts of the primitive main trunks, passed to the area vasculosa. As the umbilical vesicle dwindles and the allantois grows, two large branches are formed as lateral offshoots of the median aorta. These are the two *umbilical* or *hypogastric* arteries, and are concerned in the

* This is interesting in connection with the position of the recurrent laryngeal nerve, which is thus seen to hook round the *same* primitive fœtal structure, which becomes on the right side the subclavian artery, on the left the arch of the aorta.

placental circulation. The portion of the median aorta beyond this point becomes much diminished in size, and eventually forms the sacra media artery, and thus the two umbilical branches become in appearance bifurcating branches of the

main aorta. The common and internal iliac arteries are developed from the proximal end of these umbilical arteries; the middle portion of the vessel, after birth, becomes partially atrophied, but in part remains pervious as the superior vesical artery; the distal portion becomes obliterated, constituting part of the superior ligament of the bladder. The external iliac and femoral arteries are

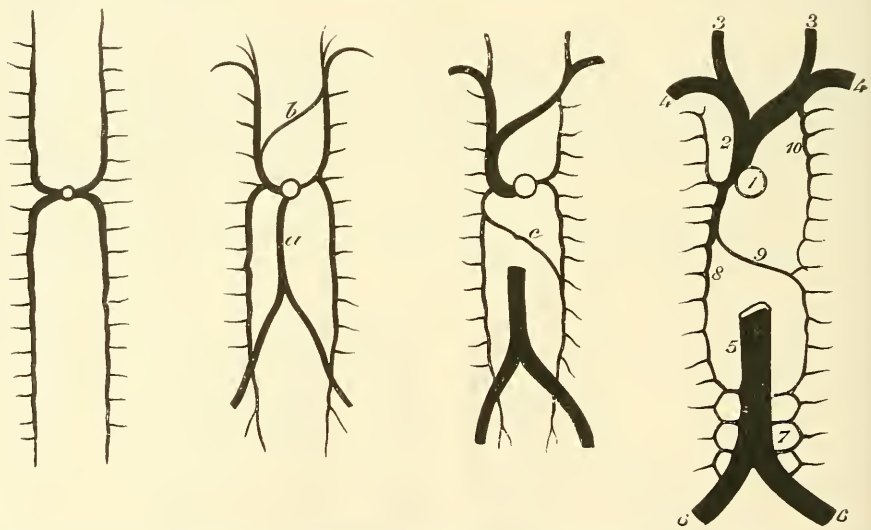
developed from a small branch given off from the umbilical arteries near their origin, and are at first of comparatively small size.

Development of the Veins.—The formation of the great veins of the embryo may be best considered under two groups, visceral and parietal.

The visceral are derived from the vitelline and umbilical veins. In the earliest period of the circulation of the embryo, we have seen that there were two veins (vitelline or omphalo-mesenteric) returning the blood from the vitelline membrane. These unite together to form a single channel, the *sinus venosus*, which opens into the auricular extremity of the heart. As soon as the placenta begins to be formed, two umbilical veins appear and open into the sinus venosus, close to the vitelline veins. The two vitelline veins enter the abdomen and run upwards, at first in front of, and subsequently on either side of the intestinal canal; at the upper part of the abdomen, in the site of the future liver, which now begins to form around them, transverse communications are formed, which encircle the duodenum and enclose it in two vascular rings. The portion of veins above these vascular rings loses its connection with the sinus, whilst the portion between them breaks up into a capillary plexus, which ramifies in the now partially developed liver together with capillary vessels from the upper venous ring. Of these latter, some pass towards the heart and join the sinus.

Fig. 104.—Diagrams illustrating the development of the great veins.



The first figure shows the vertebral veins emptying into the heart by two lateral trunks, 'the ducts of Cuvier.' The second figure shows the formation of the iliac and subclavian veins. *a*. Inferior vena cava. *b*. Left innominate vein. The third figure shows the vertebral veins much diminished in size and the duct of Cuvier on the left side, gradually disappearing. *c*. Vena azygos minor. The fourth figure shows the adult condition of the venous system. 1. Right auricle of heart. 2. Vena cava superior. 3. Jugular veins. 4. Subclavian veins. 5. Vena cava inferior. 6. Iliac veins. 7. Lumbar veins. 8. Vena azygos major. 9. Vena azygos minor. 10. Superior intercostal vein. (After Dalton.)

They have received the name of the *venæ hepaticæ revehentes*, and eventually become the hepatic veins; others ramify in the liver, under the name of *venæ hepaticæ advehentes*, and become the branches of the portal vein. The lower vascular ring receives veins from the stomach and intestines, and becomes the commencement of the portal vein.

The umbilical veins at first open into the sinus venosus near to the vitelline veins. Subsequently this communication becomes interrupted by the development of a vascular network; the vein on the right side atrophies and disappears, whilst that on the left side greatly enlarges, as the placental circulation becomes established, and communicates with the upper venous circle of the vitelline circulation. Finally a branch is formed between the upper venous circle and the right hepatic veins, which becomes the *ductus venosus*, and by it most of the blood from the umbilical vein is carried direct to the heart.

The Parietal Veins.—The first appearance of a parietal system consists in the appearance of two short transverse veins (the *ducts of Cuvier*), which open on either side of the auricular portion of the heart. Each of these ducts is formed

by an ascending and descending vein. The ascending veins return the blood from the parietes of the trunk and the Wolffian bodies, and are called *cardinal* veins. The two descending ones return the blood (fig. 104) from the head, and are called *primitive jugular* veins. As the kidneys are developed, the veins conveying the blood from them unite together to form a single trunk which passes up the abdomen behind the intestines, and, joining the common trunk of the vitelline and umbilical veins above the point of entrance of the venæ revehentes, constitutes the inferior vena cava. Two small veins receiving branches from the lower extremity unite to form the lower part of the inferior vena cava, below the point of entrance of the veins from the kidneys. These are the primitive iliac veins, and in their course upwards they cross the cardinal veins and communicate with them. The part of the iliac vein between this point of communication and their junction with one another constitutes the common iliac vein; while the distal portion forms the external iliac vein. The internal iliac vein is formed from that part of the cardinal vein which lies below the point of communication. The greater part of the remainder of the cardinal vein —that is to say, of that portion above the iliac veins—becomes obliterated; a small part, however, at the upper extremity remains persistent, and becomes continuous with two new veins, which are formed one on either side of the vertebral column. These veins receive the intercostal and lumbar veins, and eventually form the azygos veins. They become joined by an oblique communicating branch, which crosses the middle line, and constitutes the junction of the vena azygos minor with the vena azygos major. These veins are termed the *posterior vertebral veins* of Rathke. The upper part of the left one, with its continuation, the cardinal vein, forms the superior intercostal of the left side.

FIG. 105.—Diagram of the formation of the main systemic veins.

Right inferior cardinal. 6. Right jugular. 7. Anastomosing branch between the jugulars (left innominate). 8. Subclavian. 9. Internal jugular. 10. External jugular. 11. Middle obliterated portion of the posterior cardinal veins. 12. Newly-formed posterior vertebral veins. 13. Anastomosis between the two vertebrals—trunk of small azygos. 14. Iliac veins, proceeding from anastomosis between the inferior cava and posterior cardinals. 15. Crural. 16. Hypogastric—originally the distal ends of the cardinals. B. Heart and permanent veins, posterior view. 1. Obliterated left superior cava. 6. Right innominate. 7. Left innominate. 8. Subclavian. 10. Jugular. 13. Trunk of the small azygos. 17. Coronary sinus receiving the coronary vein. 18. Superior intercostal. 19. Superior small azygos. 20. Inferior small azygos.

The veins first formed in the upper part of the trunk are, as above stated, the *primitive jugular* veins. In the greater part of their extent they become the external jugular vein. Shortly, two small branches may be noticed opening into them near their termination; these form the subclavian and internal jugular veins. From the point of junction of these veins on the left side, a communicating branch makes its appearance, running obliquely across the neck downwards and to the right, to open into the primitive jugular vein of the right side below the point of entrance of the subclavian vein. At the same time, in consequence of the alteration in the position of the heart, and its descent into the thorax, the direction of the ducts of Cuvier becomes altered, and they assume an almost vertical position. From the portion of the primitive jugular veins, above the branch of communication, the internal jugulars are formed, except that part of the right one which lies between the point of entrance of the subclavian of this side, and the termination of the communicating branch, which becomes the right innominate vein. The

communicating branch becomes the left innominate vein. The primitive jugular of the right side, below the communicating vein and the right duct of Cuvier, becomes the vena cava superior, into which the right cardinal (vena azygos major) enters. The lower part of the left primitive jugular, and the left duct of Cuvier become almost entirely obliterated, except the lower end, which remains as a fibrous band, or sometimes a small vein, and runs obliquely over the posterior surface of the left auricle. The termination of the left duct of Cuvier remains persistent, and forms the coronary sinus (fig. 105).

The fœtal circulation is described at a future page.

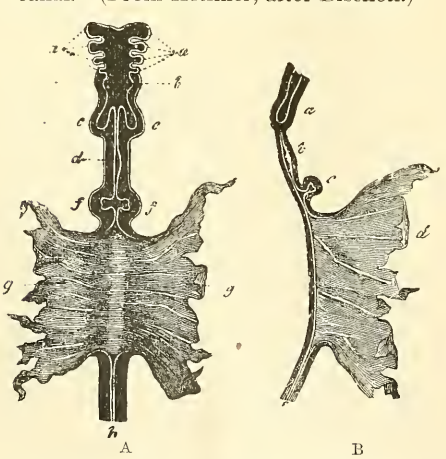
Development of the Alimentary Canal.—The development of the intestinal cavity is, as shown above (page 82), one of the earliest phenomena of embryonic

Fig. 106.—Diagrammatic outline of a longitudinal vertical section of the chick on the fourth day.

ep. (From Quain's 'Anatomy,' Allen Thomson.)

life. The original intestine consists of an inflection of the blastodermic layers extending from one end of the embryo to the other, and is situated just below the primitive vertebral column. At either extremity it forms a closed tube, in consequence of the cephalic and caudal flexures (page 81), and this manifestly divides it into three parts; a front part, enclosed in the cephalic fold, called the *fore-gut*; a posterior part, enclosed in the caudal fold, the *hind-gut*; and a central part or *mid-gut*, which at this time freely communicates with the umbilical vesicle (fig. 106). The ends of the fore- and hind-gut do not communicate with the surface of the body, the buccal and anal orifices being subsequently formed by involutions of the epiblast, which later on form communications with the gut. From the fore-gut are developed the pharynx, œsophagus, stomach, and duodenum; from the hind-gut a part of the rectum; and from the middle division the rest of the intestinal tube (fig. 107). The changes which take place in the fore-gut are as follow: The middle portion becomes dilated to form the stomach, and undergoes a vertical rotation to the right, so that the posterior border, by which it is attached to the vertebral column by a mesentery, is now

Fig. 107.—Early form of the alimentary canal. (From Kölliker, after Bischoff.)



In A a front view, and in B an antero-posterior section are represented. *a.* Four pharyngeal or visceral plates. *b.* The pharynx. *c, c.* The commencing lungs. *d.* The stomach. *f, f.* The diverticula connected with the formation of the liver. *g.* The yolk-sac into which the middle intestinal groove opens. *h.* The posterior part of the intestine.

directed to the left, and the anterior border to the right. At this time it is straight, but it soon undergoes a lateral curve or bend to the right at its upper end. It thus assumes an oblique direction, and the left border (originally the posterior or attached border) becomes inferior, and forms the great curvature. The mesentery by which it was attached forms the great omentum. The portion of the fore-gut above this dilatation remains straight, forming the pharynx and œsophagus, and in consequence of the mesoblast being here undivided, there is no serous investment to this part of the tube. Below this, division of the mesoblast has taken place, and the splanchnopleure alone forms the walls of the remainder of the intestinal canal, the space between this layer and the somatopleure constituting the pleuro-peritoneal cavity.

The part of the fore-gut below the dilated stomach forms the duodenum, and in connection with this the liver and pancreas are developed.

The *hind-gut* is also a closed tube, and from it the middle third of the rectum is developed, as well as the allantois (page 85), which will be again referred to in connection with the development of the bladder.

The *mid-gut* is at first an open cavity freely communicating with the umbilical vesicle. As the body-walls grow, this communication contracts very materially, though it still exists to a certain extent, and the open cavity becomes converted into a straight tube, still open where it communicates with the umbilical vesicle. This tube grows rapidly in length, and presents a primitive curve or loop downwards and forwards, and, in consequence of its growth exceeding that of the walls of the body-cavity, a portion of the loop protrudes into the stalk of the umbilical vesicle. At a subsequent period, however, the walls of the abdomen grow more rapidly than the intestine, which again recedes into the body-cavity. At a short distance below the most prominent point of this loop a diverticulum arises, which marks the separation between the large and small intestine. The lower part of this diverticulum forms the vermiform appendix; the proximal part, by its continued growth, constitutes the cæcum. After this the anterior or upper part of the gut, corresponding to the small intestine, rapidly increases in length, and about the eighth week becomes convoluted. The lower or posterior part, corresponding to the large intestine, is at first less in calibre than the upper part, and lies wholly to the left side of the convolutions of the small intestine; but later on the curve of the large intestine begins to form, and the first part (ascending colon) slowly crosses over to the right side, first lying in the middle line, just below the liver. It is not until the sixth month that the cæcum descends into the right iliac fossa, and so drags the ascending colon into its normal position in the right flank.

The peritoneal cavity is the space left between the visceral and parietal layers of the mesoblast, and the serous membrane is developed from these structures. The mesenteries are formed from mesoblastic tissue extending between the notochord and the gut which develops the vascular and connective-tissue elements of these parts.

The *buccal* cavity is formed by an involution of the external layers of the blastodermic membrane, which passes inwards and meets the pharynx, or upper part of the fore-gut. The two cavities are, however, at first completely separated from each other by all the layers of the blastoderm; but at an early period of development a vertical slit appears between them; this gradually widens and becomes the opening by which the common cavity of the nose and mouth communicates with the pharynx. The common cavity is afterwards divided into nose and mouth by the development of the palate, in the manner spoken of above.

The *tongue* appears about the fifth week as a small elevation behind the inferior maxillary arch, to which another projection from the second pharyngeal arch is united. The epithelial layer is furnished by the epiblast. The tonsils appear about the fourth month.

The *anus* is also formed by an inflection of the epiblast, which extends inwards to a slight extent, and approaches the termination of the hind-gut,

and finally communicates with it by a solution of continuity in the septum between the two. The persistence of the fœtal septum at either the buccal or anal orifices constitutes a well-known deformity—imperforate œsophagus or imperforate rectum, as the case may be.

The *liver* appears after the Wolffian bodies, about the third week, in the form of a bifid mass of cells, connected with the epithelial and mesoblastic layers of the splanchnopleure. It projects from the intestine at that part which afterwards forms the duodenum. This mass of cells becomes hollowed out into a cavity, lined by hypoblast, the rudiment of the main duct of the liver, the cells on either side being developed into the right and left lobes. These grow very rapidly around the vitelline and, later, the umbilical veins, which break up into a capillary plexus and ramify in its substance. About the third month the liver almost fills the abdominal cavity. From this period the relative development of the liver is less active, more especially that of the left lobe, which now becomes smaller than the right; but the liver remains up to the end of fœtal life relatively larger than in the adult.

The *gall-bladder* appears about the second month, as an extension of the cavity from which the main duct of the liver is developed; and bile is detected in the intestines by the third month.

The *pancreas* is also an early formation, being far advanced in the second month. It, as well as the salivary glands, which appear about the same period, originates in a projection from the epithelial layer, which afterwards forms a cavity, and the lobules of the gland are developed from the ramifications of this cavity. It is generally admitted that the epithelial lining of the ducts is furnished by the hypoblast, in the development of both the pancreas and the liver; and that the vessels owe their origin to the mesoblast. But authorities differ as to the mode of formation of the parenchyma, as to whether this is entirely of mesoblastic origin, or whether the hypoblast shares in its development.

The *spleen*, on the other hand, is apparently entirely of mesoblastic origin, for there is never any connection between the intestinal cavity and the substance of this organ. It originates from the mesenteric fold which connects the stomach to the vertebral column (mesogastrium).

Development of the Respiratory Organs.—The lungs appear somewhat later than the liver. They are developed from a small median *cul-de-sac* or diverticulum from the upper part of the fore-gut, immediately behind the fourth visceral cleft, as a projection from the epithelial and fibrous laminæ of the intestines. During the fourth week a pouch is formed on either side of the central diverticulum, and opens freely through it into the fore-gut (pharynx). From these, other (secondary) pouches are given off, so that by the eighth week the form of the lobes of the lungs may be made out. The two primary pouches have thus a common pedicle of communication with the pharynx. This is developed into the trachea (fig. 101, B), the cartilaginous rings of which are perceptible about the seventh week. The parts which afterwards form the larynx are recognised as early as the sixth week—viz. a projection on either side of the pharyngeal opening, which is the rudiment of the arytenoid cartilage and a transverse elevation from the third pharyngeal arch, which afterwards becomes the epiglottis; the vocal cords and ventricles of the larynx are seen about the fourth month. Traces of the diaphragm appear in the form of a fine membrane, separating the lungs from the Wolffian bodies, the stomach and the liver, whilst the heart is still near the head. As the diaphragm extends forwards from the vertebral column it separates the common pleuro-peritoneal cavity into two parts, a thoracic and abdominal.

Development of the Urinary Organs.—The urinary organs appear to be entirely of mesoblastic origin, and are developed from a mass of cells, which makes its appearance below the heart and behind the common pleuro-peritoneal cavity, from the mesoblast at the point of separation of its two layers into somatopleure and splanchnopleure. As this ridge is situated in front of the epiblast

(reflected from the medullary cavity), at the side of the protovertebræ and behind the common pleuro-peritoneal cavity, it has been named the 'intermediate cell-mass.' It is at first solid, and in it is formed a cord-like arrangement of some of the cells, which extends longitudinally from just below the heart to the posterior extremity of the body-cavity. In this cord-like structure a tube is hollowed out; it gradually becomes separated from the rest of the intermediate cell-mass, and is then named the Wolffian duct. Its posterior end becomes connected with and eventually opens into the hind-gut. On either side of its anterior end an invagination of hypoblast takes place, and in the mesoblastic tissue between these invaginations a vascular glomerulus is formed which projects into the peritoneal cavity. It is known as the *head-kidney* or *pronephros* (Lankester), and it is situated in the region of the rudimentary heart. It is a very rudimentary organ and speedily disappears. Behind this body and to the inner side of the Wolffian duct, between it and the body-cavity, a number of tubes are formed, which communicate by one extremity with the Wolffian duct, and, passing transversely towards the body-cavity, terminate in cœcal extremities. These tubes are called segmental tubes, and the whole mass is known as the *mid-kidney*, *Wolffian body*, or *mesonephros* (Lankester). After a time the cœcal extremities become dilated and enclose a tuft or glomerulus of capillary blood-vessels. The Wolffian body is not a permanent organ, at all events as regards its greater part, for as soon as the permanent kidneys are formed, it for the most part disappears. In the male, however, the vasa efferentia and rete testis of the testicle are formed as outgrowths from it. In the female traces of it are left as the *parovarium* and *epoophoron*.

Finally, in that portion of the intermediate cell-mass which lies behind the Wolffian body, a differentiation of cells takes place which results in the formation of a number of convoluted tubes; into this a hollow protrusion of the lower end of the Wolffian duct grows up, and thus is formed the *hind-kidney* or *metanephros* (Lankester). This is the rudimentary permanent kidney. The uriniferous convoluted tubes and Malpighian corpuscles are formed from the intermediate cell-mass, and the collecting tubules and ureter from the protrusion from the posterior end of the Wolffian duct.

Shortly after the formation of the Wolffian body, a second duct becomes developed. It arises on the outer side of this body as a slight thickening of the hypoblast. This thickening then becomes invaginated into the mesoblast and extends as a cord along the outer side of the Wolffian body, to the posterior extremity of the embryo. It speedily acquires a lumen, and is then known as the Müllerian duct (fig. 108). In its passage to the posterior extremity of the embryo it comes into close relation with the Wolffian duct, and the two ducts on either side become connected with their fellows on the opposite side by cellular substance into a single mass—the *genital cord*—in which the Wolffian ducts lay side by side in front, and the ducts of Müller behind. These latter tubes in the substance of the genital cord become fused together, and open by a single orifice into the hind-gut (cloaca). At their anterior extremities the ducts of Müller open by a somewhat funnel-shaped orifice into the pleuro-peritoneal cavity. The greater part of the Müllerian duct is in the female developed into the Fallopian tube, but the posterior fused portion of the ducts is converted into the uterus and vagina. In the male the greater part of the ducts disappear; the fused

portion is believed to be represented by the *sinus pocularis* (*uterus masculinus*) of the urethra.

It will be seen, therefore, that the Wolffian ducts, which in the male become the epididymis and vas deferens, and in the female a functionless tube, the duct of Gartner, and the Müllerian ducts, open into the common urogenital sinus or cloaca, which is the termination of the intestinal cavity, into which the allantois also opens in front (fig. 109). As the allantois expands into the urinary bladder this common cavity is divided into two by a septum, to form the bladder in front and the rectum behind.

The *urinary bladder*, as before stated, is formed by a dilatation of a part of the stalk of the allantois. At the end of the second month this forms a spindle-shaped cavity, the bladder. Between the lower extremity of the spindle-shaped dilatation and the primitive intestine is a small tract of undilated allantois, forming a short canal, which at first opens into the urogenital sinus, but subsequently becomes closed by the septum just mentioned. From this short canal is formed the first part of the urethra in the male and the whole of the urethra in the female. The upper part of the stalk of the allantois, which is not dilated, forms the *urachus*; this extends up into the umbilical cord, and at an early period of embryonic existence forms a tube of communication with the allantois. It is obliterated before the termination of fœtal life, but the cord formed by its obliteration is perceptible throughout life, passing from the upper part of the bladder to the umbilicus. It occasionally remains patent in the adult, constituting a well-known malformation.

Fig. 109.—Diagram of the primitive urogenital organs in the embryo previous to sexual distinction. The parts are shown chiefly in profile, but the Müllerian and Wolffian ducts are seen from the front.

Urachus. *ot.* The mass of blastema from which ovary or testicle is afterwards formed. *W.* Left Wolffian body. *w, w.* Right and left Wolffian ducts. *m, m.* Right and left Müllerian ducts uniting together and with the Wolffian ducts in *gc*, the genital cord. *ug.* Sinus urogenitalis. *i.* Lower part of the intestine. *cl.* Common opening of the intestine and urogenital sinus. *cp.* Elevation which becomes clitoris or penis. *ls.* Ridge from which the labia majora or scrotum are formed.

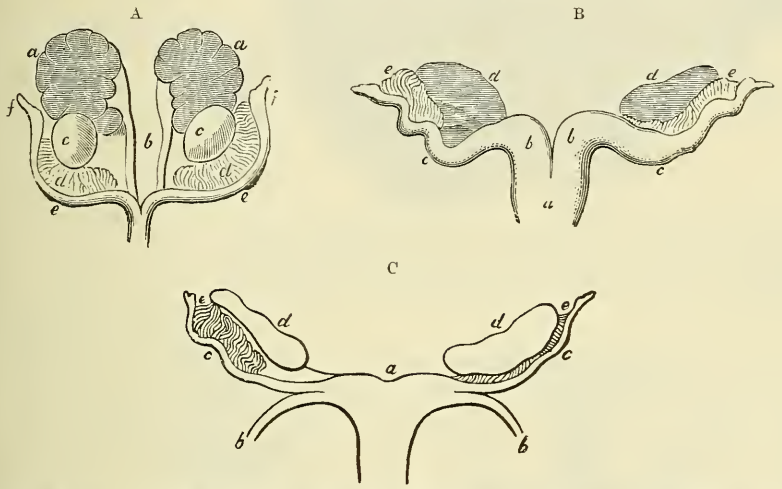
The *suprarenal* bodies are developed from two different sources. The medullary part of the organ is of epiblastic origin, and is derived from the tissues forming the sympathetic ganglia of the abdomen, while the cortical portion is of mesoblastic origin, and originates as an outgrowth from the upper part of the Wolffian body. The two parts are at first quite distinct, but become combined in the process of development. The suprarenal capsules are at first larger than the kidney, but become equal in size about the tenth week, and from that time decrease relatively to the kidney, though they remain, throughout fœtal life, much larger in proportion than in the adult.

Development of the Generative Organs.—The first appearance of the reproductive organs is essentially the same in the two sexes, and consists in a thickening at one spot of the epithelial layer which lines the peritoneal or body cavity. This is termed the *germinal epithelium*, and consists of two, three, or more layers of columnar cells. Beneath them an increase in the mesoblast takes place, forming a distinct projection or ridge. This is termed the *genital ridge*, and is situated on the mesial side of each Wolffian body, and from it the testicle in the one sex, and the ovary in the other, are developed. Amongst the cells of the germinal epithelium are to be seen some larger cells; these eventually become the ova or spermatozoa of the completed organ, either ovary or testes, as the

case may be. The genital ridge, as the embryo grows, gradually becomes pinched off from the Wolffian body, with which it is at first continuous, though it still remains connected to the remnant of this body by a fold of peritoneum, the *mesorchium* or *mesovarium*. About the seventh week the distinction of sex begins to be perceptible.

Development of the Ovary.—The ovary, thus formed from the genital ridge, has become pinched off from the remains of the Wolffian body, though still attached to it by a mesovarium, before it can be distinguished from the testicle. It now consists of a central part of connective tissue covered by a layer or layers of germ epithelium. A mingling of these two tissues takes place in the following manner. The epithelium undergoes repeated division, so that it rapidly increases in thickness and grows downwards in the form of columns into the central connective tissue, carrying with it some of the larger cells, which, as above stated, are to form the ova. Simultaneously with this an upward growth of the connective tissue takes place between the epithelial cells.

FIG. 110.—Female genital organs of the embryo, with the remains of the Wolffian bodies. (After J. Müller.)



A. From a fœtal sheep: *a*. The kidneys. *b*. The ureters. *c*. The ovaries. *d*. Remains of Wolffian bodies. *e*. Fallopian tubes. *f*. Their abdominal openings. B. More advanced, from a fœtal deer: *a*. Body of the uterus. *b*. Cornua. *c*. Tubes. *d*. Ovaries. *e*. Remains of Wolffian bodies. C. Still more advanced, from the human fœtus of three months: *a*. The body of the uterus. *b*. The round ligament. *c*. The Fallopian tubes. *d*. The ovaries. *e*. Remains of the Wolffian bodies.

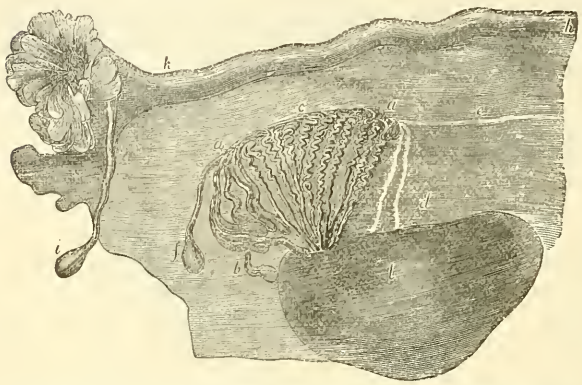
It results from this that the columns of cells, which are sometimes termed *egg-tubes*, become enclosed in meshes of connective tissue. They then become broken up into rounded masses of epithelial cells, enclosing one or more of the larger cells or primordial ova. These rounded masses form the Graafian vesicles. The larger cells form the ova, the other cells form the epithelium of the Graafian follicle, whilst the connective tissue around forms the stroma of the ovary. The remains of the genital epithelium on the surface of the ovary form the permanent epithelium of this organ.

Development of the Testicle.—The testicle is developed in a very similar way to the ovary, but the processes are not so well marked. Like the ovary, in its earliest stages it consists of a central mass of connective tissue covered by germ epithelium, amongst which may be seen larger cells, corresponding to the primordial ova of the female. A thickening of this epithelium takes place and a downward growth of columns of epithelium into the central connective tissue. From these the seminiferous tubules are developed and become connected with outgrowths from the Wolffian body, which, as before mentioned, form the rete testis and vasa efferentia.

With regard to the other parts of the internal female organs, the Fallopian

tube, as has already been mentioned, is developed from the upper part of the duct of Müller, while the lower part of the two ducts approach each other, and, lying side by side, finally coalesce to form the cavity of the uterus and vagina. This coalescence commences in the middle of the genital cord, and corresponds to the body of the uterus. The upper parts of the Müllerian ducts in the genital cord constitute the cornua of the uterus, little developed in the human species (fig. 111). With regard to the further changes in the female organs the only remains of the Wolffian body in the complete condition are two rudimentary or vestigial structures, which can be found, on careful search, in the broad ligament near the ovary; the *parovarium* or *organ of Rosenmüller* and the *epoophoron* (fig. 111). The organ of Rosenmüller consists of a number of tubes which converge to a transverse portion, the epoophoron, and this is sometimes prolonged into a distinct duct, running transversely, the *duct of Gartner*, which is much more conspicuous and extends further in some of the lower animals. This is the remains of the Wolffian duct. About the fifth month an annular constriction marks the position of the neck of the uterus, and after the sixth month the walls of the uterus begin to thicken. The round ligament is derived from a band containing involuntary muscular fibres, which runs downwards from the lower part of the Wolffian body to the groin, and which in the male forms the gubernaculum testis; the peritoneum constitutes the broad ligament; the superior ligament of the Wolffian body, which serves to connect it with the diaphragm, disappears with that structure.

Fig. 111.—Adult ovary, parovarium, and Fallopian tube. (From Farre, after Kobelt.)



a, *a*. Epoophoron formed from the upper part of the Wolffian body. *b*. Remains of the uppermost tubes sometimes forming hydatids. *c*. Middle set of tubes. *d*. Some lower atrophied tubes. *e*. Atrophied remains of the Wolffian duct. *f*. The terminal bulb or hydatid. *h*. The Fallopian tube, originally the duct of Müller. *i*. Hydatid attached to the extremity. *l*. The ovary.

With regard to the other parts of the male organs, the Müllerian ducts disappear, with the exception of their lower ends. These unite in the middle line, and open by a common orifice into the urogenital sinus. This constitutes the *utriculus hominis* or *sinus prostaticus*. Occasionally, however, the upper end of the duct of Müller remains visible in the male, constituting the little pedunculated body, called the hydatid of Morgagni, sometimes found in the neighbourhood of the epididymis,* between the testes and globus major.

The head of the epididymis, its canal, the vas deferens and ejaculatory duct, are formed from the canals and duct of the Wolffian body. One or more of the tubes of the Wolffian body form the vas aberrans and a structure described by Giraldès, and called, after him, 'the organ of Giraldès,' which bears a good deal of resemblance to the organ of Rosenmüller in the other sex. It consists of a number of convoluted tubules, lying in the cellular tissue in front of the cord, and close to the head of the epididymis.

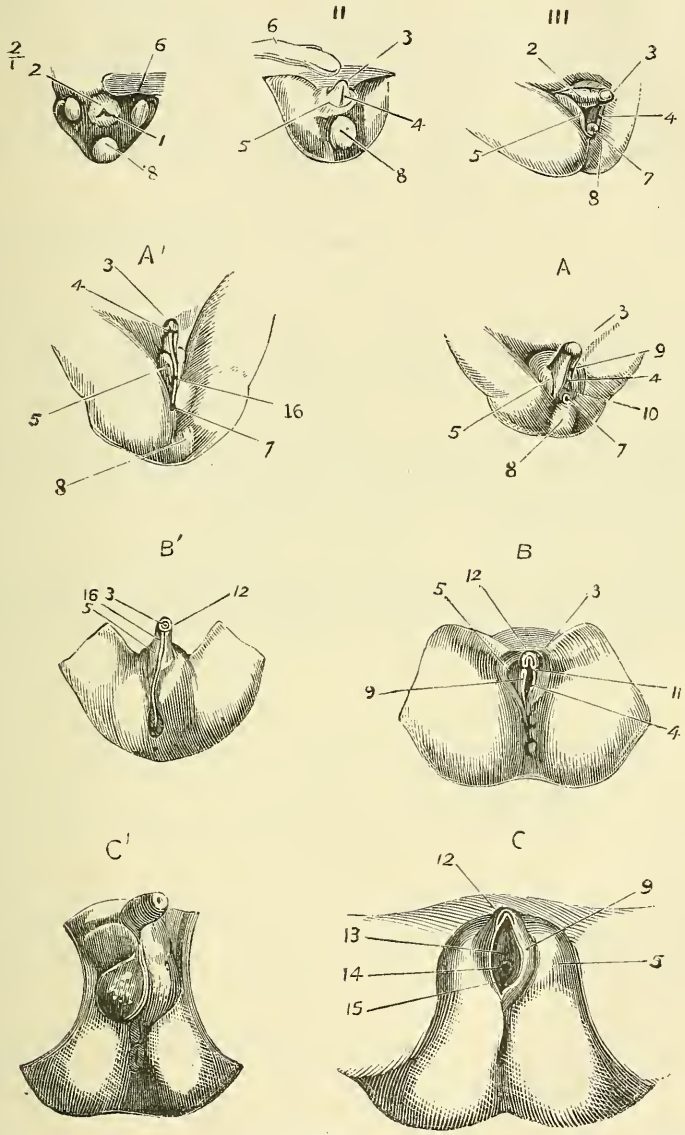
The descent of the testis and the formation of the gubernaculum are described in the body of the work.

* Mr. Osborn, in the St. Thomas's Hospital Reports, 1875, has written an interesting paper pointing out the probable connection between this fœtal structure and one form of hydrocele.

The **external organs of generation**, like the internal, pass through a stage in which there is no distinction of sex (fig. 112, I, II, III). We must therefore describe this stage, and then follow the development of the female and male organs respectively.

As stated above, the anal depression at an early period is formed by an involution of the external epithelium, and the intestine is still closed at its lower

Fig. 112.—Development of the external genital organs.



Indifferent type, I. II. III. *Female*. A. and B. At the middle of the fifth month. C. At the beginning of the sixth. *Male*. A'. At the beginning of the fourth month. B'. At the middle of the fourth month. C'. At the end of the fourth month. 1. Cloaca. 2. Genital tubercle. 3. Glans penis or clitoridis. 4. Genital furrow. 5. External genital folds (labia majora or scrotum). 6. Umbilical cord. 7. Anus. 8. Caudal extremity and coccygeal tubercle. 9. Labia minora. 10. Urogenital sinus. 11. Frænum clitoridis. 12. Preputium penis or clitoridis. 13. Opening of the urethra. 14. Opening of the vagina. 15. Hymen. 16. Scrotal raphé.

end. When the septum between the two opens, which is about the fourth week, the urachus in front and the intestine behind both communicate with the anal depression. This, which is now called the cloaca, is afterwards divided by a transverse septum, the *perinæum*, which appears about the second month. Two

tubes are thus formed; the posterior becomes the lower part of the rectum, the anterior is the urogenital sinus. In the sixth week a tubercle, the *genital tubercle*, is formed in front of the cloaca, and this is soon surrounded by two folds of skin, the *genital folds*. Towards the end of the second month the tubercle presents, on its lower aspect, a groove, the *genital furrow*, turned towards the cloaca. All these parts are well developed by the second month, yet no distinction of sex is possible.

Female Organs (fig. 112, A, B, C).—The female organs are developed by an easy transition from the above. The urogenital sinus persists as the vestibule of the vagina, and forms a single tube with the upper part of the vagina, which, as we have already seen, is developed from the united Müllerian ducts. The genital tubercle forms the clitoris, the genital folds the labia majora, and the lips of the genital furrow the labia minora, which remain open. An involution of the epithelium takes place on either side close to the root of the genital tubercle, which becomes the glands of Bartholin.

Male Organs (fig. 112, A′, B′, C′).—In the male the changes are greater. The genital tubercle is developed into the penis, the glans appearing in the third month, the prepuce and corpora cavernosa in the fourth. The genital furrow closes and thus forms a canal, the spongy portion of the urethra. The urogenital sinus becomes elongated and forms the membranous urethra. The genital folds unite in the middle line to form the scrotum, at about the same time as the genital furrow closes—viz. between the third and fourth month. A similar involution of epithelium to that which in the female forms the glands of Bartholin takes place in the male and becomes the glands of Cowper.

The following table is translated from the work of Beaunis and Bouchard, with some alterations, especially in the earlier weeks. It will serve to present a *résumé* of the above facts in an easily accessible form.*

* It will be noticed that the time assigned in this table for the appearance of the first rudiment of some of the bones varies in some cases from that assigned in the description of the various bones in the sequel. This is a point on which anatomists differ, and which probably varies in different cases.

CHRONOLOGICAL TABLE

OF

THE DEVELOPMENT OF THE FŒTUS

(From Beaunis and Bouchard)

First Week.—During this period the ovum is in the Fallopian tube. Having been fertilised in the upper part of the tube, it slowly passes down, undergoing segmentation, and reaches the uterus probably about the end of the first week. During this time it does not undergo much increase in size.

Second Week.—The ovum rapidly increases in size and becomes embedded in the decidua, so that it is completely enclosed in the decidua reflexa by the end of this period. An ovum believed to be of the thirteenth day after conception is described by Reichert. There was no appearance of any embryonic structure. The equatorial margins of the ovum were beset with villi, but the surface in contact with the uterine wall and the one opposite to it were bare. In another ovum, described by His, believed to be of about the fourteenth day, there was a distinct indication of an embryo. There was a medullary groove bounded by folds. In front of this a slightly prominent ridge, the rudimentary heart. The amnion was formed and the embryo was attached by a stalk, the allantois, to the inner surface of the chorion. It may be said, therefore, that these parts, the amnion and the allantois, and the first rudiments of the embryo, the medullary groove and the heart, are formed at the end of the second week.

Third Week.—By the end of the third week the flexures of the embryo have taken place, so that it is strongly curved. The protovertebral discs, which begin to be formed early in the third week, present their full complement. In the nervous system the primary divisions of the brain are visible, and the primitive ocular and auditory vesicles are already formed. The primary circulation is established. The alimentary canal presents a straight tube communicating with the yolk-sac. The pharyngeal arches are formed. The limbs have appeared as short buds. The Wolffian bodies are visible.

Fourth Week.—The umbilical vesicle has attained its full development. The caudal extremity projects. The upper and the lower limbs and the cloacal aperture appear. The heart separates into a right and left heart. The special ganglia and anterior roots of the spinal nerves, the olfactory fossæ, the lungs and the pancreas can be made out.

Fifth Week.—The allantois is vascular in its whole extent. The first traces of the hands and feet can be seen. The primitive aorta divides into aorta and pulmonary artery. The duct of Müller and genital gland are visible. The ossification of the clavicle and the lower jaw commences. The cartilage of Meckel occupies the first post-oral arch.

Sixth Week.—The activity of the umbilical vesicle ceases. The pharyngeal clefts disappear. The vertebral column, primitive cranium, and ribs assume the cartilaginous condition. The posterior roots of the nerves, the membranes of the nervous centres, the bladder, kidney, tongue, larynx, thyroid body, the germs of teeth, and the genital tubercle and folds are apparent.

Seventh Week.—The muscles begin to be perceptible. The points of ossification of the ribs, scapula, shaft of humerus, femur, tibia, palate, and upper jaw appear.

Eighth Week.—The distinction of arm and forearm, and of thigh and leg, is apparent, as well as the interdigital clefts. The capsule of the lens and pupillary membrane, the interventricular and commencement of the interauricular septum, the salivary glands, the spleen and suprarenal capsules are distinguishable. The larynx begins to become cartilaginous. All the vertebral bodies are cartilaginous. The points of ossification

for the ulna, radius, fibula, and ilium make their appearance. The two halves of the hard palate unite. The sympathetic nerves are now for the first time to be discerned.

Ninth Week.—The corpus striatum and the pericardium are first apparent. The ovary and testicle can be distinguished from each other. The genital furrow appears. The osseous nuclei of the bodies and arches of the vertebræ, of the frontal, vomer, and malar bones, of the shafts of the metacarpal and metatarsal bones, and of the phalanges appear. The union of the hard palate is completed. The gall-bladder is seen.

Third Month.—The formation of the fœtal placenta advances rapidly. The projection of the caudal extremity disappears. It is possible to distinguish the male and female organs from each other. The cloacal aperture is divided into two parts. The cartilaginous arches on the dorsal region of the spine close. The points of ossification for the occipital, sphenoid, lachrymal, nasal, squamous portion of temporal and ischium appear, as well as the orbital centre of the superior maxillary. The pons Varolii and fissure of Sylvius can be made out. The eyelids, the hair, and the nails begin to form. The mammary gland, the epiglottis, and prostate are beginning to develop. The union of the testicle with the canals of the Wolffian body takes place.

Fourth Month.—The closure of the cartilaginous arches of the spine is complete. Osseous points for the first sacral vertebra and os pubis appear. The ossification of the malleus and incus takes place. The corpus callosum, the membrana lamina spiralis, the cartilage of the Eustachian tube, and the tympanic ring are seen. Fat is first developed in the subcutaneous cellular tissue. The tonsils are seen, and the closure of the genital furrow and the formation of the scrotum and prepuce take place.

Fifth Month.—The two layers of the decidua begin to coalesce. Osseous nuclei of the axis and odontoid process, of the lateral points of the first sacral vertebra, of the median points of the second, and of the lateral masses of the ethmoid make their appearance. Ossification of the stapes and the petrous bone, and ossification of the germs of the teeth take place. The germs of the permanent teeth and the organ of Corti appear. The eruption of hair on the head commences. The sudoriferous glands, Brunner's glands, the follicles of the tonsil and base of the tongue, and the lymphatic glands appear at this period. The differentiation between the uterus and vagina becomes apparent.

Sixth Month.—The points of ossification for the anterior root of the transverse process of the seventh cervical vertebra, the lateral points of the second sacral vertebra, the median points of the third, the manubrium sterni and the os calcis appear. The sacro-vertebral angle forms. The cerebral hemispheres cover the cerebellum. The papillæ of the skin, the sebaceous glands, and Peyer's patches make their appearance. The free border of the nail projects from the corium of the dermis. The walls of the uterus thicken.

Seventh Month.—The additional points of the first sacral vertebra, the lateral points of the third, the median point of the fourth, the first osseous point of the body of the sternum, and the osseous point for the astragalus appear. Meckel's cartilage disappears. The cerebral convolutions, the island of Reil, and the tubercula quadrigemina are apparent. The pupillary membrane atrophies. The testicle passes into the vaginal process of the peritoneum.

Eighth Month.—Additional points for the second sacral vertebra, lateral points for the fourth and median points for the fifth sacral vertebræ, can be seen.

Ninth Month.—Additional points for the third sacral vertebra, lateral points for the fifth, osseous points for the middle turbinated bone, for the body and great cornu of the hyoid, for the second and third pieces of the body of the sternum, and for the lower end of the femur appear. Ossification of the bony lamina spiralis and axis of the cochlea takes place. The eyelids open, and the testicles are in the scrotum.

DESCRIPTIVE AND SURGICAL

ANATOMY

THE SKELETON

THE entire skeleton in the adult consists of 200 distinct bones. These are—

The Spine or vertebral column (sacrum and coccyx included)	26
Cranium	8
Face	14
Hyoid bone, sternum, and ribs	26
Upper extremities	64
Lower extremities	62
	200

In this enumeration the patellæ are included as separate bones, but the smaller sesamoid bones, and the ossicula auditûs, are not reckoned. The teeth belong to the tegumentary system.

These bones are divisible into four classes: *Long*, *Short*, *Flat*, and *Irregular*.

The **Long Bones** are found in the limbs, where they form a system of levers, which have to sustain the weight of the trunk, and to confer the power of locomotion. A long bone consists of a shaft and two extremities. The *shaft* is a hollow cylinder, contracted and narrowed to afford greater space for the bellies of the muscles; the walls consist of dense, compact tissue of great thickness in the middle, but becoming thinner towards the extremities; the spongy tissue is scanty, and the bone is hollowed out in its interior to form the *medullary canal*. The *extremities* are generally somewhat expanded, for greater convenience of mutual connection, for the purposes of articulation, and to afford a broad surface for muscular attachment. Here the bone is made up of spongy tissue with only a thin coating of compact substance. The long bones are not straight, but curved; the curve generally taking place in two directions, thus affording greater strength to the bone. The bones belonging to this class are: the *clavicle*, *humerus*, *radius*, *ulna*, *femur*, *tibia*, *fibula*, *metacarpal* and *metatarsal* bones, and the *phalanges*.

Short Bones.—Where a part of the skeleton is intended for strength and compactness, and its motion is at the same time slight and limited, it is divided into a number of small pieces united together by ligaments, and the separate bones are short and compressed, such as the bones of the *carpus* and *tarsus*. These bones, in their structure, are spongy throughout, excepting at their surface, where there is a thin crust of compact substance. The *patellæ* also, together with the other sesamoid bones, are by some regarded as short bones.

Flat Bones.—Where the principal requirement is either extensive protection or the provision of broad surfaces for muscular attachment, we find the osseous structure expanded into broad, flat plates, as is seen in the bones of the skull and the shoulder-blade. These bones are composed of two thin layers of compact tissue enclosing between them a variable quantity of cancellous tissue. In the

cranial bones, these layers of compact tissue are familiarly known as the *tables* of the skull; the outer one is thick and tough; the inner one thinner, denser, and more brittle, and hence termed the *vitreous table*. The intervening cancellous tissue is called the *diploë*. The flat bones are: the *occipital*, *parietal*, *frontal*, *nasal*, *lachrymal*, *vomer*, *scapula*, *os innominatum*, *sternum*, *ribs*, and *patella*.

The **Irregular** or **Mixed Bones** are such as, from their peculiar form, cannot be grouped under either of the preceding heads. Their structure is similar to that of other bones, consisting of a layer of compact tissue externally, and of spongy cancellous tissue within. The irregular bones are: the *vertebræ*, *sacrum*, *coccyx*, *temporal*, *sphenoid*, *ethmoid*, *malar*, *superior maxillary*, *inferior maxillary*, *palate*, *inferior turbinated*, and *hyoid*.

Surfaces of Bones.—If the surface of any bone is examined, certain eminences and depressions are seen, to which descriptive anatomists have given the following names.

These eminences and depressions are of two kinds: *articular* and *non-articular*. Well-marked examples of articular eminences are found in the heads of the humerus and femur; and of articular depressions, in the glenoid cavity of the scapula, and the acetabulum. Non-articular eminences are designated according to their form. Thus, a broad, rough, uneven elevation is called a *tuberosity*; a small, rough prominence, a *tubercle*; a sharp, slender, pointed eminence, a *spine*; a narrow, rough elevation, running some way along the surface, a *ridge* or *line*.

The non-articular depressions are also of very variable form, and are described as *fossæ*, *grooves*, *furrows*, *fissures*, *notches*, etc. These non-articular eminences and depressions serve to increase the extent of surface for the attachment of ligaments and muscles, and are usually well-marked in proportion to the muscularity of the subject.

A prominent process projecting from the surface of a bone, which it has never been separate from or movable upon, is termed an *apophysis* (from ἀπόφυσις, *an excrescence*); but if such process is developed as a separate piece from the rest of the bone, to which it is afterwards joined, it is termed an *epiphysis* (from ἐπίφυσις, *an accretion*).

THE SPINE

The **Spine** is a flexuous and flexible column, formed of a series of bones called *vertebræ* (from *vertere*, to turn).

The **Vertebræ** are thirty-three in number, exclusive of those which form the skull, and have received the names *cervical*, *dorsal*, *lumbar*, *sacral*, and *coccygeal*, according to the position which they occupy; seven being found in the cervical region, twelve in the dorsal, five in the lumbar, five in the sacral, and four in the coccygeal.

This number is sometimes increased by an additional vertebra in one region, or the number may be diminished in another region, the deficiency being supplied by an additional vertebra in another. These observations do not apply to the cervical portion of the spine, the number of bones forming which is seldom increased or diminished.

The Vertebræ in the upper three regions of the spine are separate throughout the whole of life; but those found in the sacral and coccygeal regions are in the adult firmly united, so as to form two bones—five entering into the formation of the upper bone or *sacrum*, and four into the terminal bone of the spine or *coccyx*.

General Characters of a Vertebra

Each **vertebra** consists of two essential parts—an anterior solid segment or *body*, and a posterior segment or *arch*. The arch (neural) is formed of two

pedicles, and two *laminæ*, supporting seven *processes*—viz. four *articular*, two *transverse*, and one *spinous*.

The bodies of the vertebræ are piled one upon the other, forming a strong pillar, for the support of the cranium and trunk; the arches forming a hollow cylinder behind the bodies for the protection of the spinal cord. The different vertebræ are connected together by means of the articular processes and the intervertebral cartilages; while the transverse and spinous processes serve as levers for the attachment of muscles which move the different parts of the spine. Lastly, between each pair of vertebræ apertures exist through which the spinal nerves pass from the cord. Each of these constituent parts must now be separately examined.

The **Body** or **centrum** is the largest and most solid part of a vertebra. Above and below, it is flattened; its upper and lower surfaces are rough, for the attachment of the intervertebral fibro-cartilages, and present a rim around their circumference. In front, it is convex from side to side, concave from above downwards. Behind, it is flat from above downwards and slightly concave from side to side. Its anterior surface is perforated by a few small apertures, for the passage of nutrient vessels; whilst on the posterior surface is a single large, irregular aperture, or occasionally more than one, for the exit of veins from the body of the vertebra—the *venæ basis vertebræ*.

The **Pedicles** are two short, constricted columns of bone, which project backwards, one on each side, from the upper part of the body of the vertebra, at the line of junction of its posterior and lateral surfaces. The concavities above and below the pedicles are the *intervertebral notches*; they are four in number, two on each side, the inferior ones being generally the deeper. When the vertebræ are articulated, the notches of each contiguous pair of bones form the intervertebral foramina, which communicate with the spinal canal and transmit the spinal nerves and blood-vessels.

The **Laminæ** are two broad plates of bone which complete the neural arch behind, enclosing a foramen, the *spinal foramen*, which serves for the protection of the spinal cord; they are connected to the body by means of the pedicles.

The **Spinous Process** projects backwards from the junction of the two laminæ, and serves for the attachment of muscles.

The **Articular Processes,** four in number, two on each side, spring from the junction of the pedicles with the laminæ. The two superior project upwards, their articular surfaces being directed more or less backwards; the two inferior project downwards, their articular surfaces looking more or less forwards.*

The **Transverse Processes,** two in number, project one at each side from the point where the lamina joins the pedicle, between the superior and inferior articular processes. They also serve for the attachment of muscles.

Character of the Cervical Vertebræ (fig. 113)

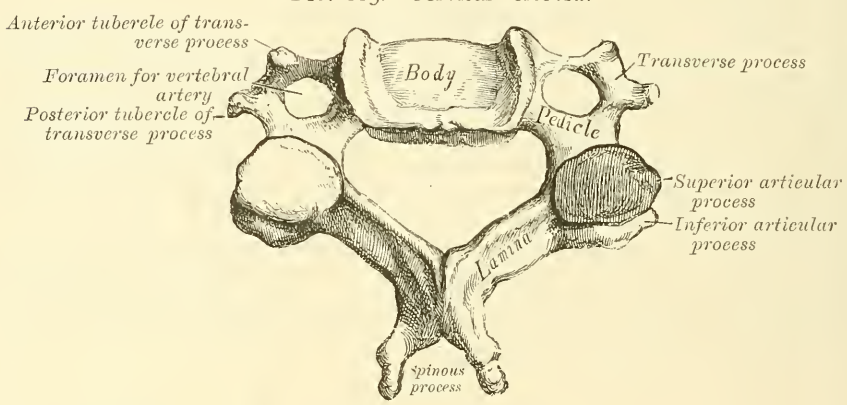
The **Cervical Vertebræ** are smaller than those in any other region of the spine, and may readily be distinguished by the foramen in the transverse process, which does not exist in the transverse process of either the dorsal or lumbar vertebræ.

The **Body** is small, comparatively dense, and broader from side to side than from before backwards. The anterior and posterior surfaces are flattened and of equal depth; the former is placed on a lower level than the latter, and its inferior border is prolonged downwards, so as to overlap the upper and fore part of the vertebra below. Its upper surface is concave transversely, and presents a projecting lip on each side; its lower surface is convex from side to side, concave from before backwards, and presents laterally a shallow concavity, which receives the corresponding projecting lip of the adjacent vertebra. The

* It may, perhaps, be as well to remind the reader that the direction of a surface is determined by that of a line drawn at right angles to it.

pedicles are directed outwards and backwards, and are attached to the body midway between the upper and lower borders, so that the superior intervertebral notch is as deep as the inferior, but it is, at the same time, narrower. The *laminæ* are narrow, long, thinner above than below, and overlap each other, enclosing the spinal foramen, which is very large, and of a triangular form. The *spinous processes* are short, and bifid at the extremity to afford greater extent of surface for the attachment of muscles, the two divisions being often of unequal size. They increase in length from the fourth to the seventh. The *articular processes* are oblique : the superior are of an oval form, flattened, and directed backwards and upwards ; the inferior forwards and downwards. The *transverse processes* are short, directed downwards, outwards, and forwards, bifid at their extremity, and marked by a groove along their upper surface, which runs downwards and outwards from the superior intervertebral notch, and serves for the transmission of one of the cervical nerves. They are situated in front of the articular processes and on the outer side of the pedicles. The transverse processes are pierced at their base by a foramen, for the transmission of the vertebral artery, vein, and plexus of nerves. Each process is formed by two roots : the anterior root, sometimes called the *costal process*, arises from the side of the

Fig. 113.—Cervical vertebra.



body, and is the homologue of the rib in the dorsal region of the spine; the posterior root springs from the junction of the pedicle with the lamina, and corresponds with the transverse process in the dorsal region. It is by the junction of the two that the foramen for the vertebral vessels is formed. The extremity of each of these roots forms the *anterior* and *posterior tubercles* of the transverse processes.*

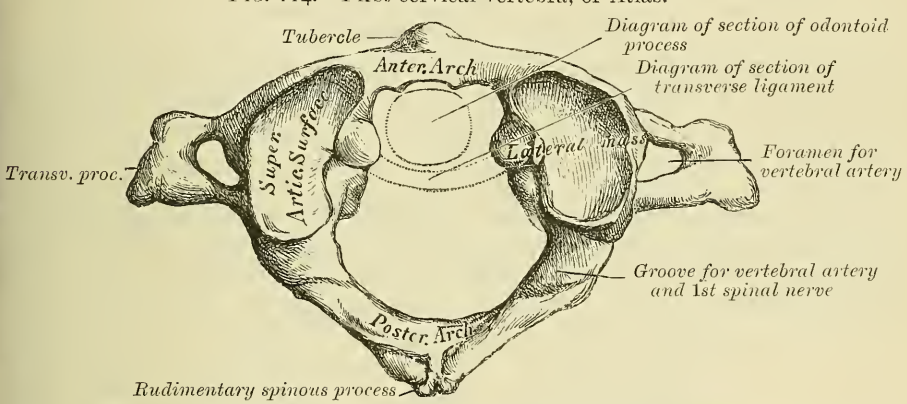
The peculiar vertebræ in the cervical region are the first, or *Atlas*; the second, or *Axis*; and the seventh, or *Vertebra prominens*. The great modifications in the form of the atlas and axis are designed to admit of the nodding and rotatory movements of the head.

The **Atlas** (fig. 114) is so named from supporting the globe of the head. The chief peculiarities of this bone are that it has neither body nor spinous process. The body is detached from the rest of the bone, and forms the odontoid process of the second vertebra ; while the parts corresponding to the pedicles join in front to form the anterior arch. The atlas consists of an anterior arch, a posterior arch, and two lateral masses. The *anterior* arch forms about one-fifth of the bone : its anterior surface is convex, and presents about its centre a

* The anterior tubercle of the transverse process of the sixth cervical vertebra is of large size, and is sometimes known as 'Chassaignac's' or the 'carotid tubercle.' It is in close relation with the carotid artery, which lies in front and a little external to it; so that, as was first pointed out by Chassaignac, the vessel can with ease be compressed against it.

tubercle, for the attachment of the Longus colli muscle; posteriorly it is concave, and marked by a smooth, oval or circular facet, for articulation with the odontoid process of the axis. The upper and lower borders give attachment to the anterior occipito-atlantal and the anterior atlanto-axial ligaments which connect it with the occipital bone above and the axis below. The *posterior* arch forms about two-fifths of the circumference of the bone; it terminates behind in a *tubercle*, which is the rudiment of a spinous process, and gives origin to the Rectus capitis posticus minor. The diminutive size of this process prevents any interference in the movements between it and the cranium. The posterior part of the arch presents above and behind a rounded edge for the attachment of the posterior occipito-atlantal ligament, whilst in front, immediately behind each superior articular process, is a groove, sometimes converted into a foramen by a delicate bony spiculum which arches backwards from the posterior extremity of the superior articular process. These grooves represent the superior intervertebral notches, and are peculiar from being situated behind the articular processes, instead of in front of them, as in the other vertebræ. They serve for the transmission of the vertebral artery, which, ascending through the foramen in the transverse process, winds round the lateral mass in a direction backwards and inwards. They also transmit the suboccipital (first spinal) nerve. On the under surface of the posterior arch, in the same situation, are two other grooves, placed

Fig. 114.—First cervical vertebra, or Atlas.

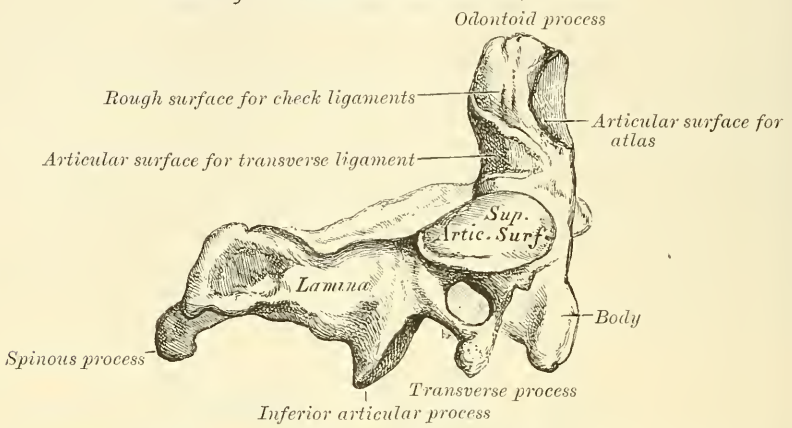


behind the lateral masses, and representing the inferior intervertebral notches of other vertebræ. They are much less marked than the superior. The lower border also gives attachment to the posterior atlanto-axial ligament, which connects it with the axis. The *lateral masses* are the most bulky and solid parts of the atlas, in order to support the weight of the head: they present two articulating processes above, and two below. The two superior are of large size, oval, concave, and approach each other in front, but diverge behind: they are directed upwards, inwards, and a little backwards, forming a kind of cup for the condyles of the occipital bone, and are admirably adapted to the nodding movements of the head. Not unfrequently they are partially subdivided by a more or less deep indentation which encroaches upon each lateral margin. The inferior articular processes are circular in form, flattened or slightly concave and directed downwards and inwards, articulating with the axis, and permitting the rotatory movements. Just below the inner margin of each superior articular surface is a small tubercle, for the attachment of the transverse ligament which, stretching across the ring of the atlas, divides it into two unequal parts—the anterior or smaller segment receiving the odontoid process of the axis, the posterior allowing the transmission of the spinal cord and its membranes. This part of the spinal canal is of considerable size, to afford space for the spinal cord; and hence lateral displacement of the atlas may

occur without compression of this structure. The *transverse processes* are of large size, project directly outwards from the lateral masses, and serve for the attachment of special muscles which assist in rotating the head. They are long, not bifid, and perforated at their base by a canal for the vertebral artery, which is directed from below, upwards and backwards.

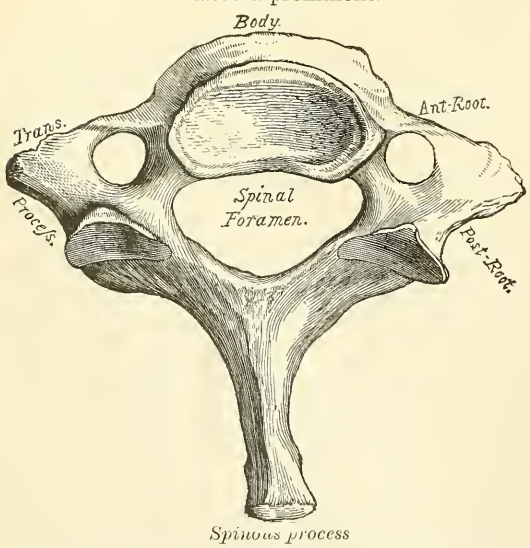
The **Axis** (fig. 115) is so named from forming the pivot upon which the first vertebra, carrying the head, rotates. The most distinctive character of this

Fig. 115.—Second cervical vertebra, or Axis.



bone is the strong, prominent process, tooth-like in form (hence the name *odontoid*), which rises perpendicularly from the upper surface of the body. The *body* is of a triangular form, deeper in front than behind, and prolonged downwards anteriorly so as to overlap the upper and fore part of the adjacent vertebra. It presents in front a median longitudinal ridge, separating two lateral depressions for the attachment of the Longus colli muscle of either side. The *odontoid process* presents two articulating surfaces: one in front, of an oval form, for articulation with the atlas; another behind for the transverse ligament—the latter frequently encroaching on the sides of the process. The apex is pointed, and gives attachment to one fasciculus of the odontoid ligament (*ligamentum suspensorium*). Below the apex the process is somewhat enlarged, and presents on either side a rough impression for the attachment of the lateral fasciculi of the odontoid or check ligaments, which connect it to the occipital bone; the base of the process, where it is attached to the body, is constricted, so as to prevent displacement from the transverse ligament, which binds it in this situation to the anterior arch of the atlas. Sometimes, however, this process does become displaced, especially in children, in whom the ligaments are more relaxed: instant death is the result of this accident. The *pedicles* are broad and strong, especially their anterior extremities, which coalesce with the sides of the body

Fig. 116.—Seventh cervical vertebra, or vertebra prominens.



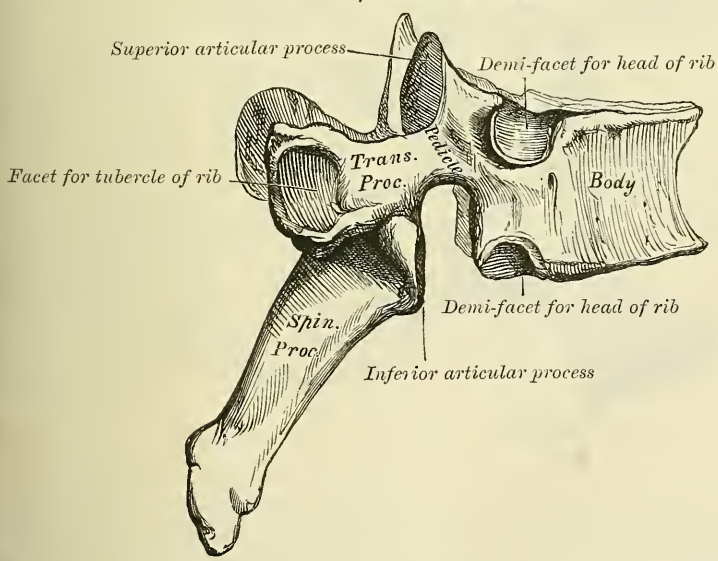
and the root of the odontoid process. The *laminæ* are thick and strong, and the spinal foramen large, but smaller than that of the atlas. The *transverse processes* are very small, not bifid, and perforated by the vertebral foramen, or foramen for the vertebral artery, which is directed obliquely upwards and outwards. The *superior articular surfaces* are round, slightly convex, directed upwards and outwards, and are peculiar in being supported on the body, pedicles, and transverse processes. The *inferior articular surfaces* have the same direction as those of the other cervical vertebræ. The *superior intervertebral notches* are very shallow, and lie behind the articular processes; the *inferior* in front of them, as in the other cervical vertebræ. The *spinous process* is of large size, very strong, deeply channelled on its under surface, and presents a bifid, tubercular extremity for the attachment of muscles which serve to rotate the head upon the spine.

Seventh Cervical (fig. 116).—The most distinctive character of this vertebra is the existence of a very long and prominent spinous process; hence the name 'vertebra prominens.' This process is thick, nearly horizontal in direction, not bifurcated, and has attached to it the ligamentum nuchæ. The *transverse process* is usually of large size, and its posterior tubercles large and prominent; its upper surface has usually a shallow groove, and it seldom presents more than a trace of bifurcation at its extremity. The vertebral foramen is sometimes as large as in the other cervical vertebræ, but is usually smaller on one or both sides, and sometimes wanting. On the left side it occasionally gives passage to the vertebral artery; more frequently the vertebral vein traverses it on both sides; but the usual arrangement is for both artery and vein to pass in front of the transverse process, and not through the foramen. Occasionally the anterior root of the transverse process exists as a separate bone, and attains a large size. It is then known as a 'cervical rib.'

Characters of the Dorsal Vertebræ

The **Dorsal Vertebræ** are intermediate in size between those in the cervical and those in the lumbar region, and increase in size from above downwards, the upper vertebræ in this segment of the spine being much smaller than those in the

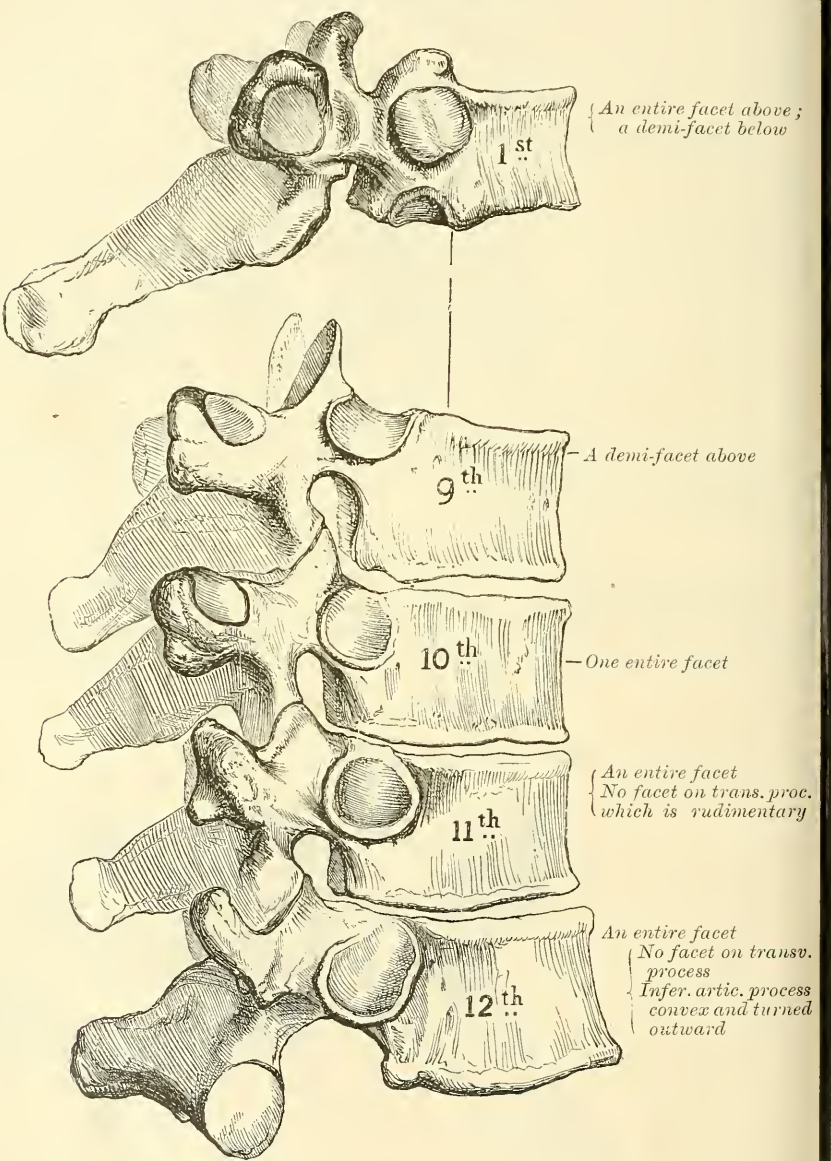
Fig. 117.—A dorsal vertebra.



lower part of the region. The dorsal vertebræ may be at once recognised by the presence on the sides of the body of one or more facets or half-facets for the heads of the ribs.

The **bodies** of the dorsal vertebræ resemble those in the cervical and lumbar regions at the respective ends of this portion of the spine; but in the middle of the dorsal region their form is very characteristic, being heart-shaped, and as broad in the antero-posterior as in the lateral direction. They are thicker behind than in front, flat above and below, convex and prominent in front, deeply concave behind, slightly constricted in front and at the sides, and marked on each side, near the root of the pedicle, by two demi-facets, one above, the other below.

Fig. 118.—Peculiar dorsal vertebræ.



These are covered with cartilage in the recent state, and, when articulated with the adjoining vertebræ, form, with the intervening fibro-cartilage, oval surfaces for the reception of the heads of the corresponding ribs. The *pedicles* are directed backwards, and the inferior intervertebral notches are of large size, and deeper than in any other region of the spine. The *laminæ* are broad, thick, and imbricated—that is to say, overlapping one another like tiles on a roof. The

spinal foramen is small, and of a circular form. The *spinous processes* are long, triangular on transverse section, directed obliquely downwards, and terminate in a tubercular extremity. They overlap one another from the fifth to the eighth, but are less oblique in direction above and below. The *articular processes* are flat, nearly vertical in direction, and project from the upper and lower parts of the pedicles; the superior being directed backwards and a little outwards and upwards, the inferior forwards and a little inwards and downwards. The *transverse processes* arise from the same parts of the arch as the posterior roots of the transverse processes in the neck, and are situated behind the articular processes and pedicles; they are thick, strong, and of great length, directed obliquely backwards and outwards, presenting a clubbed extremity, which is tipped on its anterior part by a small, concave surface, for articulation with the tubercle of a rib. Besides the articular facet for the rib, three indistinct tubercles may be seen rising from the transverse processes, one at the upper border, one at the lower border, and one externally. In man, they are comparatively of small size, and serve only for the attachment of muscles. But in some animals they attain considerable magnitude, either for the purpose of more closely connecting the segments of this portion of the spine, or for muscular and ligamentous attachment.

The peculiar dorsal vertebræ are the *first*, *ninth*, *tenth*, *eleventh*, and *twelfth* (fig. 118).

The **First Dorsal Vertebra** presents, on each side of the *body*, a single entire articular facet for the head of the first rib, and a half-facet for the upper half of the second. The body is like that of a cervical vertebra, being broad transversely; its upper surface is concave, and lipped on each side. The *articular surfaces* are oblique and the *spinous process* thick, long, and almost horizontal.

The **Ninth Dorsal** has no demi-facet below. In some subjects, however, the ninth has two demi-facets on each side, then the tenth has a demi-facet at the upper part; none below.

The **Tenth Dorsal** has (except in the cases just mentioned) an entire articular facet on each side above, which is partly placed on the outer surface of the pedicle. It has no demi-facet below.

In the **Eleventh Dorsal**, the body approaches in its form and size to the lumbar. The articular facets for the heads of the ribs, one on each side, are of large size, and placed chiefly on the pedicles, which are thicker and stronger in this and the next vertebra than in any other part of the dorsal region. The *spinous* process is short, and nearly horizontal in direction. The *transverse* processes are very short, tubercular at their extremities, and have no articular facets for the tubercles of the ribs.

The **Twelfth Dorsal** has the same general characters as the eleventh; but may be distinguished from it by the inferior articular processes being convex and turned outwards, like those of the lumbar vertebræ; by the general form of the body, laminæ, and spinous process, approaching to that of the lumbar vertebræ; and by the transverse processes being shorter, and marked by three elevations, the superior, inferior, and external tubercles, which correspond to the mammillary, accessory, and transverse processes of the lumbar vertebræ. Traces of similar elevations are usually to be found upon the other dorsal vertebræ (*vide ut supra*).

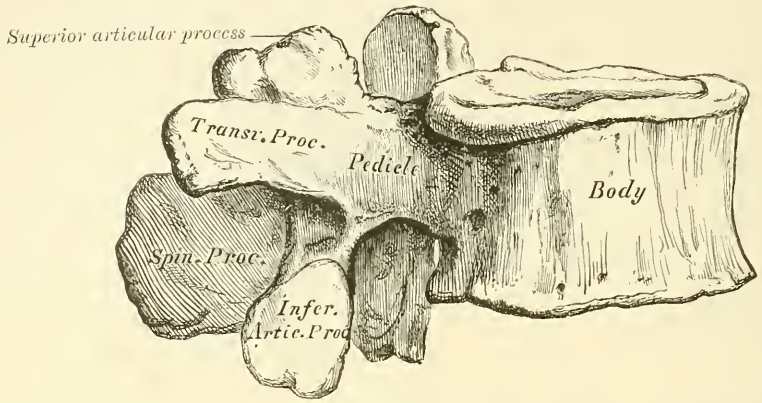
Characters of the Lumbar Vertebræ

The **Lumbar Vertebræ** (fig. 119) are the largest segments of the vertebral column, and can at once be distinguished by the absence of the foramen in the transverse process, the characteristic point of the cervical vertebræ, and by the absence of any articulating facet on the side of the body, the distinguishing mark of the dorsal vertebræ.

The **body** is large, and has a greater diameter from side to side than from before backwards, slightly thicker in front than behind, flattened or slightly

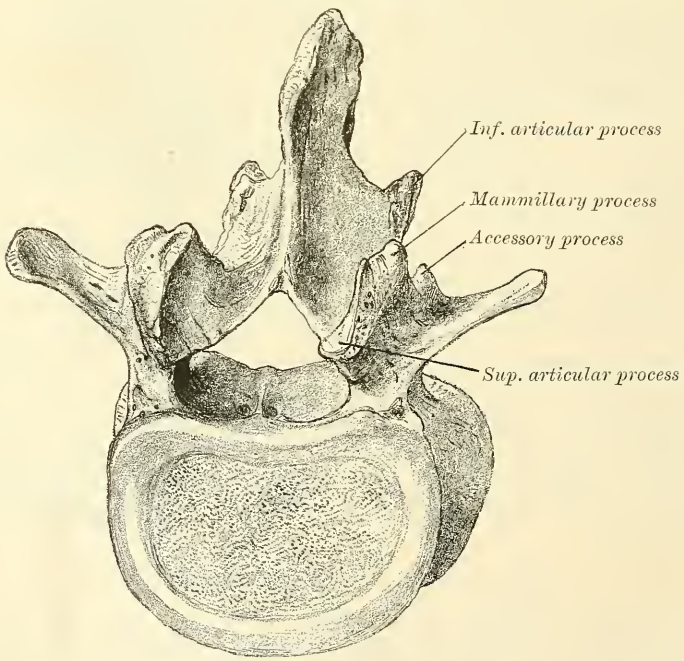
concave above and below, concave behind, and deeply constricted in front and at the sides, presenting prominent margins, which afford a broad basis for the support of the superincumbent weight. The *pedicles* are very strong, directed backwards from the upper part of the bodies; consequently, the inferior intervertebral notches are of considerable depth. The *laminæ* are broad, short, and

Fig. 119.—Lumbar vertebra.



strong; and the spinal foramen triangular, larger than in the dorsal, smaller than in the cervical, region. The *spinous processes* are thick and broad, somewhat quadrilateral, horizontal in direction, thicker below than above, and terminating by a rough, uneven border. The *superior articular processes* are concave, and look backwards and inwards; the *inferior*, convex, look forwards

Fig. 120.—Lumbar vertebra.



and outwards; the former are separated by a much wider interval than the latter, embracing the lower articulating processes of the vertebra above. The *transverse processes* are long, slender, directed transversely outwards in the upper three lumbar vertebræ, slanting a little upwards in the lower two. They are

situated in front of the articular processes instead of behind them as in the dorsal vertebræ, and are homologous with the ribs. Of the three tubercles noticed in connection with the transverse processes of the twelfth dorsal vertebra, the *superior* ones become connected in this region with the back part of the superior articular processes, and have received the name of *mammillary* processes; the *inferior* are represented by a small process pointing downwards, situated at the back part of the base of the transverse process, and called the *accessory* processes—these are the true transverse processes, which are rudimental in this region of the spine; the *external* ones are the so-called transverse processes, the homologue of the rib, and hence sometimes called *costal* processes (fig. 120). Although in man these are comparatively small, in some animals they attain considerable size, and serve to lock the vertebræ more closely together.

The **Fifth Lumbar** vertebra is characterised by having the body much thicker in front than behind, which accords with the prominence of the sacro-vertebral articulation; by the smaller size of its spinous process; by the wide interval between the inferior articulating processes; and by the greater size and thickness of its transverse processes.

Structure of the Vertebræ.—The structure of a vertebra differs in different parts. The body is composed of light, spongy, cancellous tissue, having a thin coating of compact tissue on its external surface perforated by numerous orifices, some of large size, for the passage of vessels; its interior is traversed by one or two large canals, for the reception of veins, which converge towards a single large, irregular aperture, or several small apertures, at the posterior part of the body of each bone. The arch and processes projecting from it have, on the contrary, an exceedingly thick covering of compact tissue.

Development.—Each vertebra is formed of four primary centres of ossification (fig. 121), one for each lamina and its processes, and two for the body.* Ossification commences in the laminæ about the sixth week of fœtal life, in the situation where the transverse processes afterwards project, the ossific granules shooting backwards to the spine, forwards into the pedicles, and outwards into the transverse and articular processes. Ossification in the body commences in the middle of the cartilage about the eighth week by two closely approximated centres, which speedily coalesce to form one central ossific point. According to some authors, ossification commences in the laminæ, only in the upper vertebræ—i.e. in the cervical and upper dorsal; the first ossific points in the lower vertebræ being those which are to form the body, the osseous centres for the laminæ appearing at a subsequent period. At birth these three pieces are perfectly separate. During the first year the laminæ become united behind by a portion of cartilage in which the spinous process is ultimately formed, and thus the arch is completed. About the third year the body is joined to the arch on each side, in such a manner that the body is formed from the three original centres of ossification, the amount contributed by the pedicles increasing in extent from below upwards. Thus the bodies of the sacral vertebræ are formed almost entirely from the central nuclei; the bodies of the lumbar are formed laterally and behind by the pedicles; in the dorsal region, the pedicles advance as far forward as the articular depressions for the head of the ribs, forming these cavities of reception; and in the neck the lateral portions of the bodies are formed entirely by the advance of the pedicles. Before puberty, no other changes occur, excepting a gradual increase in the growth of these primary centres; the upper and under surfaces of the bodies, and the ends of the transverse and

* By many observers it is asserted that the bodies of the vertebræ are developed from a single centre which speedily becomes bilobed, so as to give the appearance of two nuclei, but that there are two centres, at all events sometimes, is evidenced by the fact that the two halves of the body of the vertebra may remain distinct throughout life, and be separated by a fissure through which a protrusion of the spinal membranes may take place, constituting an anterior spina bifida.

spinous processes, being tipped with cartilage, in which ossific granules are not as yet deposited. At sixteen years (fig. 122), four secondary centres appear, one for the tip of each transverse process, and two (sometimes united into one) for the end of the spinous process. At twenty-one years (fig. 123), a thin circular epiphysial plate of bone is formed in the layer of cartilage situated on the upper and under surfaces of the body, the former being the thicker of the two. All these become joined, and the bone is completely formed between the twenty-fifth and thirtieth year of life.

Exceptions to this mode of development occur in the first, second, and seventh cervical, and in the vertebræ of the lumbar region.

Fig. 121.—Development of a vertebra.

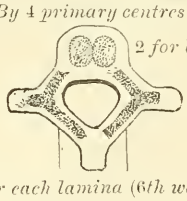


Fig. 122.

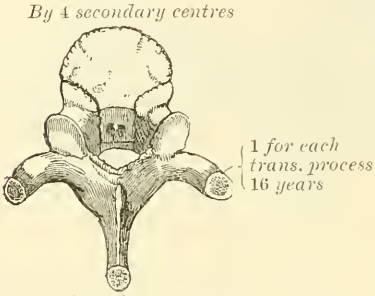

Fig. 123.

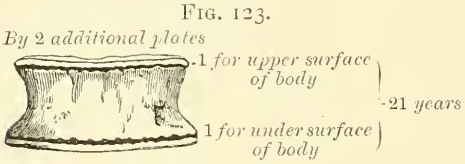

Fig. 124.—Atlas.

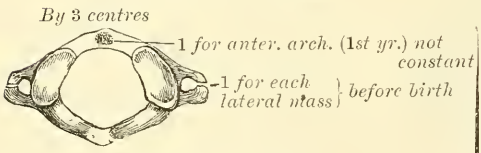

Fig. 125.—Axis.

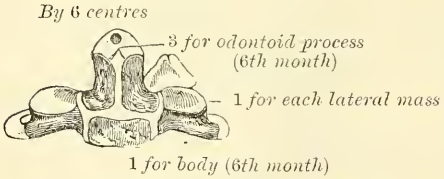

Fig. 126.—Lumbar vertebra.

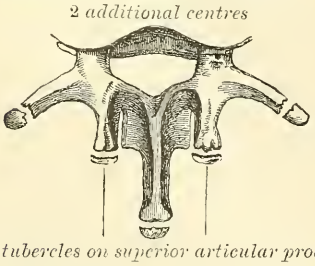


The Atlas (fig. 124).—The number of centres of ossification of the atlas is very variable. It may be developed from two, three, four, or five centres. The most frequent arrangement is by three centres. Two of these are destined for the two lateral or neural masses, the ossification of which commences about the seventh week near the articular processes, and extends backwards; these portions of bone are separated from one another behind, at birth, by a narrow interval filled in with cartilage. Between the second and third years they unite either directly or through the medium of a separate centre, developed in the cartilage in the middle line. The anterior arch, at birth, is altogether cartilaginous, and in this a separate nucleus appears about the end of the first year after birth, and extending laterally joins the neural processes in front of the pedicles. Sometimes there are two nuclei developed in the cartilage, one on either side of the median line, which join to form a single mass. And occasionally there is no separate centre, but the anterior arch is formed by the gradual extension forwards and ultimate junction of the two neural processes.

Exceptional cases

The **Axis** (fig. 125) is developed by *six* centres. The body and arch of this bone are formed in the same manner as the corresponding parts in the other

vertebræ: one centre (or two, which speedily coalesce) for the lower part of the body, and one for each lamina. The odontoid process consists originally of an extension upwards of the cartilaginous mass, in which the lower part of the body is formed. At about the sixth month of fœtal life, two osseous nuclei make their appearance in the base of this process: they are placed laterally, and join before birth to form a conical bilobed mass deeply cleft above; the interval between the cleft and the summit of the process is formed by a wedge-shaped piece of cartilage, the base of the process being separated from the body by a cartilaginous interval, which gradually becomes ossified at its circumference, but remains cartilaginous in its centre until advanced age.* Finally, as Humphry has demonstrated, the apex of the odontoid process has a separate nucleus, which appears in the second year and joins about the twelfth year. In addition to these there is a secondary centre for a thin epiphysial plate on the under surface of the body of the bone.

The Seventh Cervical.—The anterior or costal part of the transverse process of the seventh cervical is developed from a separate osseous centre at about the sixth month of fœtal life, and joins the body and posterior division of the transverse process between the fifth and sixth years. Sometimes this process continues as a separate piece, and, becoming lengthened outwards, constitutes what is known as a cervical rib.

The **Lumbar Vertebræ** (fig. 126) have *two additional centres* (besides those common to the vertebræ generally) for the mammillary tubercles, which project from the back part of the superior articular processes. The transverse process of the first lumbar is sometimes developed as a separate piece, which may remain permanently unconnected with the remaining portion of the bone, thus forming a lumbar rib—a peculiarity which is rarely met with.

Progress of Ossification in the Spine generally.—Ossification of the laminæ of the vertebræ commences at the upper part of the spine, and proceeds gradually downwards. Ossification of the bodies, on the other hand, commences a little below the centre of the spinal column (about the ninth or tenth dorsal vertebra), and extends both upwards and downwards. Although, however, the ossific nuclei make their first appearance in the lower dorsal vertebræ, the lumbar and first sacral are those in which these nuclei are largest at birth.

Attachment of Muscles.—To the *Atlas* are attached nine pairs: the Longus colli, Rectus capitis anticus minor, Rectus lateralis, Obliquus capitis superior and inferior, Splenius colli, Levator anguli scapulæ, First Intertransverse, and Rectus capitis posticus minor.

To the *Axis* are attached eleven pairs: the Longus colli, Levator anguli scapulæ, Splenius colli, Scalenus medius, Transversalis colli, Intertransversales, Obliquus capitis inferior, Rectus capitis posticus major, Semi-spinalis colli, Multifidus spinæ, Interspinales.

To the remaining vertebræ, generally, are attached thirty-five pairs and a single muscle: *anteriorly*, the Rectus capitis anticus major, Longus colli, Scalenus anticus, medius, and posticus, Psoas magnus and parvus, Quadratus lumborum, Diaphragm, Obliquus abdominis internus, and Transversalis abdominis,—*posteriorly*, the Trapezius, Latissimus dorsi, Levator anguli scapulæ, Rhomboideus major and minor, Serratus posticus superior and inferior, Splenius, Erector spinæ, Ilio-costalis, Longissimus dorsi, Spinalis dorsi, Cervicalis ascendens, Transversalis colli, Trachelo-mastoid, Complexus, Biventer cervicis, Semi-spinalis dorsi et colli, Multifidus spinæ, Rotatores spinæ, Interspinales, Supraspinales, Intertransversales, Levatores costarum.

Sacral and Coccygeal Vertebræ

The **Sacral** and **Coccygeal Vertebræ** consist at an early period of life of nine separate pieces which are united in the adult, so as to form two bones, five

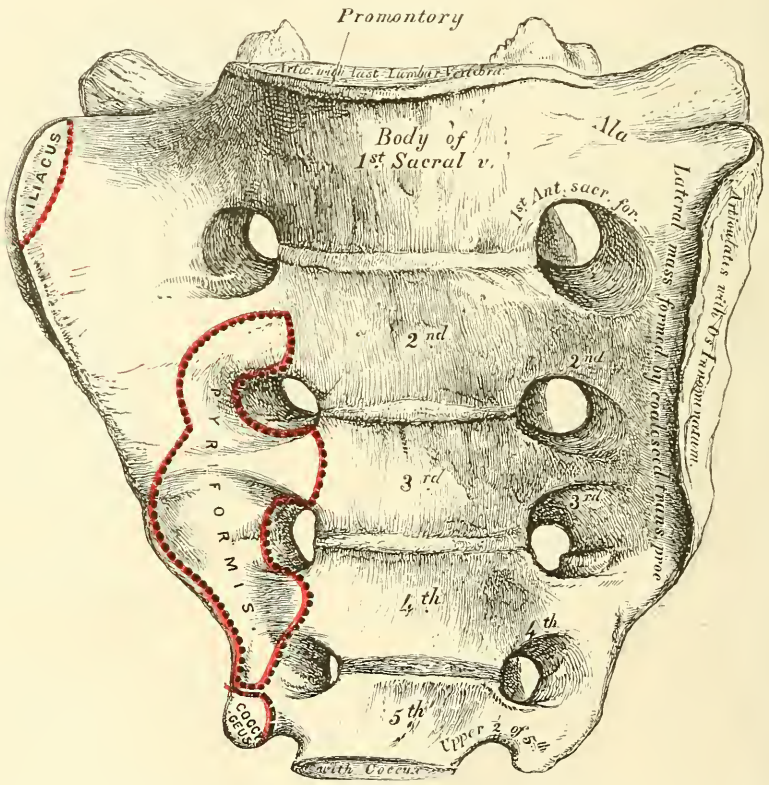
* See Cunningham, *Journ. Anat.* vol. xx. p. 238.

entering into the formation of the sacrum, four into that of the coccyx. Occasionally, the coccyx consists of five bones.*

The Sacrum

The **Sacrum** (sacer, *sacred*) is a large, triangular bone (fig. 127), situated at the lower part of the vertebral column, and at the upper and back part of the pelvic cavity, where it is inserted like a wedge between the two innominate bones; its upper part or base, articulating with the last lumbar vertebra, its apex with the coccyx. The sacrum is curved upon itself, and placed very obliquely, its upper extremity projecting forwards, and forming, with the last lumbar vertebra, a very prominent angle, called the *promontory* or *sacro-vertebral angle*; whilst its central part is directed backwards, so as to give increased

Fig. 127.—Sacrum, anterior surface.



capacity to the pelvic cavity. It presents for examination an anterior and posterior surface, two lateral surfaces, a base, an apex and a central canal.

The **Anterior Surface** is concave from above downwards, and slightly so from side to side. In the middle are seen four transverse ridges, indicating the original division of the bone into five separate pieces. The portions of bone intervening between the ridges correspond to the bodies of the vertebræ. The body of the first segment is of large size, and in form resembles that of a lumbar vertebra; the succeeding ones diminish in size from above downwards, are flattened from before backwards, and curved so as to accommodate themselves to the form of the sacrum, being concave in front, convex behind. At each end of the ridges above mentioned are seen the *anterior sacral foramina*, analogous to the intervertebral foramina, four in number on each side, somewhat rounded in

* The late Sir George Humphry described this as the usual composition of the coccyx.—*On the Skeleton*, p. 456.

form, diminishing in size from above downwards, and directed outwards and forwards : they transmit the anterior branches of the sacral nerves and the lateral sacral arteries. External to these foramina is the *lateral mass*, consisting, at an early period of life, of separate segments ; these become blended, in the adult, with the bodies, with each other, and with the posterior transverse processes. Each lateral mass is traversed by four broad, shallow grooves, which lodge the anterior sacral nerves as they pass outwards, the grooves being separated by prominent ridges of bone which give attachment to the slips of the Pyriformis muscle.

Fig. 128.—Vertical section of the sacrum.

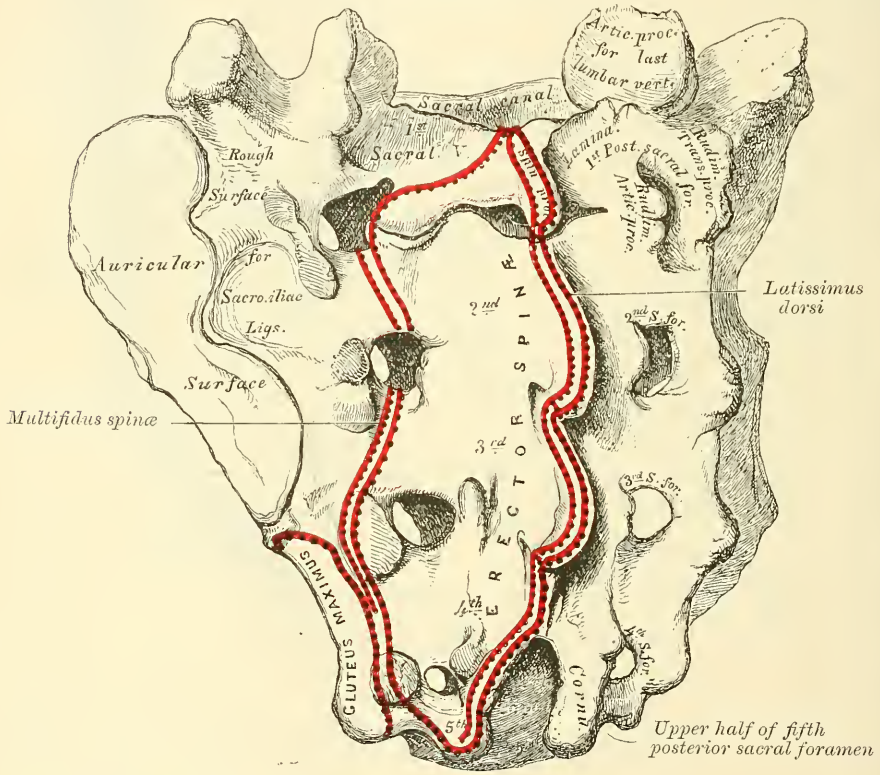
If a vertical section is made through the centre of the bone (fig. 128), the bodies are seen to be united at their circumference by bone, a wide interval being left centrally, which, in the recent state, is filled by intervertebral substance. In some bones, this union is more complete between the lower segments than between the upper ones.

The **Posterior Surface** (fig. 129) is convex and much narrower than the anterior. In the middle line are three or four tubercles, which represent the rudimentary spinous processes of the sacral vertebræ. Of these tubercles, the first is usually prominent, and perfectly distinct from the rest ; the second and third are either separate or united into a tubercular ridge, which diminishes in size from above downwards ; the fourth usually, and the fifth always remaining undeveloped. External to the spinous processes on each side are the *laminæ*, broad and well marked in the first three pieces ; sometimes the fourth, and generally the fifth, are only partially developed and fail to meet in the middle line. These partially-developed laminæ are prolonged downwards, as rounded processes, the *sacral cornua*, and are connected to the cornua of the coccyx. Between them the bony wall of the lower end of the sacral canal is imperfect, and is liable to be opened in the sloughing of bed-sores. External to the laminæ is a linear series of indistinct tubercles representing the *articular processes* ; the upper pair are large, well developed, and correspond in shape and direction to the superior articulating processes of a lumbar vertebra ; the second and third are small ; the fourth and fifth (usually blended together) are situated on each side of the sacral canal and assist in forming the sacral cornua. External to the articular processes are the four *posterior sacral foramina* ; they are smaller in size and less regular in form than the anterior, and transmit the posterior branches of the sacral nerves. On the outer side of the posterior sacral foramina is a series of tubercles, the rudimentary *transverse processes* of the sacral vertebræ. The first pair of transverse tubercles are of large size, very distinct, and correspond with each superior angle of the bone ; the second, small in size, enter into the formation of the sacro-iliac articulation ; the third give attachment to the oblique fasciculi of the posterior sacro-iliac ligaments ; and the fourth and fifth to the great sacro-sciatic ligaments. The interspace between the spinous and trans-

verse processes on the back of the sacrum presents a wide, shallow concavity, called the *sacral groove*; it is continuous above with the vertebral groove, and lodges the origin of the Erector spinæ.

The **Lateral Surface**, broad above, becomes narrowed into a thin edge below. Its upper half presents in front a broad, ear-shaped surface for articulation with the ilium. This is called the *auricular* surface, and in the fresh state is coated with fibro-cartilage. It is bounded posteriorly by deep and uneven impressions, for the attachment of the posterior sacro-iliac ligaments. The lower half is thin and sharp, and gives attachment to the greater and lesser sacro-sciatic ligaments, and to some fibres of the Gluteus maximus; below, it presents a deep notch,

Fig. 129.—Sacrum, posterior surface.



which is converted into a foramen by articulation with the transverse process of the upper piece of the coccyx, and transmits the anterior division of the fifth sacral nerve.

The **Base** of the sacrum, which is broad and expanded, is directed upwards and forwards. In the middle is seen a large oval articular surface, which is connected with the under surface of the body of the last lumbar vertebra by a fibro-cartilaginous disc. It is bounded behind by the large, triangular orifice of the sacral canal. The orifice is formed behind by the laminæ and spinous process of the first sacral vertebra: the superior articular processes project from it on each side; they are oval, concave, directed backwards and inwards, like the superior articular processes of a lumbar vertebra; and in front of each articular process is an intervertebral notch, which forms the lower half of the last intervertebral foramen. Lastly, on each side of the large oval articular surface is a broad and flat triangular surface of bone, which extends outwards, supports the Psoas magnus muscle and lumbo-sacral cord, and is continuous on each side with the iliac fossa. This is called the *ala* of the sacrum, and gives attachment to a few of the fibres of the Iliacus muscle.

The **Apex**, directed downwards and forwards, presents a small, oval, concave surface for articulation with the coccyx.

The **Spinal Canal** runs throughout the greater part of the bone; it is large and triangular in form above; small and flattened, from before backwards, below. In this situation its posterior wall is incomplete, from the non-development of the laminæ and spinous processes. It lodges the sacral nerves, and is perforated by the anterior and posterior sacral foramina, through which these pass out.

Structure.—It consists of much loose, spongy tissue within, invested externally by a thin layer of compact tissue.

Differences in the Sacrum of the Male and Female.—The sacrum in the female is usually wider than in the male; the lower half forms a greater angle with the upper; the upper half of the bone being nearly straight, the lower half presenting the greatest amount of curvature. The bone is also directed more obliquely backwards, which increases the size of the pelvic cavity; but the sacro-vertebral angle projects less. In the male the curvature is more evenly distributed over the whole length of the bone, and is altogether greater than in the female.

Peculiarities of the Sacrum.—This bone, in some cases, consists of six pieces; occasionally, the number is reduced to four. Sometimes the bodies of the first and second segments are not joined, or the laminæ and spinous processes have not coalesced. Occasionally, the upper pair of transverse tubercles are not joined to the rest of the bone on one or both sides; and, lastly, the sacral canal may be open for nearly the lower half of the bone, in consequence of the imperfect development of the laminæ and spinous processes. The sacrum, also, varies considerably with respect to its degree of curvature. From the examination of a large number of skeletons, it would appear that, in one set of cases, the anterior surface of this bone was nearly straight, the curvature, which was very slight, affecting only its lower end. In another set of cases, the bone was curved throughout its whole length, but especially towards its middle. In a third set, the degree of curvature was less marked, and affected especially the lower third of the bone.

Development (fig. 130).—The sacrum, formed by the union of five vertebræ, has *thirty-five* centres of ossification.

The *bodies* of the sacral vertebræ have each three ossific centres: one for the central part, and one for the epiphysial plates on its upper and under surface. Occasionally the primary centres for the bodies of the first and second piece of the sacrum are double.

The arch of each sacral vertebra is developed by two centres, one for each lamina. These unite with each other behind, and subsequently join the body.

The *lateral masses* have six additional centres, two for each of the first three vertebræ. These centres make their appearance above and to the outer side of the anterior sacral foramina (fig. 130), and are developed into separate segments (fig. 131); they are subsequently blended with each other, and with the bodies and transverse processes, to form the lateral mass.

Lastly, each *lateral surface* of the sacrum is developed by two epiphysial plates (fig. 132): one for the auricular surface, and one for the remaining part of the thin lateral edge of the bone.

Period of Development.—At about the eighth or ninth week of fœtal life, ossification of the central part of the bodies of the first three vertebræ commences; and, at a somewhat later period, that of the last two. Between the sixth and eighth month ossification of the laminæ takes place; and at about the same period, the characteristic osseous tubercles for the first three sacral vertebræ make their appearance. The period at which the arch becomes completed by the junction of the laminæ with the bodies in front, and with each other behind, varies in different segments. The junction between the laminæ and the bodies takes place first in the lower vertebræ as early as the second year, but is not

effected in the uppermost until the fifth or sixth year. About the sixteenth year the epiphyses for the upper and under surfaces of the bodies are formed; and between the eighteenth and twentieth years, those for each lateral surface of the sacrum make their appearance. The bodies of the sacral vertebræ are, during early life, separated from each other by intervertebral discs. But about the eighteenth year the two lowest segments become joined together by ossification extending through the disc. This process gradually extends upwards until all the segments become united; and the bone is completely formed from the twenty-fifth to the thirtieth year of life.

Fig. 130.—Development of the sacrum.

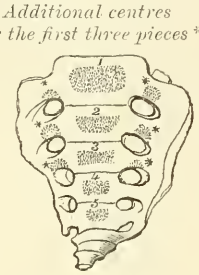


Fig. 131.

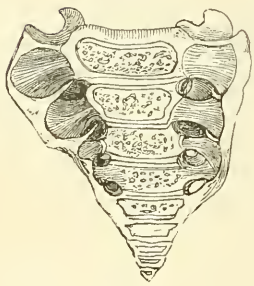

Fig. 132.

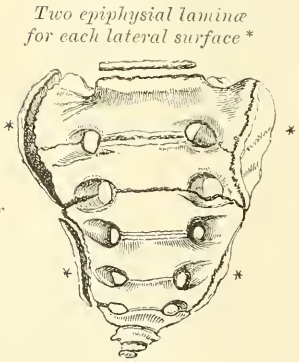


Articulations.—With four bones: the last lumbar vertebra, coccyx, and the two innominate bones.

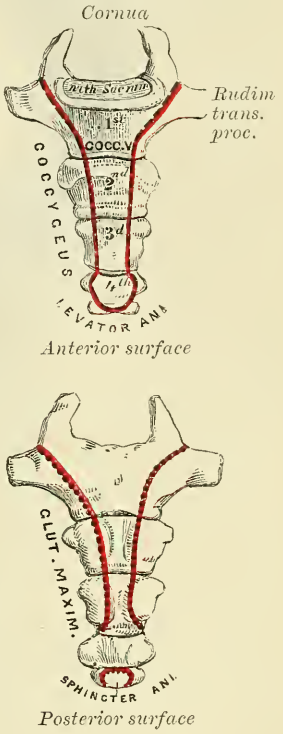
Attachment of Muscles.—To eight pairs: in front, the Pyriformis and Coccygeus, and a portion of the Iliacus to the base of the bone; behind, the Gluteus maximus, Latissimus dorsi, Multifidus spinæ, and Erector spinæ, and sometimes the Extensor coccygis.

The Coccyx

The **Coccyx** (*κόκκυξ, cuckoo*), so called from having been compared to a cuckoo's beak (fig. 133), is usually formed of four small segments of bone, and is the most rudimentary part of the vertebral column. In each of the first three segments may be traced a rudimentary body, articular and transverse processes; the last piece (sometimes the third) is a mere nodule of bone, without distinct processes. All the segments are destitute of pedicles, laminæ, and spinous processes; and, consequently, of intervertebral foramina and spinal canal. The first segment is the largest; it resembles the lowermost sacral vertebra, and often exists as a separate piece; the last three, diminishing in size from above downwards, are usually blended together so as to form a single bone. The gradual diminution in the size of the pieces gives this bone a triangular form, the base of the triangle joining the end of the sacrum. It presents for examination an anterior and posterior surface, two borders, a base, and an apex. The *anterior surface* is slightly concave, and marked with three transverse grooves, indicating the points of junction of the different pieces. It has attached to it the anterior sacro-coccygeal ligament and Levator ani muscle, and supports the lower end of the rectum. The *posterior surface* is convex, marked by transverse grooves similar to those on the anterior surface; and presents on each side a lineal row of tubercles, the rudimentary articular processes of the coccygeal vertebræ. Of these, the superior pair are large, and are called the *cornua of the coccyx*: they project upwards, and articulate with the cornua of the sacrum, the junction between these two bones com-

pleting the fifth posterior sacral foramen for the transmission of the posterior division of the fifth sacral nerve. The *lateral borders* are thin, and present a series of small eminences, which represent the transverse processes of the coccygeal vertebræ. Of these, the first on each side is the largest, flattened from before backwards, and often ascends to join the lower part of the thin lateral edge of the sacrum, thus completing the fifth anterior sacral foramen for the transmission of the anterior division of the fifth sacral nerve; the others diminish in size from above downwards, and are often wanting. The *borders* of the coccyx are narrow, and give attachment on each side to the sacro-sciatic ligaments, to the Coccygeus muscle in front of the ligaments, and to the Gluteus maximus behind them. The *base* presents an oval surface for articulation with the sacrum. The *apex* is rounded, and has attached to it the tendon of the external Sphincter muscle. It is occasionally bifid, and sometimes deflected to one or other side.

Fig. 133.—Coccyx.



Anterior surface

Posterior surface

Development.—The coccyx is developed by *four* centres, one for each piece. Occasionally one of the first three pieces of this bone is developed by two centres, placed side by side. The ossific nuclei make their appearance in the following order: in the first segment at birth; in the second piece, at from five to ten years; in the third, from ten to fifteen years; in the fourth from fifteen to twenty years. As age advances, these various segments become united in the following order: the first two pieces join; then the third and fourth; and, lastly, the bone is completed by the union of the second and third. At a late period of life, especially in females, the coccyx often becomes joined to the end of the sacrum.

Articulation.—With the sacrum.

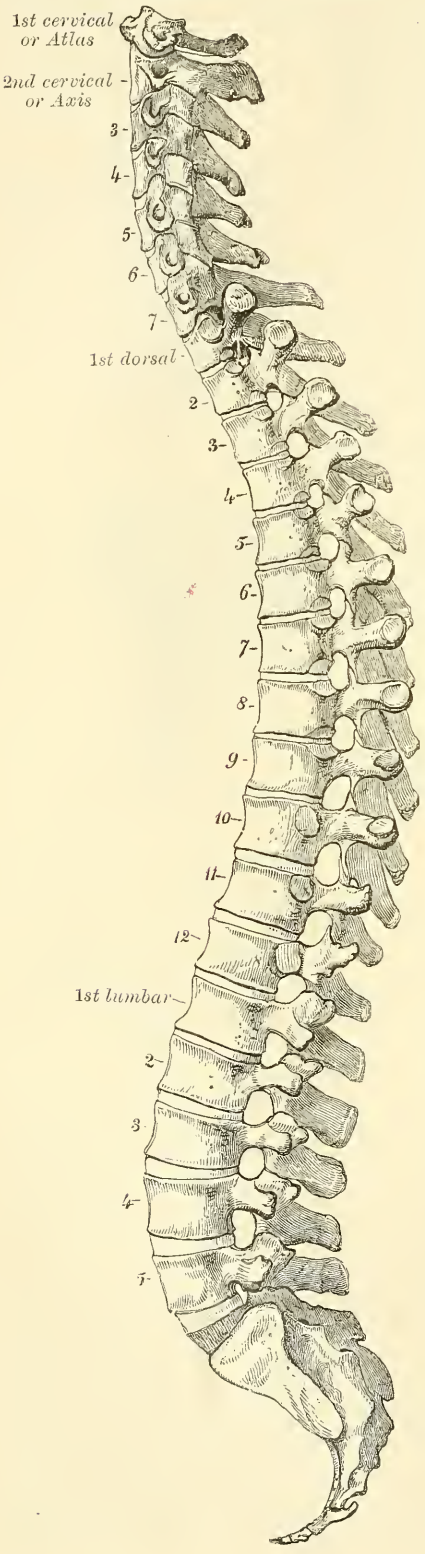
Attachment of Muscles.—To four pairs and one single muscle: on either side, the Coccygeus; behind, the Gluteus maximus and Extensor coccygis, when present; at the apex, the Sphincter ani; and in front, the Levator ani.

Of the Spine in general

The **Spinal Column**, formed by the junction of the vertebræ, is situated in the median line, at the posterior part of the trunk; its average length is about two feet two or three inches, measuring along the curved anterior surface of the column. Of this length the cervical part measures about five, the dorsal about eleven, the lumbar about seven inches, and the sacrum and coccyx the remainder. The female spine is about one inch less than the male.

Viewed in front, it presents two pyramids joined together at their bases, the upper one being formed by all the vertebræ from the second cervical to the last lumbar, the lower one by the sacrum and coccyx. When examined more closely, the upper pyramid is seen to be formed of three smaller pyramids. The uppermost of these consists of the six lower cervical vertebræ; its apex being formed by the axis or second cervical, its base by the first dorsal. The second pyramid, which is inverted, is formed by the four upper dorsal vertebræ, the base being at the first dorsal, the smaller end at the fourth. The third pyramid commences at the fourth dorsal, and gradually increases in size to the fifth lumbar.

Fig. 134.—Lateral view of the spine.



Viewed laterally (fig. 134), the spinal column presents several curves, which correspond to the different regions of the column, and are called *cervical*, *dorsal*, *lumbar*, and *pelvic*. The *cervical* curve commences at the apex of the odontoid process, and terminates at the middle of the second dorsal vertebra; it is convex in front, and is the least marked of all the curves. The *dorsal* curve, which is concave forwards, commences at the middle of the second and terminates at the middle of the twelfth dorsal vertebra. Its most prominent point behind corresponds to the spine of the seventh dorsal. The *lumbar* curve commences at the middle of the last dorsal vertebra, and terminates at the sacro-vertebral angle. It is convex anteriorly; the convexity of the lower three vertebræ being much greater than that of the upper ones. The *pelvic* curve commences at the sacro-vertebral articulation, and terminates at the point of the coccyx. It is concave anteriorly. The dorsal and pelvic curves are the primary curves, and begin to be formed at an early period of fœtal life, and are due to the shape of the bodies of the vertebræ. The cervical and lumbar curves are compensatory or secondary, and are developed after birth in order to maintain the erect position. They are due mainly to the shape of the intervertebral discs.

The spine has also a slight lateral curvature, the convexity of which is directed towards the right side. This is most probably produced, as Bichat first explained, chiefly by muscular action; most persons using the right arm in preference to the left, especially in making long-continued efforts, when the body is curved to the right side. In support of this explanation, it has been found, by Béclard, that in one or two individuals who were left-handed, the lateral curvature was directed to the left side.

The spinal column presents for examination an anterior, a posterior, and two lateral surfaces: a base, summit, and spinal canal.

The **anterior surface** presents the bodies of the vertebræ separated in the recent state by the intervertebral discs. The bodies are broad in the cervical

region, narrow in the upper part of the dorsal, and broadest in the lumbar region. The whole of this surface is convex transversely, concave from above downwards in the dorsal region, and convex in the same direction in the cervical and lumbar regions.

The **posterior surface** presents in the median line the spinous processes. These are short, horizontal, with bifid extremities, in the cervical region. In the dorsal region, they are directed obliquely above, assume almost a vertical direction in the middle, and are horizontal below, as are also the spines of the lumbar vertebræ. They are separated by considerable intervals in the loins, by narrower intervals in the neck, and are closely approximated in the middle of the dorsal region. Occasionally one of these processes deviates a little from the median line—a fact to be remembered in practice, as irregularities of this sort are attendant also on fractures or displacements of the spine. On either side of the spinous processes, extending the whole length of the column, is the vertebral groove formed by the laminæ in the cervical and lumbar regions, where it is shallow, and by the laminæ and transverse processes in the dorsal region, where it is deep and broad. In the recent state, these grooves lodge the deep muscles of the back. External to the vertebral grooves are the articular processes, and still more externally the transverse process. In the dorsal region, the latter processes stand backwards, on a plane considerably posterior to the same processes in the cervical and lumbar regions. In the cervical region, the transverse processes are placed in front of the articular processes, and on the outer side of the pedicles, between the intervertebral foramina. In the dorsal region they are posterior to the pedicles, intervertebral foramina, and articular processes. In the lumbar, they are placed also in front of the articular processes, but behind the intervertebral foramina.

The **lateral surfaces** are separated from the posterior by the articular processes in the cervical and lumbar regions, and by the transverse processes in the dorsal. These surfaces present in front the sides of the bodies of the vertebræ, marked in the dorsal region by the facets for articulation with the heads of the ribs. More posteriorly are the intervertebral foramina, formed by the juxtaposition of the intervertebral notches, oval in shape, smallest in the cervical and upper part of the dorsal regions, and gradually increasing in size to the last lumbar. They are situated between the transverse processes in the neck, and in front of them in the back and loins, and transmit the spinal nerves.

The **base** of that portion of the vertebral column formed by the twenty-four movable vertebræ is formed by the under surface of the body of the fifth lumbar vertebra; and the **summit** by the upper surface of the atlas.

The **vertebral** or **spinal canal** follows the different curves of the spine; it is largest in those regions in which the spine enjoys the greatest freedom of movement, as in the neck and loins, where it is wide and triangular; and narrow and rounded in the back, where motion is more limited.

Surface Form.—The only part of the vertebral column which lies closely under the skin, and so directly influences surface form, is the apices of the spinous processes. These are always distinguishable at the bottom of a median furrow, which, more or less evident, runs down the mesial line of the back from the external occipital protuberance above to the middle of the sacrum below. In the neck the furrow is broad, and terminates in a conspicuous projection, which is caused by the spinous process of the seventh cervical vertebra (vertebra prominens). Above this the spinous process of the sixth cervical vertebra may sometimes be seen; the other cervical spines are sunken, and are not visible, though the spine of the axis can be felt, and generally also the spines of the third, fourth, and fifth cervical vertebræ. In the dorsal region, the furrow is shallow, and during stooping disappears, and then the spinous processes become more or less visible. The markings produced by these spines are small and close together. In the lumbar region the furrow is deep, and the situation of the lumbar spines is frequently indicated by little pits or depressions, especially if the muscles in the loins are well developed and the spine incurved. They are much larger and farther apart than in the dorsal region. In the sacral region the furrow is shallower, presenting a flattened area which terminates below at the most prominent part of the posterior surface of the sacrum, formed by the spinous

process of the third sacral vertebra. At the bottom of the furrow may be felt the irregular posterior surface of the bone. Below this, in the deep groove leading to the anus, the coccyx may be felt. The only other portions of the vertebral column which can be felt from the surface are the transverse processes of three of the cervical vertebræ—viz. the first, the sixth, and the seventh. The transverse process of the atlas can be felt as a rounded nodule of bone just below and in front of the apex of the mastoid process, along the anterior border of the sterno-mastoid. The transverse process of the sixth cervical vertebra is of surgical importance. If deep pressure be made in the neck, in the course of the carotid artery, opposite the cricoid cartilage, the prominent anterior tubercle of the transverse process of the sixth cervical vertebra can be felt. This has been named *Chassaignac's tubercle*, and against it the carotid artery may be most conveniently compressed by the finger. The transverse process of the seventh cervical vertebra can also often be felt. Occasionally the anterior root, or costal process, is large and segmented off, forming a cervical rib.

Surgical Anatomy.—Occasionally the coalescence of the laminæ is not completed, and consequently a cleft is left in the arches of the vertebræ, through which a protrusion of the spinal membranes (dura mater and arachnoid), and sometimes of the spinal cord itself, takes place, constituting the disease known as *spina bifida*. This disease is most common in the lumbo-sacral region, on account of the fact, previously stated, that the closure of the arches takes place gradually from above downwards; but it may occur in the dorsal or cervical region, or the arches throughout the whole length of the canal may remain unapproximated. In some rare cases, in consequence of the non-coalescence of the two primary centres from which the body is formed, a similar condition may occur in front of the canal, the bodies of the vertebræ being found cleft and the tumour projecting into the thorax, abdomen, or pelvis, between the lateral halves of the bodies affected.

The construction of the spinal column of a number of pieces, securely connected together and enjoying only a slight degree of movement between any two individual pieces, though permitting of a very considerable range of movement as a whole, allows a sufficient degree of mobility without any material diminution of strength. The many joints of which the spine is composed, together with the very varied movements to which it is subjected, render it liable to sprains; but so closely are the individual vertebræ articulated that these sprains are rarely or ever severe, and any amount of violence sufficiently great to produce tearing of the ligaments would tend rather to cause a dislocation or fracture. The further safety of the column and its less liability to injury is provided for by its disposition in curves, instead of in one straight line. For it is an elastic column, and must first bend before it breaks; under these circumstances, being made up of three curves, it represents three columns, and greater force is required to produce bending of a short column, than of a longer one that is equal to it in breadth and material. Again, the safety of the column is provided for by the interposition of the intervertebral disc between the bodies of the vertebræ, which act as admirable buffers in counteracting the effects of violent jars or shocks. Fracture-dislocation of the spine may be caused by direct or indirect violence or by a combination of the two, as when a person, falling from a height, strikes against some prominence and is doubled over it. The fractures from indirect violence are the more common, and here the bodies of the vertebræ are compressed, whilst the arches are torn asunder; in fractures from direct violence, on the other hand, the arches are compressed and the bodies of the vertebræ separated from each other. It will therefore be seen that in both classes of injury the spinal marrow is the part least likely to be injured, and may escape damage even where there has been considerable lesion of the bony framework. For, as Mr. Jacobson states, 'being lodged in the centre of the column, it occupies neutral ground in respect to forces which might cause fracture. For it is a law in mechanics that when a beam, as of timber, is exposed to breakage and the force does not exceed the limits of the strength of the material, one division resists compression, another laceration of the particles, while the third, between the two, is in a negative condition.' * Applying this principle to the spine, it will be seen that, whether the fracture-dislocation be produced by direct violence or indirect, one segment, either the anterior or posterior, will be exposed to compression, the other to laceration, and the intermediate part, where the cord is situated, will be in a neutral state. When a fracture-dislocation is produced by indirect violence, the displacement is almost always the same; the upper segment being driven forwards on the lower, so that the cord is compressed between the body of the vertebra below and the arch of the vertebra above.

The parts of the spine most liable to be injured are (1) the dorsi-lumbar region, for this part is near the middle of the column and there is therefore a greater amount of leverage, and moreover the portion above is comparatively fixed, and the vertebræ which form it, though much smaller, have nevertheless to bear almost as great a weight as those below; (2) the cervico-dorsal region, because here the flexible cervical portion of the spine joins the more fixed dorsal region; and (3) the alto-axoid region, because it enjoys an extensive range of movement, and, being near the skull, is influenced by violence applied to the head. In fracture-dislocation it has been proposed to trephine the spine and remove portions of the laminæ and spinous processes. The operation can only be of use when

* Holmes's *System of Surgery*, vol. i. p. 529. 1883.

the paralysis is due to the pressure of bone or the effusion of blood, and not to cases, which are by far the most common, where the cord is crushed to a pulp. And even in those cases where the cord is compressed by bone, the portion of displaced bone which presses on the cord is generally the body of the vertebra below, and is therefore inaccessible to operation. The operative proceeding is one of great severity, involving an extensive and deep wound and great risk of septic meningitis, and as the advantages to be derived from it are exceedingly problematical and confined to a very few cases, it is not often resorted to. Trephining has also been employed in some cases of paraplegia, due to Potts's disease of the spine. Here the paralysis is due to the pressure of inflammatory products, and where this is new scar-tissue, formed by the organisation of granulation tissue, its removal has been attended with a very considerable amount of success.

THE SKULL

The **Skull**, or superior expansion of the vertebral column, has been described as if composed of four vertebræ, the elementary parts of which are specially modified in form and size, and almost immovably connected, for the reception of the brain and special organs of the senses. These vertebræ are the occipital, parietal, frontal, and nasal. Descriptive anatomists, however, divide the skull into two parts, the Cranium and the Face. The Cranium (*κράνος, a helmet*) is composed of *eight* bones—viz. the *occipital*, two *parietal*, *frontal*, two *temporal*, *sphenoid*, and *ethmoid*. The face is composed of *fourteen* bones—viz. the two *nasal*, two *superior maxillary*, two *lachrymal*, two *malar*, two *palate*, two *inferior turbinated*, *vomer*, and *inferior maxillary*. The *ossicula auditûs*, the *teeth*, and *Wormian bones* are not included in this enumeration.

- *Skull, 22 bones*
  - *Cranium, 8 bones*
    - Occipital.
    - Two parietal.
    - Frontal.
    - Two Temporal.
    - Sphenoid.
    - Ethmoid.
  - *Face, 14 bones*
    - Two Nasal.
    - Two Superior Maxillary.
    - Two Lachrymal.
    - Two Malar.
    - Two Palate.
    - Two Inferior Turbinated.
    - Vomer.
    - Inferior Maxillary.

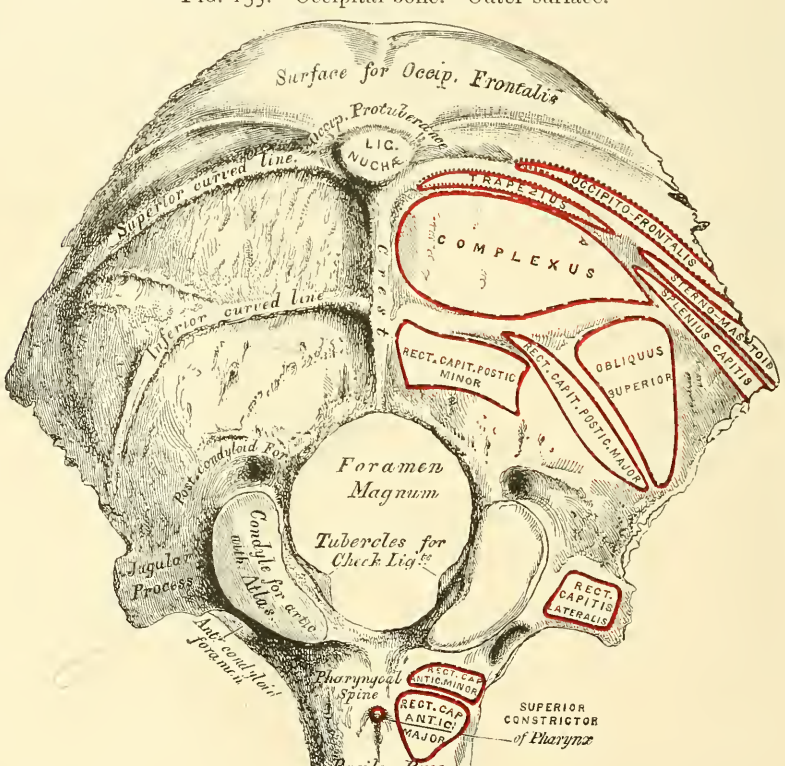
The Occipital Bone

The **Occipital Bone** (ob, caput, *against the head*) is situated at the back part and base of the cranium. It is trapezoid in shape and is much curved on itself (fig. 135). It presents at its front and lower part a large oval aperture, the *foramen magnum*, by which the cranial cavity communicates with the spinal canal. The portion of bone behind this opening is flat and expanded and forms the *tabula*; the portion in front is a thick, elongated mass of bone, the *basilar process*; whilst on either side of the foramen are situated processes bearing the condyles, by which the bone articulates with the atlas. These processes are known as the *condylar portions*. It presents for examination two surfaces, four borders, and four angles.

The **external surface** is convex. Midway between the summit of the bone and the posterior margin of the foramen magnum is a prominent tubercle, the *external occipital protuberance*, for the attachment of the Ligamentum nuchæ; and descending from it as far as the foramen, a vertical ridge, the *external occipital crest*. This tubercle and crest vary in prominence in different skulls. Passing outwards from the occipital protuberance is a semicircular ridge on each side,

the *superior curved line*. Above this line there is often a second less distinctly marked ridge, called the *highest curved line* (*linea suprema*), to it the epicranial aponeurosis is attached. The bone between these two lines is smoother and denser than the rest of the surface. Running parallel with these from the middle of the crest is another semicircular ridge on each side, the *inferior curved line*. The surface of the bone above the linea suprema is rough and porous, and, in the recent state, is covered by the Occipito-frontalis muscle, whilst the ridges, as well as the surface of the bone between them, serve for the attachment of numerous muscles. The superior curved line gives attachment internally to the Trapezius, externally to the muscular origin of the Occipito-frontalis, and to the Sterno-cleido-mastoid, to the extent shown in fig. 135 ; the depressions between the curved lines to the Complexus internally, the Splenius capitis and Obliquus

Fig. 135.—Occipital bone. Outer surface.



capitis superior externally. The inferior curved line, and the depressions below it, afford insertion to the Rectus capitis posticus, major and minor.

The **foramen magnum** is a large, oval aperture, its long diameter extending from before backwards. It transmits the medulla oblongata and its membranes, the spinal accessory nerves, the vertebral arteries, the anterior and posterior spinal arteries, and the occipito-axial ligaments. Its back part is wide for the transmission of the medulla, and the corresponding margin rough for the attachment of the dura mater enclosing it ; the fore part is narrower, being encroached upon by the condyles ; it has projecting towards it, from below, the odontoid process, and its margins are smooth and bevelled internally to support the medulla oblongata. On each side of the foramen magnum are the *condyles*, for articulation with the atlas ; they are convex, oblong or reniform in shape, and directed downwards and outwards ; they converge in front, and encroach slightly upon the anterior segment of the foramen. On the inner border of each

condyle is a rough tubercle for the attachment of the ligaments (*check*) which connect this bone with the odontoid process of the axis; whilst external to them is a rough tubercular prominence, the *transverse* or *jugular process* (the representative of the transverse process of a vertebra), channelled in front by a deep notch, which forms part of the jugular foramen, or foramen lacerum posterius. The under surface of this process presents an eminence, which represents the *paramastoid process* of some mammals. The eminence is occasionally large, and extends as low as the transverse process of the atlas. This surface affords attachment to the Rectus capitis lateralis muscle and to the lateral occipito-atlantal ligament; its upper or cerebral surface presents a deep groove which lodges part of the lateral sinus, whilst its external surface is marked by a quadrilateral rough facet, covered with cartilage in the fresh state, and articulating with a similar surface on the petrous portion of the temporal bone. On the outer side of each condyle, near its fore part, is a foramen, the *anterior condyloid*; it is directed downwards, outwards, and forwards, and transmits the hypoglossal nerve, and occasionally a meningeal branch of the ascending pharyngeal artery. This foramen is sometimes double. Behind each condyle is a fossa,* sometimes perforated at the bottom by a foramen, the *posterior condyloid*, for the transmission of a vein to the lateral sinus. In front of the foramen magnum is a strong quadrilateral plate of bone, the *basilar process*, wider behind than in front; its under surface, which is rough, presenting in the median line a tubercular ridge, the *pharyngeal spine*, for the attachment of the tendinous raphé and Superior constrictor of the pharynx; and on each side of it, rough depressions for the attachment of the Rectus capitis anticus, major and minor.

The **Internal** or **Cerebral Surface** (fig. 136) is deeply concave. The posterior part or tabula is divided by a crucial ridge into four fossæ. The two superior fossæ receive the occipital lobes of the cerebrum, and present slight eminences and depressions corresponding to their convolutions. The two inferior, which receive the hemispheres of the cerebellum, are larger than the former, and comparatively smooth; both are marked by slight grooves for the lodgment of arteries. At the point of meeting of the four divisions of the crucial ridge is an eminence, the *internal occipital protuberance*. It nearly corresponds to that on the outer surface, and is perforated by one or more large vascular foramina. From this eminence, the superior division of the crucial ridge runs upwards to the superior angle of the bone; it presents a deep groove for the superior longitudinal sinus, the margins of which give attachment to the falx cerebri. The inferior division, the *internal occipital crest*, runs to the posterior margin of the foramen magnum, on the edge of which it becomes gradually lost; this ridge, which is bifurcated below, serves for the attachment of the falx cerebelli. It is usually marked by a single groove, which commences at the back part of the foramen magnum and lodges the occipital sinus. Occasionally the groove is double where two sinuses exist. The transverse grooves pass outwards to the lateral angles; they are deeply channelled, for the lodgment of the lateral sinuses, their prominent margins affording attachment to the tentorium cerebelli.† At the point of meeting of these grooves is a depression, the *torcular Herophili*,‡ placed a little to one or the other side of the internal occipital protuberance. More anteriorly is the foramen magnum, and on each side of it, but nearer its anterior than its posterior part, the internal openings of the anterior condyloid foramina; the internal

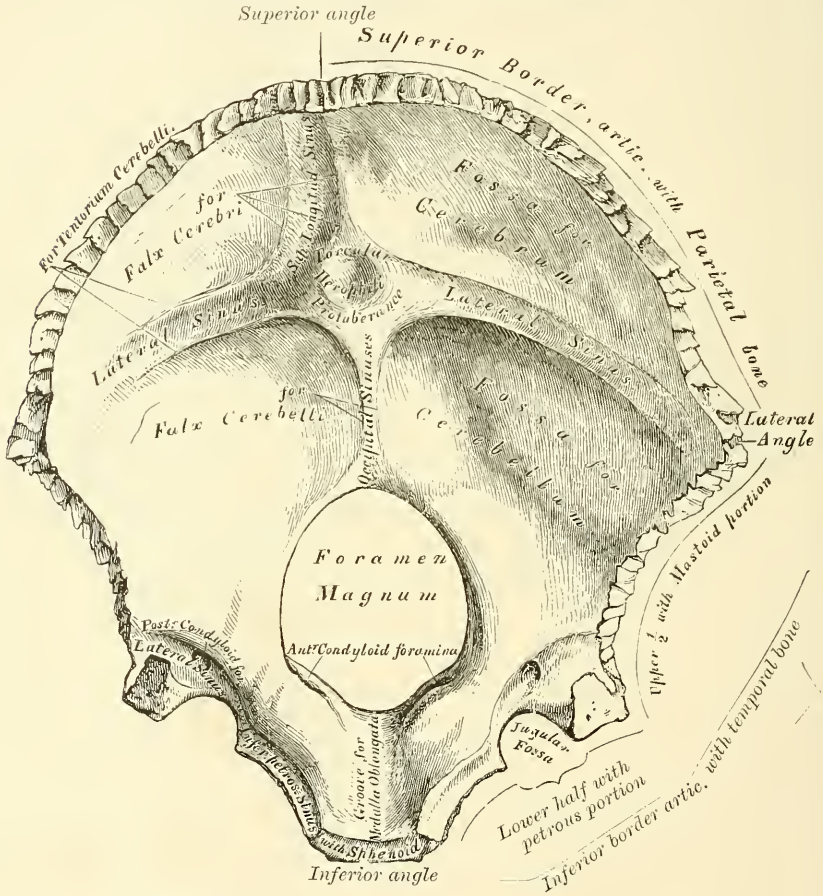
* This fossa presents many variations in size. It is usually shallow, and the foramen small; occasionally wanting on one or both sides. Sometimes both fossa and foramen are large, but confined to one side only; more rarely, the fossa and foramen are very large on both sides.

† Usually one of the transverse grooves is deeper and broader than the other: occasionally, both grooves are of equal depth and breadth, or both equally indistinct. The broader of the two transverse grooves is nearly always continuous with the vertical groove for the superior longitudinal sinus.

‡ The columns of blood coming in different directions were supposed to be *pressed* together at this point (*torcular*, a wine-press).

openings of the posterior condyloid foramina are a little external and posterior to them, protected by a small arch of bone. At this part of the internal surface there is a very deep groove, in which the posterior condyloid foramen, when it exists, has its termination. This groove is continuous, in the complete skull, with the transverse groove on the posterior part of the bone, and lodges the end of the same sinus, the lateral. In front of the foramen magnum is the basilar process, presenting a shallow depression, the *basilar groove*, which slopes from behind, upwards and forwards, and supports the medulla oblongata and part of the pons Varolii, and on each side of the basilar process is a narrow channel,

FIG. 136.—Occipital bone. Inner surface.



which, when united with a similar channel on the petrous portion of the temporal bone, forms a groove, which lodges the inferior petrosal sinus.

Angles.—The *superior* angle is received into the interval between the posterior superior angles of the two parietal bones: it corresponds with that part of the skull in the fœtus which is called the *posterior fontanelle*. The *inferior* angle is represented by the square-shaped surface of the basilar process. At an early period of life, a layer of cartilage separates this part of the bone from the sphenoid; but in the adult, the union between them is osseous. The *lateral* angles correspond to the outer ends of the transverse grooves, and are received into the interval between the posterior inferior angles of the parietal and the mastoid portion of the temporal.

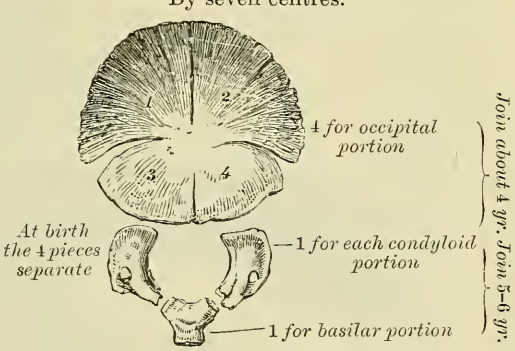
Borders.—The *superior* border extends on each side from the superior to the lateral angle, is deeply serrated for articulation with the parietal bone, and forms,

by this union, the lambdoid suture; the *inferior* border extends from the lateral to the inferior angle; its upper half is rough, and articulates with the mastoid portion of the temporal, forming the masto-occipital suture; the inferior half articulates with the petrous portion of the temporal, forming the petro-occipital suture; these two portions are separated from one another by the jugular process. In front of this process is a deep notch, which, with a similar one on the petrous portion of the temporal, forms the *foramen lacerum posterius* or *jugular foramen*. This notch is occasionally subdivided into two parts by a small process of bone, and it generally presents an aperture at its upper part, the internal opening of the posterior condyloid foramen.

Structure.—The occipital bone consists of two compact laminæ, called the *outer* and *inner tables*, having between them the diploic tissue; this bone is especially thick at the ridges, protuberances, condyles, and anterior part of the basilar process; whilst at the bottom of the fossæ, especially the inferior, it is thin, semi-transparent, and destitute of diploë.

Development (fig. 137).—At birth the bone consists of four distinct parts: a *tabular* or expanded portion, which lies behind the foramen magnum; two *condylar* parts which form the sides of the foramen; and a *basilar* part which lies in front of the foramen. The number of nuclei for the tabular part vary. As a rule there are four, but there may be only one (Blandin), or as many as eight (Meckel). They appear about the eighth week of fœtal life, and soon unite to form a single piece; which is, however, fissured in the direction indicated in the plate. The basilar and two condyloid portions are each developed from a single nucleus, which appears a little later. The upper portion of the tabular surface, that is to say, the portion above the transverse fissures, is developed from membrane; the rest of the bone is developed from cartilage. At about the fourth year, the tabular and the two condyloid pieces join; and about the sixth year, the bone consists of a single piece. At a later period, between the eighteenth and twenty-fifth years, the occipital and sphenoid become united, forming a single bone.

Fig. 137.—Development of occipital bone. By seven centres.



Articulations.—With six bones: two parietal, two temporal, sphenoid, and atlas.

Attachment of Muscles.—To twelve pairs; to the superior curved line are attached the Occipito-frontalis, Trapezius, and Sterno-cleido-mastoid. To the space between the curved lines, the Complexus,* Splenius capitis, and Obliquus capitis superior; to the inferior curved line, and the space between it and the foramen magnum, the Rectus capitis posticus, major and minor; to the transverse process, the Rectus capitis lateralis; and to the basilar process, the Rectus capitis anticus, major and minor, and Superior constrictor of the pharynx.

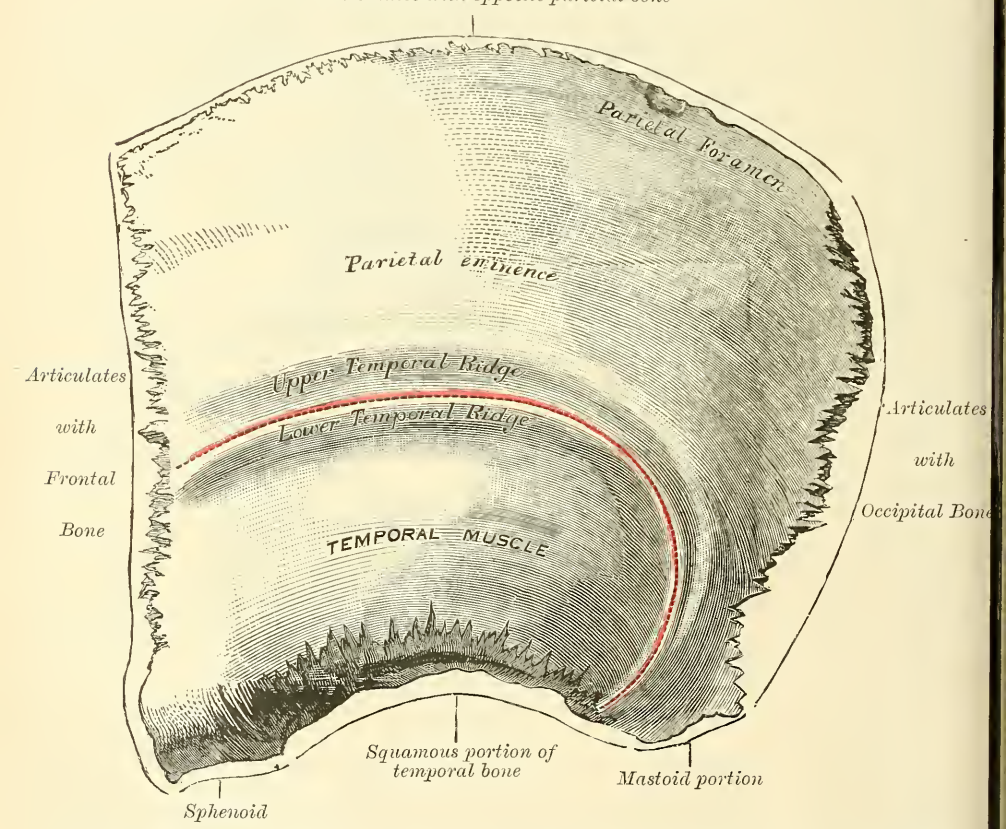
The Parietal Bones

The **Parietal Bones** (paries, *a wall*) form, by their union, the sides and roof of the skull. Each bone is of an irregular quadrilateral form, and presents for examination two surfaces, four borders, and four angles.

* To these the Biventer cervicis should be added, if it is regarded as a separate muscle.

Surfaces.—The *external surface* (fig. 138) is convex, smooth, and marked about its centre by an eminence, called the *parietal eminence*, which indicates the point where ossification commenced. Crossing the middle of the bone in an arched direction are two well-marked curved lines or ridges, of which the lower is the more distinct and is termed the *temporal ridge*; it marks the upper attachment of the temporal muscle, and follows a semicircular course across the bone. The upper ridge is less marked, and pursues a similar course across the bone, but about two-fifths of an inch above the temporal ridge; it marks the attachment of the temporal fascia. Above these ridges, the surface of the bone is rough and porous, and covered by the aponeurosis of the Occipito-frontalis; between them the bone is smoother and more polished than the rest; below them the bone forms part of the temporal fossa, and affords attachment to the Temporal muscle. At the back part of the superior border, close to the sagittal suture, is a small

Fig. 138.—Left parietal bone. External surface.



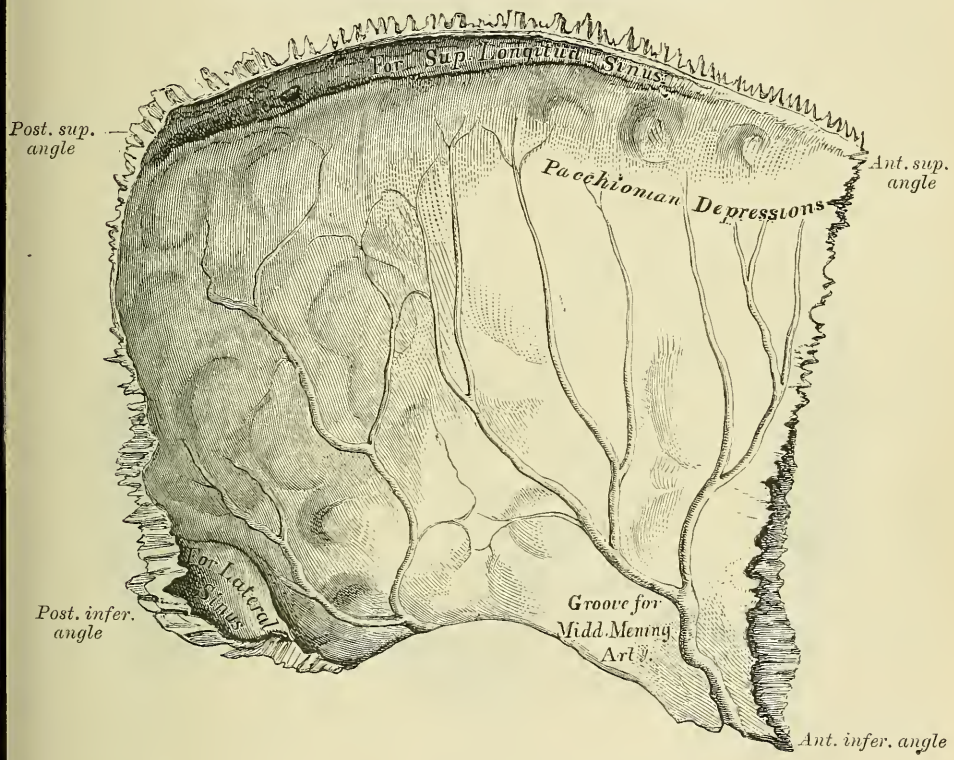
foramen, the *parietal foramen*, which transmits a vein to the superior longitudinal sinus, and sometimes a small branch of the occipital artery. Its existence is not constant, and its size varies considerably.

The **internal surface** (fig. 139), concave, presents eminences and depressions for lodging the convolutions of the cerebrum, and numerous furrows for the ramifications of the meningeal arteries; the latter run upwards and backwards from the anterior inferior angle, and from the central and posterior part of the lower border of the bone. Along the upper margin is part of a shallow groove, which, when joined to the opposite parietal, forms a channel for the superior longitudinal sinus, the elevated edges of which afford attachment to the falx cerebri. Near the groove are seen several depressions, especially in the skulls

of old persons; they lodge the Pacchionian bodies. The internal opening of the parietal foramen is also seen when that aperture exists.

Borders.—The *superior*, the longest and thickest, is dentated to articulate with its fellow of the opposite side, forming the sagittal suture. The *inferior* is divided into three parts: of these, the anterior is thin and pointed, bevelled at the expense of the outer surface, and overlapped by the tip of the great wing of the sphenoid; the middle portion is arched, bevelled at the expense of the outer surface, and overlapped by the squamous portion of the temporal; the posterior portion is thick and serrated for articulation with the mastoid portion of the temporal. The *anterior* border, deeply serrated, is bevelled at the expense of the outer surface above and of the inner below; it articulates with the frontal bone, forming the *coronal suture*. The *posterior* border, deeply denticulated, articulates with the occipital, forming the *lambdoid suture*.

FIG. 139.—Left parietal bone. Internal surface.



Angles.—The *anterior superior* angle, thin and pointed, corresponds with that portion of the skull which in the fœtus is membranous, and is called the *anterior fontanelle*. The *anterior inferior* angle is thin and lengthened, being received in the interval between the great wing of the sphenoid and the frontal. Its inner surface is marked by a deep groove, sometimes a canal, for the anterior branch of the middle meningeal artery. The *posterior superior* angle corresponds with the junction of the sagittal and lambdoid sutures. In the fœtus this part of the skull is membranous, and is called the *posterior fontanelle*. The *posterior inferior* angle articulates with the mastoid portion of the temporal bone, and generally presents on its inner surface a broad, shallow groove for lodging part of the lateral sinus.

Development.—The parietal bone is formed in membrane, being developed by one centre, which corresponds with the parietal eminence, and makes its first appearance about the seventh or eighth week of fœtal life. Ossification gradually

extends from the centre to the circumference of the bone: the angles are consequently the parts last formed, and it is in their situation that the fontanelles exist previous to the completion of the growth of the bone.

Articulations.—With five bones: the opposite parietal, the occipital, frontal, temporal, and sphenoid.

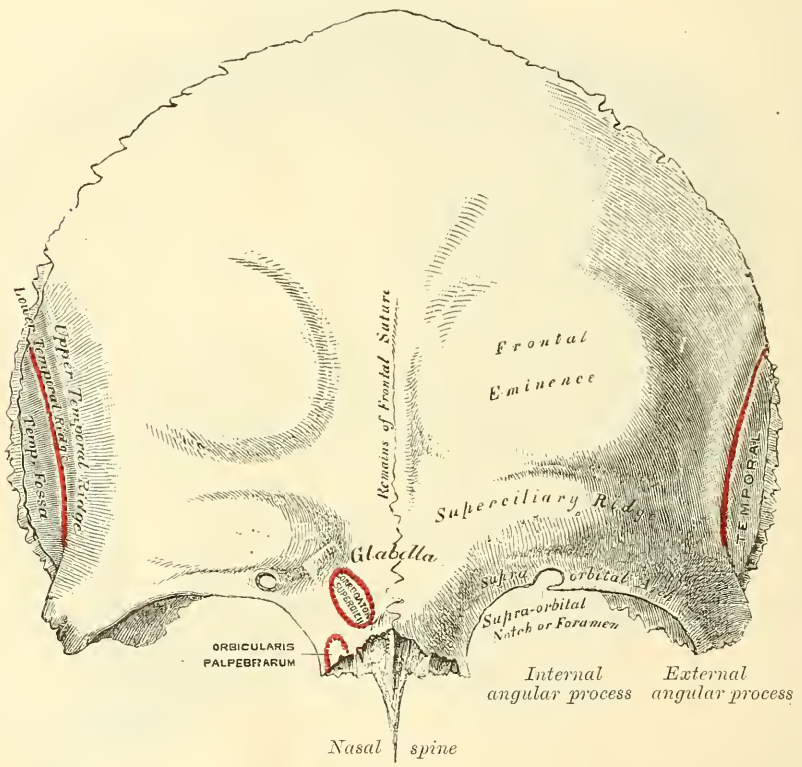
Attachment of Muscles.—One only, the Temporal.

The Frontal Bone

The **Frontal Bone** (frons, *the forehead*) resembles a cockle-shell in form, and consists of two portions—a *vertical* or *frontal* portion situated at the anterior part of the cranium, forming the forehead; and a *horizontal* or *orbito-nasal* portion which enters into the formation of the roof of the orbits and nasal fossæ.

Vertical Portion.—*External Surface* (fig. 140).—In the median line, traversing

Fig. 140.—Frontal bone. Outer surface.



the bone from the upper to the lower part, is occasionally seen a slightly elevated ridge, and in young subjects a suture, which represents the line of union of the two lateral halves of which the bone consists at an early period of life: in the adult this suture is usually obliterated, and the bone forms one piece; traces of the obliterated suture are, however, generally perceptible at the lower part. On either side of this ridge, a little below the centre of the bone, is a rounded eminence, the *frontal eminence*. These eminences vary in size in different individuals, and are occasionally unsymmetrical in the same subject. They are especially prominent in cases of well-marked cerebral development. The whole surface of the bone above this part is smooth, and covered by the aponeurosis of the Occipito-frontalis muscle. Below the frontal eminence, and separated from it by a slight groove, is the *superciliary ridge*, broad internally, where it is continuous with the nasal eminence, but less distinct as it arches outwards. These

ridges are caused by the projection outwards of the frontal sinuses,* and give attachment to the Orbicularis palpebrarum and Corrugator supercilii. Between the two superciliary ridges is a smooth surface, the *glabella* or *nasal eminence*. Beneath the superciliary ridge is the *supra-orbital arch*, a curved and prominent margin, which forms the upper boundary of the orbit, and separates the vertical from the horizontal portion of the bone. The outer part of the arch is sharp and prominent, affording to the eye, in that situation, considerable protection from injury; the inner part is less prominent. At the junction of the internal and middle third of this arch is a notch, sometimes converted into a foramen by a bony process, and called the *supra-orbital notch* or *foramen*. It transmits the supra-orbital artery, vein, and nerve. A small aperture is seen in the upper part of the notch, which transmits a vein from the diploë to join the supra-orbital vein. The supra-orbital arch terminates externally in the *external angular process*, and internally in the *internal angular process*. The external angular process is strong, prominent, and articulates with the malar bone; running upwards and backwards from it are two well-marked lines, which, commencing together from the external angular process, soon diverge from each other and run in a curved direction across the bone. The lower one, the *temporal ridge*, gives attachment to the Temporal muscle, the upper one to the temporal fascia. Beneath them is a slight concavity, that forms the anterior part of the temporal fossa, and gives origin to the Temporal muscle. The internal angular processes are less marked than the external, and articulate with the lachrymal bones. Between the internal angular processes is a rough, uneven interval, the *nasal notch*, which articulates in the middle line with the nasal bone, and on either side with the nasal process of the superior maxillary bone. From the concavity of this notch projects a process, the *nasal process*, which extends beneath the nasal bones and nasal processes of the superior maxillary bones, and supports the bridge of the nose. On the under surface of this is a long pointed process, the *nasal spine*, and on either side a small grooved surface enters into the formation of the roof of the nasal fossa. The nasal spine forms part of the septum of the nose, articulating in front with the nasal bones and behind with the perpendicular plate of the ethmoid.

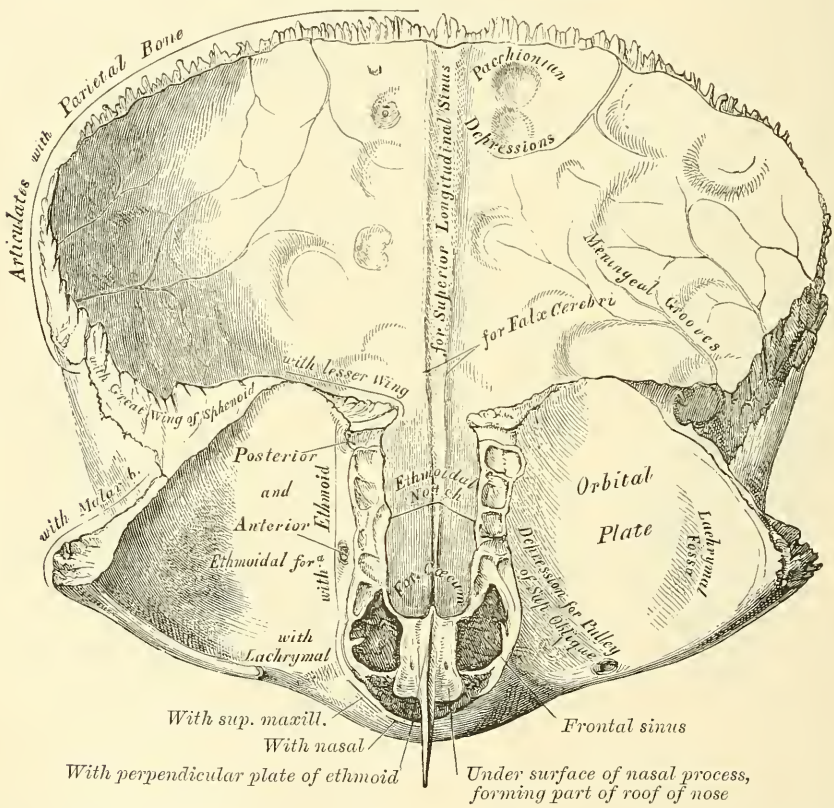
Internal Surface (fig. 141).—Along the middle line is a vertical groove, the edges of which unite below to form a ridge, the *frontal crest*; the groove lodges the superior longitudinal sinus, whilst its margins afford attachment to the falx cerebri. The crest terminates below at a small notch which is converted into a foramen by articulation with the ethmoid. It is called the *foramen cæcum*, and varies in size in different subjects; it is sometimes partially or completely impervious, lodges a process of the falx cerebri, and, when open, transmits a vein from the lining membrane of the nose to the superior longitudinal sinus. On either side of the groove the bone is deeply concave, presenting eminences and depressions for the convolutions of the brain, and numerous small furrows for lodging the ramifications of the anterior meningeal arteries. Several small, irregular fossæ are also seen on either side of the groove, for the reception of the Pacchionian bodies.

Horizontal Portion.—*External Surface.*—This portion of the bone consists of two thin plates, the *orbital plates*, which form the vault of the orbit, separated from one another by a median gap, the *ethmoidal notch*. Each orbital plate consists of a smooth, concave, triangular lamina of bone, marked at its anterior and

* Some confusion is occasioned to students commencing the study of anatomy by the name 'sinuses' having been given to two perfectly different kinds of spaces connected with the skull. It may be as well, therefore, to state here, at the outset, that the 'sinuses' in the interior of the cranium which produce the grooves on the inner surface of the bones are venous channels along which the blood runs in its passage back from the brain, while the 'sinuses' external to the cranial cavity (the frontal, sphenoidal, ethmoidal, and maxillary) are hollow spaces in the bones themselves which communicate with the nostrils, and contain air.

external part (immediately beneath the external angular process) by a shallow depression, the *lachrymal fossa*, for lodging the lachrymal gland; and at its anterior and internal part, by a depression (sometimes a small tubercle), the *trochlear fossa*, for the attachment of the cartilaginous pulley of the Superior oblique muscle of the eye. The ethmoidal notch separates the two orbital plates; it is quadrilateral, and filled up, when the bones are united, by the cribriform plate of the ethmoid. The margins of this notch present several half-cells, which, when united with corresponding half-cells on the upper surface of the ethmoid, complete the ethmoidal cells; two grooves are also seen crossing these edges transversely; they are converted into canals by articulation with the ethmoid, and are called the *anterior* and *posterior ethmoidal* canals: they open on the inner wall of the orbit. The anterior one transmits the nasal nerve and anterior ethmoidal vessels, the posterior one the posterior ethmoidal vessels. In

Fig. 141.—Frontal bone. Inner surface.



front of the ethmoidal notch, on either side of the nasal spine, are the openings of the frontal sinuses. These are two irregular cavities, which extend upwards and outwards, a variable distance, between the two tables of the skull, and are separated from one another by a thin, bony septum. They give rise to the prominences above the supra-orbital arches called the *superciliary ridges*. In the child they are generally absent, and they become gradually developed as age advances. These cavities vary in size in different persons, are larger in men than in women, and are frequently of unequal size on the two sides, the right being commonly the larger. They are subdivided by a bony lamina, which is often displaced to one side. They are lined by mucous membrane, and communicate with the nose by the infundibulum, and occasionally with each other by apertures in their septum.

The **internal surface of the horizontal portion** presents the convex upper

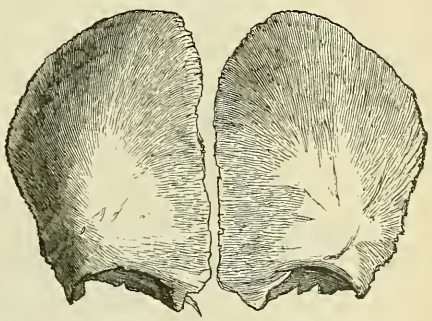
surfaces of the orbital plates, separated from each other in the middle line by the ethmoidal notch, and marked by eminences and depressions for the convolutions of the frontal lobes of the brain.

Borders.—The border of the vertical portion is thick, strongly serrated, bevelled at the expense of the internal table above, where it rests upon the parietal bones, and at the expense of the external table at each side, where it receives the lateral pressure of those bones; this border is continued below into a triangular, rough surface, which articulates with the great wing of the sphenoid. The border of the horizontal portion is thin, serrated, and articulates with the lesser wing of the sphenoid.

Structure.—The vertical portion and external angular processes are very thick, consisting of diploic tissue contained between two compact laminæ. The horizontal portion is thin, translucent, and composed entirely of compact tissue; hence the facility with which instruments can penetrate the cranium through this part of the orbit.

Development (fig. 142).—The frontal bone is formed in membrane, being developed by *two* centres, one for each lateral half, which make their appearance about the seventh or eighth week, above the orbital arches. From this point ossification extends, in a radiating manner, upwards into the forehead, and backwards over the orbit. At birth the bone consists of two pieces, which afterwards become united, along the middle line, by a suture which runs from the vertex to the root of the nose. This suture usually becomes obliterated within a few years after birth; but it occasionally remains throughout life. Occasionally secondary centres of ossification appear for the nasal spine; one on either side at the internal angular process where it articulates with the lachrymal bone; and sometimes there is one on either side at the lower end of the coronal suture. This latter centre sometimes remains ununited, and is known as the pterion ossicle; or it may join with the parietal, sphenoid, or temporal bone.

Fig. 142.—Frontal bone at birth. Developed by two lateral halves.



Articulations.—With twelve bones: two parietal, the sphenoid, the ethmoid, two nasal, two superior maxillary, two lachrymal, and two malar.

Attachment of Muscles.—To three pairs: the Corrugator supercilii, Orbicularis palpebrarum, and Temporal on each side.

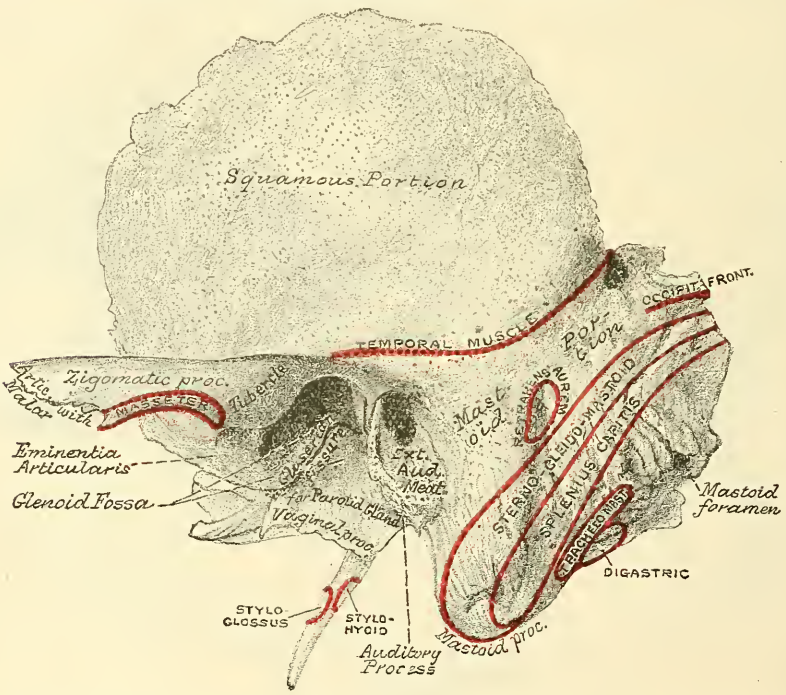
The Temporal Bones

The **Temporal Bones** (tempus, *time*) are situated at the sides and base of the skull, and present for examination a *squamous*, *mastoid*, and *petrous* portion.

The **squamous portion** (squama, *a scale*), the anterior and upper part of the bone, is scale-like in form, and thin and translucent in texture (fig. 143). Its *outer surface* is smooth, convex, and grooved at its back part for the deep temporal arteries; it affords attachment to the Temporal muscle, and forms part of the temporal fossa. At its back part may be seen a curved ridge—part of the *temporal ridge*; it serves for the attachment of the temporal fascia, limits the origin of the Temporal muscle, and marks the boundary between the squamous and mastoid portions of the bone. Projecting from the lower part of the squamous portion is a long, arched process of bone, the *zygoma* or zygomatic process. This process is at first directed outwards, its two surfaces looking upwards and downwards; it then appears as if twisted upon itself, and runs forwards, its surfaces now looking inwards and outwards. The superior border

of the process is long, thin, and sharp, and serves for the attachment of the temporal fascia. The inferior, short, thick, and arched, has attached to it some fibres of the Masseter muscle. Its outer surface is convex and subcutaneous; its inner is concave, and also affords attachment to the Masseter. The extremity, broad and deeply serrated, articulates with the malar bone. The zygomatic process is connected to the temporal bone by three divisions, called its *roots*—an anterior, middle, and posterior. The anterior, which is short, but broad and strong, is directed inwards, to terminate in a rounded eminence, the *eminentia articularis*. This eminence forms the front boundary of the glenoid fossa, and in the recent state is covered with cartilage. The middle root forms the outer margin of the glenoid fossa; running obliquely inwards, it terminates at the commencement of a well-marked fissure, the *Glaserian fissure*; whilst the posterior root, which is strongly marked, runs from the upper border of the zygoma, backwards over the external auditory meatus. It is termed the *supra-*

FIG. 143.—Left temporal bone. Outer surface.

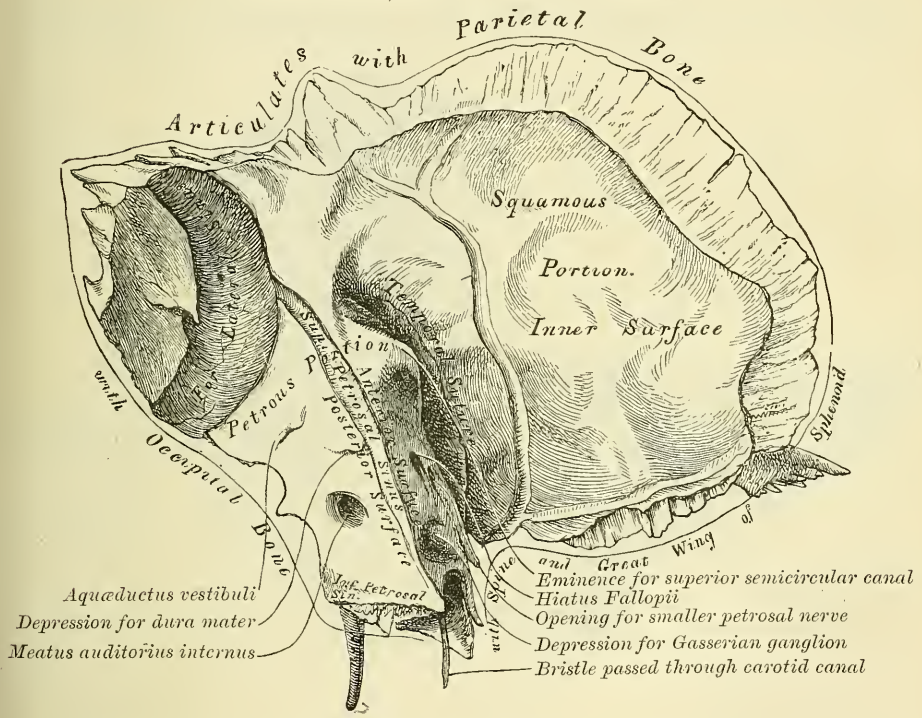


mastoid crest, and separates the squamous from the mastoid portion of the bone. At its posterior extremity it becomes continuous with the temporal ridge. At the junction of the anterior root with the zygoma is a projection, called the *tubercle*, for the attachment of the external lateral ligament of the lower jaw; and between the anterior and middle roots is an oval depression, forming part of the glenoid fossa (γλήνη, *a socket*), for the reception of the condyle of the lower jaw. This fossa is bounded, in front, by the eminentia articularis; behind, by the tympanic plate; and, externally, by the middle root of the zygoma; and is divided into two parts by a narrow slit, the *Glaserian fissure*. The anterior part, formed by the squamous portion of the bone, is smooth, covered in the recent state with cartilage, and articulates with the condyle of the lower jaw. This part of the glenoid fossa presents posteriorly a small conical eminence, situated at the extremity of the middle root and in front of the external auditory meatus; it is known as the *post-glenoid process*, and is the representative of a prominent tubercle which, in some of the mammalia, descends behind the condyle of the jaw, and prevents it being displaced backwards during mastication

(Humphry). The posterior part of the glenoid fossa, which lodges a portion of the parotid gland, is formed chiefly by a lamina of bone, the *tympanic plate*, which forms the anterior wall of the tympanum and external auditory meatus. This plate of bone terminates above in the Glaserian fissure, and below forms a sharp edge, the *vaginal* process, which gives origin to some of the fibres of the Tensor palati muscle. The Glaserian fissure, which leads into the tympanum, lodges the processus gracilis of the malleus, and transmits the tympanic branch of the internal maxillary artery. The chorda tympani nerve passes through a separate canal, parallel to the Glaserian fissure (*canal of Huguier*), on the outer side of the Eustachian tube, in the retiring angle between the squamous and petrous portions of the temporal bone.*

The **internal surface** of the squamous portion (fig. 144) is concave, presents numerous eminences and depressions for the convolutions of the cerebrum, and two well-marked grooves for the branches of the middle meningeal artery.

Fig. 144.—Left temporal bone. Inner surface.



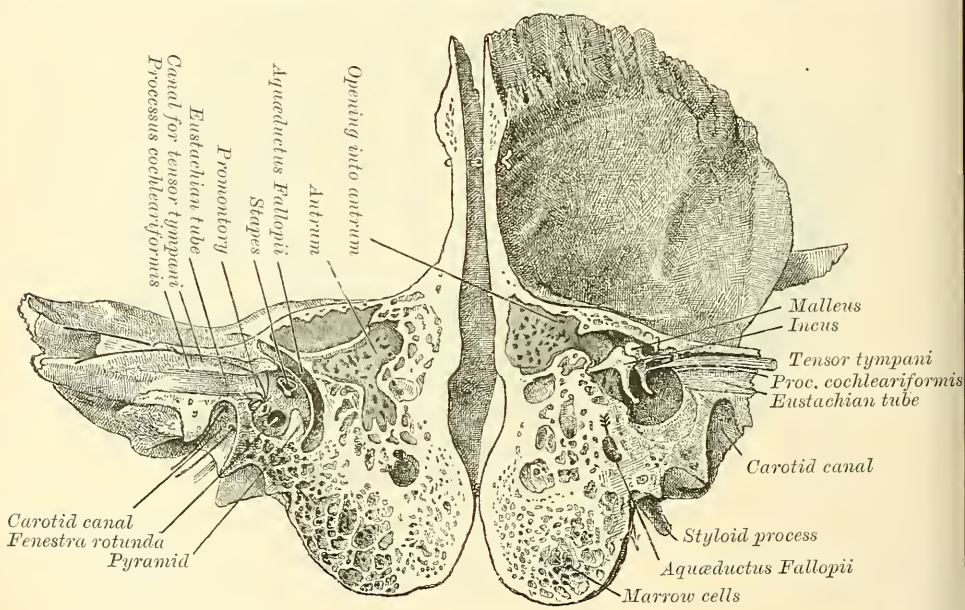
Borders.—The superior border is thin, bevelled at the expense of the internal surface, so as to overlap the lower border of the parietal bone, forming the squamous suture. The anterior inferior border is thick, serrated, and bevelled, alternately at the expense of the inner and outer surfaces, for articulation with the great wing of the sphenoid.

The **Mastoid Portion** (μαστός, *a nipple* or *teat*) is situated at the posterior part of the bone; its outer surface is rough, and gives attachment to the Occipito-frontalis and Retrahens aurem muscles. It is perforated by numerous foramina; one of these, of large size, situated at the posterior border of the bone, is termed the *mastoid foramen*; it transmits a vein to the lateral sinus and a small artery from the occipital, to supply the dura mater. The position and size of this foramen are very variable. It is not always present; sometimes it is situated in

* This small fissure must not be confounded with the large canal which lies above the Eustachian tube and transmits the Tensor tympani muscle.

the occipital bone, or in the suture between the temporal and the occipital. The mastoid portion is continued below into a conical projection, the *mastoid process*, the size and form of which vary somewhat. This process serves for the attachment of the Sterno-mastoid, Splenius capitis, and Trachelo-mastoid muscles. On the inner side of the mastoid process is a deep groove, the *digastric fossa*, for the attachment of the Digastric muscle; and, running parallel with it, but more internal, the *occipital groove*, which lodges the occipital artery. The internal surface of the mastoid portion presents a deep, curved groove, the *fossa sigmoidea*, which lodges part of the lateral sinus; and into it may be seen opening the mastoid foramen. A section of the mastoid process shows it to be hollowed out into a number of cellular spaces, communicating with each other, called the *mastoid cells*. These cells, at the upper and front part of the bone, are large and irregular and contain air, but towards the lower part of the bone they diminish in size, whilst those at the apex of the mastoid process are quite small and usually contain marrow. In addition to these may be seen a large

Fig. 145.—Section through the petrous and mastoid portions of the temporal bone, showing the communication of the cavity of the tympanum with the mastoid antrum.



irregular cavity (fig. 145) situated at the upper and front part of the section. It is called the *mastoid antrum* and must be distinguished from the mastoid cells, though it communicates with them. It is filled with air and is lined by a prolongation of the mucous membrane of the tympanum, which extends into it through an opening, by which it communicates with the cavity of the tympanum. The mastoid antrum is bounded above by a thin plate of bone, which separates it from the middle fossa of the base of the skull on the anterior surface of the petrous portion of the temporal bone; below by the mastoid process; externally by the squamous portion of the bone just below the supra-mastoid crest, and internally by the external semicircular canal of the internal ear which projects into its cavity. The opening by which it communicates with the tympanum is situated at the superior internal angle of the posterior wall of that cavity, and opens into that portion of the tympanic cavity which is known as the *attic*, that is to say, that portion of the tympanum which is above the level of the superior margin of the external auditory meatus.

The mastoid cells, like the other sinuses of the cranium, are not developed

until after puberty; hence the prominence of this process in the adult. But the mastoid antrum is of large size at birth; as however the bone increases in thickness the cavity becomes relatively smaller.

In consequence of the communication which exists between the tympanum and mastoid antrum, inflammation of the lining membrane of the former cavity may easily travel backwards to that of the antrum, leading to caries and necrosis of its walls and the risk of transference of the inflammation to the lateral sinus or encephalon.

Borders.—The superior border of the mastoid portion is broad and rough, its serrated edge sloping outwards, for articulation with the posterior inferior angle of the parietal bone. The posterior border, also uneven and serrated, articulates with the inferior border of the occipital bone between its lateral angle and jugular process.

The **Petrous Portion** (*πέτρος, a stone*), so named from its extreme density and hardness, is a pyramidal process of bone, wedged in at the base of the skull between the sphenoid and occipital bones. Its direction from without is inwards, forwards, and a little downwards. It presents for examination a base, an apex, three surfaces, and three borders; and contains, in its interior, the essential parts of the organ of hearing. The *base* is applied against the internal surface of the squamous and mastoid portions, its upper half being concealed; but its lower half is exposed by the divergence of these two portions of the bone, which brings into view the oval expanded orifice of a canal leading into the tympanum, the *meatus auditorius externus*. This canal is situated in front of the mastoid process, and between the posterior and middle roots of the zygoma; its upper margin is smooth and rounded, but the greater part of its circumference is surrounded by a curved plate of bone, the *tympanic plate*, the free margin of which is thick and rough, for the attachment of the cartilage of the external ear.

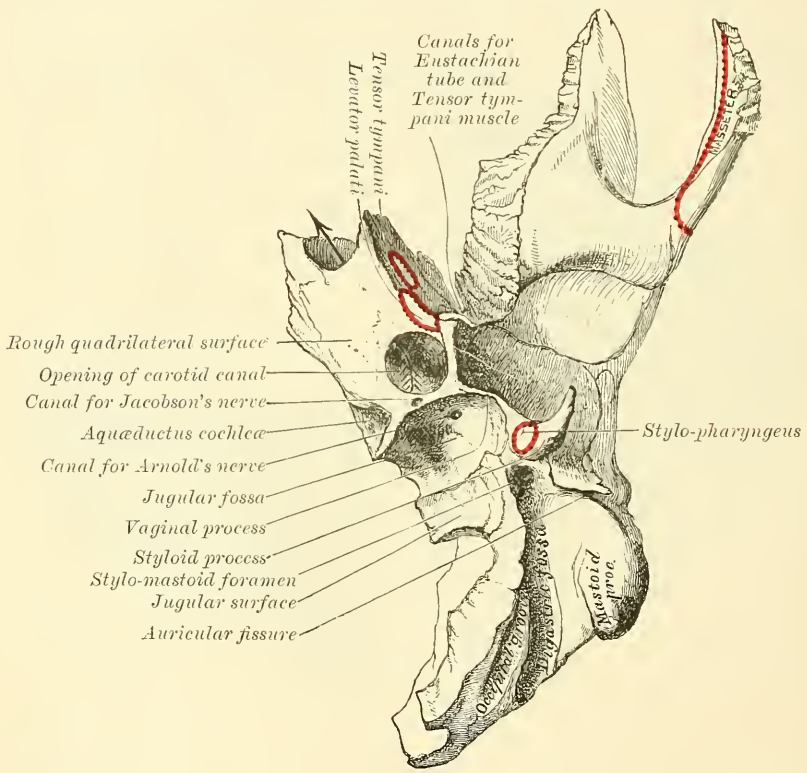
The **apex** of the petrous portion, rough and uneven, is received into the angular interval between the posterior border of the greater wing of the sphenoid and the basilar process of the occipital; it presents the anterior or internal orifice of the carotid canal, and forms the posterior and external boundary of the foramen lacerum medium.

The **anterior surface** of the petrous portion (fig. 144) forms the posterior part of the middle fossa of the skull. This surface is continuous with the squamous portion, to which it is united by a suture, the *temporal* or *petro-squamous suture*, the remains of which are distinct even at a late period of life; it presents six points for examination: 1. an eminence near the centre, which indicates the situation of the superior semicircular canal: 2. in front and a little to the outer side of this eminence a depression, indicating the position of the tympanum; here the layer of bone which separates the tympanum from the cranial cavity is extremely thin, and is known as the *tegmen tympani*: 3. a shallow groove, sometimes double, leading outwards and backwards to an oblique opening, the *hiatus Fallopii*, for the passage of the petrosal branch of the Vidian nerve and the petrosal branch of the middle meningeal artery: 4. a smaller opening, occasionally seen external to the latter, for the passage of the smaller petrosal nerve: 5. near the apex of the bone, the termination of the carotid canal, the wall of which in this situation is deficient in front: 6. above this canal a shallow depression for the reception of the Gasserian ganglion.

The **posterior surface** forms the front part of the posterior fossa of the skull, and is continuous with the inner surface of the mastoid portion of the bone. It presents three points for examination: 1. about its centre, a large orifice, the *meatus auditorius internus*, the size of which varies considerably; its margins are smooth and rounded; and it leads into a short canal, about four lines in length, which runs directly outwards, and is closed by a vertical plate, the *lamina cribrosa*, which is divided by a horizontal crest, the *crista falciformis*, into two unequal portions; the *lower* presenting three foramina, or sets of foramina; one, just below the posterior part of the crest, consisting of a number of small openings

for the nerves to the saccule; a second, below and posterior to this, for the nerve to the posterior semicircular canal; and a third, in front and below the first, consisting of a number of small openings which terminate in the canalis centralis cochleæ and transmit the nerve to the cochlea; the *upper* portion, that above the crista, presents behind a series of small openings for the passage of filaments to the vestibule and superior and external semicircular canals, and, in front, one large opening, the commencement of the aquæductus Fallopii, for the passage of the facial nerve: 2. behind the meatus auditorius, a small slit almost hidden by a thin plate of bone, leading to a canal, the *aquæductus vestibuli*, which transmits a small artery and vein, and lodges a process of the dura mater: 3. in the interval between these two openings, but above them, an angular depression which lodges a process of the dura mater, and transmits a small vein into the cancellous tissue of the bone.

Fig. 146.—Petrous portion. Inferior surface.



The **inferior** or **basilar** surface (fig. 146) is rough and irregular, and forms part of the base of the skull. Passing from the apex to the base, this surface presents eleven points for examination: 1. a rough surface, quadrilateral in form, which serves partly for the attachment of the Levator palati and Tensor tympani muscles: 2. the large, circular aperture of the carotid canal, which ascends at first vertically, and then, making a bend, runs horizontally forwards and inwards; it transmits the internal carotid artery, and the carotid plexus: 3. the *aquæductus cochleæ*, a small, triangular opening, lying on the inner side of the latter, close to the posterior border of the petrous portion; it transmits a vein from the cochlea, which joins the internal jugular: 4. behind these openings a deep depression, the *jugular fossa*, which varies in depth and size in different skulls; it lodges the lateral sinus, and, with a similar depression on the margin of the jugular process of the occipital bone, forms the foramen lacerum posterius, or jugular foramen: 5. a small foramen for the passage of Jacobson's nerve (the tympanic branch of

the glosso-pharyngeal); this foramen is seen in the bony ridge dividing the carotid canal from the jugular fossa: 6. a small foramen on the wall of the jugular fossa, for the entrance of the auricular branch of the pneumogastric (Arnold's nerve): 7. behind the jugular fossa, a smooth, square-shaped facet, the *jugular surface*; it is covered with cartilage in the recent state, and articulates with the jugular process of the occipital bone: 8. the *vaginal process*, a very broad, sheath-like plate of bone, which extends backwards from the carotid canal and gives attachment to part of the Tensor palati muscle; this plate divides behind into two laminæ, the outer of which is continuous with the auditory process, the inner with the jugular process: between these laminæ is the 9th point for examination, the *styloid process*; a long, sharp spine, about an inch in length; it is directed downwards, forwards, and inwards, varies in size and shape, and sometimes consists of several pieces united by cartilage; it affords attachment to three muscles, the Stylo-pharyngeus, Stylo-hyoideus, and Stylo-glossus; and two ligaments, the stylo-hyoid and stylo-maxillary: 10. the *stylo-mastoid foramen*, a rather large orifice, placed between the styloid and mastoid processes; it is the termination of the aquæductus Fallopii, and transmits the facial nerve and stylo-mastoid artery: 11. the *auricular fissure*, situated between the tympanic plate and mastoid processes, for the exit of the auricular branch of the pneumogastric nerve.

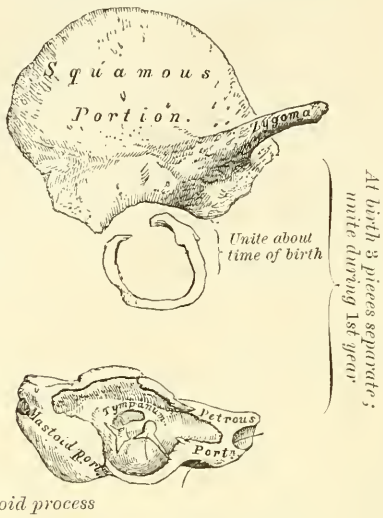
Borders.—The *superior*, the longest, is grooved for the superior petrosal sinus, and has attached to it the tentorium cerebelli; at its inner extremity is a semilunar notch, upon which the fifth nerve lies. The *posterior* border is intermediate in length between the superior and the anterior. Its inner half is marked by a groove, which, when completed by its articulation with the occipital, forms the channel for the inferior petrosal sinus. Its outer half presents a deep excavation—the *jugular fossa*—which, with a similar notch on the occipital, forms the foramen lacerum posterius. A projecting eminence of bone occasionally stands out from the centre of the notch, and divides the foramen into two parts. The *anterior* border is divided into two parts—an outer joined to the squamous portion by a suture, the remains of which are distinct; an inner, free, articulating with the spinous process of the sphenoid. At the angle of junction of the petrous and squamous portions are seen two canals, separated from one another by a thin plate of bone, the *processus cochleariformis*; they both lead into the tympanum, the upper one transmitting the Tensor tympani muscle, the lower one the Eustachian tube.

Structure.—The squamous portion is like that of the other cranial bones: the mastoid portion cellular, and the petrous portion dense and hard.

Development (fig. 147).—The temporal bone is developed by *ten* centres, exclusive of those for the internal ear and the ossicula—viz. one for the squamous portion including the zygoma, one for the tympanic plate, six for the petrous and mastoid parts, and two for the styloid process. Just before the close of fœtal life the temporal bone consists of four parts: 1. The *squamo-zygomatic*, which is ossified in membrane from a single nucleus, which appears at its lower part about the second month. 2. The *tympanic plate*, an imperfect ring, which encloses the tympanic membrane. This is also ossified from a single centre which appears rather later than that for the squamous portion. 3. The *petro-mastoid*, which is developed from six centres, which appear about the fifth or sixth month. Four of these are for the petrous portion, and are placed around the labyrinth, and two for the mastoid (Vrolik). According to Huxley, the centres are more numerous, and are disposed so as to form three portions: (1) including most of the labyrinth with a part of the petrous and mastoid, he has named *prootic*; (2) the rest of the petrous, the *opisthotic*; and (3) the remainder of the mastoid, the *epiotic*. The petro-mastoid is ossified in cartilage. 4. The *styloid process* is also ossified in cartilage from two centres: one for the base, which appears before birth, and is termed the *tympano-hyal*; the other, comprising the rest of the process, is named the *stylo-hyal*, and does not appear until after birth. Shortly before birth the

tympanic plate joins with the squamous. The petrous and mastoid join with the squamous during the first year, and the tympano-hyal portion of the styloid process about the same time. The stylo-hyal does not join the rest of the bone until after puberty, and in some skulls never becomes united. The subsequent changes in this bone are, that the tympanic plate extends outwards, so as to form the meatus auditorius; the glenoid fossa becomes deeper; and the mastoid part, which at an early period of life is quite flat, enlarges from the development of the cellular cavities in its interior.

Fig. 147.—Development of the temporal bone. By ten centres.



Articulations.—With five bones—occipital, parietal, sphenoid, inferior maxillary, and malar.

Attachment of Muscles.—To fifteen: to the squamous portion, the Temporal; to the zygoma, the Masseter; to the mastoid portion, the Occipito-frontalis, Sterno-mastoid, Splenius capitis, Trachelo-mastoid, Digastricus, and Retrahens aurem; to the styloid process, the Stylo-pharyngeus, Stylo-hyoideus, and Stylo-glossus; and to the petrous portion, the Levator palati, Tensor tympani, Tensor palati, and Stapedius.

The Sphenoid Bone

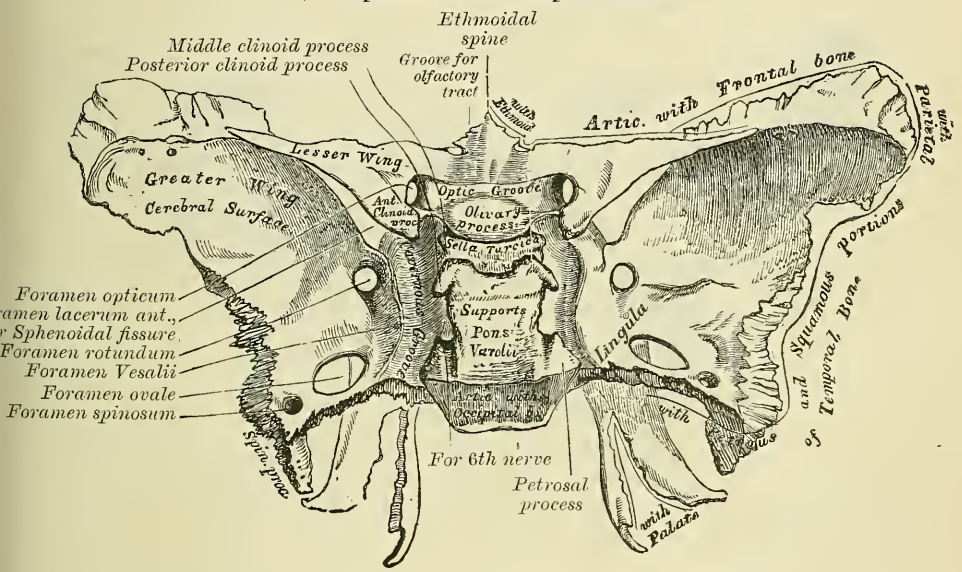
The **Sphenoid Bone** (*σφήν, a wedge*) is situated at the anterior part of the base of the skull, articulating with all the other cranial bones, which it binds firmly and solidly together. In its form it somewhat resembles a bat with its wings extended; and is divided into a central portion or body, two greater and two lesser wings extending outwards on each side of the body, and two processes—the pterygoid processes—which project from it below.

The **body** is of large size, cuboid in form, and hollowed out in its interior so as to form a mere shell of bone. It presents for examination *four* surfaces—a superior, an inferior, an anterior, and a posterior.

The Superior Surface (fig. 148).—In front is seen a prominent spine, the *ethmoidal spine*, for articulation with the cribriform plate of the ethmoid; behind this a smooth surface presenting, in the median line, a slight longitudinal eminence, with a depression on each side, for lodging the olfactory tracts. This surface is bounded behind by a ridge, which forms the anterior border of a narrow, transverse groove, the *optic groove*; it lodges the optic commissure, and terminates on either side in the *optic foramen*, for the passage of the optic nerve and ophthalmic artery. Behind the optic goove is a small eminence, olive-like in shape, the *olivary process*; and still more posteriorly, a deep depression, the *pituitary fossa*, or *sella turcica*, which lodges the pituitary body. This fossa is perforated by numerous foramina, for the transmission of nutrient vessels into the substance of the bone. It is bounded in front by two small eminences, one on either side, called the *middle clinoid processes* (*κλίνη, a bed*), which are sometimes connected by a spiculum of bone to the anterior clinoid processes, and behind by a square-shaped plate of bone, the *dorsum ephippii* or *dorsum sellæ*, terminating at each superior angle in a tubercle, the *posterior clinoid processes*, the size and form of which vary considerably in different individuals. These processes deepen the pituitary fossa, and serve for the attachment of prolonga-

tions from the tentorium cerebelli. The sides of the dorsum ephippii are notched for the passage of the sixth pair of nerves, and below present a sharp process, the *petrosal process*, which is joined to the apex of the petrous portion of the temporal bone, forming the inner boundary of the middle lacerated foramen. Behind this plate, the bone presents a shallow depression, which slopes obliquely backwards, and is continuous with the basilar groove of the occipital bone; it is called the *clivus*, and supports the upper part of the pons Varolii. On either side of the body is a broad groove, curved something like the italic letter *f*; it lodges the internal carotid artery and the cavernous sinus, and is called the *carotid* or *cavernous groove*. Along the outer margin of this groove, at its posterior part, is a ridge of bone, in the angle between the body and greater wing, called the *lingula*. The **posterior surface**, quadrilateral in form, is joined to the basilar process of the occipital bone. During childhood these bones are separated by a layer of cartilage; but in after-life (between the eighteenth and twenty-fifth years) this becomes ossified, ossification commencing above and extending downwards; and the two bones then form one piece. The **anterior surface** (fig. 149)

Fig. 148.—Sphenoid bone. Superior surface.

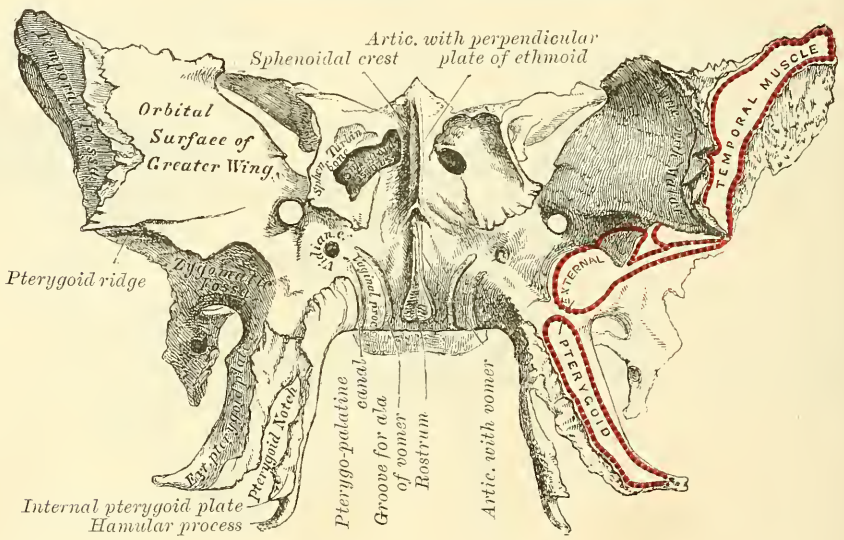


presents, in the middle line, a vertical ridge of bone, the *sphenoidal crest*, which articulates in front with the perpendicular plate of the ethmoid, forming part of the septum of the nose. On either side of it are irregular openings leading into the *sphenoidal cells* or *sinuses*. These are two large, irregular cavities hollowed out of the interior of the body of the sphenoid bone, and separated from one another by a more or less complete perpendicular bony septum. Their form and size vary considerably; they are seldom symmetrical, and are often partially subdivided by irregular osseous laminæ. Occasionally, they extend into the basilar process of the occipital nearly as far as the foramen magnum. The septum is seldom quite vertical, being commonly bent to one or the other side. These sinuses do not exist in children, but they increase in size as age advances. They are partially closed, in front and below, by two thin, curved plates of bone, the *sphenoidal turbinated* bones, leaving a round opening at their upper parts, by which they communicate with the upper and back part of the nose and occasionally with the posterior ethmoidal cells or sinuses. The lateral margins of this surface present a serrated edge, which articulates with the os planum of the ethmoid, completing the posterior ethmoidal cells; the lower margin, also rough and serrated, articulates with the orbital process of the palate bone;

and the upper margin with the orbital plate of the frontal bone. The **inferior surface** presents, in the middle line, a triangular spine, the *rostrum*, which is continuous with the ethmoidal crest on the anterior surface, and is received into a deep fissure between the alæ of the vomer. On each side may be seen a projecting lamina of bone, which runs horizontally inwards from near the base of the pterygoid process: these plates, termed the *vaginal processes*, articulate with the edges of the vomer. Close to the root of the pterygoid process is a groove, formed into a complete canal when articulated with the sphenoidal process of the palate bone; it is called the *pterygo-palatine canal*, and transmits the pterygo-palatine vessels and pharyngeal nerve.

The **Greater Wings** are two strong processes of bone, which arise from the sides of the body, and are curved in a direction upwards, outwards and backwards; being prolonged behind into a sharp-pointed extremity, the *spinous process* of the sphenoid. Each wing presents three surfaces and a circumference. The *superior* or *cerebral* surface (fig. 148) forms part of the middle fossa of the skull; it is deeply concave, and presents eminences and depres-

Fig. 149.—Sphenoid bone. Anterior surface.*



sions for the convolutions of the brain. At its anterior and internal part is seen a circular aperture, the *foramen rotundum*, for the transmission of the second division of the fifth nerve. Behind and external to this is a large, oval foramen, the *foramen ovale*, for the transmission of the third division of the fifth nerve, the small meningeal artery, and sometimes the small petrosal nerve.† At the inner side of the foramen ovale, a small aperture may occasionally be seen opposite the root of the pterygoid process; it is the *foramen Vesalii*, transmitting a small vein. Lastly, in the posterior angle, near to the spine of the sphenoid, is a short canal, sometimes double, the *foramen spinosum*; it transmits the middle meningeal artery. The *external* surface (fig. 149) is convex, and divided by a transverse ridge, the *pterygoid ridge*,‡ into two portions. The superior or larger, convex from above downwards, concave from before backwards, enters into the formation of the temporal fossa, and gives attachment to part of the Temporal muscle. The inferior portion, smaller in size and con-

* In this figure, both the anterior and inferior surfaces of the body of the sphenoid bone are shown, the bone being held with the pterygoid processes almost horizontal.

† The small petrosal nerve sometimes passes through a special foramen between the foramen ovale and foramen spinosum.

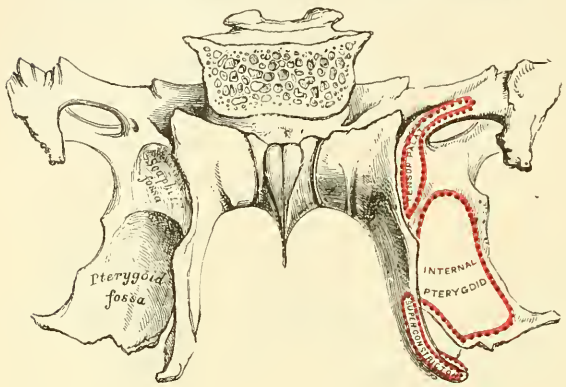
‡ Sometimes called *infra-temporal crest*.

cave, enters into the formation of the zygomatic fossa, and affords attachment to the External pterygoid muscle. It presents, at its posterior part, a sharp-pointed eminence of bone, the *spinous process*, to which are connected the internal lateral ligament of the lower jaw and the Tensor palati muscle. The pterygoid ridge, dividing the temporal and zygomatic portions, gives attachment to part of the External pterygoid muscle. At its inner and anterior extremity is a triangular spine of bone, which serves to increase the extent of origin of this muscle. The *anterior* or *orbital* surface, smooth, and quadrilateral in form, assists in forming the outer wall of the orbit. It is bounded above by a serrated edge, for articulation with the frontal bone; below, by a rounded border, which enters into the formation of the spheno-maxillary fissure. Internally, it presents a sharp border, which forms the lower boundary of the sphenoidal fissure, and has projecting from about its centre a little tubercle of bone, which gives origin to one head of the External rectus muscle of the eye; and at its upper part is a notch for the transmission of a branch of the lachrymal artery: externally, it presents a serrated margin for articulation with the malar bone. One or two small foramina may occasionally be seen for the passage of branches of the deep temporal arteries: they are called the *external orbital foramina*. *Circumference of the great wing* (fig. 148): commencing from behind; that portion of the circumference which extends from the body of the sphenoid to the spine is serrated and articulates by its outer half with the petrous portion of the temporal bone; whilst the inner half forms the anterior boundary of the foramen lacerum medium, and presents the posterior aperture of the Vidian canal for the passage of the Vidian nerve and artery. In front of the spine the circumference of the great wing presents a serrated edge, bevelled at the expense of the inner table below, and of the external above, which articulates with the squamous portion of the temporal bone. At the tip of the great wing a triangular portion is seen bevelled at the expense of the internal surface, for articulation with the anterior inferior angle of the parietal bone. Internal to this is a broad, serrated surface, for articulation with the frontal bone: this surface is continuous internally with the sharp inner edge of the orbital plate, which assists in the formation of the sphenoidal fissure, and externally with the serrated margin for articulation with the malar bone.

The **Lesser Wings** (*processes of Ingrassias*) are two thin, triangular plates of bone, which arise from the upper and lateral parts of the body of the sphenoid, and, projecting transversely outwards, terminate in a sharp point (fig. 148). The superior surface of each is smooth, flat, broader internally than externally, and supports part of the frontal lobe of the brain. The inferior surface forms the back part of the roof of the orbit, and the upper boundary of the sphenoidal fissure or foramen lacerum anterius. This fissure is of a triangular form, and leads from the cavity of the cranium into the orbit; it is bounded internally by the body of the sphenoid; above, by the lesser wing; below, by the internal margin of the orbital surface of the great wing; and is converted into a foramen by the articulation of this bone with the frontal. It transmits the third, the fourth, the three branches of the ophthalmic division of the fifth, the sixth nerve, some filaments from the cavernous plexus of the sympathetic, the orbital branch of the middle meningeal artery, a recurrent branch from the lachrymal artery to the dura mater, and the ophthalmic vein. The anterior border of the lesser wing is serrated for articulation with the frontal bone; the posterior, smooth and rounded, is received into the fissure of Sylvius of the brain. The inner extremity of this border forms the *anterior clinoid process*. The lesser wing is connected to the side of the body by two roots, the upper thin and flat, the lower thicker, obliquely directed, and presenting on its outer side, near its junction with the body, a small tubercle, for the attachment of the common tendon of origin of three of the muscles of the eye. Between the two roots is the *optic foramen*, for the transmission of the optic nerve and ophthalmic artery.

The **Pterygoid Processes** (*πτέρυξ, a wing*; *εἶδος, likeness*), one on each side, descend perpendicularly from the point where the body and greater wing unite (fig. 150). Each process consists of an external and an internal plate, which are joined together by their anterior borders above, but are separated below, leaving an angular cleft, the *pterygoid notch*, in which the pterygoid process or tuberosity of the palate bone is received. The two plates diverge from each other from their line of connection in front, so as to form a V-shaped fossa, the *pterygoid fossa*. The *external pterygoid plate* is broad and thin, turned a little outwards, and, by its outer surface, forms part of the inner wall of the zygomatic fossa, giving attachment to the External pterygoid; its inner surface forms part of the pterygoid fossa, and gives attachment to the Internal pterygoid. The *internal pterygoid plate* is much narrower and longer, curving outwards, at its extremity, into a hook-like process of bone, the *hamular process*, around which turns the tendon of the Tensor palati muscle. The outer surface of this plate forms part of the pterygoid fossa, the inner surface forming the outer boundary of the posterior aperture of the nares. On the posterior surface of the base of the process, above the pterygoid fossa, is a small, oval, shallow depression, the *scaphoid fossa*, from which arises the Tensor palati, and above which is seen the posterior orifice of the Vidian canal. Below and to the inner side of the Vidian canal, on the posterior surface of the base of the internal plate, is a little prominence, which is known by the name of the *pterygoid tubercle*. The Superior constrictor of the pharynx is attached to the posterior edge of the internal plate. The anterior surface of the pterygoid process is very broad at its base, and forms the posterior wall of the spheno-maxillary fossa. It supports Meckel's ganglion. It presents, above, the anterior orifice of the Vidian canal; and below, a rough margin, which articulates with the perpendicular plate of the palate bone.

Fig. 150.—Sphenoid bone. Posterior surface.



The **Sphenoidal Spongy Bones** are two thin, curved plates of bones, which exist as separate pieces until puberty, and occasionally are not joined to the sphenoid in the adult. They are situated at the anterior and inferior part of the body of the sphenoid, an aperture of variable size being left in their anterior wall, through which the sphenoidal sinuses open into the nasal fossæ. They are irregular in form, and taper to a point behind, being broader and thinner in front. Their upper surface, which looks towards the cavity of the sinus, is concave; their under surface convex. Each bone articulates in front with the ethmoid, externally with the palate; its pointed posterior extremity is placed above the vomer, and is received between the root of the pterygoid process on the outer side, and the rostrum of the sphenoid on the inner.*

Development.—Up to about the eighth month of fœtal life the sphenoid bone consists of two distinct parts: a posterior or *post-sphenoid* part, which comprises the pituitary fossa, the greater wings, and the pterygoid processes; and an anterior or *pre-sphenoid* part, to which the anterior part of the body and lesser

* A small portion of the sphenoidal turbinated bone sometimes enters into the formation of the inner wall of the orbit, between the os planum of the ethmoid in front, the orbital plate of the palate below, and the frontal above. Cleland, *Roy. Soc. Trans.* 1862.

wings belong. It is developed by fourteen centres: eight for the posterior sphenoid division, and six for the anterior sphenoid. The eight centres for the posterior sphenoid are—one for each greater wing and external pterygoid plate, one for each internal pterygoid plate, two for the posterior part of the body, and one on each side for the lingula. The six for the anterior sphenoid are one for each lesser wing, two for the anterior part of the body, and one for each sphenoidal turbinated bone.

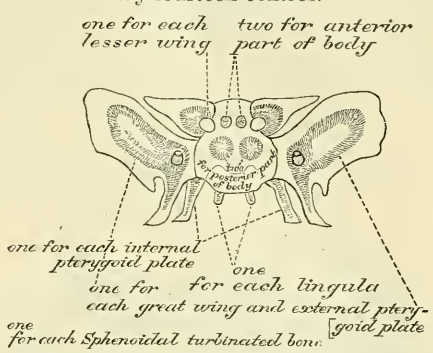


Fig. 151.—Plan of the development of sphenoid. By fourteen centres.

Post-sphenoid Division.—The first nuclei to appear are those for the greater wings. They make their appearance between the foramen rotundum and foramen ovale about the eighth week, and from them the external pterygoid plates are also formed. Soon after, the nuclei for the posterior part of the body appear, one on either side of the sella turcica, and become blended together about the middle of fœtal life. About the fourth month the remaining four centres appear, those for the internal pterygoid plates being ossified in membrane and becoming joined to the external pterygoid plate about the sixth month. The centres for the lingulæ speedily become joined to the rest of the bone.

Pre-sphenoid Division.—The first nuclei to appear are those for the lesser wings. They make their appearance about the ninth week, at the outer borders of the optic foramina. A second pair of nuclei appear on the inner side of the foramina shortly after, and becoming united, form the front part of the body of the bone. The remaining two centres for the sphenoidal turbinated bones make their appearance about the fifth month. At birth they consist of small triangular laminæ, and it is not till the third year that they become hollowed out and cone shaped.

The pre-sphenoid is united to the body of the post-sphenoid about the eighth month, so that at birth the bone consists of three pieces—viz. the body in the centre, and on each side the great wings with the pterygoid processes. The lesser wings become joined to the body at about the time of birth. At the first year after birth the greater wings and body are united. From the tenth to the twelfth year the spongy bones are partially united to the sphenoid, their junction being complete by the twentieth year. Lastly, the sphenoid joins the occipital from the eighteenth to the twenty-fifth year.

Articulations.—The sphenoid articulates with *all* the bones of the cranium, and five of the face—the two malar, two palate, and vomer: the exact extent of articulation with each bone is shown in the accompanying figures.*

Attachment of Muscles.—To eleven pairs: the Temporal, External pterygoid, Internal pterygoid, Superior constrictor, Tensor palati, Levator palpebræ, Obliquus oculi superior, Superior rectus, Internal rectus, Inferior rectus, External rectus.

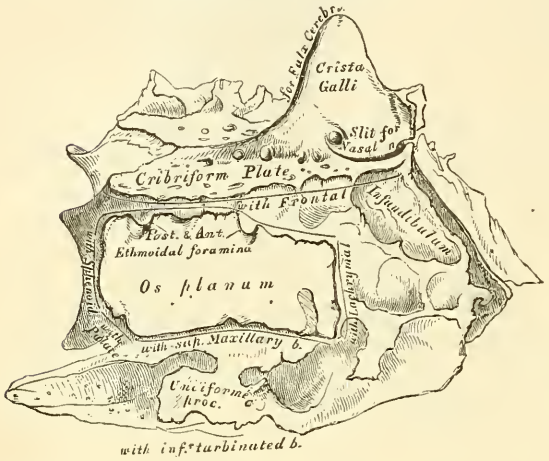
The Ethmoid Bone

The **Ethmoid** (ἠθμός, *a sieve*) is an exceedingly light, spongy bone, of a cubical form, situated at the anterior part of the base of the cranium, between the two orbits, at the root of the nose, and contributing to form each of these cavities. It consists of three parts: a horizontal plate, which forms part of the base of the cranium; a perpendicular plate, which forms part of the septum nasi; and two lateral masses of cells.

* It also sometimes articulates with the tuberosity of the superior maxilla (see p. 170).

The **Horizontal** or **Cribriform Plate** (fig. 152) forms part of the anterior fossa of the base of the skull, and is received into the ethmoid notch of the frontal bone between the two orbital plates. Projecting upwards from the middle line of this plate is a thick, smooth, triangular process of bone, the *crista galli*, so called from its resemblance to a cock's comb. Its base joins the cribriform plate. Its posterior border, long, thin, and slightly curved, serves for the attachment of the falx cerebri. Its anterior border, short and thick, articulates with the frontal bone, and presents two small projecting alæ, which are received into corresponding depressions in the frontal, completing the foramen cæcum behind. Its sides are smooth and sometimes bulging; in which case it is found to enclose a small sinus.* On each side of the crista galli, the cribriform plate is narrow, and deeply grooved, to support the bulb of the olfactory tract, and perforated by foramina for the passage of the olfactory nerves. These foramina are arranged in three rows: the innermost, which are the largest and least numerous, are lost in grooves on the upper part of the septum; the foramina of the outer row are continued on to the surface of the upper spongy bone. The foramina of the middle row are the smallest; they perforate the bone, and transmit nerves to the roof of the nose. At the front part of the cribriform plate, on each side of the crista galli, is a small fissure, which transmits the nasal branch of the ophthalmic nerve; and at its posterior part a triangular notch, which receives the ethmoidal spine of the sphenoid.

Fig. 152.—Ethmoid bone. Outer surface of right lateral mass (enlarged).



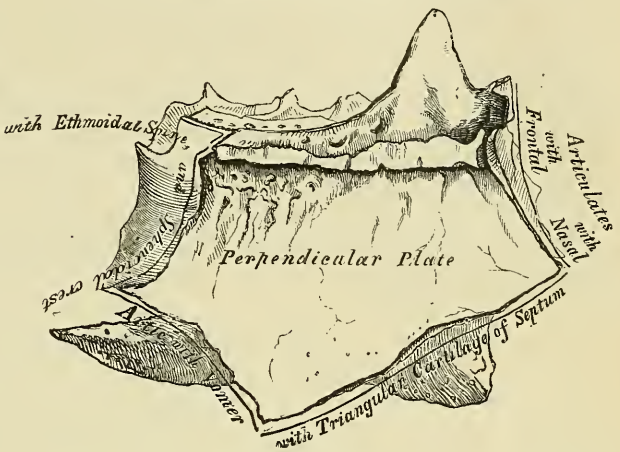
The **Perpendicular Plate** (fig. 153) is a thin, flattened lamella of bone, which descends from the under surface of the cribriform plate, and assists in forming the septum of the nose. It is much thinner in the middle than at the circumference, and is generally deflected a little to one side. Its anterior border articulates with the nasal spine of the frontal bone and crest of the nasal bones. Its posterior, divided into two parts, articulates by its upper half with the sphenoidal crest of the sphenoid, by its lower half with the vomer. The inferior border serves for the attachment of the triangular cartilage of the nose. On each side of the perpendicular plate numerous grooves and canals are seen, leading from foramina on the cribriform plate; they lodge filaments of the olfactory nerves.

The **Lateral Masses** of the ethmoid consist of a number of thin-walled cellular cavities, the *ethmoidal cells*, interposed between two vertical plates of bone, the outer one of which forms part of the orbit, and the inner one part of the nasal fossa of the corresponding side. In the disarticulated bone many of these cells appear to be broken; but when the bones are articulated, they are closed in at every part. The upper surface of each lateral mass presents a number of apparently half-broken cellular spaces; these are closed in when articulated by the edges of the ethmoidal notch of the frontal bone. Crossing this surface are two

* Sir George Humphry states that the crista galli is commonly inclined to one side, usually the opposite to that towards which the lower part of the perpendicular plate is bent.—*The Human Skeleton*, 1858, p. 277.

grooves on each side, converted into canals by articulation with the frontal; they are the *anterior* and *posterior ethmoidal* canals, and open on the inner wall of the orbit. The posterior surface also presents large, irregular cellular cavities, which are closed in by articulation with the sphenoidal turbinated bones and orbital process of the palate. The cells at the anterior surface are completed by the lachrymal bone and nasal process of the superior maxillary, and those below by the superior maxillary. The outer surface of each lateral mass is formed of a thin, smooth, square plate of bone, called the *os planum*; it forms part of the inner wall of the orbit, and articulates, above, with the orbital plate of the frontal; below, with the superior maxillary; in front, with the lachrymal; and behind, with the sphenoid and orbital process of the palate.

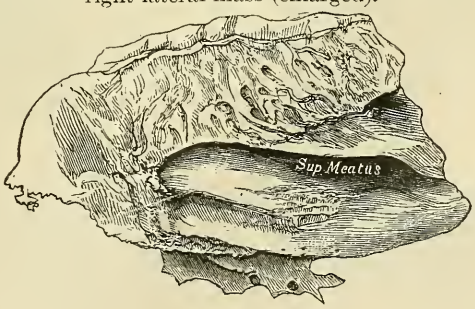
Fig. 153.—Perpendicular plate of ethmoid (enlarged). Shown by removing the right lateral mass.



From the inferior part of each lateral mass, immediately beneath the os planum, there projects downwards and backwards an irregular lamina of bone, called the *uncinate process*, from its hook-like form; it serves to close in the upper part of the orifice of the antrum, and articulates with the ethmoidal process of the inferior turbinated bone. It is often broken in disarticulating the bones.

The inner surface of each lateral mass forms part of the outer wall of the nasal fossa of the corresponding side. It is formed of a thin lamella of bone, which descends from the under surface of the cribriform plate, and terminates below in a free, convoluted margin, the *middle turbinated* bone. The whole of this surface is rough, and marked above by numerous grooves, which run nearly vertically downwards from the cribriform plate; they lodge branches of the olfactory nerve, which are distributed on the mucous membrane covering the bone. The back part of this surface is subdivided by a narrow oblique fissure, the *superior meatus* of the nose, bounded above by a thin, curved plate of bone, the *superior turbinated* bone. By means of an orifice at the upper part of this fissure, the posterior ethmoidal cells open into the nose. Below, and in front of the superior meatus, is seen the convex surface of the middle turbinated bone. It extends along the whole length of the inner surface of each lateral mass; its lower margin is free and thick, and its concavity, directed outwards, assists in forming the middle meatus. It is by a large orifice at the upper and front part of the middle meatus that the anterior ethmoidal cells, and through them the frontal sinuses, communicate with the nose, by means of a funnel-

Fig. 154.—Ethmoid bone. Inner surface of right lateral mass (enlarged).



shaped canal, the *infundibulum*. The cellular cavities of each lateral mass, thus walled in by the os planum on the outer side, and by the other bones already mentioned, are divided by a thin transverse bony partition into two sets, which do not communicate with each other; they are termed the *anterior* and *posterior ethmoidal cells*, or *sinuses*. The former, more numerous, communicate with the frontal sinuses above, and the middle meatus below, by means of a long, flexuous canal, the *infundibulum*; the posterior, less numerous, open into the superior meatus, and communicate (occasionally) with the sphenoidal sinuses.

Development.—By *three* centres: one for the perpendicular lamella, and one for each lateral mass.

The lateral masses are first developed, ossific granules making their appearance in the os planum between the fourth and fifth months of fœtal life, and extending into the spongy bones. At birth, the bone consists of the two lateral masses, which are small and ill-developed. During the first year after birth, the perpendicular and horizontal plates begin to ossify, from a single nucleus, and become joined to the lateral masses about the beginning of the second year. The formation of the ethmoidal cells, which completes the bone, does not commence until about the fourth or fifth year.

Articulations.—With fifteen bones: the sphenoid, two sphenoidal turbinated, the frontal, and eleven of the face—the two nasal, two superior maxillary, two lachrymal, two palate, two inferior turbinated, and the vomer. No muscles are attached to this bone.

Development of the Cranium

The early stages of the development of the cranium have already been described (see page 90). We have seen that it is formed from a layer of mesoblast, derived from the protovertebral plates of the trunk, which is spread over the whole surface of the rudimentary brain. That portion of this layer from which the bones of the skull are to be developed consists of a thin, membranous capsule.

Ossification commences in the roof, and is preceded by the deposition of a membranous blastema upon the surface of the cerebral capsule, in which the ossifying process extends; the primitive membranous capsule becoming the internal periosteum, and

Fig. 155.—Skull at birth, showing the anterior and posterior fontanelles.

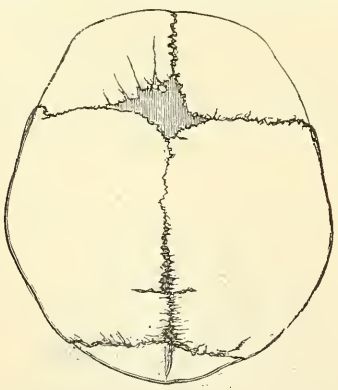


Fig. 156.—The lateral fontanelles.

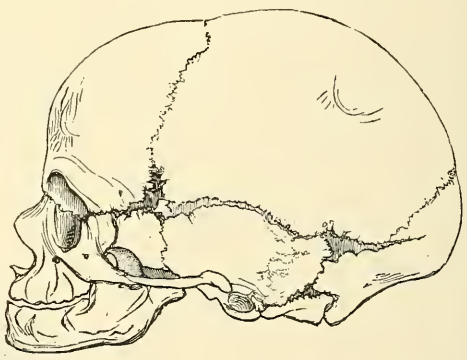


being ultimately blended with the dura mater. The ossification of the bones of the base takes place for the most part in cartilage, and although the bones of the vertex of the skull appear before those at the base, and make considerable progress in their growth, at birth ossification is more advanced in the base, this portion of the skull forming a solid, immovable groundwork.

The Fontanelles

Before birth, the bones at the vertex and side of the skull are separated from each other by membranous intervals, in which bone is deficient. These intervals are principally found at the four angles of the parietal bones. Hence there are six of these intervals.

Their formation is due to the wave of ossification being circular and the bones quadrilateral; the ossific matter first meets at the margins of the bones, at the points nearest to their centres of ossification, and vacuities or spaces are left at the angles, which are called *fontanelles*, so named from the pulsations of the brain, which are perceptible at the anterior fontanelle, and were likened to the rising of water in a fountain. The anterior fontanelle is the largest, and corresponds to the junction of the sagittal and coronal sutures; the posterior fontanelle, of smaller size, is situated at the junction of the sagittal and lambdoid sutures; the remaining ones are situated at the inferior angles of each parietal bone. The latter are closed soon after birth; the two at the two superior angles remain open longer; the posterior being closed in a few months after birth; the anterior remaining open until the first or second year. These spaces are gradually filled in by an extension of the ossifying process, or by the development of a Wormian bone. Sometimes the anterior fontanelle remains open beyond two years, and is occasionally persistent throughout life.

Supernumerary or Wormian* Bones

In addition to the constant centres of ossification of the skull, additional ones are occasionally found in the course of the sutures. These form irregular, isolated bones, interposed between the cranial bones, and have been termed *Wormian bones* or *ossa triquetra*. They are most frequently found in the course of the lambdoid suture, but occasionally also occupy the situation of the fontanelles, especially the posterior and, more rarely, the anterior. Frequently one is found between the anterior inferior angle of the parietal bone and the greater wing of the sphenoid, the *pterion ossicle* (fig. 156). They have a great tendency to be symmetrical on the two sides of the skull, and they vary much in size, being in some cases not larger than a pin's head, and confined to the outer table; in other cases so large that one pair of these bones may form the whole of the occipital bone above the superior curved lines, as described by Béclard and Ward. Their number is generally limited to two or three; but more than a hundred have been found in the skull of an adult hydrocephalic skeleton. In their development, structure, and mode of articulation, they resemble the other cranial bones.

Congenital Fissures and Gaps

An arrest in the ossifying process may give rise to deficiencies, or gaps; or to fissures which are of importance in a medico-legal point of view, as they are liable to be mistaken for fractures. The fissures generally extend from the margins towards the centre of the bone, but the gaps may be found in the middle as well as at the edges. In course of time they may become covered with a thin lamina of bone.

Bones of the Face

The Facial Bones are fourteen in number—viz. the

Two Nasal.	Two Palate.
Two Superior Maxillary.	Two Inferior Turbinated.
Two Lachrymal.	Vomer.
Two Malar.	Inferior Maxillary.

'Of these, the upper and lower jaws are the fundamental bones for mastication, and the others are accessories; for the chief function of the facial bones is to provide an apparatus for mastication, while subsidiary functions are to provide for the sense-organs (eye, nose, tongue) and a vestibule to the respiratory and vocal organs. Hence the variations in the shape of the face in man and the lower animals depend chiefly on the question of the character of their food and their mode of obtaining it.'†

Nasal Bones

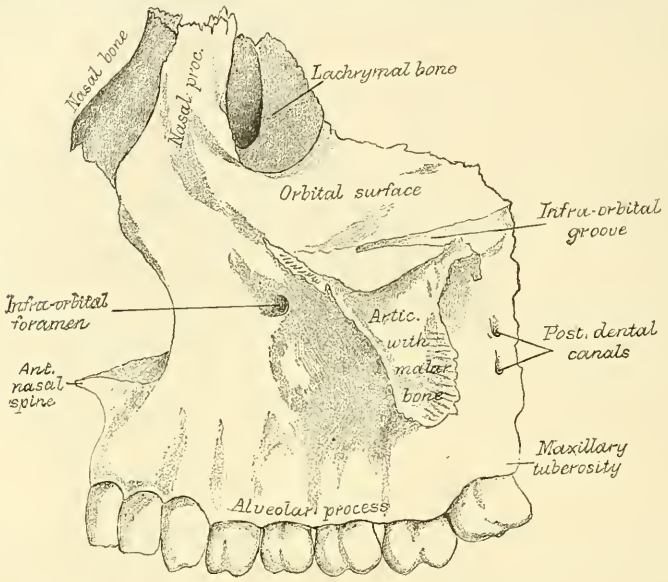
The **Nasal** (nasus, *the nose*) are two small oblong bones, varying in size and form in different individuals; they are placed side by side at the middle and upper part of the face, forming, by their junction, 'the bridge' of the nose (fig. 157). Each bone presents for examination two surfaces and four borders. The *outer* surface is concave from above downwards, convex from side to side;

* Wormius, a physician in Copenhagen, is said to have given the first detailed description of these bones.

† W. W. Keen. American edition, p. 185.

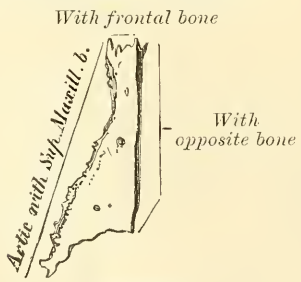
it is covered by the Pyramidalis and Compressor nasi muscles, and gives attachment at its upper part to a few fibres of the Occipito-frontalis muscle (Theile). It is marked by numerous small arterial furrows, and perforated about its centre by a foramen, sometimes double, for the transmission of a small vein. Sometimes this foramen is absent on one or both sides, and occasionally the foramen cæcum opens on this surface. The *inner* surface is concave from side to side, convex from above downwards; in which direction it is traversed by a longitu-

Fig. 157.—Nasal bone and Lachrymal bone *in situ*.



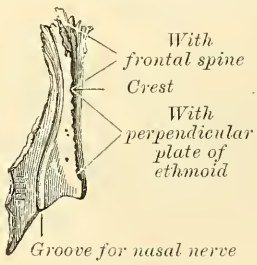
dinal groove (sometimes a canal), for the passage of a branch of the nasal nerve. The *superior* border is narrow, thick, and serrated for articulation with the nasal notch of the frontal bone. The *inferior* border is broad, thin, sharp, inclined obliquely downwards, outwards, and backwards, and serves for the attachment of the lateral cartilage of the nose. This border presents, about its middle, a notch, through which passes the branch of the nasal nerve above re-

Fig. 158.—Right nasal bone.



Outer Surface

Fig. 159.—Left nasal bone.



Inner Surface

ferred to; and is prolonged at its inner extremity into a sharp spine, which, when articulated with the opposite bone, forms the *nasal angle*. The *external* border is serrated, bevelled at the expense of the internal surface above, and of the external below, to articulate with the nasal process of the superior maxillary. The *internal* border, thicker above than below, articulates with its fellow of the opposite side, and is prolonged behind into a vertical crest, which forms part of the septum of the nose: this crest articulates, from above downwards, with the

nasal spine of the frontal, the perpendicular plate of the ethmoid, and the triangular septal cartilage of the nose.

Development.—By *one* centre for each bone, which appears about the same period as in the vertebræ.

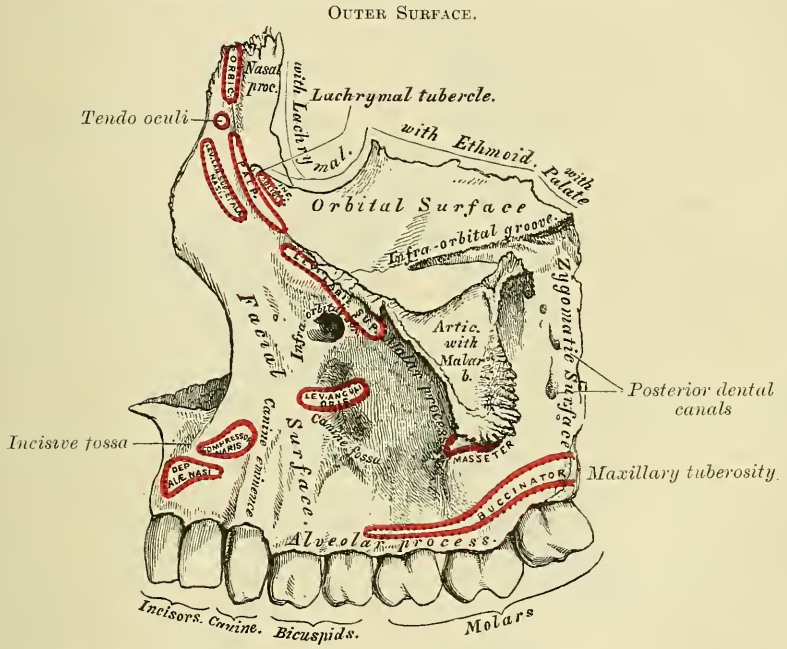
Articulations.—With four bones : two of the cranium, the frontal and ethmoid, and two of the face, the opposite nasal and the superior maxillary.

Attachment of Muscles.—A few fibres of the Occipito-frontalis muscle.

Superior Maxillary Bones

The **Superior Maxillary Bones** (maxilla, *the jaw-bone*) are the most important bones of the face from a surgical point of view, on account of the number of diseases to which some of their parts are liable. Their careful examination becomes, therefore, a matter of considerable interest. They are the largest bones of the face, excepting the lower jaw, and form, by their union, the whole of the upper jaw. Each bone assists in the formation of three cavities,

Fig. 160.—Left superior maxillary bone. Outer surface.



the roof of the mouth, the floor and outer wall of the nasal fossæ, and the floor of the orbit; and also enters into the formation of two fossæ, the zygomatic and spheno-maxillary, and two fissures, the spheno-maxillary and pterygo-maxillary.

The bone presents for examination a body and four processes—malar, nasal, alveolar, and palate.

The **body** is somewhat cuboid, and is hollowed out in its interior to form a large cavity, the *antrum of Highmore*. Its surfaces are four—an external or facial, a posterior or zygomatic, a superior or orbital, and an internal.

The **external** or **facial surface** (fig. 160) is directed forwards and outwards. It presents at its lower part a series of eminences corresponding to the position of the teeth. Just above those for the incisor teeth is a depression, the *incisive* or *myrtiform fossa*, which gives origin to the Depressor alæ nasi; and, below it, to the alveolar border is attached a slip of the Orbicularis oris. Above and a little external to it, the Compressor nasi arises. More external is another depression, the *canine fossa*, larger and deeper than the incisive fossa, from which it is separated by a vertical ridge, the *canine eminence*, corresponding to the socket of

the canine tooth. The canine fossa gives origin to the Levator anguli oris. Above the canine fossa is the *infra-orbital foramen*, the termination of the infra-orbital canal; it transmits the infra-orbital vessels and nerve. Above the infra-orbital foramen is the margin of the orbit, which affords partial attachment to the Levator labii superioris proprius. To the sharp margin of bone which bounds this surface in front and separates it from the internal surface is attached the Dilator naris posterior.

The **posterior** or **zygomatic surface** is convex, directed backwards and outwards, and forms part of the zygomatic fossa. It is separated from the facial surface by a strong ridge of bone, which extends upwards from the socket of the second molar tooth. It presents about its centre several apertures leading to canals in the substance of the bone; they are termed the *posterior dental canals*, and transmit the posterior dental vessels and nerves. At the lower part of this surface is a rounded eminence, the *maxillary tuberosity*, especially prominent after the growth of the wisdom-tooth, rough on its inner side for articulation with the tuberosity of the palate-bone and sometimes with the external pterygoid plate. It gives attachment to a few fibres of origin of the Internal pterygoid muscle. Immediately above this is a smooth surface, which forms the anterior boundary of the spheno-maxillary fossa; it presents a groove, which, running obliquely downwards, is converted into a canal by articulation with the palate-bone, forming the *posterior palatine* canal.

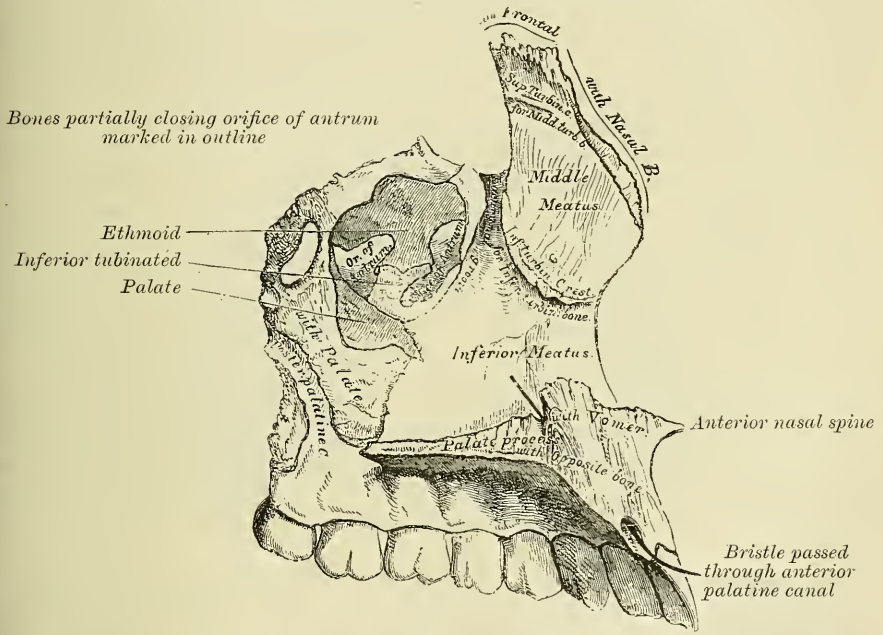
The **superior** or **orbital surface** is thin, smooth, triangular, and forms part of the floor of the orbit. It is bounded internally by an irregular margin which in front presents a notch, the *lachrymal notch*, which receives the lachrymal bone; in the middle articulates with the os planum of the ethmoid, and behind with the orbital process of the palate-bone; it is bounded externally by a smooth, rounded edge which enters into the formation of the spheno-maxillary fissure, and which sometimes articulates at its anterior extremity with the orbital plate of the sphenoid; and it is bounded in front by part of the circumference of the orbit, which is continuous, on the inner side with the nasal, on the outer side with the malar process. Along the middle line of the orbital surface is a deep groove, the *infra-orbital*, for the passage of the infra-orbital vessels and nerve. The groove commences at the middle of the outer border of this surface, and, passing forwards, terminates in a canal, which subdivides into two branches. One of the canals, the *infra-orbital*, opens just below the margin of the orbit; the other, which is smaller, runs in the substance of the anterior wall of the antrum; it is called the *anterior dental* canal, and transmits the anterior dental vessels and nerve to the front teeth of the upper jaw. From the back part of the infra-orbital canal, a second small canal is sometimes given off, which runs in the substance of the bone, and conveys the middle dental nerve to the bicuspid teeth. Occasionally, this canal is derived from the anterior dental. At the inner and fore part of the orbital surface, just external to the lachrymal groove for the nasal duct, is a depression, which gives origin to the Inferior oblique muscle of the eye.

The **internal surface** (fig. 161) is unequally divided into two parts by a horizontal projection of bone, the *palate process*: the portion above the palate process forms part of the outer wall of the nasal fossæ; that below it forms part of the cavity of the mouth. The superior division of this surface presents a large, irregular opening leading into the *antrum of Highmore*. At the upper border of this aperture are numerous broken cellular cavities, which, in the articulated skull, are closed in by the ethmoid and lachrymal bones. Below the aperture is a smooth concavity which forms part of the inferior meatus of the nasal fossæ, and behind it is a rough surface which articulates with the perpendicular plate of the palate-bone, traversed by a groove which, commencing near the middle of the posterior border, runs obliquely downwards and forwards, and forms, when completed by its articulation with the palate-bone, the *posterior palatine canal*. In front of the opening of the antrum is a deep groove, converted into a canal by the lachrymal and inferior turbinated bones. It is called the *lachrymal groove*, and lodges the

nasal duct. More anteriorly is a well-marked rough ridge, the *inferior turbinated crest*, for articulation with the inferior turbinated bone. The concavity above this ridge forms part of the middle meatus of the nose; whilst that below it forms part of the inferior meatus. The portion of this surface below the palate process is concave, rough and uneven, and perforated by numerous small foramina for the passage of nutrient vessels. It enters into the formation of the roof of the mouth.

The **Antrum of Highmore,** or **Maxillary Sinus,** is a large pyramidal cavity, hollowed out of the body of the maxillary bone: its apex, directed outwards, is formed by the malar process; its base, by the outer wall of the nose. Its walls are everywhere exceedingly thin, and correspond to the orbital, facial, and zygomatic surfaces of the body of the bone. Its inner wall, or base, presents, in the disarticulated bone, a large, irregular aperture, which communicates with the nasal fossa. The margins of this aperture are thin and ragged, and the aperture itself is much contracted by its articulation with the ethmoid above, the

Fig. 161.—Left superior maxillary bone. Inner surface.



inferior turbinated below, and the palate-bone behind.* In the articulated skull, this cavity communicates with the middle meatus of the nasal fossæ, generally by two small apertures left between the above-mentioned bones. In the recent state, usually only one small opening exists, near the upper part of the cavity sufficiently large to admit the end of a probe, the other being closed by the lining membrane of the sinus.

Crossing the cavity of the antrum are often seen several projecting laminæ of bone, similar to those seen in the sinuses of the cranium; and on its posterior wall are the *posterior dental canals*, transmitting the posterior dental vessels and nerves to the teeth. Projecting into the floor are several conical processes, corresponding to the roots of the first and second molar teeth; † in some cases the floor is perforated by the teeth in this situation.

* In some cases, at any rate, the lachrymal bone also encroaches slightly on the anterior superior portion of the opening, and assists in forming the inner wall of the antrum.

† The number of teeth whose fangs are in relation with the floor of the antrum is variable. The antrum 'may extend so as to be in relation to all the teeth of the true maxilla, from the canine to the *dens sapientiæ*.'—See Mr. Salter on Abscess of the Antrum, in a *System of Surgery*, edited by T. Holmes, 2nd edit. vol. iv. p. 356.

It is from the extreme thinness of the walls of this cavity that we are enabled to explain how a tumour growing from the antrum encroaches upon the adjacent parts, pushing up the floor of the orbit, and displacing the eyeball, projecting inwards into the nose, protruding forwards on to the cheek, and making its way backwards into the zygomatic fossa, and downwards into the mouth.

The **Malar Process** is a rough triangular eminence, situated at the angle of separation of the facial from the zygomatic surface. In front it is concave, forming part of the facial surface; behind, it is also concave, and forms part of the zygomatic fossa; above, it is rough and serrated for articulation with the malar bone; whilst below, a prominent ridge marks the division between the facial and zygomatic surfaces. A small part of the Masseter muscle arises from this process.

The **Nasal Process** is a thick, triangular plate of bone, which projects upwards, inwards, and backwards, by the side of the nose, forming part of its lateral boundary. Its *external* surface is concave, smooth, perforated by numerous foramina, and gives attachment to the Levator labii superioris alæque nasi, the Orbicularis palpebrarum, and Tendo oculi. Its *internal* surface forms part of the outer wall of the nasal fossæ: at its upper part it presents a rough, uneven surface, which articulates with the ethmoid bone, closing in the anterior ethmoidal cells; below this is a transverse ridge, the *superior turbinated crest*, for articulation with the middle turbinated bone of the ethmoid, bounded below by a smooth concavity which forms part of the middle meatus; below this again is the inferior turbinated crest (already described), where the process joins the body of the bone. Its upper border articulates with the frontal bone. The *anterior* border of the nasal process is thin, directed obliquely downwards and forwards, and presents a serrated edge for articulation with the nasal bone; its *posterior* border is thick, and hollowed into a groove, the *lachrymal groove*, for the nasal duct: of the two margins of this groove, the inner one articulates with the lachrymal bone, the outer one forms part of the circumference of the orbit. Just where the latter joins the orbital surface is a small tubercle, the *lachrymal tubercle*; this serves as a guide to the position of the lachrymal sac in the operation for fistula lachrymalis. The lachrymal groove in the articulated skull is converted into a canal by the lachrymal bone and lachrymal process of the inferior turbinated; it is directed downwards, and a little backwards and outwards, is about the diameter of a goose-quill, slightly narrower in the middle than at either extremity, and terminates below in the inferior meatus. It lodges the nasal duct.

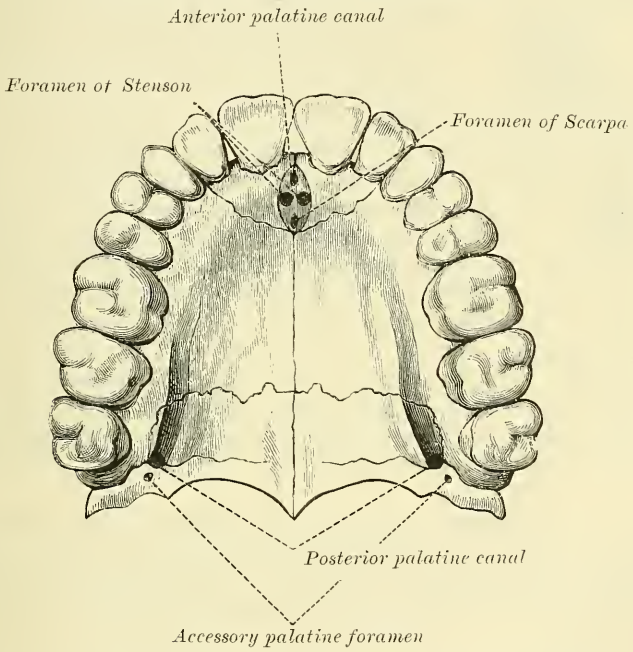
The **Alveolar Process** is the thickest and most spongy part of the bone, broader behind than in front, and excavated into deep cavities for the reception of the teeth. These cavities are eight in number, and vary in size and depth according to the teeth they contain. That for the canine tooth is the deepest; those for the molars are the widest, and subdivided into minor cavities; those for the incisors are single, but deep and narrow. The Buccinator muscle arises from the outer surface of this process, as far forward as the first molar tooth.

The **Palate Process**, thick and strong, projects horizontally inwards from the inner surface of the bone. It is much thicker in front than behind, and forms a considerable part of the floor of the nostril and the roof of the mouth.

Its *inferior* surface (fig. 162) is concave, rough and uneven, and forms part of the roof of the mouth. This surface is perforated by numerous foramina for the passage of the nutrient vessels; channelled at the back part of its alveolar border by a longitudinal groove, sometimes a canal, for the transmission of the posterior palatine vessels, and the anterior and external palatine nerves from Meckel's ganglion; and presents little depressions for the lodgment of the palatine glands. When the two superior maxillary bones are articulated together, a large orifice may be seen in the middle line, immediately behind the incisor teeth. This is the *anterior palatine canal* or *fossa*. This canal, as it passes through the thickness of the palate process, is divided into four compartments; that is to say, two

canals branch off laterally to the right and left nasal fossæ, and two canals, one in front and one behind, lie in the middle line. The former pair of these canals is named the *foramina of Stenson*, and through them passes the anterior or terminal branch of the descending or posterior palatine arteries, which ascends from the mouth to the nasal fossæ. The remaining pair of canals is termed the *foramina of Scarpa*, and transmit the naso-palatine nerves, the left passing through the anterior, and the right through the posterior canal. On the palatal surface of the process, a delicate linear suture may sometimes be seen extending from the anterior palatine fossa to the interval between the lateral incisor and the canine tooth. This marks out the intermaxillary, or incisive bone, which in some animals exists permanently as a separate piece. It includes the whole thickness of the alveolus, the corresponding part of the floor of the nose and the anterior nasal spine, and contains the sockets of the incisor teeth. One or two small foramina in the alveolar margin behind the incisor teeth are occasionally seen in the adult, almost constantly in the young subject. They are called the

Fig. 162.—The palate and alveolar arch.

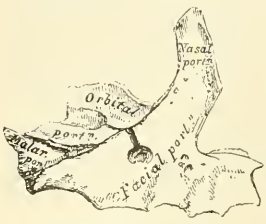


incisive foramina, and transmit vessels and nerves to the incisor teeth. The *upper* surface is concave from side to side, smooth, and forms part of the floor of the nose. It presents the upper orifices of the foramina of Stenson and Scarpa, the former being on each side of the middle line, the latter being situated in the intermaxillary suture, and therefore not visible unless the two bones are placed in apposition. The *outer* border of the palate process is incorporated with the rest of the bone. The *inner* border is thicker in front than behind, and is raised above into a ridge, the *nasal crest*, which, with the corresponding ridge in the opposite bone, forms a groove for the reception of the vomer. In front, this crest rises to a considerable height, and this portion is named the *incisor crest*. The *anterior* margin is bounded by the thin, concave border of the opening of the nose prolonged forwards internally into a sharp process, forming, with a similar process of the opposite bone, the *anterior nasal spine*. The *posterior* border is serrated for articulation with the horizontal plate of the palate-bone.

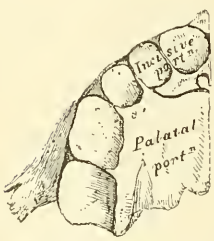
Development.—This bone commences to ossify at a very early period, and ossification proceeds in it with great rapidity, so that it is difficult to ascertain

with certainty its precise number of centres. It appears, however, probable that it is ossified from four centres, which are deposited in membrane. 1. One which forms that portion of the body of the bone which lies internal to the infra-orbital canal, including the floor of the orbit, the outer wall of the nasal fossa and the nasal process; 2. a second which gives origin to that portion of the bone which lies external to the infra-orbital canal and the malar process; 3. a third from which is developed the palatine process posterior to Stenson's canal and the adjoining part of the nasal wall; 4. and a fourth for the front part of the alveolus which carries the incisor teeth and corresponds to the pre-maxillary bone of the lower animals. These centres appear about the eighth week, and by the tenth week the three first named centres have become fused together and the bone consists of two portions, one the greater part of the bone, and the other the pre-maxillary portion. The suture between these two portions on the palate persists till middle life, but is not to be seen on the facial surface. This is believed by Callender to be due to the fact that the front wall of the sockets of the incisive teeth is not formed by the pre-maxillary bone, but by an outgrowth from the facial part of the superior maxilla. The antrum appears as a shallow groove on the inner surface of the bone at an earlier period than any of the other nasal sinuses, its development commencing about the fourth month of fœtal life. The sockets for the teeth are formed by the growing downwards of two plates from the dental groove, which subsequently becomes divided by partitions jutting across from the one to the other.

Fig. 163.—Development of superior maxillary bone. At birth.



Anterior Surface.



Inferior Surface.

Articulations.—With *nine* bones: two of the cranium, the frontal and ethmoid, and seven of the face—viz. the nasal, malar, lachrymal, inferior turbinated, palate, vomer, and its fellow of the opposite side. Sometimes it articulates with the orbital plate of the sphenoid, and sometimes with its external pterygoid plate.

Attachment of Muscles.—To twelve: the Orbicularis palpebrarum, Obliquus oculi inferior, Levator labii superioris alæque nasi, Levator labii superioris proprius, Levator anguli oris, Compressor nasi, Depressor alæ nasi, Dilatator naris posterior, Masseter, Buccinator, Internal pterygoid, and Orbicularis oris.

Changes produced in the Upper Jaw by Age

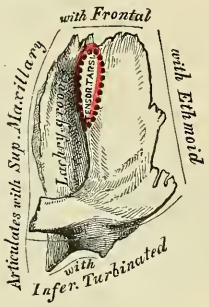
At birth and during infancy the diameter of the bone is greater in an antero-posterior than in a vertical direction. Its nasal process is long, its orbital surface large, and its tuberosity well marked. In the adult the vertical diameter is the greater, owing to the development of the alveolar process and the increase in size of the antrum. In old age the bone approaches again in character to the infantile condition: its height is diminished, and after the loss of the teeth the alveolar process is absorbed, and the lower part of the bone contracted and diminished in thickness.

The Lachrymal Bone

The **Lachrymal** (lachryma, *a tear*) are the smallest and most fragile bones of the face. They are situated at the front part of the inner wall of the orbit (fig. 157), and resemble somewhat in form, thinness, and size, a finger-nail; hence they are termed the *ossa unguis*. Each bone presents for examination two surfaces and four borders. The *external* or *orbital* surface (fig. 164) is divided by a vertical ridge, the *lachrymal crest*, into two parts. The portion of bone in

front of this ridge presents a smooth, concave, longitudinal groove, the free margin of which unites with the nasal process of the superior maxillary bone, completing the lachrymal groove. The upper part of this groove lodges the lachrymal sac; the lower part lodges the nasal duct. The portion of bone behind the ridge is smooth, slightly concave, and forms part of the inner wall of the orbit. The ridge, with a part of the orbital surface immediately behind it, affords attachment to the Tensor tarsi: the ridge terminates below in a small, hook-like projection, the *hamular process*, which articulates with the lachrymal tubercle of the superior maxillary bone, and completes the upper orifice of the lachrymal groove. It sometimes exists as a separate piece, which is then called the *lesser lachrymal bone*. The *internal* or *nasal* surface presents a depressed furrow, corresponding to the ridge on its outer surface. The surface of bone in front of this forms part of the middle meatus; and that behind it articulates with the ethmoid bone, filling in the anterior ethmoidal cells. Of the *four borders* the *anterior* is the longest, and articulates with the nasal process of the superior maxillary bone. The *posterior*, thin and uneven, articulates with the os planum of the ethmoid. The *superior*, the shortest and thickest, articulates with the internal angular process of the frontal bone. The *inferior* is divided by the lower edge of the vertical crest into two parts: the posterior part articulates with the orbital plate of the superior maxillary bone; the anterior portion is prolonged downwards into a pointed process, which articulates with the lachrymal process of the inferior turbinated bone, and assists in the formation of the lachrymal groove.

Fig. 164.—Left lachrymal bone. External surface. (Slightly enlarged.)



Development.—By a single centre, which makes its appearance soon after ossification of the vertebræ has commenced.

Articulations.—With four bones: two of the cranium, the frontal and ethmoid, and two of the face, the superior maxillary and the inferior turbinated.

Attachment of Muscles.—To one muscle, the Tensor tarsi.

The Malar Bones

The **Malar** (mala, *the cheek*) are two small, quadrangular bones, situated at the upper and outer part of the face: they form the prominence of the cheek, part of the outer wall and floor of the orbit, and part of the temporal and zygomatic fossæ (fig. 165). Each bone presents for examination an external and an internal surface; four processes, the frontal, orbital, maxillary, and zygomatic; and four borders. The **external surface** (fig. 166) is smooth, convex, perforated near its centre by one or two small apertures, the *malar foramina*, for the passage of nerves and vessels, covered by the Orbicularis palpebrarum muscle, and affords attachment to the Zygomaticus major and minor muscles.

The **internal surface** (fig. 167), directed backwards and inwards, is concave, presenting internally a rough, triangular surface, for articulation with the superior maxillary bone; and externally, a smooth, concave surface, which above forms the anterior boundary of the temporal fossa, and below, where it is wider, forms part of the zygomatic fossa. This surface presents, a little above its centre, the aperture of one or two malar canals, and affords attachment to a portion of the Masseter muscle at its lower part. Of the four processes, the **frontal** is thick and serrated, and articulates with the external angular process of the frontal bone. To its orbital margin is attached the external tarsal ligament. The **orbital** process is a thick and strong plate, which projects backwards from the orbital margin of the bone. Its *supero-internal* surface

smooth and concave, forms, by its junction with the orbital surface of the superior maxillary bone and with the great wing of the sphenoid, part of the floor and outer wall of the orbit. Its *infero-external* surface, smooth and convex, forms part of the zygomatic and temporal fossæ. Its *anterior* margin is smooth and rounded, forming part of the circumference of the orbit. Its *superior* margin, rough, and directed horizontally, articulates with the frontal bone behind the external angular process. Its *posterior* margin is rough, and serrated for articulation with the sphenoid; *internally* it is also serrated for articulation with the orbital surface of the superior maxillary. At the angle of junction of the sphenoidal and maxillary portions, a short, rounded, non-articular margin is generally seen; this forms the anterior boundary of the sphenomaxillary fissure: occasionally, no such non-articular margin exists, the fissure being completed by the direct junction of the maxillary and sphenoid bones, or by the interposition of a small Wormian bone in the angular interval between them. On the *upper* surface of the orbital process are seen the orifices of one or two temporo-malar canals; one of these usually opens on the posterior surface, the other (occasionally two) on the facial surface: they transmit filaments (temporo-malar) of the orbital branch of the superior maxillary nerve. The **maxillary** process is a rough, triangular surface which articulates with the superior maxillary bone. The **zygomatic** process, long, narrow, and serrated, articulates with the zygomatic process of the temporal bone. Of the **four borders**, the *antero-superior* or *orbital* is smooth, arched, and forms a considerable part of the circumference of the orbit. The *antero-inferior* or *maxillary* border is rough, and bevelled at the expense of its inner table, to articulate with the superior maxillary bone; affording attachment by its margin to the Levator labii superioris proprius, just at its point of junction with the superior maxillary. The *postero-superior* or *temporal* border, curved like an italic letter *f*, is continuous above with the commencement of the temporal ridge; below, with the upper border of the zygomatic arch: it affords attachment to the temporal fascia. The *postero-inferior* or *zygomatic* border is continuous with the lower border of the zygomatic arch, affording attachment by its rough edge to the Masseter muscle.

Fig. 165.—Malar bone *in situ*.

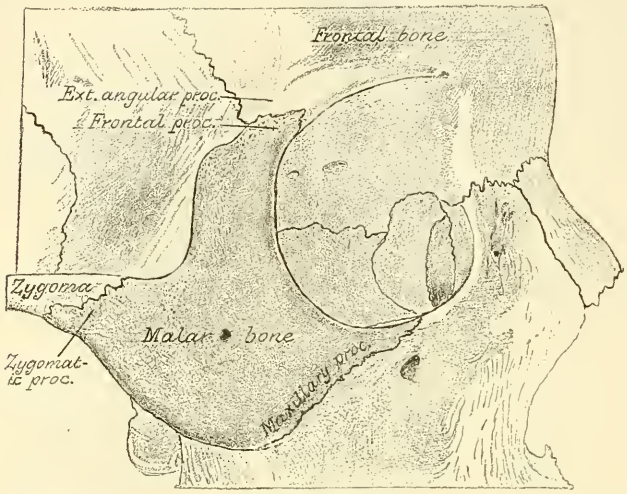


Fig. 166.—Left malar bone. Outer surface.

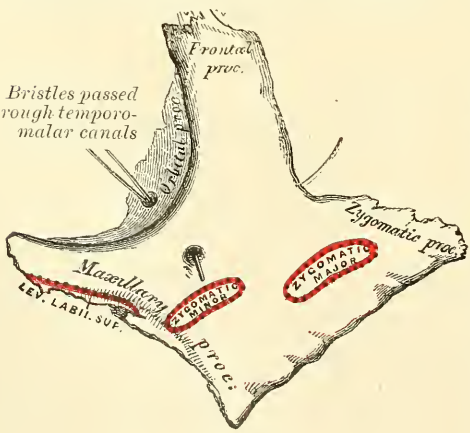


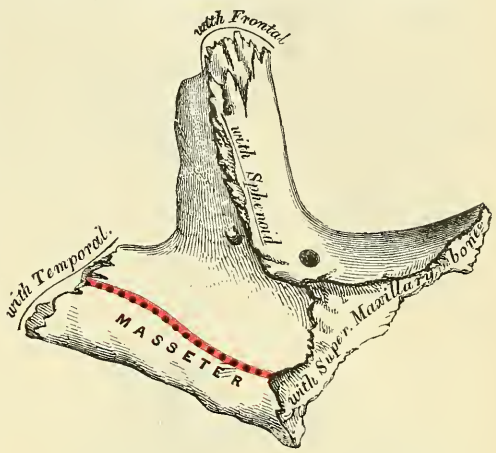
Development.—The malar bone ossifies generally from two, but occasionally

from three, centres. One, which forms the chief part of the bone, appears about the seventh week, near the orbital margin. The second appears somewhat later, along the lower margin. The third, when it exists, is found in the hinder border. The bone is sometimes, after birth, seen to be divided, by a horizontal suture, into an upper and larger division, and a lower and smaller. This divided condition is probably due to the persistent separation of the two centres of ossification. In some quadrumana the malar bone consists of two parts, an orbital and a malar, which are ossified by separate centres.

Articulations.—With four bones: three of the cranium, frontal, sphenoid, and temporal; and one of the face, the superior maxillary.

Attachment of Muscles.—To four: the Levator labii superioris proprius, Zygomaticus major and minor, and Masseter.

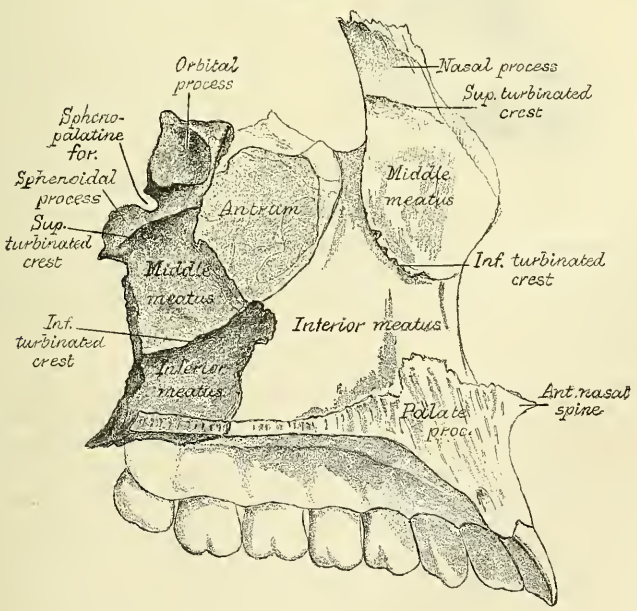
Fig. 167.—Left malar bone. Inner surface.



The Palate Bones

The **Palate Bones** (palatum, *the palate*) are situated at the back part of the nasal fossæ: they are wedged in between the superior maxillary bones and the pterygoid processes of the sphenoid (fig. 168). Each bone assists in the formation of three cavities: the floor and outer wall of the nose, the roof of the mouth, and the floor of the orbit; and enters into the formation of two fossæ: the

Fig. 168.—Palate bone *in situ*.

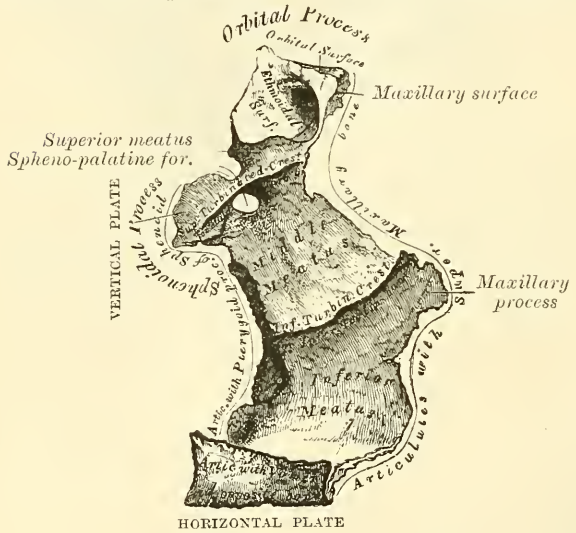


spheno-maxillary and pterygoid; and one fissure, the spheno-maxillary. In form the palate-bone somewhat resembles the letter L, and may be divided into an inferior or horizontal plate and a superior or vertical plate.

The **Horizontal Plate** is thick, of a quadrilateral form, and presents two

surfaces and four borders. The *superior* surface, concave from side to side, forms the back part of the floor of the nostril. The *inferior* surface, slightly concave and rough, forms the back part of the hard palate. At its posterior part may be seen a transverse ridge, more or less marked, for the attachment of part of the aponeurosis of the Tensor palati muscle. At the outer extremity of this ridge is a deep groove converted into a canal by its articulation with the tuberosity of the superior maxillary bone, and forming the *posterior palatine canal*. Near this groove, the orifices of one or two small canals, *accessory posterior palatine*, may be seen. The *anterior* border is serrated, bevelled at the expense of its inferior surface, and articulates with the palate process of the superior maxillary bone. The *posterior* border is concave, free, and serves for the attachment of the soft palate. Its inner extremity is sharp and pointed, and, when united with the opposite bone, forms a projecting process, the *posterior nasal spine*, for the attachment of the Azygos uvulæ. The *external* border is united with the lower part of the perpendicular plate almost at right angles. The *internal* border, the thickest, is serrated for articulation with its fellow of the opposite side; its superior edge is raised into a ridge, which, united with the opposite bone, forms a crest in which the vomer is received.

Fig. 169.—Left palate bone. Internal view. (Enlarged.)



The **Vertical Plate** (fig. 169) is thin, of an oblong form, and directed upwards and a little inwards. It presents two surfaces, an external and an internal, and four borders.

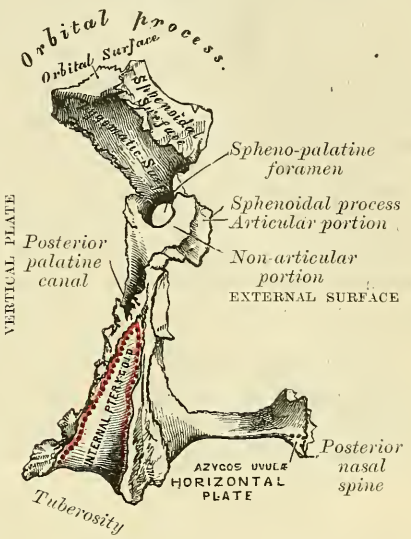
The **internal surface** presents at its lower part a broad, shallow depression, which forms part of the inferior meatus of the nose. Immediately above this is a well-marked, horizontal ridge, the *inferior turbinated crest*, for articulation with the inferior turbinated bone; above this, a second broad, shallow depression, which forms part of the middle meatus, surmounted above by a horizontal ridge less prominent than the inferior, the *superior turbinated crest*, for articulation with the middle turbinated bone. Above the superior turbinated crest is a narrow, horizontal groove, which forms part of the superior meatus.

The **external surface** is rough and irregular throughout the greater part of its extent, for articulation with the inner surface of the superior maxillary bone, its upper and back part being smooth where it enters into the formation of the spheno-maxillary fossa; it is also smooth in front, where it covers the orifice of the antrum. Towards the back part of this surface is a deep groove, converted into a canal, the *posterior palatine*, by its articulation with the superior maxillary bone. It transmits the posterior or descending palatine vessels, and one of the descending palatine branches from Meckel's ganglion.

The *anterior* border is thin, irregular, and presents, opposite the inferior turbinated crest, a pointed, projecting lamina, the *maxillary process*, which is directed forwards, and closes in the lower and back part of the opening of the antrum. The *posterior* border (fig. 170) presents a deep groove, the edges of which are serrated for articulation with the pterygoid process of the sphenoid. At the lower part of this border is seen a pyramidal process of bone, the *pterygoid*

process or tuberosity of the palate, which is received into the angular interval between the two pterygoid plates of the sphenoid at their inferior extremity. This process presents at its back part a median groove and two lateral surfaces. The groove is smooth, and forms part of the pterygoid fossa affording attachment to the Internal pterygoid muscle; whilst the lateral surfaces are rough and uneven, for articulation with the anterior border of each pterygoid plate. A few fibres of the Superior constrictor arise from the tuberosity of the palate-bone. The base of this process, continuous with the horizontal portion of the bone, presents the apertures of the *accessory descending palatine canals*, through which pass the two smaller descending branches of Meckel's ganglion; whilst its outer surface is rough for articulation with the inner surface of the body of the superior maxillary bone.

Fig. 170.—Left palate bone. Posterior view. (Enlarged.)



The *superior* border of the vertical plate presents two well-marked processes separated by an intervening notch or foramen. The anterior, or larger, is called the *orbital process*; the posterior, the *sphenoidal*.

The **Orbital Process,** directed upwards and outwards, is placed on a higher level than the sphenoidal. It presents five surfaces, which enclose a hollow cellular cavity, and is connected to the perpendicular plate by a narrow, constricted neck. Of these five surfaces, three are articular, two non-articular or free surfaces. The three articular are the *anterior* or *maxillary* surface, which is directed forwards, outwards, and downwards, is of an oblong form, and rough for articulation with the superior maxillary bone. The *posterior* or *sphenoidal* surface is directed backwards, upwards, and inwards. It ordinarily presents a small, open cell, which communicates with the sphenoidal cells, and the margins of which are serrated for articulation with the vertical part of the sphenoidal turbinated bone. The *internal* or *ethmoidal* surface is directed inwards, upwards, and forwards, and articulates with the lateral mass of the ethmoid bone. In some cases, the cellular cavity above mentioned opens on this surface of the bone; it then communicates with the posterior ethmoidal cells. More rarely it opens on both surfaces, and then communicates both with the posterior ethmoidal and the sphenoidal cells. The non-articular or free surfaces are the *superior* or *orbital*, directed upwards and outwards, of triangular form, concave, smooth, and forming the back part of the floor of the orbit; and the *external* or *zygomatic* surface, directed outwards, backwards, and downwards, of an oblong form, smooth, lying in the spheno-maxillary fossa, and looking into the zygomatic fossa. The latter surface is separated from the orbital by a smooth, rounded border, which enters into the formation of the spheno-maxillary fissure.

The **Sphenoidal Process** of the palate-bone is a thin, compressed plate, much smaller than the orbital, and directed upwards and inwards. It presents three surfaces and two borders. The *superior* surface, the smallest of the three, articulates with the under surface of the sphenoidal turbinated bone; it presents a groove, which contributes to the formation of the pterygo-palatine canal. The *internal* surface is concave, and forms part of the outer wall of the nasal fossa. The *external* surface is divided into an articular and non-articular portion: the

former is rough, for articulation with the inner surface of the internal pterygoid plate of the sphenoid; the latter is smooth, and forms part of the spheno-maxillary fossa. The *anterior* border forms the posterior boundary of the spheno-palatine foramen. The *posterior* border, serrated at the expense of the outer table, articulates with the inner surface of the internal pterygoid plate.

The orbital and sphenoidal processes are separated from one another by a deep notch, which is converted into a foramen, the *spheno-palatine*, by articulation with the sphenoidal turbinated bone. Sometimes the two processes are united above, and form between them a complete foramen, or the notch is crossed by one or more spiculæ of bone, so as to form two or more foramina. In the articulated skull, this foramen opens into the back part of the outer wall of the superior meatus, and transmits the spheno-palatine vessels and the superior nasal and naso-palatine nerves.

Development.—From a single centre, which makes its appearance about the second month at the angle of junction of the two plates of the bone. From this point ossification spreads inwards to the horizontal plate, downwards into the tuberosity, and upwards into the vertical plate. In the fœtus, the horizontal plate is much longer than the vertical; and even after it is fully ossified, the whole bone is at first remarkable for its shortness.

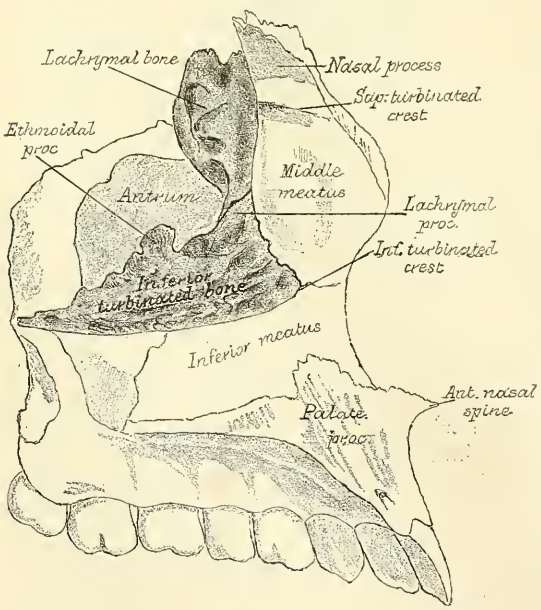
Articulations.—With six bones: the sphenoid, ethmoid, superior maxillary, inferior turbinated, vomer, and opposite palate.

Attachment of Muscles.—To four: the Tensor palati, Azygos uvulæ, Internal pterygoid, and Superior constrictor of the pharynx.

The Inferior Turbinated Bones

The **Inferior Turbinated Bones** (turbo, *a whirl*) are situated one on each side of the outer wall of the nasal fossæ. Each consists of a layer of thin, spongy bone, curled upon itself like a scroll—hence its name 'turbinated'—and extends horizontally along the outer wall of the nasal fossa, immediately below the orifice of the antrum (fig. 171). Each bone presents two surfaces, two borders, and two extremities.

Fig. 171.—Inferior turbinated bone and Lachrymal bone *in situ*.



The **internal surface** (fig. 172) is convex, perforated by numerous apertures, and traversed by longitudinal grooves and canals for the lodgment of arteries and veins. In the recent state it is covered by the lining membrane of the nose. The **external surface** is concave (fig. 173), and forms part of the inferior meatus. Its *upper border* is thin, irregular, and connected to various bones along the outer wall of the nose. It may be divided into three portions; of these, the anterior articulates with the inferior turbinated crest of the superior maxillary bone; the posterior with the inferior turbinated crest of the palate-bone; the middle portion of the superior border presents three well-marked processes, which vary much in their size and form. Of these, the anterior and smallest is situated at the

junction of the anterior fourth with the posterior three-fourths of the bone: it is small and pointed, and is called the *lachrymal process*; it articulates, by its apex, with the anterior inferior angle of the lachrymal bone, and, by its margins, with the groove on the back of the nasal process of the superior maxillary, and thus assists in forming the canal for the nasal duct. At the junction of the two middle fourths of the bone, but encroaching on its posterior fourth, a broad, thin plate, the *ethmoidal process*, ascends to join the unciform process of the ethmoid; from the lower border of this process a thin lamina of bone curves downwards and outwards, hooking over the lower edge of the orifice of the antrum, which it narrows below: it is called the *maxillary process*, and fixes the bone firmly on to the outer wall of the nasal fossa. The *inferior border* is free, thick, and cellular in structure, more especially in the middle of the bone. Both *extremities* are more or less narrow and pointed, the posterior being the more tapering. If the bone is held so that its outer concave surface is directed backwards (i.e. towards the holder), and its superior border, from which the

Fig. 172.—Right inferior turbinated bone. Internal surface.

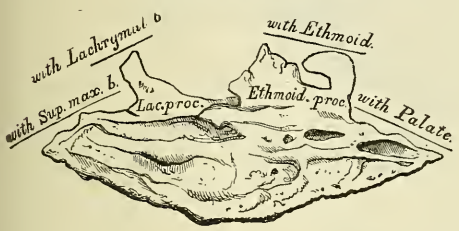


Fig. 173.—Right inferior turbinated bone. External surface.

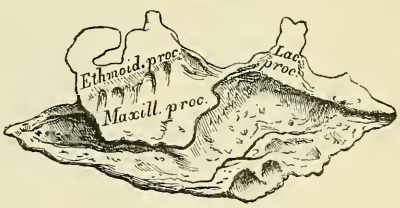


lachrymal and ethmoidal processes project, upwards, the lachrymal process will be directed to the side to which the bone belongs.*

Development.—By a single centre, which makes its appearance about the middle of fœtal life.

Articulations.—With four bones: one of the cranium, the ethmoid, and three of the face, the superior maxillary, lachrymal, and palate.

No muscles are attached to this bone.

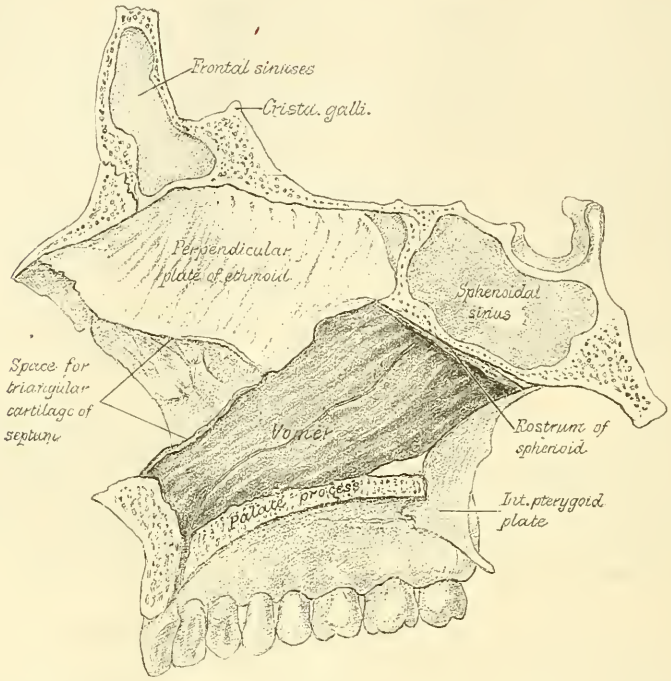
The Vomer

The **Vomer** (vomer, *a ploughshare*) is a single bone, situated vertically at the back part of the nasal fossæ, forming part of the septum of the nose (fig. 174). It is thin, somewhat like a ploughshare in form; but it varies in different individuals, being frequently bent to one or the other side; it presents for examination two surfaces and four borders. The *lateral surfaces* are smooth, marked by small furrows for the lodgment of blood-vessels, and by a groove on each side, sometimes a canal, the *naso-palatine*, which runs obliquely downwards and forwards to the intermaxillary suture; it transmits the naso-palatine nerve. The *superior border*, the thickest, presents a deep groove, bounded on each side by a horizontal projecting ala of bone; the groove receives the rostrum of the sphenoid, whilst the alæ are overlapped and retained by laminæ (the *vaginal processes*) which project from the under surface of the body of the sphenoid at the base of the pterygoid processes. At the front of the groove a fissure is left for the transmission of blood-vessels to the substance of the bone. The *inferior border*, the longest, is broad and uneven in front, where it articulates with the two superior maxillary bones; thin and sharp behind, where it joins with the palate-bones. The upper half of the *anterior border* usually consists of two

* If the lachrymal process is broken off, as is often the case, the side to which the bone belongs may be known by recollecting that the maxillary process is nearer the back than the front of the bone.

laminæ of bone, between which is received the perpendicular plate of the ethmoid; the lower half, also separated into two lamellæ, receives between them the lower margin of the triangular cartilage of the nose. The *posterior border* is

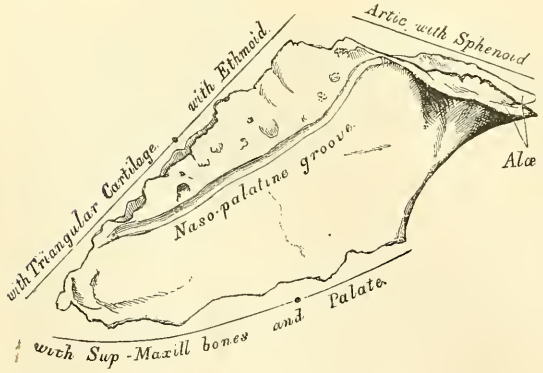
Fig. 174.—Vomer *in situ*.



free, concave, and separates the nasal fossæ behind. It is thick and bifid above, thin below.

The surfaces of the vomer are covered by mucous membrane, which is intimately connected with the periosteum, with the intervention of very little, if any, submucous connective tissue. Hence polypi are rarely found growing from this surface, though they frequently grow from the outer wall of the nasal fossæ, where the submucous tissue is abundant.

Fig. 175.—The vomer.



Development.—The vomer at an early period consists of two laminæ, separated by a very considerable interval, and enclosing between them a plate of cartilage, which is prolonged forwards to form the remainder of the septum. Ossification commences in it by a single centre about the eighth week. From this nucleus the two laminæ are formed. They begin to coalesce at the lower part, but their union is not complete until after puberty.

Articulations.—With six bones: two of the cranium, the sphenoid and ethmoid; and four of the face, the two superior maxillary and the two palate-bones; and with the cartilage of the septum.

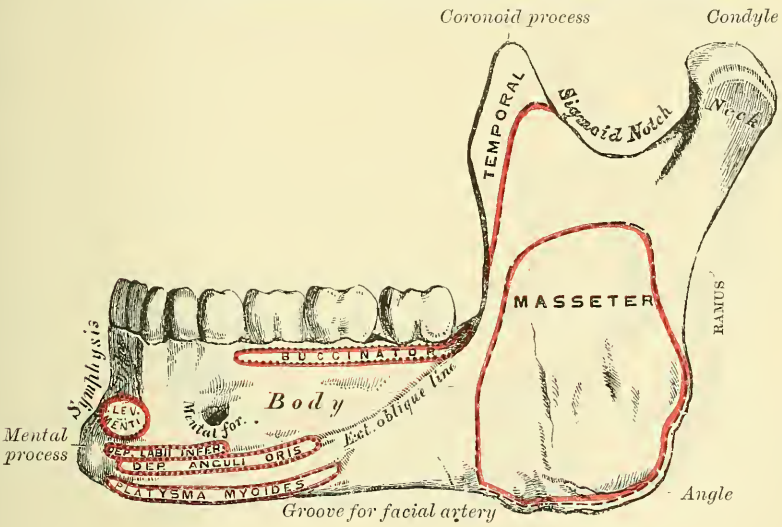
The vomer has no muscles attached to it.

The Inferior Maxillary Bone

The **Inferior Maxillary Bone** (the *Mandible*), the largest and strongest bone of the face, serves for the reception of the lower teeth. It consists of a curved, horizontal portion, the *body*, and two perpendicular portions, the *rami*, which join the back part of the body nearly at right angles.

The **Horizontal Portion**, or **Body** (fig. 176), is convex in its general outline, and curved somewhat like a horse-shoe. It presents for examination two surfaces and two borders. The **external surface** is convex from side to side, concave from above downwards. In the median line is a vertical ridge, the *symphysis*, which extends from the upper to the lower border of the bone, and indicates the point of junction of the two pieces of which the bone is composed at an early period of life. The lower part of the ridge terminates in a prominent triangular eminence, the *mental process*. This eminence is rounded below, and often presents a median depression separating two processes, the *mental tubercles*. It forms the chin, a feature peculiar to the human skull. On either side of the symphysis,

Fig. 176.—Inferior maxillary bone. Outer surface. Side view.

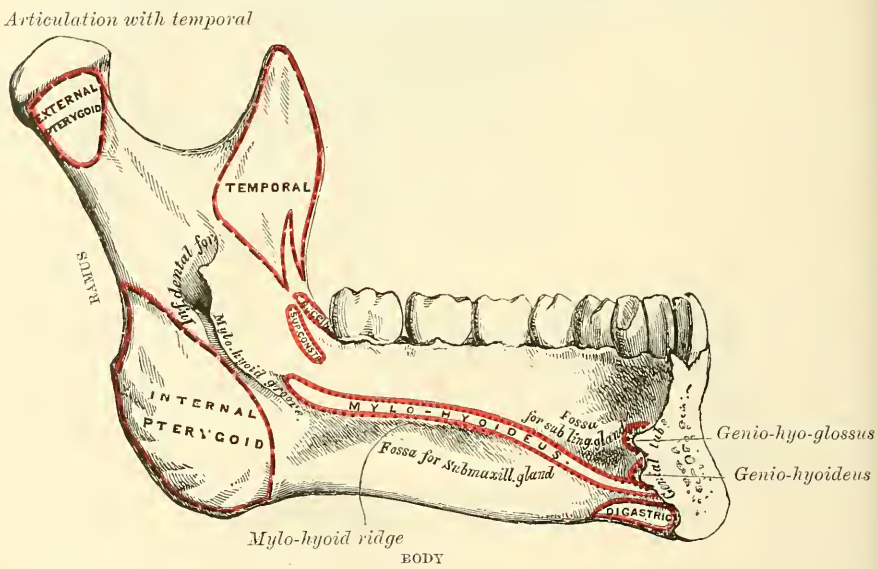


just below the cavities for the incisor teeth, is a depression, the *incisive fossa*, for the attachment of the Levator menti (or Levator labii inferioris); more externally is attached a portion of the Orbicularis oris (*Accessorii Orbicularis inferioris*), and, still more externally, a foramen, the *mental foramen*, for the passage of the mental vessels and nerve. This foramen is placed just below the interval between the two bicuspid teeth. Running outwards from the base of the mental process on each side is a ridge, the *external oblique* line. The ridge is at first nearly horizontal, but afterwards inclines upwards and backwards, and is continuous with the anterior border of the ramus: it affords attachment to the Depressor labii inferioris and Depressor anguli oris; below it the Platysma myoides is attached.

The **internal surface** (fig. 177) is concave from side to side, convex from above downwards. In the middle line is an indistinct linear depression, corresponding to the symphysis externally; on either side of this depression, just below its centre, are four prominent tubercles, placed in pairs, two above and two below; they are called the *genial tubercles*, and afford attachment, the upper pair to the Genio-hyo-glossi muscles, the lower pair to the Genio-hyoidei muscles. Sometimes the tubercles on each side are blended into one, at others they all unite into

an irregular eminence, or again, nothing but an irregularity may be seen on the surface of the bone at this part. On either side of the genial tubercles is an oval depression, the *sublingual fossa*, for lodging the sublingual gland; and beneath the fossa, a rough depression on each side, which gives attachment to the anterior belly of the Digastric muscle. At the back part of the sublingual fossa, the *internal oblique line* (*mylo-hyoidean*) commences; it is at first faintly marked, but becomes more distinct as it passes upwards and outwards, and is especially prominent opposite the last two molar teeth; it affords attachment throughout its whole extent to the Mylo-hyoid muscle: the Superior constrictor of the pharynx with the pterygo-maxillary ligament, being attached above its posterior extremity, near the alveolar margin. The portion of bone above this ridge is smooth, and covered by the mucous membrane of the mouth; the portion below presents an oblong depression, the *submaxillary fossa*, wider behind than in front, for the lodgment of the submaxillary gland. The external oblique line and the internal or mylo-hyoidean line divide the body of the bone into a superior or alveolar and an inferior or basilar portion.

FIG. 177.—Inferior maxillary bone. Inner surface. Side view.



The **superior** or **alveolar** border is wider, and its margins thicker, behind than in front. It is hollowed into numerous cavities, for the reception of the teeth; these cavities are sixteen in number, and vary in depth and size according to the teeth which they contain. To its outer side, the Buccinator muscle is attached as far forward as the first molar tooth. The **inferior** border is rounded, longer than the superior and thicker in front than behind; it presents a shallow groove, just where the body joins the ramus, over which the facial artery turns.

The **Perpendicular Portions**, or **Rami**, are of a quadrilateral form. Each presents for examination two surfaces, four borders, and two processes. The *external surface* is flat, marked with ridges, and gives attachment throughout nearly the whole of its extent to the Masseter muscle. The *internal surface* presents about its centre the oblique aperture of the inferior dental canal, for the passage of the inferior dental vessels and nerve. The margin of this opening is irregular; it presents in front a prominent ridge, surmounted by a sharp spine, the *lingula*, which gives attachment to the internal lateral ligament of the lower jaw, and at its lower and back part a notch leading to a groove, the *mylo-hyoidean*, which runs obliquely downwards to the back part of the submaxillary fossa,

and lodges the mylo-hyoid vessels and nerve. Behind the groove is a rough surface, for the insertion of the Internal pterygoid muscle. The inferior dental canal runs obliquely downwards and forwards in the substance of the ramus, and then horizontally forwards in the body; it is here placed under the alveoli, with which it communicates by small openings. On arriving at the incisor teeth, it turns back to communicate with the mental foramen, giving off two small canals, which run forward, to be lost in the cancellous tissue of the bone beneath the incisor teeth. This canal, in the posterior two-thirds of the bone, is situated nearer the internal surface of the jaw; and in the anterior third, nearer its external surface. Its walls are composed of compact tissue at either extremity, and of cancellous in the centre. It contains the inferior dental vessels and nerve, from which branches are distributed to the teeth through small apertures at the bases of the alveoli. The *lower border* of the ramus is thick, straight, and continuous with the body of the bone. At its junction with the posterior border is the *angle of the jaw*, which is either inverted or everted, and marked by rough, oblique ridges on each side, for the attachment of the Masseter externally, and the Internal pterygoid internally; the stylo-maxillary ligament is attached to the bone between these muscles. The *anterior border* is thin above, thicker below, and continuous with the external oblique line. The *posterior border* is thick, smooth, rounded, and covered by the parotid gland. The *upper border* of the ramus is thin, and presents two processes, separated by a deep concavity, the *sigmoid notch*. Of these processes, the anterior is the *coronoid*, the posterior the *condyloid*.

The **Coronoid Process** is a thin, flattened triangular eminence of bone, which varies in shape and size in different subjects, and serves chiefly for the attachment of the Temporal muscle. Its *external surface* is smooth, and affords attachment to the Temporal muscle. Its *internal surface* gives attachment to the Temporal muscle, and presents the commencement of a longitudinal ridge, which is continued to the posterior part of the alveolar process. On the outer side of this ridge is a deep groove, continued below on the outer side of the alveolar process; this ridge and part of the groove afford attachment, above, to the Temporal; below, to the Buccinator muscle.

The **Condyloid Process,** shorter but thicker than the coronoid, consists of two portions: the *condyle*, and the constricted portion which supports the condyle, the *neck*. The *condyle* is of an oblong form, its long axis being transverse, and set obliquely on the neck in such a manner that its outer end is a little more forward and a little higher than its inner. It is convex from before backwards, and from side to side, the articular surface extending further on the posterior than on the anterior aspect. At its outer extremity is a small tubercle for the attachment of the external lateral ligament of the temporo-maxillary joint. The *neck* of the condyle is flattened from before backwards, and strengthened by ridges which descend from the fore part and sides of the condyle. Its lateral margins are narrow, and present externally a tubercle for the external lateral ligament. Its posterior surface is convex; its anterior is hollowed out on its inner side by a depression (the *pterygoid fossa*) for the attachment of the External pterygoid.

The **Sigmoid Notch,** separating the two processes, is a deep semilunar depression, crossed by the masseteric vessels and nerve.

Development.—The lower jaw is developed principally from membrane, but partly from cartilage. The process of ossification commences early—earlier than any other bone except the clavicle. Between the fifth and sixth week a centre of ossification appears in the membrane on the outer surface of Meckel's cartilage (see page 93), from which the greater part of the bone is formed. A second centre appears in the membrane on the inner surface of the tooth sockets, from which the inner wall of the sockets of the teeth is formed; this terminates above in the lingula. The anterior extremity of Meckel's cartilage becomes ossified, forming the body of the bone on each side of the symphysis. And, finally, two

Side View of the Lower Jaw at Different Periods of Life

Fig. 178.—At birth.

Fig. 179.—At puberty.

Fig. 180.—In the adult.

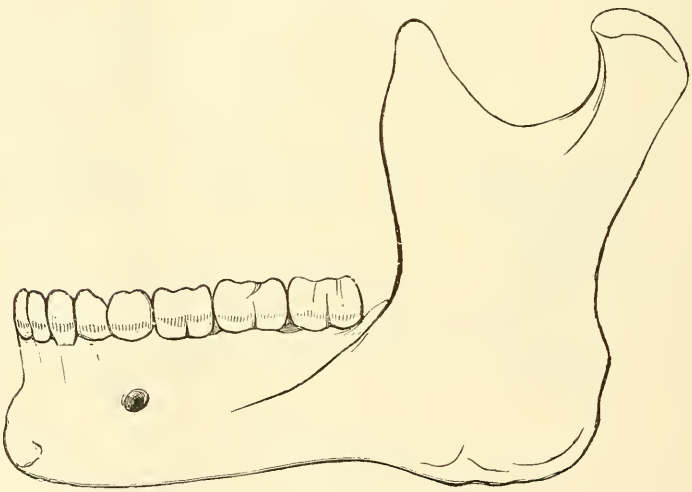


Fig. 181.—In old age.

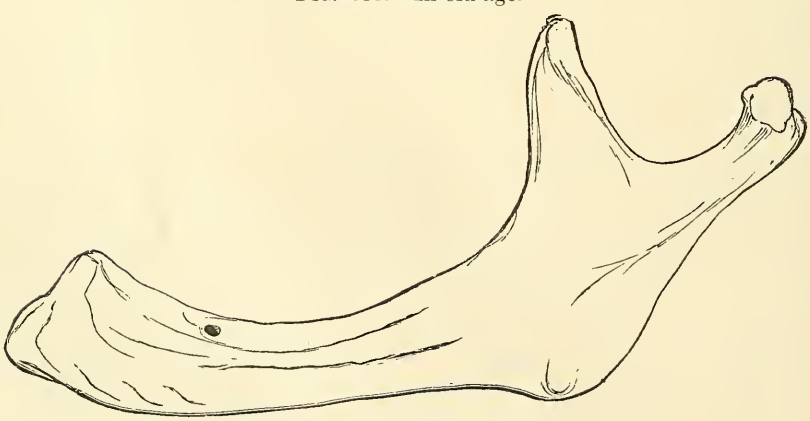


supplemental patches of cartilage appear at the condyle and at the angle, in which centres of ossification for these parts appear. At birth the bone consists of two halves, united by a fibrous symphysis, in which ossification takes place during the first year.

Articulation.—With the glenoid fossæ of the two temporal bones.

Attachment of Muscles.—To fifteen pairs; to its external surface, commencing at the symphysis, and proceeding backwards: Levator menti, Depressor labii inferioris, Depressor anguli oris, Platysma myoides, Buccinator, Masseter; a portion of the Orbicularis oris (Accessorii Orbicularis inferioris) is also attached to this surface. To its internal surface, commencing at the same point: Genio-hyoglossus, Genio-hyoideus, Mylo-hyoideus, Digastric, Superior constrictor, Temporal, Internal pterygoid, External pterygoid.

Changes produced in the Lower Jaw by Age

The changes which the Lower Jaw undergoes after birth, relate (1) to the alterations effected in the body of the bone by the first and second dentitions, the loss of the teeth in the aged, and the subsequent absorption of the alveoli; (2) to the size and situation of the dental canal; and (3) to the angle at which the ramus joins with the body.

At birth (fig. 178), the bone consists of lateral halves, united by fibrous tissue. The body is a mere shell of bone, containing the sockets of the two incisor, the canine, and the two temporary molar teeth, imperfectly partitioned from one another. The dental canal is of large size, and runs near the lower border of the bone, the mental foramen opening beneath the socket of the first molar. The angle is obtuse (175°), and the condyloid portion nearly in the same horizontal line with the body; the neck of the condyle is short, and bent backwards. The coronoid process is of comparatively large size, and situated at right angles with the rest of the bone.

After birth (fig. 179), the two segments of the bone become joined at the symphysis, from below upwards, in the first year; but a trace of separation may be visible in the beginning of the second year, near the alveolar margin. The body becomes elongated in its whole length, but more especially behind the mental foramen, to provide space for the three additional teeth developed in this part. The depth of the body becomes greater, owing to increased growth of the alveolar part, to afford room for the fangs of the teeth, and by thickening of the subdental portion which enables the jaw to withstand the powerful action of the masticatory muscles; but the alveolar portion is the deeper of the two and, consequently, the chief part of the body lies above the oblique line. The dental canal, after the second dentition, is situated just above the level of the mylo-hyoid ridge; and the mental foramen occupies the position usual to it in the adult. The angle becomes less obtuse, owing to the separation of the jaws by the teeth. (About the fourth year it is 140°.)

In the adult (fig. 180), the alveolar and basilar portions of the body are usually of equal depth. The mental foramen opens midway between the upper and lower border of the bone, and the dental canal runs nearly parallel with the mylo-hyoid line. The ramus is almost vertical in direction, and joins the body nearly at right angles.

In old age (fig. 181), the bone becomes greatly reduced in size: for with the loss of the teeth the alveolar process is absorbed, and the basilar part of the bone alone remains; consequently, the chief part of the bone is *below* the oblique line. The dental canal, with the mental foramen opening from it, is close to the alveolar border. The rami are oblique in direction, the angle obtuse, and the neck of the condyle more or less bent backwards.

THE SUTURES

The bones of the cranium and face are connected to each other by means of *Sutures*. That is, the articulating surfaces or edges of the bones are more or less roughened or uneven, and are closely adapted to each other, a small amount of intervening fibrous tissue fastening them together. The *Cranial Sutures* may be divided into three sets: 1. Those at the vertex of the skull. 2. Those at the side of the skull. 3. Those at the base.

The sutures at the vertex of the skull are three: the *sagittal*, *coronal*, and *lambdoid*.

The **Sagittal Suture** (*interparietal*) is formed by the junction of the two parietal bones, and extends from the middle of the frontal bone, backwards to the superior angle of the occipital. In childhood, and occasionally in the adult, when the two halves of the frontal bone are not united, it is continued forwards

to the root of the nose. This suture is sometimes perforated, near its posterior extremity, by the parietal foramen; and in front, where it joins the coronal suture, a space is occasionally left, which encloses a large Wormian bone.

The **Coronal Suture** (*fronto-parietal*) extends transversely across the vertex of the skull, and connects the frontal with the parietal bones. It commences at the extremity of the greater wing of the sphenoid on one side, and terminates at the same point on the opposite side. The dentations of the suture are more marked at the sides than at the summit, and are so constructed that the frontal rests on the parietal above, whilst laterally the frontal supports the parietal.

The **Lambdoid Suture** (*occipito-parietal*), so called from its resemblance to the Greek letter Λ, connects the occipital with the parietal bones. It commences on each side at the mastoid portion of the temporal bone, and inclines upwards to the end of the sagittal suture. The dentations of this suture are very deep and distinct, and are often interrupted by several small Wormian bones.

The sutures at the side of the skull extend from the external angular process of the frontal bone to the lower end of the lambdoid suture behind. The anterior portion is formed between the lateral part of the frontal bone above and the malar and great wing of the sphenoid below, forming the *fronto-malar* and *fronto-sphenoidal* sutures. These sutures can also be seen in the orbit, and form part of the so-called *transverse facial* suture. The posterior portion is formed between the parietal bone above and the great wing of the sphenoid, the squamous and mastoid portions of the temporal bone, forming the *spheno-parietal*, *squamo-parietal*, and *masto-parietal* sutures.

The **Spheno-parietal** is very short; it is formed by the tip of the great wing of the sphenoid, which overlaps the anterior inferior angle of the parietal bone.

The **Squamo-parietal,** or **Squamous Suture,** is arched. It is formed by the squamous portion of the temporal bone overlapping the middle division of the lower border of the parietal.

The **Masto-parietal** is a short suture, deeply dentated, formed by the posterior inferior angle of the parietal, and the superior border of the mastoid portion of the temporal.

The sutures at the base of the skull are, the *basilar* in the centre, and on each side, the *petro-occipital*, the *masto-occipital*, the *petro-sphenoidal*, and the *squamo-sphenoidal*.

The **Basilar Suture** is formed by the junction of the basilar surface of the occipital bone with the posterior surface of the body of the sphenoid. At an early period of life a thin plate of cartilage exists between these bones; but in the adult they become fused into one. Between the outer extremity of the basilar suture and the termination of the lambdoid, an irregular suture exists, which is subdivided into two portions. The inner portion, formed by the union of the petrous part of the temporal with the occipital bone, is termed the **petro-occipital**. The outer portion, formed by the junction of the mastoid part of the temporal with the occipital, is called the **masto-occipital**. Between the bones forming the petro-occipital suture, a thin plate of cartilage exists; in the masto-occipital is occasionally found the opening of the mastoid foramen. Between the outer extremity of the basilar suture and the spheno-parietal, an irregular suture may be seen, formed by the union of the sphenoid with the temporal bone. The inner and smaller portion of this suture is termed the **petro-sphenoidal**; it is formed between the petrous portion of the temporal and the great wing of the sphenoid: the outer portion, of greater length, and arched, is formed between the squamous portion of the temporal and the great wing of the sphenoid; it is called the **squamo-sphenoidal.**

The cranial bones are connected with those of the face, and the facial bones with each other, by numerous sutures, which, though distinctly marked, have received no special names. The only remaining suture deserving especial consideration is the **transverse.** This extends across the upper part of the face, and is formed by the junction of the frontal with the facial bones; it extends from the

external angular process of one side to the same point on the opposite side, and connects the frontal with the malar, the sphenoid, the ethmoid, the lachrymal, the superior maxillary, and the nasal bones on each side.

The sutures remain separate for a considerable period after the complete formation of the skull. It is probable that they serve the purpose of permitting the growth of the bones at their margins; while their peculiar formation, together with the interposition of the sutural ligament between the bones forming them, prevents the dispersion of blows or jars received upon the skull. Humphry remarks 'that, as a general rule, the sutures are first obliterated at the parts in which the ossification of the skull was last completed—viz. in the neighbourhood of the fontanelles; and the cranial bones seem in this respect to observe a similar law to that which regulates the union of the epiphyses to the shafts of the long bones.' The same author remarks that the time of their disappearance is extremely variable: they are sometimes found well marked in skulls edentulous with age, while in others which have only just reached maturity they can hardly be traced.

THE SKULL AS A WHOLE

The Skull, formed by the union of the several cranial and facial bones already described, when considered as a whole, is divisible into five regions: a superior region or vertex, an inferior region or base, two lateral regions, and an anterior region, the face.

Vertex of the Skull

The **Superior Region**, or **Vertex**, presents two surfaces, an external and an internal.

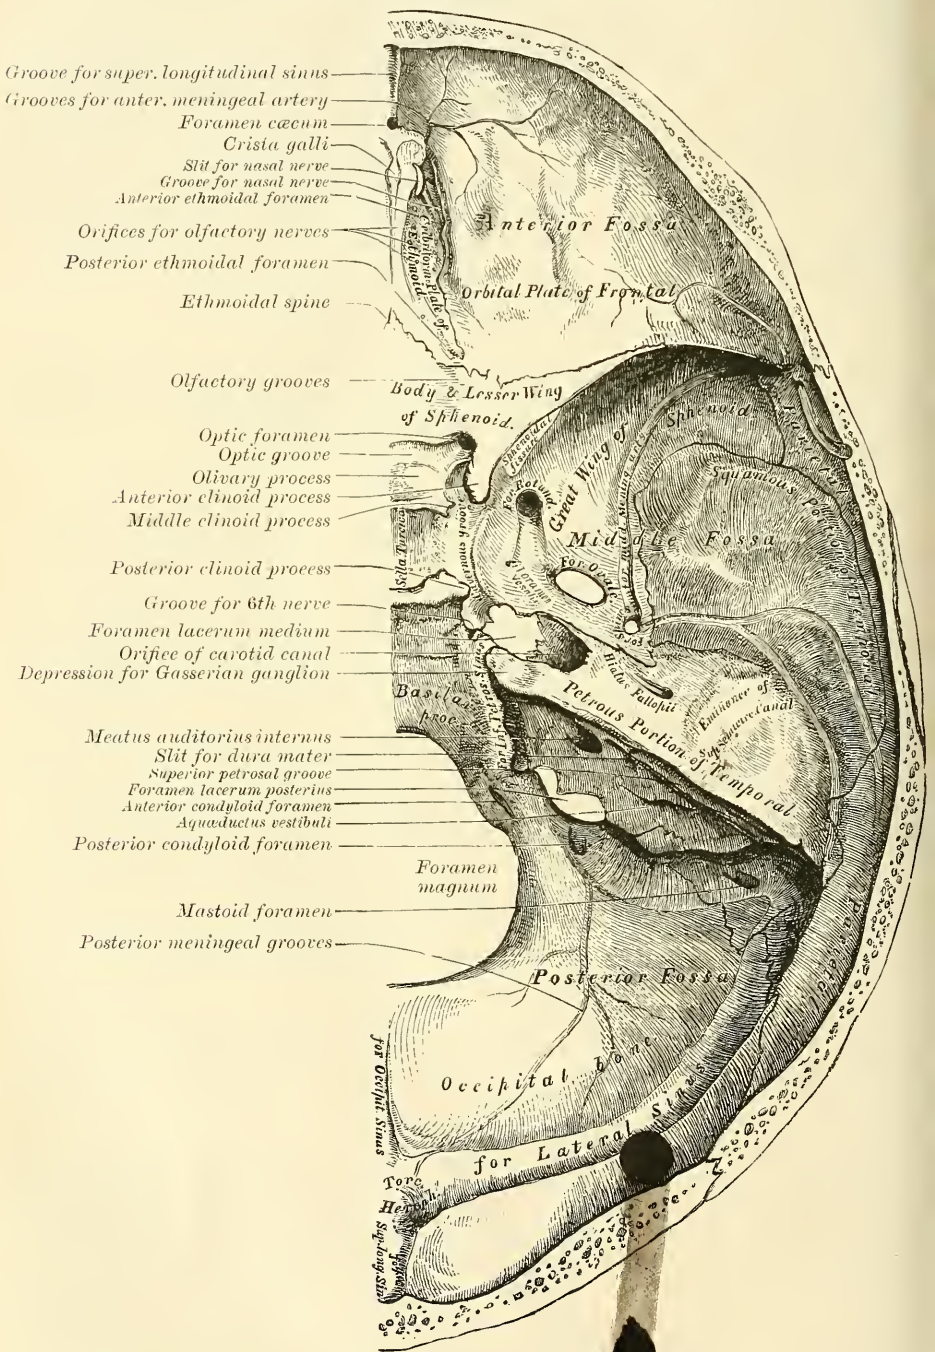
The **external surface** is bounded, in front, by the glabella and supra-orbital ridges; behind, by the occipital protuberance and superior curved lines of the occipital bone; laterally, by an imaginary line extending from the outer end of the superior curved line, along the temporal ridge, to the external angular process of the frontal. This surface includes the vertical portion of the frontal, the greater part of the parietal, and the superior third of the occipital bone; it is smooth, convex, of an elongated oval form, crossed transversely by the coronal suture, and from before backwards by the sagittal, which terminates behind in the lambdoid. The point of junction of the coronal and sagittal sutures is named the *bregma*, and is represented by a line drawn vertically upwards from the external auditory meatus, the head being in its normal position. The point of junction of the sagittal and lambdoid sutures is called the *lambda*, and is about $2\frac{3}{4}$ inches above the external occipital protuberance. From before backwards may be seen the frontal eminences and remains of the suture connecting the two lateral halves of the frontal bone; on each side of the sagittal suture are the parietal foramen and parietal eminence, and still more posteriorly the convex surface of the occipital bone. In the neighbourhood of the parietal foramen the skull is often flattened, and to this region the name of *obelion* is sometimes given.

The **internal surface** is concave, presents eminences and depressions for the convolutions of the cerebrum, and numerous furrows for the lodgment of branches of the meningeal arteries. Along the middle line of this surface is a longitudinal groove, narrow in front, where it commences at the frontal crest; but broader behind, where it lodges the superior longitudinal sinus, and by its margin affords attachment to the falx cerebri. On either side of it are several depressions for the Pacchionian bodies, and at its back part, the internal openings of the parietal foramina. This surface is crossed, in front, by the coronal suture; from before backwards, by the sagittal; behind by the lambdoid.

Base of the Skull

The **Inferior Region,** or **Base of the Skull,** presents two surfaces—an internal or cerebral, and an external or basilar.

Fig. 182.—Base of the skull. Inner or cerebral surface.



The **internal** or **cerebral surface** (fig. 182) presents three fossæ, called the *anterior, middle,* and *posterior* fossæ of the cranium.

The **Anterior Fossa** is formed by the orbital plates of the frontal, the cribriform

plate of the ethmoid, the anterior third of the superior surface of the body, and the upper surface of the lesser wings of the sphenoid. It is the most elevated of the three fossæ, convex externally where it corresponds to the roof of the orbit, concave in the median line in the situation of the cribriform plate of the ethmoid. It is traversed by three sutures, the *ethmo-frontal*, *ethmo-sphenoidal*, and *fronto-sphenoidal*; and lodges the frontal lobes of the cerebrum. It presents, in the median line, from before backwards, the commencement of the *groove* for the superior longitudinal sinus, and the *frontal crest* for the attachment of the falx cerebri; the *foramen cæcum*, an aperture formed between the frontal bone and the crista galli of the ethmoid, which, if pervious, transmits a small vein from the nose to the superior longitudinal sinus; behind the foramen cæcum, the *crista galli*, the posterior margin of which affords attachment to the falx cerebri; on either side of the crista galli, the *olfactory groove*, which supports the bulb of the olfactory tract, and presents three rows of foramina for its filaments, and in front a slit-like opening for the nasal branch of the ophthalmic division of the fifth nerve. On the outer side of each olfactory groove are the internal openings of the *anterior* and *posterior ethmoidal foramina*; the former, situated about the middle of the outer margin of the olfactory groove, transmits the anterior ethmoidal vessels and the nasal nerve, which latter runs in a depression along the surface of the ethmoid, to the slit-like opening above mentioned; whilst the posterior ethmoidal foramen opens at the back part of this margin under cover of the projecting lamina of the sphenoid, and transmits the posterior ethmoidal vessels. Further back in the middle line is the *ethmoidal spine*, bounded behind by an elevated ridge, separating two longitudinal grooves which support the olfactory tracts. Behind this is a transverse sharp ridge, running outwards on either side to the anterior margin of the optic foramen, and separating the anterior from the middle fossa of the base of the skull. The anterior fossa presents, laterally, eminences and depressions for the convolutions of the brain, and grooves for the lodgment of the anterior meningeal arteries.

The **Middle Fossa**, deeper than the preceding, is narrow in the middle line, but becomes wider at the side of the skull. It is bounded in front by the posterior margin of the lesser wing of the sphenoid, the anterior clinoid process, and the ridge forming the anterior margin of the optic groove; behind, by the superior border of the petrous portion of the temporal, and the dorsum ephippii; externally by the squamous portion of the temporal, anterior inferior angle of the parietal bone, and greater wing of the sphenoid. It is traversed by four sutures, the squamo-parietal, spheno-parietal, squamo-sphenoidal, and petro-sphenoidal.

In the middle line, from before backwards, is the *optic groove*, which supports the optic commissure, and terminates on each side in the optic foramen, for the passage of the optic nerve and ophthalmic artery; behind the optic groove is the *olivary process*, and laterally the *anterior clinoid processes*, to which are attached processes of the tentorium cerebelli. Further back is the *sella turcica*, a deep depression, which lodges the pituitary gland, bounded in front by a small eminence on either side, the *middle clinoid process*, and behind by a broad square plate of bone, the *dorsum ephippii*, surmounted at each superior angle by a tubercle, the *posterior clinoid process*; beneath the latter process is a notch, for the sixth nerve. On each side of the sella turcica is the *cavernous groove*: it is broad, shallow, and curved somewhat like the italic letter *f*; it commences behind at the foramen lacerum medium, and terminates on the inner side of the anterior clinoid process, and presents along its outer margin a ridge of bone. This groove lodges the cavernous sinus, the internal carotid artery, and the nerves of the orbit. The sides of the middle fossa are of considerable depth; they present eminences and depressions for the convolutions of the brain, and grooves for the branches of the middle meningeal artery; the latter commence on the outer side of the foramen spinosum, and consist of two large branches,

an anterior and a posterior; the former passing upwards and forwards to the anterior inferior angle of the parietal bone, the latter passing upwards and backwards. The following foramina may also be seen from before backwards. Most anteriorly is the *foramen lacerum anterius*, or *sphenoidal fissure*, formed above by the lesser wing of the sphenoid; below, by the greater wing; internally, by the body of the sphenoid; and sometimes completed externally by the orbital plate of the frontal bone. It transmits the third, the fourth, the three branches of the ophthalmic division of the fifth, the sixth nerve, some filaments from the cavernous plexus of the sympathetic, the orbital branch of the middle meningeal artery, a recurrent branch from the lachrymal artery to the dura mater, and the ophthalmic vein. Behind the inner extremity of the sphenoidal fissure is the *foramen rotundum*, for the passage of the second division of the fifth or superior maxillary nerve; still more posteriorly is seen a small orifice, the *foramen Vesalii*, an opening situated between the foramen rotundum and ovale, a little internal to both: it varies in size in different individuals, and is often absent; when present, it transmits a small vein. It opens below into the pterygoid fossa, just at the outer side of the scaphoid depression. Behind and external to the latter opening is the *foramen ovale*, which transmits the third division of the fifth or inferior maxillary nerve, the small meningeal artery, and the small petrosal nerve.* On the outer side of the foramen ovale is the *foramen spinosum*, for the passage of the middle meningeal artery; and on the inner side of the foramen ovale, the *foramen lacerum medium*. The lower part of this aperture is filled up with cartilage in the recent state. The Vidian nerve and a meningeal branch from the ascending pharyngeal artery pierce this cartilage. On the anterior surface of the petrous portion of the temporal bone is seen, from without inwards, the eminence caused by the projection of the superior semicircular canal; in front of and a little outside this a depression corresponding to the roof of the tympanum; the groove leading to the hiatus Fallopii, for the transmission of the petrosal branch of the Vidian nerve and the petrosal branch of the middle meningeal artery; beneath it, the smaller groove, for the passage of the lesser petrosal nerve, and, near the apex of the bone, the depression for the Gasserian ganglion; and the orifice of the carotid canal, for the passage of the internal carotid artery and carotid plexus of nerves.

The **Posterior Fossa**, deeply concave, is the largest of the three, and situated on a lower level than either of the preceding. It is formed by the posterior third of the superior surface of the body of the sphenoid, by the occipital, the petrous and mastoid portions of the temporal, and the posterior inferior angle of the parietal bone; it is crossed by four sutures, the petro-occipital, the masto-occipital, the masto-parietal, and the basilar; and lodges the cerebellum, pons Varolii, and medulla oblongata. It is separated from the middle fossa in the median line by the dorsum ephippii, and on each side by the superior border of the petrous portion of the temporal bone. This border serves for the attachment of the tentorium cerebelli, is grooved for the superior petrosal sinus, and at its inner extremity presents a notch, upon which rests the fifth nerve. The circumference of the fossa is bounded posteriorly by the grooves for the lateral sinuses. In the centre of this fossa is the *foramen magnum*, bounded on either side by a rough tubercle, which gives attachment to the odontoid or check ligaments; and a little above these are seen the internal openings of the *anterior condyloid foramina*, through which pass the hypoglossal nerve and a meningeal branch from the ascending pharyngeal artery. In front of the foramen magnum is a grooved surface, formed by the basilar process of the occipital bone and by the posterior third of the superior surface of the body of the sphenoid, which supports the medulla oblongata and pons Varolii, and articulates on each side with the petrous portion of the temporal bone, forming the petro-occipital suture, the anterior half of which is grooved for the inferior petrosal sinus, the posterior half being encroached

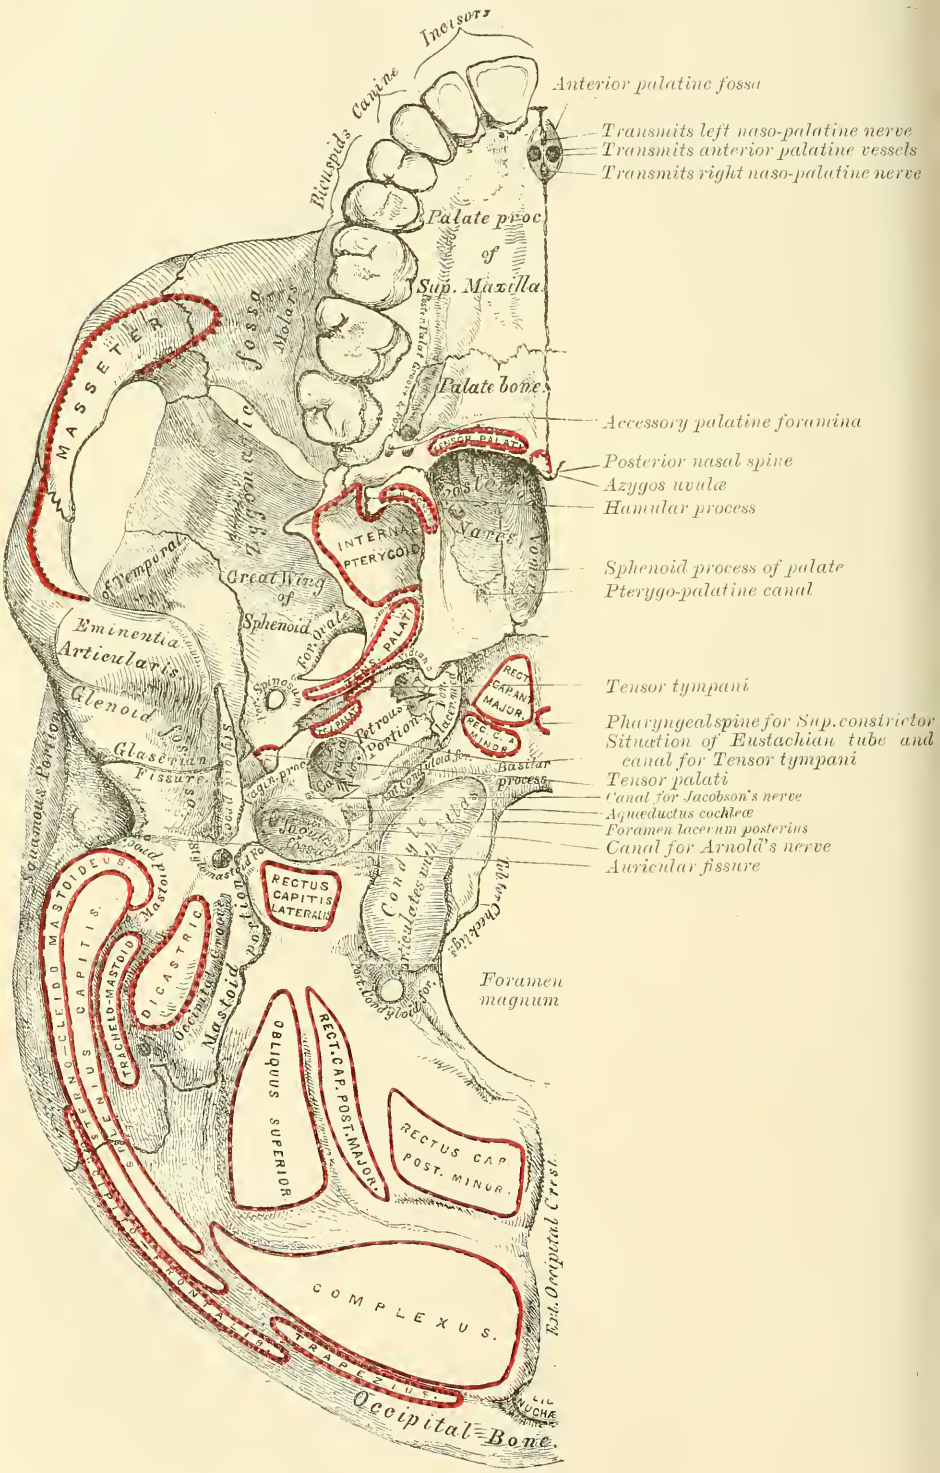
* See footnote, p. 160.

upon by the *foramen lacerum posterius*, or *jugular foramen*. This foramen presents three compartments: through the anterior, passes the inferior petrosal sinus; through the posterior, the lateral sinus and some meningeal branches from the occipital and ascending pharyngeal arteries; and through the middle, the glosso-pharyngeal, pneumo-gastric and spinal accessory nerves. Above the jugular foramen is the *internal auditory meatus*, for the facial and auditory nerves and auditory artery; behind and external to this is the slit-like opening leading into the aquæductus vestibuli; whilst between the two latter, and near the superior border of the petrous portion, is a small, triangular depression which lodges a process of the dura mater and occasionally transmits a small vein into the substance of the bone. Behind the foramen magnum are the *inferior occipital fossæ*, which lodge the hemispheres of the cerebellum, separated from one another by the *internal occipital crest*, which serves for the attachment of the falx cerebelli, and lodges the occipital sinus. The posterior fossæ are surmounted, above, by the deep transverse grooves for the lodgment of the *lateral sinuses*. These channels, in their passage outwards, groove the occipital bone, the posterior inferior angle of the parietal, the mastoid portion of the temporal, and the jugular process of the occipital, and terminate at the back part of the jugular foramen. Where this sinus grooves the mastoid portion of the temporal bone, the orifice of the *mastoid foramen* may be seen; and, just previous to its termination, it has opening into it the *posterior condyloid foramen*. Neither foramen is constant.

The **External Surface** of the Base of the Skull (fig. 183) is extremely irregular. It is bounded in front by the incisor teeth in the upper jaw; behind, by the superior curved lines of the occipital bone; and laterally by the alveolar arch, the lower border of the malar bone, the zygoma, and an imaginary line, extending from the zygoma to the mastoid process and extremity of the superior curved line of the occiput. It is formed by the palate processes of the superior maxillary and palate bones, the vomer, the pterygoid processes, under surface of the great wing, spinous processes and part of the body of the sphenoid, the under surface of the squamous, mastoid, and petrous portions of the temporal, and the under surface of the occipital bone. The anterior part of the base of the skull is raised above the level of the rest of this surface (when the skull is turned over for the purpose of examination), surrounded by the alveolar process, which is thicker behind than in front, and excavated by sixteen depressions for lodging the teeth of the upper jaw, the cavities varying in depth and size according to the teeth they contain. Immediately behind the incisor teeth is the *anterior palatine fossa*. At the bottom of this fossa may usually be seen four apertures: two placed laterally, the *foramina of Stenson*, which open above, one in the floor of each nostril, and transmit the anterior branch of the posterior palatine vessels, and two in the median line in the intermaxillary suture, the *foramina of Scarpa*, one in front of the other, the anterior transmitting the left, and the posterior (the larger) the right, naso-palatine nerve. These two latter canals are sometimes wanting, or they may join to form a single one, or one of them may open into one of the lateral canals above referred to. The palatine vault is concave, uneven, perforated by numerous foramina, marked by depressions for the palatine glands, and crossed by a crucial suture, formed by the junction of the four bones of which it is composed. At the front part of this surface, a delicate linear suture may frequently be seen, marking off the pre-maxillary portion of the bone. One or two small foramina in the alveolar margin behind the incisor teeth, occasionally seen in the adult, almost constantly in young subjects, are called the *incisive foramina*; they transmit nerves and vessels to the incisor teeth. At each posterior angle of the hard palate is the *posterior palatine foramen*, for the transmission of the posterior palatine vessels and large descending palatine nerve; and running forwards and inwards from it a groove, for the same vessels and nerve. Behind the posterior palatine foramen is the *tuberosity of the palate-bone*, perforated by one or more accessory posterior palatine canals, and marked by the commencement of a ridge, which runs transversely inwards, and

serves for the attachment of the tendinous expansion of the Tensor palati muscle. Projecting backwards from the centre of the posterior border of the hard palate is the *posterior nasal spine*, for the attachment of the Azygos uvulæ. Behind and

Fig. 183.—Base of the skull. External surface.

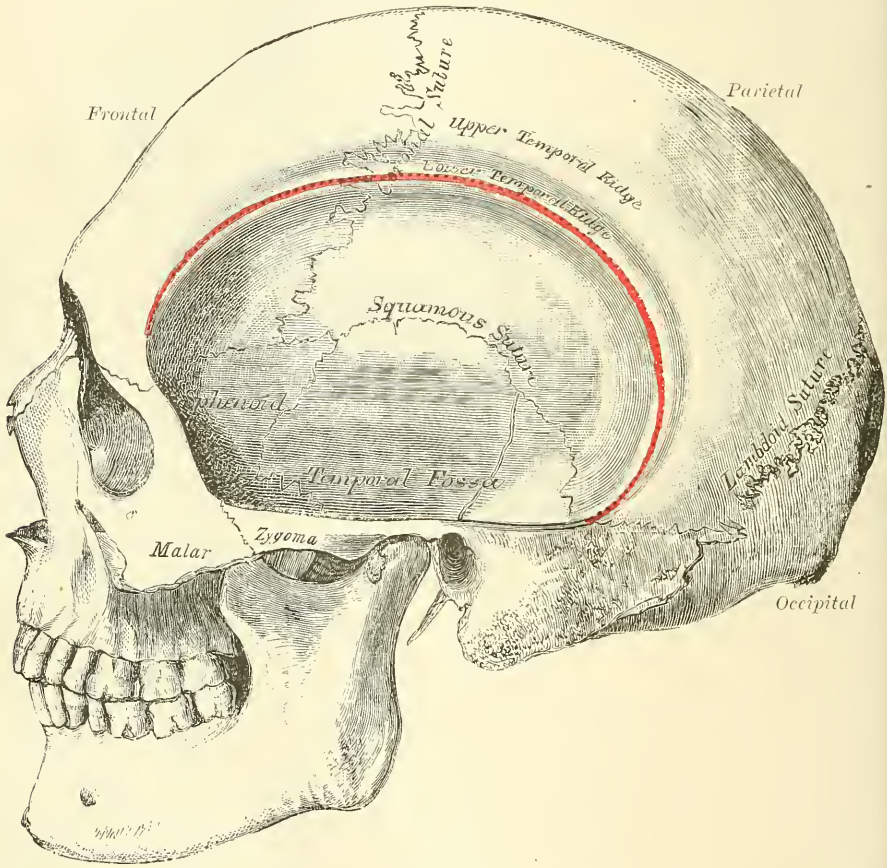


above the hard palate is the posterior aperture of the nares, divided into two parts by the vomer, bounded above by the body of the sphenoid, below by the horizontal plate of the palate-bone, and laterally by the pterygoid processes of the sphenoid. Each aperture measures about an inch and a quarter in the vertical, and about half an inch in the transverse direction. At the base of the vomer may be seen the expanded alæ of this bone, receiving between them the rostrum of the sphenoid. Near the lateral margins of the vomer, at the root of the pterygoid processes, are the *pterygo-palatine canals*. The pterygoid process, which bounds the posterior nares on each side, presents near its base the *pterygoid* or *Vidian canal*, for the Vidian nerve and artery. Each process consists of two plates, which bifurcate at the extremity to receive the tuberosity of the palate-bone, and are separated behind by the pterygoid fossa, which lodges the Internal pterygoid muscle. The internal plate is long and narrow, presenting on the outer side of its base the *scaphoid fossa*, for the origin of the Tensor palati muscle, and at its extremity the *hamular process*, around which the tendon of this muscle turns. The external pterygoid plate is broad, forms the inner boundary of the zygomatic fossa, and affords attachment, by its outer surface, to the External pterygoid muscle.

Behind the nasal fossæ in the middle line is the basilar surface of the occipital bone, presenting in its centre the *pharyngeal spine* for the attachment of the Superior constrictor muscle of the pharynx, with depressions on each side for the insertion of the Rectus capitis anticus major and minor. At the base of the external pterygoid plate is the *foramen ovale*; behind this, the *foramen spinosum*, and the prominent spinous process of the sphenoid, which gives attachment to the internal lateral ligament of the lower jaw and the Tensor palati muscle. External to the spinous process is the *glenoid fossa*, divided into two parts by the Glaserian fissure (page 152), the anterior portion concave, smooth, bounded in front by the eminentia articularis, and serving for the articulation of the condyle of the lower jaw; the posterior portion rough, bounded behind by the tympanic plate, and serving for the reception of part of the parotid gland. Emerging from between the laminæ of the vaginal process of the tympanic plate is the *styloid process*; and at the base of this process is the *stylo-mastoid foramen*, for the exit of the facial nerve, and entrance of the stylo-mastoid artery. External to the stylo-mastoid foramen is the *auricular fissure* for the auricular branch of the pneumogastric, bounded behind by the mastoid process. Upon the inner side of the mastoid process is a deep groove, the *digastric fossa*; and a little more internally, the *occipital groove*, for the occipital artery. At the base of the internal pterygoid plate is a large and somewhat triangular aperture, the *foramen lacerum medium*, bounded in front by the great wing of the sphenoid, behind by the apex of the petrous portion of the temporal bone, and internally by the body of the sphenoid and basilar process of the occipital bone: it presents in front the posterior orifice of the Vidian canal; behind, the aperture of the carotid canal. The basilar surface of this opening is filled up in the recent state by a fibro-cartilaginous substance; across its upper or cerebral aspect pass the internal carotid artery and Vidian nerve. External to this aperture, the *petro-sphenoidal suture* is observed, at the outer termination of which is seen the orifice of the canal for the Eustachian tube, and that for the Tensor tympani muscle. Behind this suture is seen the under surface of the petrous portion of the temporal bone, presenting, from within outwards, the quadrilateral, rough surface, part of which affords attachment to the Levator palati and Tensor tympani muscles; external to this surface the orifices of the carotid canal and the aquæductus cochleæ, the former transmitting the internal carotid artery and the ascending branches of the superior cervical ganglion of the sympathetic, the latter serving for the passage of a small artery and vein to the cochlea. Behind the carotid canal is a large aperture, the *jugular fossa*, formed in front by the petrous portion of the temporal, and behind by the occipital; it is generally larger on the right than on the left side, and is divided into three compartments by processes of dura mater. The anterior is for the passage of the inferior petrosal sinus; the posterior for

the lateral sinus and some meningeal branches from the occipital and ascending pharyngeal arteries; the central one for the glosso-pharyngeal, pneumogastric, and spinal accessory nerves. On the ridge of bone dividing the carotid canal from the jugular fossa is the small foramen for the transmission of Jacobson's nerve; and on the wall of the jugular foramen, near the root of the styloid process, is the small aperture for the transmission of Arnold's nerve. Behind the basilar surface of the occipital bone is the *foramen magnum*, bounded on each side by the condyles, rough internally for the attachment of the check or odontoid ligaments, and presenting externally a rough surface, the *jugular process*, which serves for the attachment of the Rectus capitis lateralis muscle and the lateral occipito-atlantal ligament. On either side of each condyle anteriorly is the *anterior*

Fig. 184.—Side view of the skull.



condyloid fossa, perforated by the anterior condyloid foramen, for the passage of the hypoglossal nerve and a meningeal artery. Behind each condyle is the *posterior condyloid fossa*, perforated on one or both sides by the posterior condyloid foramen, for the transmission of a vein to the lateral sinus. Behind the foramen magnum is the *external occipital crest*, terminating above at the *external occipital protuberance*, whilst on each side are seen the *superior* and *inferior curved lines*; these, as well as the surfaces of bone between them, are rough for the attachment of the muscles, which are enumerated on page 142.

Lateral Region of the Skull

The **Lateral Region** of the Skull is of a somewhat triangular form, the base of the triangle being formed by a line extending from the external angular process

of the frontal bone along the temporal ridge backwards to the outer extremity of the superior curved line of the occiput: and the sides by two lines, the one drawn downwards and backwards from the external angular process of the frontal bone to the angle of the lower jaw, the other from the angle of the jaw upwards and backwards to the outer extremity of the superior curved line. This region is divisible into three portions—temporal fossa, mastoid portion, and zygomatic fossa.

The Temporal Fossa

The **Temporal Fossa** is bounded above and behind by the temporal ridge, which extends from the external angular process of the frontal upwards and backwards across the frontal and parietal bones, curving downwards behind to terminate in the posterior root of the zygomatic process (*supra mastoid crest*). This ridge is generally double, at all events in front, where it is most marked. In front, it is bounded by the frontal, malar, and great wing of the sphenoid; externally, by the zygomatic arch, formed conjointly by the malar and temporal bones; below, it is separated from the zygomatic fossa by the pterygoid ridge, seen on the outer surface of the great wing of the sphenoid. This fossa is formed by five bones, part of the frontal, great wing of the sphenoid, parietal, squamous portion of the temporal, and malar bones, and is traversed by six sutures, part of the transverse facial, spheno-malar, coronal, spheno-parietal, squamo-parietal, and squamo-sphenoidal. The point where the coronal suture crosses the superior temporal ridge is sometimes named the *stephanion*; and the region where the four bones, the parietal, the frontal, the squamous, and the greater wing of the sphenoid, meet at the anterior inferior angle of the parietal bone, is named the *pterion*. This point is about on a level with the external angular process of the frontal bone and about one and a half inch behind it. This fossa is deeply concave in front, convex behind, traversed by grooves which lodge branches of the deep temporal arteries, and filled by the Temporal muscles.

The Mastoid Portion

The **Mastoid Portion** of the side of the skull is bounded in front by the tubercle of the zygoma; above, by a line which runs from the posterior root of the zygoma to the end of the masto-parietal suture; behind and below by the masto-occipital suture. It is formed by the mastoid and part of the squamous and petrous portions of the temporal bone; its surface is convex and rough for the attachment of muscles, and presents, from behind forwards, the mastoid foramen, the mastoid process, the external auditory meatus, surrounded by the tympanic plate, and, most anteriorly, the temporo-maxillary articulation.

The Zygomatic Fossa

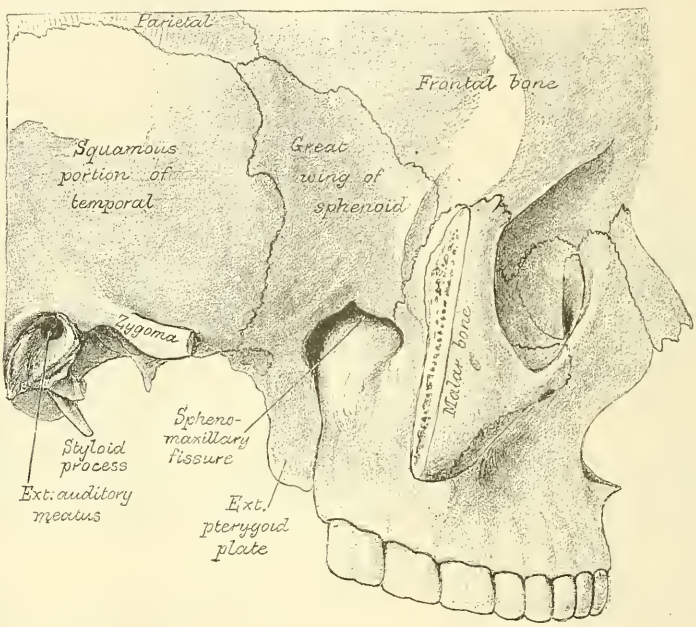
The **Zygomatic Fossa** is an irregularly shaped cavity, situated below and on the inner side of the zygoma; bounded, in front, by the zygomatic surface of the superior maxillary bone and the ridge which descends from its malar process; behind, by the posterior border of the pterygoid process and the eminentia articularis; above, by the pterygoid ridge on the outer surface of the great wing of the sphenoid, and the under part of the squamous portion of the temporal; below, by the alveolar border of the superior maxilla; internally, by the external pterygoid plate; and externally, by the zygomatic arch and ramus of the lower jaw (fig. 185). It contains the lower part of the Temporal, the External and Internal pterygoid muscles, the internal maxillary artery and vein, and inferior maxillary nerve and their branches. At its upper and inner part may be observed two fissures, the spheno-maxillary and pterygo-maxillary.

The **Spheno-maxillary Fissure**, horizontal in direction, opens into the outer and back part of the orbit. It is formed above by the lower border of the orbital

surface of the great wing of the sphenoid; below, by the external border of the orbital surface of the superior maxilla and a small part of the palate-bone; externally, by a small part of the malar bone: * internally, it joins at right angles with the pterygo-maxillary fissure. This fissure opens a communication from the orbit into three fossæ—the temporal, zygomatic, and spheno-maxillary; it transmits the superior maxillary nerve and its orbital branch, the infra-orbital vessels, and ascending branches from the spheno-palatine or Meckel's ganglion.

The **Pterygo-maxillary Fissure** is vertical, and descends at right angles from the inner extremity of the preceding; it is a V-shaped interval, formed by the

Fig. 185.—Zygomatic fossa.



divergence of the superior maxillary bone from the pterygoid process of the sphenoid. It serves to connect the spheno-maxillary fossa with the zygomatic fossa, and transmits branches of the internal maxillary artery.

The Spheno-maxillary Fossa

The **Spheno-maxillary Fossa** is a small, triangular space situated at the angle of junction of the spheno-maxillary and pterygo-maxillary fissures, and placed beneath the apex of the orbit. It is formed above by the under surface of the body of the sphenoid and by the orbital process of the palate-bone; in front, by the superior maxillary bone; behind, by the anterior surface of the base of the pterygoid process and lower part of the anterior surface of the great wing of the sphenoid; internally by the vertical plate of the palate. This fossa has three fissures terminating in it, the *sphenoidal*, *spheno-maxillary*, and *pterygo-maxillary*; it communicates with the orbit by the spheno-maxillary fissure; with the nasal fossæ by the spheno-palatine foramen, and with the zygomatic fossa by the pterygo-maxillary fissure. It also communicates with the cavity of the cranium, and has opening into it five foramina. Of these there are three on the posterior wall: the *foramen rotundum* above; below, and internal to this, the *Vidian*; and still

* Occasionally the superior maxillary bone and the sphenoid articulate with each other at the anterior extremity of this fissure; the malar is then excluded from entering into its formation.

more inferiorly and internally, the *pterygo-palatine*. On the inner wall is the *spheno-palatine foramen* by which the spheno-maxillary communicates with the nasal fossa; and below is the superior orifice of the *posterior palatine canal*, besides occasionally the orifices of the *accessory posterior palatine* canals. The fossa contains the superior maxillary nerve and Meckel's ganglion, and the termination of the internal maxillary artery.

Anterior Region of the Skull

The **Anterior Region** of the Skull, which forms the face, is of an oval form, presents an irregular surface, and is excavated for the reception of two of the organs of sense, the eye and the nose. It is bounded above by the glabella and margins of the orbit; below, by the prominence of the chin; on each side, by the malar bone, and anterior margin of the ramus of the jaw. In the median line are seen from above downwards the glabella, and diverging from it are the *superciliary ridges*, which indicate the situation of the frontal sinuses and support the eyebrows. Beneath the glabella is the fronto-nasal suture, the mid-point of which is termed the *nasion*, and below this is the arch of the nose, formed by the nasal bones, and the nasal processes of the superior maxillary. The nasal arch is convex from side to side, concave from above downwards, presenting in the median line the inter-nasal suture formed between the nasal bones, laterally the naso-maxillary suture formed between the nasal bone and the nasal process of the superior maxillary bone. Below the nose is seen the opening of the anterior nares, which is heart-shaped, with the narrow end upwards, and presents laterally the thin, sharp margins serving for the attachment of the lateral cartilages of the nose, and in the middle line below, a prominent process, the *anterior nasal spine*, bounded by two deep notches. Below this is the *intermaxillary suture*, and on each side of it the *incisive fossa*. Beneath this fossa are the alveolar processes of the upper and lower jaws, containing the incisor teeth, and at the lower part of the median line, the *symphysis of the chin*, the *mental process*, with its two *mental tubercles*, separated by a median groove, and the *incisive fossa* of the lower jaw.

On each side, proceeding from above downwards, is the *supra-orbital ridge*, terminating externally in the external angular process at its junction with the malar, and internally in the internal angular process; towards the inner third of this ridge is the *supra-orbital notch* or *foramen*, for the passage of the supra-orbital vessels and nerve. Beneath the supra-orbital ridge is the opening of the orbit, bounded externally by the orbital ridge of the malar bone; below, by the orbital ridge formed by the malar, superior maxillary, and lachrymal bones; internally, by the nasal process of the superior maxillary, and the internal angular process of the frontal bone. On the outer side of the orbit is the quadrilateral anterior surface of the malar bone perforated by one or two small malar foramina. Below the inferior margin of the orbit is the *infra-orbital foramen*, the termination of the infra-orbital canal, and beneath this the *canine fossa*, which gives attachment to the Levator anguli oris; bounded below by the alveolar processes, containing the teeth of the upper and lower jaws. Beneath the alveolar arch of the lower jaw is the *mental foramen* for the passage of the mental vessels and nerve, the *external oblique line*, and at the lower border of the bone, at the point of junction of the body with the ramus, a shallow groove for the passage of the facial artery.

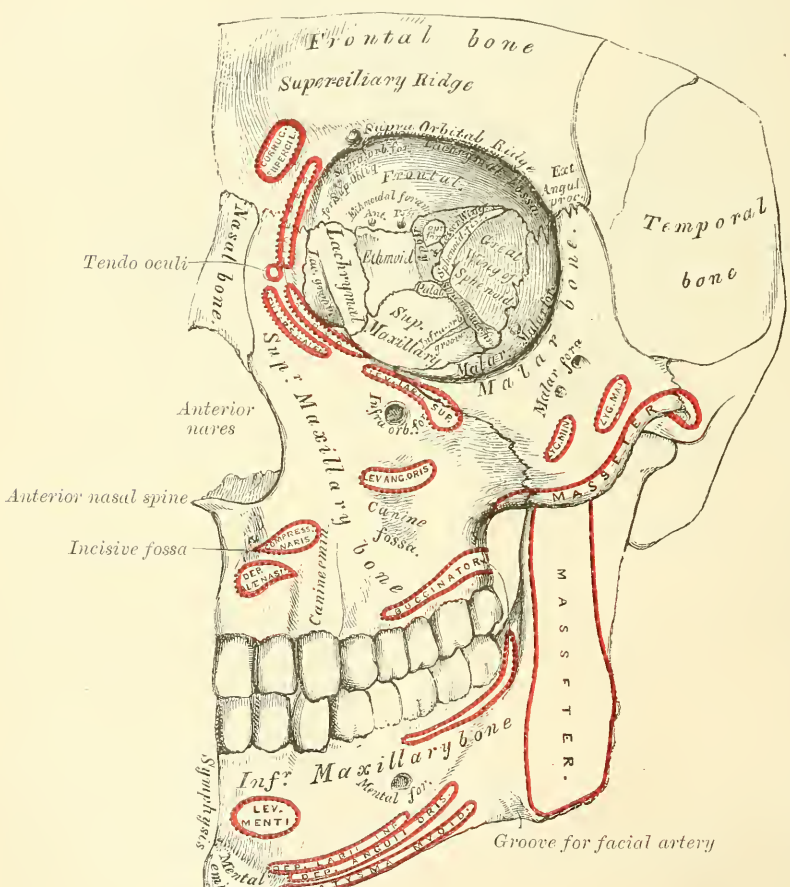
The Orbits

The **Orbits** (fig. 186) are two quadrilateral pyramidal cavities, situated at the upper and anterior part of the face, their bases being directed forwards and outwards, and their apices backwards and inwards, so that the axes of the two, if continued backwards, would meet over the body of the sphenoid bone. Each orbit is formed of *seven* bones, the frontal, sphenoid, ethmoid, superior maxillary,

malar, lachrymal, and palate; but three of these, the frontal, ethmoid, and sphenoid, enter into the formation of *both* orbits, so that the two cavities are formed of *eleven* bones only. Each cavity presents for examination a roof, a floor, an inner and an outer wall, four angles, a circumference or base, and an apex. The **roof** is concave, directed downwards and forwards, and formed in front by the orbital plate of the frontal; behind by the lesser wing of the sphenoid. This surface presents internally the depression for the cartilaginous pulley of the Superior oblique muscle; externally, the depression for the lachrymal gland; and posteriorly, the suture connecting the frontal and lesser wing of the sphenoid.

The **floor** is nearly flat, and of less extent than the roof; it is formed chiefly by the orbital process of the superior maxillary; in front, to a small extent, by

Fig. 186.—Anterior region of the skull.



the orbital process of the malar, and behind, by the superior surface of the orbital process of the palate. This surface presents at its anterior and internal part, just external to the lachrymal groove, a depression for the attachment of the Inferior oblique muscle; externally, the suture between the malar and superior maxillary bones; near its middle, the infra-orbital groove; and posteriorly, the suture between the maxillary and palate bones.

The **inner wall** is flattened, and formed from before backwards by the nasal process of the superior maxilla, the lachrymal, os planum of the ethmoid, and a small part of the body of the sphenoid. This surface presents the lachrymal groove, and crest of the lachrymal bone, and the sutures connecting the lachrymal

with the superior maxillary, the ethmoid with the lachrymal in front, and the ethmoid with the sphenoid behind.

The **outer wall** is formed in front by the orbital process of the malar bone; behind, by the orbital surface of the sphenoid. On it are seen the orifices of one or two malar canals, and the suture connecting the sphenoid and malar bones.

Angles.—The *superior external angle* is formed by the junction of the upper and outer walls; it presents, from before backwards, the suture connecting the frontal with the malar in front, and with the great wing of the sphenoid behind; quite posteriorly is the foramen lacerum anterius, or sphenoidal fissure, which transmits the third, the fourth, the three branches of the ophthalmic division of the fifth, the sixth nerve, some filaments from the cavernous plexus of the sympathetic, the orbital branch of the middle meningeal artery, a recurrent branch from the lachrymal artery to the dura mater, and the ophthalmic vein. The *superior internal angle* is formed by the junction of the upper and inner wall, and presents the suture connecting the frontal bone with the lachrymal in front, and with the ethmoid behind. The point of junction of these three sutures has been named the *dacryon*. This angle presents two foramina, the anterior and posterior ethmoidal, the former transmitting the anterior ethmoidal vessels and nasal nerve, the latter the posterior ethmoidal vessels. The *inferior external angle*, formed by the junction of the outer wall and floor, presents the spheno-maxillary fissure, which transmits the superior maxillary nerve and its orbital branches, the infra-orbital vessels, and the ascending branches from the spheno-palatine or Meckel's ganglion. The *inferior internal angle* is formed by the union of the lachrymal and os planum of the ethmoid, with the superior maxillary and palate bones. The *circumference*, or base, of the orbit, quadrilateral in form, is bounded above by the supra-orbital ridge; below, by the anterior border of the orbital plate of the malar, superior maxillary, and lachrymal bones; externally, by the external angular process of the frontal and the malar bones; internally, by the internal angular process of the frontal, and the nasal process of the superior maxillary. The circumference is marked by three sutures, the fronto-maxillary internally, the fronto-malar externally, and the malo-maxillary below; it contributes to the formation of the lachrymal groove, and presents, above, the supra-orbital notch (or foramen), for the passage of the supra-orbital vessels and nerve. The *apex*, situated at the back of the orbit, corresponds to the optic foramen, a short, circular canal, which transmits the optic nerve and ophthalmic artery. It will thus be seen that there are *nine* openings communicating with each orbit—viz. the optic foramen, sphenoidal fissure, spheno-maxillary fissure, supra-orbital foramen, infra-orbital canal, anterior and posterior ethmoidal foramina, malar foramina, and canal for the nasal duct.

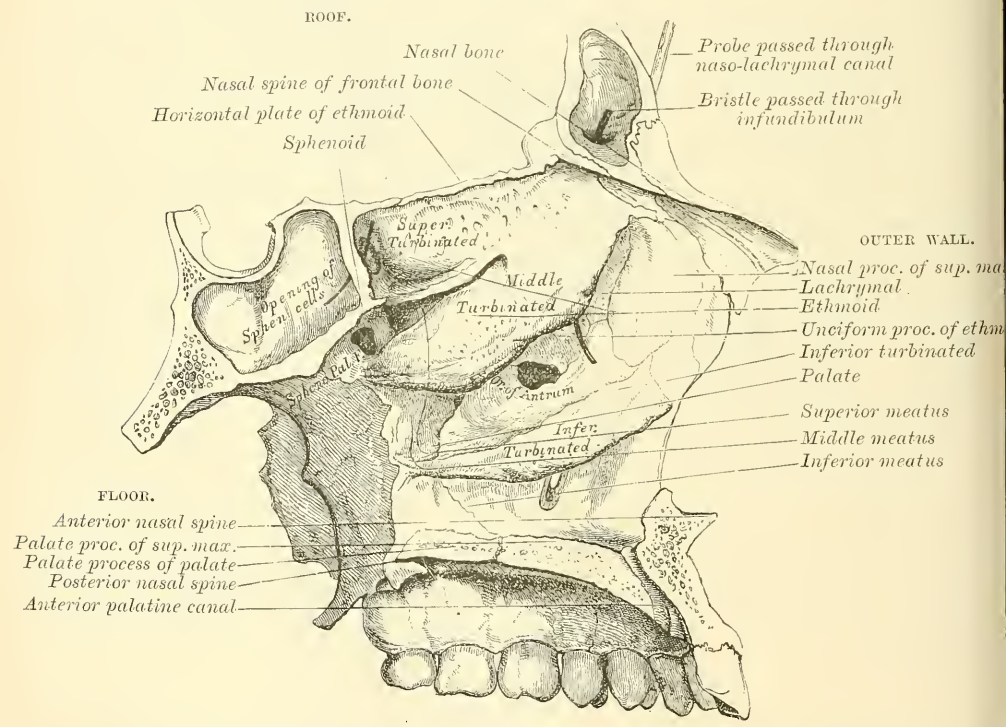
The Nasal Fossæ

The **Nasal Fossæ** are two large, irregular cavities, situated on either side of the middle line of the face, extending from the base of the cranium to the roof of the mouth, and separated from each other by a thin vertical septum. They communicate by two large apertures, the anterior nares, with the front of the face; and by the two posterior nares with the pharynx behind. These fossæ are much narrower above than below, and in the middle than at the anterior or posterior openings: their depth, which is considerable, is much greater in the middle than at either extremity. Each nasal fossa communicates with four sinuses, the frontal above, the sphenoidal behind, and the maxillary and ethmoidal on the outer wall. Each fossa also communicates with four cavities: with the orbit by the lachrymal groove, with the mouth by the anterior palatine canal, with the cranium by the olfactory foramina, and with the spheno-maxillary fossa by the spheno-palatine foramen; and they occasionally communicate with each other by an aperture in the septum. The bones entering into their formation are fourteen in number: three of the cranium, the frontal, sphenoid, and ethmoid, and all

the bones of the face, excepting the malar and lower jaw. Each cavity is bounded by a roof, a floor, an inner and an outer wall.

The **upper wall**, or **roof** (fig. 187) is long, narrow, and horizontal in its centre, but sloped downwards at its anterior and posterior extremities; it is formed in front by the nasal bones and nasal spine of the frontal, which are directed downwards and forwards; in the middle, by the cribriform plate of the ethmoid, which is horizontal; and behind, by the under surface of the body of the sphenoid, and sphenoidal turbinated bones, the ala of the vomer and the sphenoidal process of the palate bone, which are directed downwards and backwards. This surface presents, from before backwards, the internal aspect of the nasal bones; on their outer side, the suture formed between the nasal bone and the nasal process of the superior maxillary; on their inner side, the elevated crest which receives the nasal spine of the frontal and the perpendicular plate of the ethmoid, and articulates with its fellow of the opposite side; whilst the surface of the bones is

FIG. 187.—Roof, floor, and outer wall of left nasal fossa.



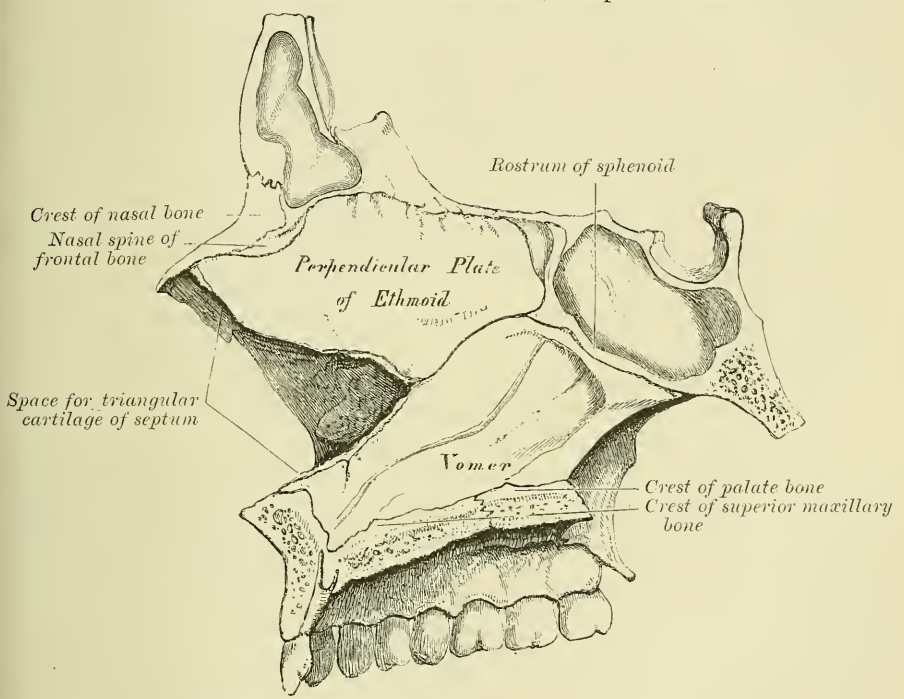
perforated by a few small vascular apertures, and presents the longitudinal groove for the nasal nerve: further back is the transverse suture, connecting the frontal with the nasal in front, and the ethmoid behind, the olfactory foramina and nasal slit on the under surface of the cribriform plate, and the suture between it and the sphenoid behind: quite posteriorly are seen the sphenoidal turbinated bones, the orifices of the sphenoidal sinuses, and the articulation of the alæ of the vomer with the under surface of the body of the sphenoid.

The **floor** is flattened from before backwards, concave from side to side, and wider in the middle than at either extremity. It is formed in front by the palate process of the superior maxillary; behind, by the palate process of the palate-bone. This surface presents, from before backwards, the anterior nasal spine; behind this, the upper orifices of the anterior palatine canal; internally, the elevated crest which articulates with the vomer; and behind, the suture between the palate and superior maxillary bones, and the posterior nasal spine.

The **inner wall,** or septum (fig. 188), is a thin vertical partition, which separates the nasal fossæ from one another ; it is occasionally perforated, so that the fossæ communicate, and it is frequently deflected considerably to one side.* It is formed, in front, by the crest of the nasal bones and nasal spine of the frontal ; in the middle, by the perpendicular plate of the ethmoid ; behind, by the vomer and rostrum of the sphenoid ; below, by the crest of the superior maxillary and palate bones. It presents, in front, a large, triangular notch, which receives the triangular cartilage of the nose ; and behind, the guttural edge of the vomer. Its surface is marked by numerous vascular and nervous canals and the groove for the naso-palatine nerve, and is traversed by sutures connecting the bones of which it is formed.

The **outer wall** (fig. 187) is formed, in front, by the nasal process of the superior maxillary and lachrymal bones ; in the middle, by the ethmoid and

Fig. 188.—Inner wall of nasal fossæ, or septum of nose.



inner surface of the superior maxillary and inferior turbinated bones ; behind, by the vertical plate of the palate-bone, and the internal pterygoid plate of the sphenoid. This surface presents three irregular longitudinal passages, or *meatuses*, formed between three horizontal plates of bone that spring from it ; they are termed the superior, middle, and inferior meatuses of the nose. The *superior meatus*, the smallest of the three, is situated at the upper and back part of each nasal fossa, occupying the posterior third of the outer wall. It is situated between the superior and middle turbinated bones, and has opening into it two foramina, the *spheno-palatine* at the back of its outer wall, and the *posterior ethmoidal cells* at the front part of the outer wall. The opening of the sphenoidal sinuses is usually at the upper and back part of the nasal fossæ immediately behind the superior turbinated bone. The *middle meatus* is situated between the middle and inferior turbinated bones, and occupies the posterior two-thirds of the outer wall of the nasal fossa. It presents two apertures. In front is the orifice of the *infundibulum*, by which the middle meatus communicates with the

* See footnote, p. 164.

anterior ethmoidal cells, and through these with the frontal sinuses. At the centre of the outer wall is the *orifice of the antrum*, which varies somewhat as to its exact position in different skulls. The *inferior meatus*, the largest of the three, is the space between the inferior turbinated bone and the floor of the nasal fossa. It extends along the entire length of the outer wall of the nose, is broader in front than behind, and presents anteriorly the lower *orifice of the canal for the nasal duct.*

The **anterior nares** present a heart-shaped or pyriform opening, whose long axis is vertical, and narrow extremity upwards. This opening in the recent state is much contracted by the cartilages of the nose. It is bounded above by the inferior border of the nasal bone ; laterally by the thin, sharp margin which separates the facial from the nasal surface of the superior maxillary bone ; and below by the same border, where it slopes inwards to join its fellow of the opposite side at the anterior nasal spine.

The **posterior nares** are the two posterior oval openings of the nasal fossæ, by which they communicate with the upper part of the pharynx. They are situated immediately in front of the basilar process, and are bounded above by the under surface of the body of the sphenoid ; below, by the posterior border of the horizontal plate of the palate-bone ; externally, by the internal surface of the internal pterygoid plate ; and internally, in the middle line, they are separated from each other by the guttural border of the Vomer.

Surface Form.—The various bony prominences or landmarks which are to be easily felt and recognised in the head and face, and which afford the means of mapping out the important structures comprised in this region, are as follow :—

1. Supra-orbital arch.
2. Internal angular process.
3. External angular process.
4. Zygomatic arch.
5. Mastoid process.
6. External occipital protuberance.
7. Superior curved line of occipital bone.
8. Parietal eminence.
9. Temporal ridge.
10. Frontal eminence.
11. Superciliary ridge.
12. Nasal bone.
13. Lower margin of orbit.
14. Lower jaw.

1. The *supra-orbital arch* is to be felt throughout its entire extent, covered by the eyebrow. It forms the upper boundary of the circumference or base of the orbit and separates the face from the forehead. It is strong and arched, and terminates internally at the root of the nose, in the *internal angular process*, which articulates with the lachrymal bone. Externally it terminates in the *external angular process* which articulates with the malar bone. This arched ridge is sharper and more defined in its outer than in its inner half, and forms an overhanging process which protects and shields the lachrymal gland. It thus protects the eye in its most exposed situation and in the direction from which blows are more likely to descend. The supra-orbital arch varies in prominence in different individuals. It is more marked in the male than in the female, and in some races of mankind than others. In the less civilised races, as the forehead recedes backwards, the supra-orbital arch becomes more prominent and approaches more to the characters of the monkey tribe, in which the supra-orbital arches are very largely developed and acquire additional prominence from the oblique direction of the frontal bone. 2. The *internal angular process* is scarcely to be felt. Its position is indicated by the angle formed by the supra-orbital arch with the nasal process of the superior maxillary bone and the lachrymal bone at the inner side of the orbit. Between the internal angular processes of the two sides is a broad surface which assists in forming the root of the nose, and immediately above this a broad, smooth, somewhat triangular surface, the *glabella*, situated between the superciliary ridges. 3. The *external angular process* is much more strongly marked than the internal, and is plainly to be felt. It is formed by the junction or confluence of the supra-orbital and temporal ridges, and, articulating with the malar bone, it serves to a very considerable extent to support the bones of the face. In carnivorous animals the external angular process does not articulate with the malar, and therefore this lateral support to the bones of the face is not present. 4. The *zygomatic arch* is plainly to be felt throughout its entire length, being situated almost immediately under the skin. It is formed by the malar bone and the zygomatic process of the temporal bone. At its anterior extremity, where it is formed by the malar bone, it is broad and forms the prominence of the cheek ; the posterior part is narrower, and terminates just in front and a little above the tragus of the external ear. The lower border is more plainly to be felt than the upper, in consequence of the dense temporal fascia being attached to the upper border, which somewhat obscures its outline. Its shape differs very much in individuals and in different races of mankind. In the most degraded type of skull—as, for instance, in the skull of the

negro of the Guinea Coast—the malar bones project forwards and not outwards, and the zygoma at its posterior extremity extends further outwards before it is twisted on itself to be prolonged forwards. This makes the zygomatic arch stand out in bold relief, and affords greater space for the Temporal muscle. In skulls which have a more pyramidal shape, as in the Esquimaux or Greenlander, the malar bones do not project forwards and downwards under the eyes, as in the preceding form, but take a direction outwards, forming with the zygoma a large, rounded sweep or segment of a circle. Thus it happens that if two lines are drawn from the zygomatic arches, touching the temporal ridges, they meet over the top of the head, instead of being parallel, or nearly so, as in the European skull, in which the zygomatic arches are not nearly so prominent. This gives to the face a more or less oval type. 5. Behind the ear is the *mastoid portion of the temporal bone*, plainly to be felt, and terminating below in a nipple-shaped process. Its anterior border can be traced immediately behind the concha, and its apex is on about a level with the lobule of the ear. It is rudimentary in infancy, but gradually develops in childhood, and is more marked in the negro than in the European. 6. The *external occipital protuberance* is always plainly to be felt just at the level where the skin of the neck joins that of the head. At this point the skull is thick for the purposes of safety, while radiating from it are numerous curved arches or buttresses of bone which give to this portion of the skull further security. 7. Running outwards on either side from the external occipital protuberance is an arched ridge of bone, which can be more or less plainly perceived. This is the *superior curved line* of the occipital bone, and gives attachment to some of the muscles which keep the head erect on the spine; accordingly, we find it more developed in the negro tribes, in whom the jaws are much more massive, and therefore require stronger muscles to prevent their extra weight carrying the head forwards. Below this line the surface of bone at the back of the head is obscured by the overlying muscles. Above it, the vault of the cranium is thinly covered with soft structures, so that the form of this part of the head is almost exactly that of the upper portion of the occipital, the parietal, and the frontal bones themselves; and, in bald persons, even the lines of junction of the bones, especially the junction of the occipital and parietal at the lambdoid suture, may be defined as a slight depression, caused by the thickening of the borders of the bones in this situation. 8. In the line of the greatest transverse diameter of the head, on each side of the middle line, are generally to be found the *parietal eminences*; though sometimes these eminences are not situated at the point of the greatest transverse diameter, which is at some other prominent part of the parietal region. They denote the point where ossification of the bone began. They are much more prominent and well-marked in early life, in consequence of the sharper curve of the bone at this period, so that it describes the segment of a smaller circle. Later in life, as the bone grows, the curve spreads out and forms the segment of a larger circle, so that the eminence becomes less distinguishable. In consequence of this sharp curve of the bone in early life, the whole of the vault of the skull has a squarer shape than it has in later life, and this appearance may persist in some rickety skulls. The eminence is more apparent in the negro's skull than in that of the European. This is due to greater flattening of the temporal fossa in the former skull to accommodate the larger Temporal muscle which exists in these races. The parietal eminence is particularly exposed to injury from blows or falls on the head, but fracture is to a certain extent prevented by the shape of the bone, which forms an arch, so that the force of the blow is diffused over the bone in every direction. 9. At the side of the head may be felt the *temporal ridge*. Commencing at the external angular process, it may be felt as a curved ridge, passing upwards and then curving backwards, on the frontal bone, separating the forehead from the temporal fossa. It may then be traced, passing backwards in a curved direction, over the parietal bone, and, though less marked, still generally to be recognised. Finally, the ridge curves downwards, and terminates in the posterior root of the zygoma, which separates the squamous from the subcutaneous mastoid portion of the temporal bone. Mr. Victor Horsley has recently shown, in an article on the 'Topography of the Cerebral Cortex,' that the second temporal ridge (see page 146) can be made out on the living body. 10. The *frontal eminences* vary a good deal in different individuals, being considerably more prominent in some than in others, and they are often not symmetrical on the two sides of the body, the one being much more pronounced than the other. This is often especially noticeable in the skull of the young child or infant, and becomes less marked as age advances. The prominence of the frontal eminences depends more upon the general shape of the whole bone than upon the size of the protuberances themselves. As the skull is more highly developed in consequence of increased intellectual capacity, so the frontal bone becomes more upright, and the frontal eminences stand out in bolder relief. Thus they may be considered as affording, to a certain extent, an indication of the development of the hemispheres of the brain beneath, and of the mental powers of the individual. They are not so much exposed to injury as the parietal eminences. In falls forward the upper extremities are involuntarily thrown out, and break the force of the fall, and thus shield the frontal bone from injury. 11. Below the frontal eminences on the forehead are the *superciliary ridges*, which denote the position of the frontal sinuses, and vary according to the size of the sinuses in different individuals, being, as a rule, small in the female, absent in children, and sometimes unusually prominent in the male, when the frontal sinuses are largely developed. They commence on either side

of the glabella, and at first present a rounded form, which gradually fades away at their outer ends. 12. The *nasal bones* form the prominence of the nose. They vary much in size and shape, and to them is due the varieties in the contour of this organ and much of the character of the face. Thus, in the Mongolian or Ethiopian they are flat, broad, and thick at their base, giving to these tribes the flattened nose by which they are characterised, and differing very decidedly from the Caucasian, in whom the nose, owing to the shape of the nasal bones, is narrow, elevated at the bridge, and elongated downwards. Below, the nasal bones are thin and connected with the cartilages of the nose, and the angle or arch formed by their union serves to throw out the bridge of the nose, and is much more marked in some individuals than others. 13. The *lower margin of the orbit*, formed by the superior maxillary bone and the malar bone, is plainly to be felt throughout its entire length. It is continuous internally with the nasal process of the superior maxillary bone, which forms the inner boundary of the orbit. At the point of junction of the lower margin of the orbit with the nasal process is to be felt a little tubercle of bone, which can be plainly perceived by running the finger along the bone in this situation. This tubercle serves as a guide to the position of the lachrymal sac, which is situated above and behind it. 14. The outline of the *lower jaw* is to be felt throughout its entire length. Just in front of the tragus of the external ear, and below the zygomatic arch, the condyle can be made out. When the mouth is opened, this prominence of bone can be perceived advancing out of the glenoid fossa on to the eminentia articularis, and receding again when the mouth is closed. From the condyle the posterior border of the ramus can be felt extending down to the angle. A line drawn from the condyle to the angle would indicate the exact position of this border. From the angle to the symphysis of the chin, the lower, rounded border of the body of the bone is plainly to be felt. At the point of junction of the two halves of the bone is a well-marked, triangular eminence, the *mental process*, which forms the prominence of the chin.

Surgical Anatomy.—An arrest in the ossifying process may give rise to deficiencies or gaps; or to fissures, which are of importance in a medico-legal point of view, as they are liable to be mistaken for fractures. The fissures generally extend from the margin towards the centre of the bone, but gaps may be found in the middle, as well as at the edges. In course of time they may become covered with a thin lamina of bone.

Occasionally a protrusion of the brain or its membranes may take place through one of these gaps in an imperfectly developed skull. When the protrusion consists of membranes only, and is filled with cerebro-spinal fluid, it is called a *meningocele*; when the protrusion consists of brain as well as membranes, it is termed an *encephalocele*; and when the protruded brain is a prolongation from one of the ventricles, and is distended by a collection of fluid from an accumulation in the ventricle, it is termed an *hydrencephalocele*. This latter condition is frequently found at the root of the nose, where a protrusion of the anterior horn of the lateral ventricle takes place through a deficiency of the fronto-nasal suture. These malformations are usually found in the middle line, and most frequently at the back of the head, the protrusion taking place through the fissures which separate the four centres of ossification from which the tabular portion of the occipital bone is originally developed (see page 145). They most frequently occur through the upper part of the vertical fissure, which is the last to ossify, but not uncommonly through the lower part, when the foramen magnum may be incomplete. More rarely these protrusions have been met with in other situations than those two above mentioned, both through normal fissures, as the sagittal, lambdoid, and other sutures, and also through abnormal gaps and deficiencies at the sides, and even at the base of the skull.

Fractures of the skull may be divided into those of the vault and those of the base. Fractures of the vault are usually produced by direct violence. This portion of the skull varies in thickness and strength in different individuals, but, as a rule, is sufficiently strong to resist a very considerable amount of violence without being fractured. This is due to several causes:—the rounded shape of the head and its construction of a number of secondary elastic arches, each made up of a single bone; the fact that it consists of a number of bones, united, at all events in early life, by a sutural ligament, which acts as a sort of buffer and interrupts the continuity of any violence applied to the skull; the presence of arches or ridges, both on the inside and outside of the skull, which materially strengthen it; and the mobility of the head upon the spine which further enables it to withstand violence. The elasticity of the bones of the head is especially marked in the skull of the child, and this fact, together with the wide separation of the individual bones from each other, and the interposition between them of other softer structures, renders fracture of the bones of the head a very uncommon event in infants and quite young children; as age advances, and the bones become joined, fracture is more common, though still less liable to occur than in the adult. Fractures of the vault may, and generally do, involve the whole thickness of the bone; but sometimes one table may be fractured without any corresponding injury to the other. Thus, the outer table of the skull may be splintered and driven into the diploë, or in the frontal or mastoid regions into the frontal or mastoid cells, without any injury to the internal table. And, on the other hand, the internal table has been fractured, and portions of it depressed and driven inwards, without any fracture of the outer table. As a rule, in fractures of the skull, the inner table is more splintered and comminuted than the outer, and this is due to

several causes. It is thinner and more brittle; the force of the violence as it passes inwards becomes broken up, and is more diffused by the time it reaches the inner table; the bone being in the form of an arch bends as a whole and spreads out, and thus presses the particles together on the convex surface of the arch, i.e. the outer table, and forces them asunder on the concave surface or inner table; and, lastly, there is nothing firm under the inner table to support it and oppose the force. Fractures of the vault may be simple fissures, or starred and comminuted fractures, and these may be depressed or elevated. These latter cases of fracture with elevation of the fractured portion are uncommon, and can only be produced by direct wound. In comminuted fracture, a portion of the skull is broken into several pieces, the lines of fracture radiating from a centre where the chief impact of the blow was felt; if depressed, a fissure circumscribes the radiating lines, enclosing a portion of skull. If this area is circular it is termed a 'pond' fracture, and would in all probability have been caused by a round instrument, as a life preserver or hammer; if elliptical in shape it is termed a 'gutter fracture,' and would owe its shape to the instrument which had produced it, as a poker.

Fractures of the base are most frequently produced by the extension of a fissure from the vault, as in falls on the head, where the fissure starts from the part of the vault which first struck the ground. Sometimes, however, they are caused by direct violence, when foreign bodies have been forced through the thin roof of the orbit, through the cribriform plate of the ethmoid from being thrust up the nose, or through the roof of the pharynx. Other cases of fracture of the base occur from indirect violence, as in fracture of the occipital bone from impaction of the spinal column against its condyles in falls on the buttocks, knees, or feet, or in cases where the glenoid cavity has been fractured by the violent impact of the condyle of the lower jaw against it from blows on the chin.

The most common place for fracture of the base to occur is through the middle fossa, and here the fissure usually takes a fairly definite course. Starting from the point struck, which is generally somewhere in the neighbourhood of the parietal eminence, it runs downwards through the parietal and squamous portion of the temporal bone and across the petrous portion of this bone, frequently traversing and implicating the internal auditory meatus, to the middle lacerated foramen. From this it may pass across the body of the sphenoid, through the pituitary fossa to the middle lacerated foramen of the other side, and may indeed travel round the whole cranium, so as to completely separate the anterior from the posterior part. The course of the fracture should be borne in mind, as it explains the symptoms to which fracture in this region may give rise: thus, if the fissure pass across the internal auditory meatus, injury to the facial and auditory nerves may result, with consequent facial paralysis and deafness; or the tubular prolongation of the arachnoid around these nerves in the meatus may be torn and thus permit of the escape of the cerebro-spinal fluid should there be a communication between the internal ear and the tympanum and the membrana tympani be ruptured, as is frequently the case: again, if the fissure passes across the pituitary fossa and the muco-periosteum covering the under surface of the body of the sphenoid is torn, blood will find its way into the pharynx and be swallowed, and after a time vomiting of blood will result. Fractures of the anterior fossa, involving the bones forming the roof of the orbit and nasal fossa, are generally the results of blows on the forehead; but fracture of the cribriform plate of the ethmoid may be a complication of fracture of the nasal bone. When the fracture implicates the roof of the orbit, the blood finds its way into this cavity and, travelling forwards, appears as a subconjunctival ecchymosis. If the roof of the nasal fossa be fractured, the blood escapes from the nose. In rare cases there may be also escape of cerebro-spinal fluid from the nose, where the dura mater and arachnoid have been torn. In fractures of the posterior fossa, extravasation of blood may appear at the nape of the neck.

The bones of the skull being subcutaneous are frequently the seat of nodes, and not uncommonly necrosis results from this cause, as well as from injury. Necrosis may involve the entire thickness of the skull, but is usually confined to the external table. Necrosis of the internal table alone is rarely met with. The bones of the skull are also frequently the seat of sarcomatous tumour.

The skull in rickets is peculiar: the forehead is high, square, and projecting; and the antero-posterior diameter of the skull is long, in relation to the transverse diameter. The bones of the face are small and ill-developed, and this gives the appearance of a larger head than actually exists. The bones of the head are often thick, especially in the neighbourhood of the sutures, and the anterior fontanelle is late in closing, sometimes remaining unclosed till the fourth year. The condition of *cranio-tabes* has by some been also believed to be the result of rickets; by others is believed to be due to inherited syphilis. In these cases the bone undergoes atrophic changes in patches, so that it becomes greatly thinned in places, generally where there is pressure, as from the pillow or nurse's arm. It is, therefore, usually met with in the parietal bone and vertical plate of the occipital bone.

In congenital syphilis deposits of porous bone are often found at the angles of the parietal bones, and two halves of the frontal bone which bound the anterior fontanelle. These deposits are separated by the coronal and sagittal sutures, and give to the skull an appearance like a 'hot cross bun.' They are known as Parrot's nodes, and such a skull has received the name of *natiform*, from its fancied resemblance to the buttocks.

In connection with the bones of the face a common malformation is *cleft palate*, owing to the non-union of the palatal processes of the maxillary or pre-oral arch (see page 92). This cleft may involve the whole or only a portion of the hard palate, and usually involves the soft palate also. The cleft is in the middle line, except it involves the alveolus in front, when it follows the suture between the main portion of the bone and the pre-maxillary bone. Sometimes the cleft runs on either side of the pre-maxillary bone, so that this bone is quite isolated from the maxillary bones and hangs from the end of the vomer. The malformation is usually associated with hare-lip, which, when single, is almost always on one side, corresponding to the position of the suture between the lateral incisor and canine tooth. Some few cases of median hare-lip have been described. In double hare-lip there is a cleft on each side of the middle line.

The bones of the face are sometimes fractured as the result of direct violence. The two most commonly broken are the nasal bone and the inferior maxilla, and of these, the latter is by far the most frequently fractured of all the bones of the face. Fracture of the *nasal* bone is for the most part transverse, and takes place about half an inch from the free margin. The broken portion may be displaced backwards or more generally to one side by the force which produced the lesion, as there are no muscles here which can cause displacement. The *malar* bone is probably never broken alone, that is to say, unconnected with a fracture of the other bones of the face. The *zygomatic arch* is occasionally fractured, and when this occurs from direct violence, as is usually the case, the fragments may be displaced inwards. This lesion is often attended with great difficulty or even inability to open and shut the mouth, and this has been stated to be due to the depressed fragments perforating the temporal muscle, but would appear rather to be caused by the injury done to the bony origin of the masseter muscle. Fractures of the *superior maxilla* may vary much in degree, from the chipping off of a portion of the alveolar arch, a frequent accident when the old 'key' instrument was used for the extraction of teeth, to an extensive comminution of the whole bone from severe violence, as the kick of a horse. The most common situation for a fracture of the *inferior maxillary bone* is in the neighbourhood of the canine tooth, as at this spot the jaw is weakened by the deep socket for the fang of this tooth; it is next most frequently fractured at the angle; then at the symphysis, and finally the neck of the condyle or the coronoid process may be broken. Occasionally a double fracture may occur, one in either half of the bone. The fractures are usually compound, from laceration of the mucous membrane covering the gums. The displacement is mainly the result of the same violence as produced the injury, but may be further increased by the action of the muscles passing from the neighbourhood of the symphysis to the hyoid bone.

The superior and inferior maxillary bones are both of them frequently the seat of necrosis: though the disease affects the lower much more frequently than the upper jaw, probably on account of the greater supply of blood to the latter. It may be the result of periostitis, from tooth irritation, injury, or the action of some specific poison, as syphilis, or from salivation by mercury; it not unfrequently occurs in children after attacks of the exanthematous fevers, and a special form occurs from the action of the fumes of phosphorus in persons engaged in match-making.

Tumours attack the jaw-bones not unfrequently, and these may be either innocent or malignant: in the upper jaw cysts may occur in the antrum, constituting the so-called dropsy of the antrum; or, again, cysts may form in either jaw in connection with the teeth: either cysts connected with the roots of fully developed teeth, the 'dental cyst'; or cysts connected with imperfectly developed teeth, the 'dentigerous cyst.' Solid innocent tumours include the fibroma, the chondroma, and the osteoma. Of malignant tumours there are two classes, the sarcomata and the epithelioma. The sarcoma are of various kinds, the spindle-celled and round-celled of a very malignant character, and the myeloid sarcoma principally affecting the alveolar margin of the bone. Of the epitheliomata we find the squamous variety spreading to the bone from the palate or gum, and the cylindrical epithelioma originating in the antrum or nasal fossæ.

Both superior and inferior maxillary bones occasionally require removal for tumours and in some other conditions. The upper jaw is removed by an incision from the inner canthus of the eye, along the side of the nose, round the ala, and down the middle line of the upper lip. A second incision is carried outwards from the inner canthus of the eye along the lower margin of the orbit as far as the prominence of the malar bone. The flap thus formed is reflected outwards and the surface of the bone exposed. The connections of the bone to the other bones of the face are then divided with a narrow saw. They are (1) the junction with the malar bone, passing into the spheno-maxillary fissure: (2) the nasal process; a small portion of its upper extremity, connected with the nasal bone in front, the lachrymal bone behind, and the frontal bone above, being left: (3) the connection with the bone on the opposite side and the palate in the roof of the mouth. The bone is now firmly grasped with lion-forceps, and by means of a rocking movement upwards and downwards the remaining attachments of the orbital plate with the ethmoid, and of the back of the bone with the palate, broken through. The soft palate is first separated from the hard with a scalpel and is not removed. Occasionally in removing the upper jaw, it will be found that the orbital plate can be spared, and this should always be done if possible. A horizontal saw-cut is to be made just below the infra-orbital foramen, and the bone cut through with a chisel and mallet.

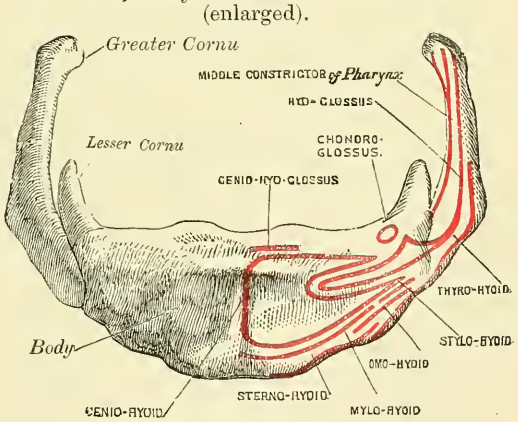
Removal of one half of the lower jaw is sometimes required. If possible, the section of the bone should be made to one side of the symphysis so as to save the genial tubercles and the origin of the Genio-hyo-glossus muscle, as otherwise the tongue tends to fall backwards and may produce suffocation. Having extracted the central or preferably the lateral incisor tooth, a vertical incision is made down to the bone, commencing at the free margin of the lip, and carried to the lower border of the bone; it is then carried along its lower border to the angle and up the posterior margin of the ramus to a level with the lobule of the ear. The flap thus formed is raised by separating all the structures attached to the outer surface of the bone. The jaw is now sawn through at the point where the tooth has been extracted, and the knife passed along the inner side of the jaw, separating the structures attached to this surface. The jaw is then grasped by the surgeon and strongly depressed, so as to bring down the coronoid process and enable the operator to sever the tendon of the Temporal muscle. The jaw can be now further depressed, care being taken not to evert it or rotate it outwards, which would endanger the internal maxillary artery, and the External pterygoid torn through or divided. The capsular ligament is now opened in front and the lateral ligaments divided, and the jaw removed with a few final touches of the knife.

The antrum occasionally requires tapping for suppuration. This may be done through the socket of a tooth, preferably the first molar, the fangs of which are most intimately connected with the antrum, or through the facial aspect of the bone above the alveolar process. This latter method does not perhaps afford such efficient drainage, but there is less chance of food finding its way into the cavity. The operation may be performed by incising the mucous membrane above the second molar tooth, and driving a trocar or any sharp pointed instrument into the cavity.

Hyoid Bone

The **Hyoid bone** is named from its resemblance to the Greek upsilon; it is also call the *lingual bone*, because it supports the tongue, and gives attachment to its numerous muscles. It is a bony arch, shaped like a horse-shoe, and consisting of five segments, a body, two greater cornua, and two lesser cornua. It is suspended from the tip of the styloid processes of the temporal bones by ligamentous bands, the *stylo-hyoid* ligaments.

Fig. 189.—Hyoid bone. Anterior surface (enlarged).



The **Body** (*basi-hyal*) forms the central part of the bone, and is of a quadrilateral form; its *anterior surface* (fig. 189), convex, directed forwards and upwards, is divided into two parts by a vertical ridge which descends along the median line, and is crossed at right angles by a horizontal ridge, so that this surface is divided into four spaces or depressions. At the point of meeting of these two lines is a prominent elevation, the *tubercle*. The portion above the horizontal ridge is directed upwards, and is sometimes described as the superior border. The anterior surface gives attachment to the Genio-hyoid in the greater part of its extent; above, to the Genio-hyo-glossus; below, to the Mylo-hyoid, Stylo-hyoid, and aponeurosis of the Digastric (suprahyoid aponeurosis); and between these to part of the Hyo-glossus. The *posterior surface* is smooth, concave, directed backwards and downwards, and separated from the epiglottis by the thyro-hyoid membrane, and by a quantity of loose areolar tissue. The *superior border* is rounded, and gives attachment to the thyro-hyoid membrane, part of the Genio-hyo-glossi, and Chondro-glossi muscles. The *inferior border* gives attachment, in front, to the Sterno-hyoid; behind, to the Omo-hyoid and to part of the Thyro-hyoid, at its junction with the great cornu. It also gives attachment to the Levator glandulæ thyroideæ, when this muscle is present. The *lateral surfaces*

are small, oval, convex facets, covered with cartilage for articulation with the greater cornua.

The **Greater Cornua** (*thyro-hyal*) project backwards from the lateral surfaces of the body; they are flattened from above downwards, diminish in size from before backwards, and terminate posteriorly in a tubercle for the attachment of the lateral thyro-hyoid ligament. The outer surface gives attachment to the Hyo-glossus, their upper border to the Middle constrictor of the pharynx, their lower border to part of the Thyro-hyoid muscle. In youth, the great cornua are connected to the body by cartilaginous surfaces, and held together by ligaments; in middle life they usually become joined.

The **Lesser Cornua** (*cerato-hyals*) are two small, conical-shaped eminences, attached by their bases to the angles of junction between the body and greater cornua, and giving attachment by their apices to the stylo-hyoid ligaments.* The smaller cornua are connected to the body of the bone by a distinct diarthrodial joint, which usually persists throughout life, but occasionally becomes ankylosed.

Development.—By *five* centres: one for the body, and one for each cornu. Ossification commences in the body about the eighth month, and in the greater cornua towards the end of fœtal life. Ossification of the lesser cornua commences some months after birth.

Attachment of Muscles.—Sterno-hyoid, Thyro-hyoid, Omo-hyoid, aponeurosis of the Digastric, Stylo-hyoid, Mylo-hyoid, Genio-hyoid, Genio-hyo-glossus, Chondro-glossus, Hyo-glossus, Middle constrictor of the pharynx, and occasionally a few fibres of the Inferior lingualis. It also gives attachment to the thyro-hyoidean membrane, and the stylo-hyoid, thyro-hyoid, and hyo-epiglottic ligaments.

Surface Form.—The hyoid bone can be felt in the receding angle below the chin, and the finger can be carried along the whole length of the bone to the greater cornu, which is situated just below the angle of the jaw. This process of bone is best perceived by making pressure on one cornu and so pushing the bone over to the opposite side, when the cornu of this side will be distinctly felt immediately beneath the skin. This process of bone is an important landmark in ligature of the lingual artery.

Surgical Anatomy.—The hyoid bone is occasionally fractured, generally from direct violence, as in the act of garotting or throttling. The great cornu is the part of the bone most frequently broken, but sometimes the fracture takes place through the body of the bone. In consequence of the muscles of the tongue having important connections with this bone, there is great pain upon any attempt being made to move the tongue, as in speaking or swallowing.

THE THORAX

The **Thorax**, or **Chest**, is an osseo-cartilaginous cage, containing and protecting the principal organs of respiration and circulation. It is conical in shape, being narrow above and broad below, flattened from before backwards, and longer behind than in front. It is somewhat cordiform on transverse section.

Boundaries.—The *posterior* surface is formed by the twelve dorsal vertebræ and the posterior part of the ribs. It is convex from above downwards, and presents on each side of the middle line a deep groove, in consequence of the direction backwards and outwards which the ribs take from their vertebral extremities to their angles. The *anterior* surface is flattened or slightly convex, and inclined forwards from above downwards. It is formed by the sternum and costal cartilages. The *lateral* surfaces are convex; they are formed by the ribs, separated from each other by spaces, the *intercostal spaces*. These spaces are eleven in number, and are occupied by the intercostal muscles.

The *upper opening* of the thorax is reniform in shape, being broader from side to side than from before backwards. It is formed by the first dorsal vertebra behind, the upper margin of the sternum in front, and the first rib on each side. It slopes downwards and forwards, so that the anterior part of the

* These ligaments in many animals are distinct bones, and in man are occasionally ossified to a certain extent.

ring is on a lower level than the posterior. The antero-posterior diameter is about two inches. The *lower* opening is formed by the twelfth dorsal vertebra behind, by the twelfth rib at the sides, and in front by the cartilages of the eleventh, tenth, ninth, eighth, and seventh ribs, which ascend on either side and form an angle, the *subcostal angle*, from the centre of which the ensiform cartilage projects. It is wider transversely than from before backwards. It slopes obliquely downwards and backwards; so that the cavity of the thorax is much deeper behind than in front. The Diaphragm closes in the opening forming the floor of the thorax.

In the female, the thorax differs as follows from the male:—1. Its general capacity is less. 2. The sternum is shorter. 3. The upper margin of the sternum is on a level with the lower part of the body of the third dorsal vertebra, whereas in the male it is on a level with the lower part of the body of the second dorsal vertebra. 4. The upper ribs are more movable, and so allow a greater enlargement of the upper part of the thorax than in the male.

The Sternum

The **Sternum** (*στέρνον*, the chest) (figs. 190, 191) is a flat, narrow bone, situated in the median line of the front of the chest, and consisting, in the adult, of three portions. It has been likened to an ancient sword: the upper piece, representing the handle, is termed the *manubrium*; the middle and largest piece, which represents the chief part of the blade, is termed the *gladiolus*; and the inferior piece, which is likened to the point of the sword, is termed the *ensiform* or *xiphoid appendix*. In its natural position its inclination is oblique from above, downwards and forwards. It is flattened in front, concave behind, broad above, becoming narrowed at the point where the first and second pieces are connected; after which it again widens a little, and is pointed at its extremity. Its average length in the adult is six inches, being rather longer in the male than in the female.

The **First Piece** of the sternum, or **Manubrium** (*pre-sternum*), is of a somewhat triangular form, broad and thick above, narrow below at its junction with the middle piece. Its *anterior surface*, convex from side to side, concave from above downwards, is smooth, and affords attachment on each side to the Pectoralis major and sternal origin of the Sterno-cleido-mastoid muscles. In well-marked bones the ridges limiting the attachment of these muscles are very distinct. Its *posterior surface*, concave and smooth, affords attachment on each side to the Sterno-hyoid and Sterno-thyroid muscles. The *superior border*, the thickest, presents at its centre the *pre-sternal notch*; and on each side an oval articular surface, directed upwards, backwards, and outwards, for articulation with the sternal end of the clavicle. The *inferior border* presents an oval, rough surface, covered in the recent state with a thin layer of cartilage, for articulation with the second portion of the bone. The *lateral borders* are marked above by a depression for the first costal cartilage, and below by a small facet, which, with a similar facet on the upper angle of the middle portion of the bone, forms a notch for the reception of the costal cartilage of the second rib. These articular surfaces are separated by a narrow, curved edge, which slopes from above downwards and inwards.

The **Second Piece** of the sternum, or **Gladiolus** (*meso-sternum*), considerably longer, narrower, and thinner than the first piece, is broader below than above. Its *anterior surface* is nearly flat, directed upwards and forwards, and marked by three transverse lines which cross the bone opposite the third, fourth, and fifth articular depressions. These lines are produced by the union of the four separate pieces of which this part of the bone consists at an early period of life. At the junction of the third and fourth pieces is occasionally seen an orifice, the *sternal foramen*; it varies in size and form in different individuals, and pierces the bone from before backwards. This surface affords attachment on each side to the

FIG. 190.—Sternum and costal cartilages.

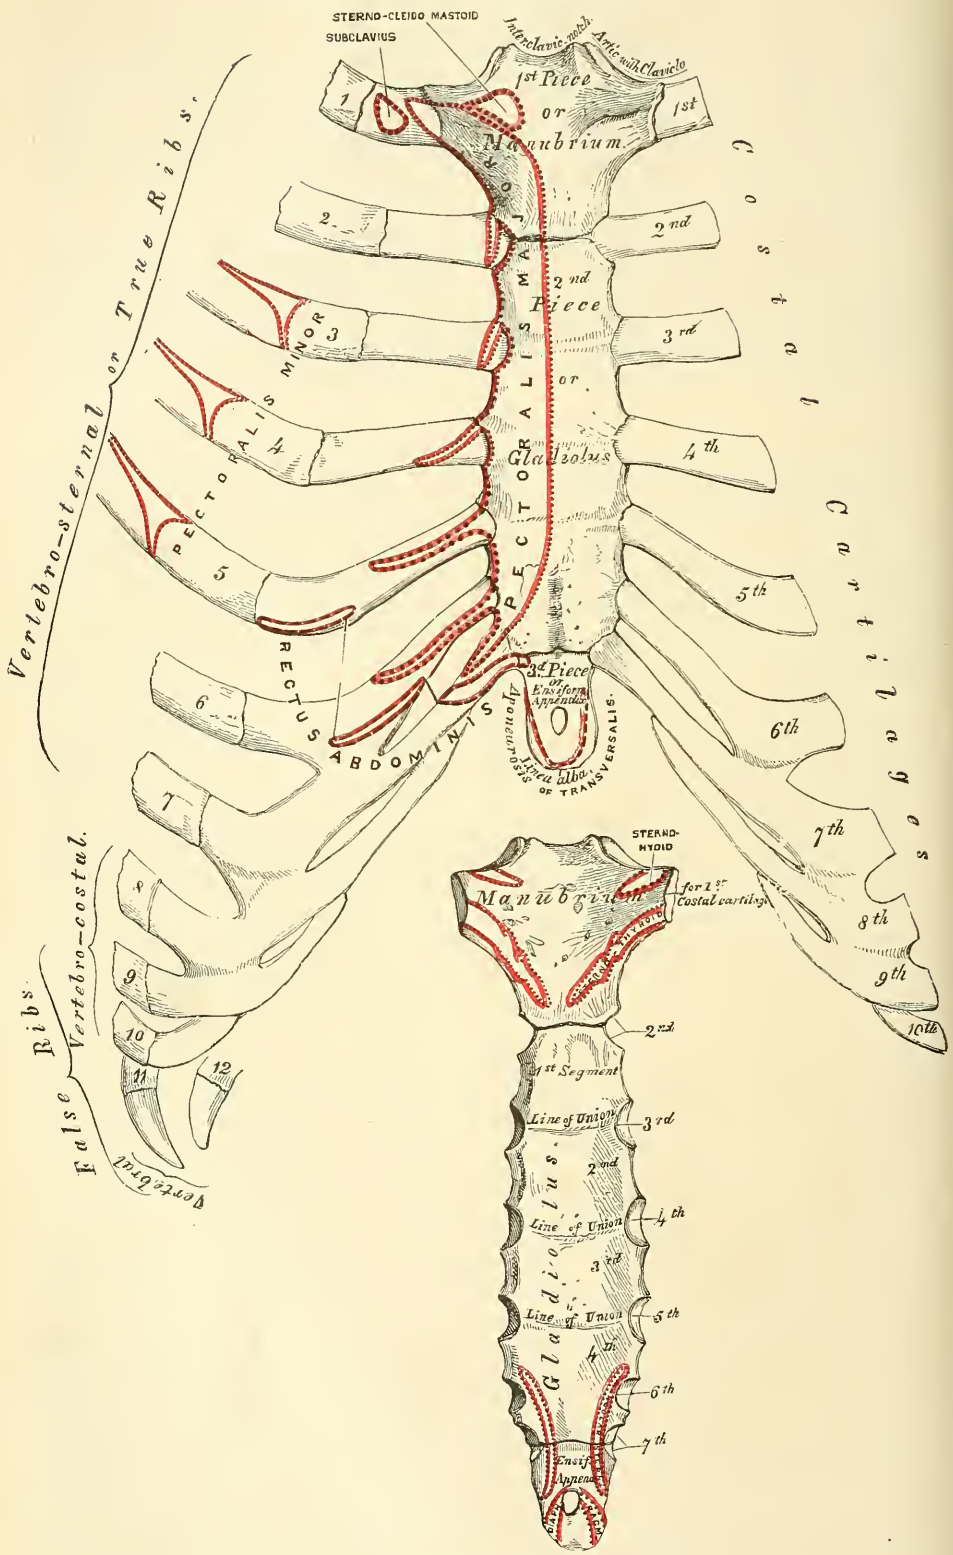


FIG. 191.—Posterior surface of sternum.

sternal origin of the Pectoralis major. The *posterior surface*, slightly concave, is also marked by three transverse lines; but they are less distinct than those in front: this surface affords attachment below, on each side, to the Triangularis sterni muscle, and occasionally presents the posterior opening of the sternal foramen. The *superior border* presents an oval surface for articulation with the manubrium. The *inferior border* is narrow, and articulates with the ensiform appendix. Each *lateral border* presents, at each superior angle, a small facet, which, with a similar facet on the manubrium, forms a cavity for the cartilage of the second rib; the four succeeding angular depressions receive the cartilages of the third, fourth, fifth, and sixth ribs, whilst each inferior angle presents a small facet, which, with a corresponding one on the ensiform appendix, forms a notch for the cartilage of the seventh rib. These articular depressions are separated by a series of curved interarticular intervals, which diminish in length from above downwards, and correspond to the intercostal spaces. Most of the cartilages belonging to the true ribs, as will be seen from the foregoing description, articulate with the sternum at the line of junction of two of its primitive component segments. This is well seen in many of the lower animals, where the separate parts of the bone remain ununited longer than in man. In this respect a striking analogy exists between the mode of connection of the ribs with the vertebral column, and the connection of the costal cartilages with the sternum.

The **Third Piece** of the sternum, the **Ensiform** or **Xiphoid Appendix** (*metasternum*), is the smallest of the three; it is thin and elongated in form, cartilaginous in structure in youth, but more or less ossified at its upper part in the adult. Its *anterior surface* affords attachment to the chondro-xiphoid ligament; its *posterior surface*, to some of the fibres of the Diaphragm and Triangularis sterni muscles; its *lateral borders*, to the aponeurosis of the abdominal muscles. Above, it articulates with the lower end of the gladiolus, and at each superior angle presents a facet for the lower half of the cartilage of the seventh rib; below, by its pointed extremity, it gives attachment to the linea alba. This portion of the sternum is very various in appearance, being sometimes pointed, broad and thin, sometimes bifid, or perforated by a round hole, occasionally curved, or deflected considerably to one or the other side.

Structure.—The bone is composed of delicate cancellous structure, covered by a thin layer of compact tissue, which is thickest in the manubrium, between the articular facets for the clavicles.

Development.—The sternum, including the ensiform appendix, is developed by *six* centres: one for the first piece or manubrium, four for the second piece or gladiolus, and one for the ensiform appendix. Up to the middle of fœtal life the sternum is entirely cartilaginous, and when ossification takes place the ossific granules are deposited in the middle of the intervals between the articular depressions for the costal cartilages, in the following order: in the first piece, between the fifth and sixth months; in the second and third, between the sixth and seventh months; in the fourth piece, at the ninth month; in the fifth, within the first year, or between the first and second years after birth; and in the ensiform appendix, between the second and the seventeenth or eighteenth years by a single centre which makes its appearance at the upper part, and proceeds gradually downwards (fig. 192). To these may be added the occasional existence, as described by Breschet, of two small episternal centres, which make their appearance one on each side of the pre-sternal notch. They are probably vestiges of the episternal bone of the monotremata and lizards. It occasionally happens that some of the segments are formed from more than one centre, the number and position of which vary (fig. 194). Thus, the first piece may have two, three, or even six centres. When two are present, they are generally situated one above the other, the upper one being the larger;* the second piece has seldom more than one; the third, fourth, and fifth pieces are often

* Sir George Humphry states that this is 'probably the more complete condition.'

Fig. 192.—Development of the sternum, by six centres.

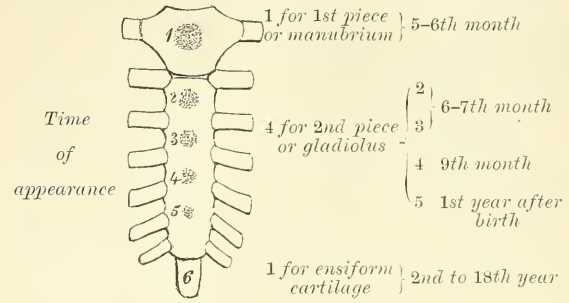

Fig. 193.

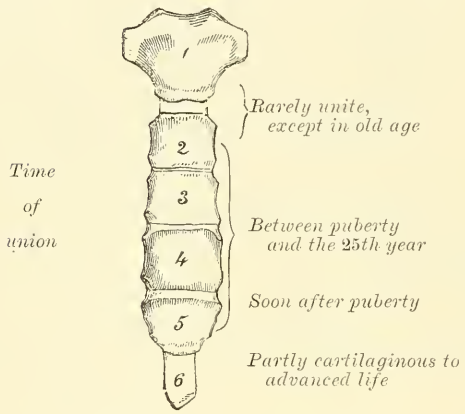

Fig. 194.—Peculiarities.

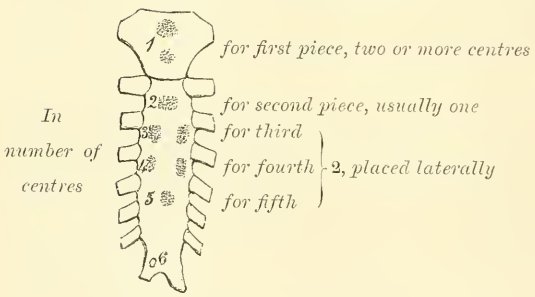

Fig. 195.

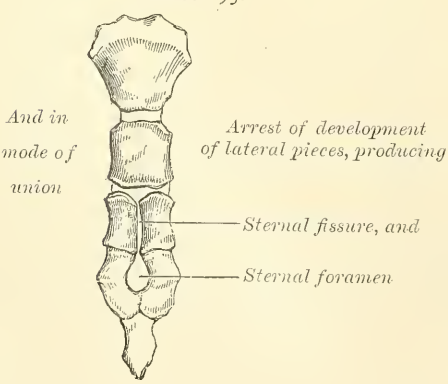


formed from two centres placed laterally, the irregular union of which will serve to explain the occasional occurrence of the sternal foramen (fig. 195), or of the vertical fissure which occasionally intersects this part of the bone, and which is further explained by the manner in which the cartilaginous matrix, in which ossification takes place, is formed (see page 90). Union of the various centres of the gladiolus commences about puberty, from below, and proceeds upwards, so that by the age of twenty-five they are all united, and this portion of bone consists of one piece (fig. 193). The ensiform cartilage becomes joined to the gladiolus about forty. The manubrium is occasionally, but not invariably, joined to the gladiolus in advanced life by bone. When this union takes place, however, it is generally only superficial, a portion of the centre of the sutural cartilage remaining unossified.

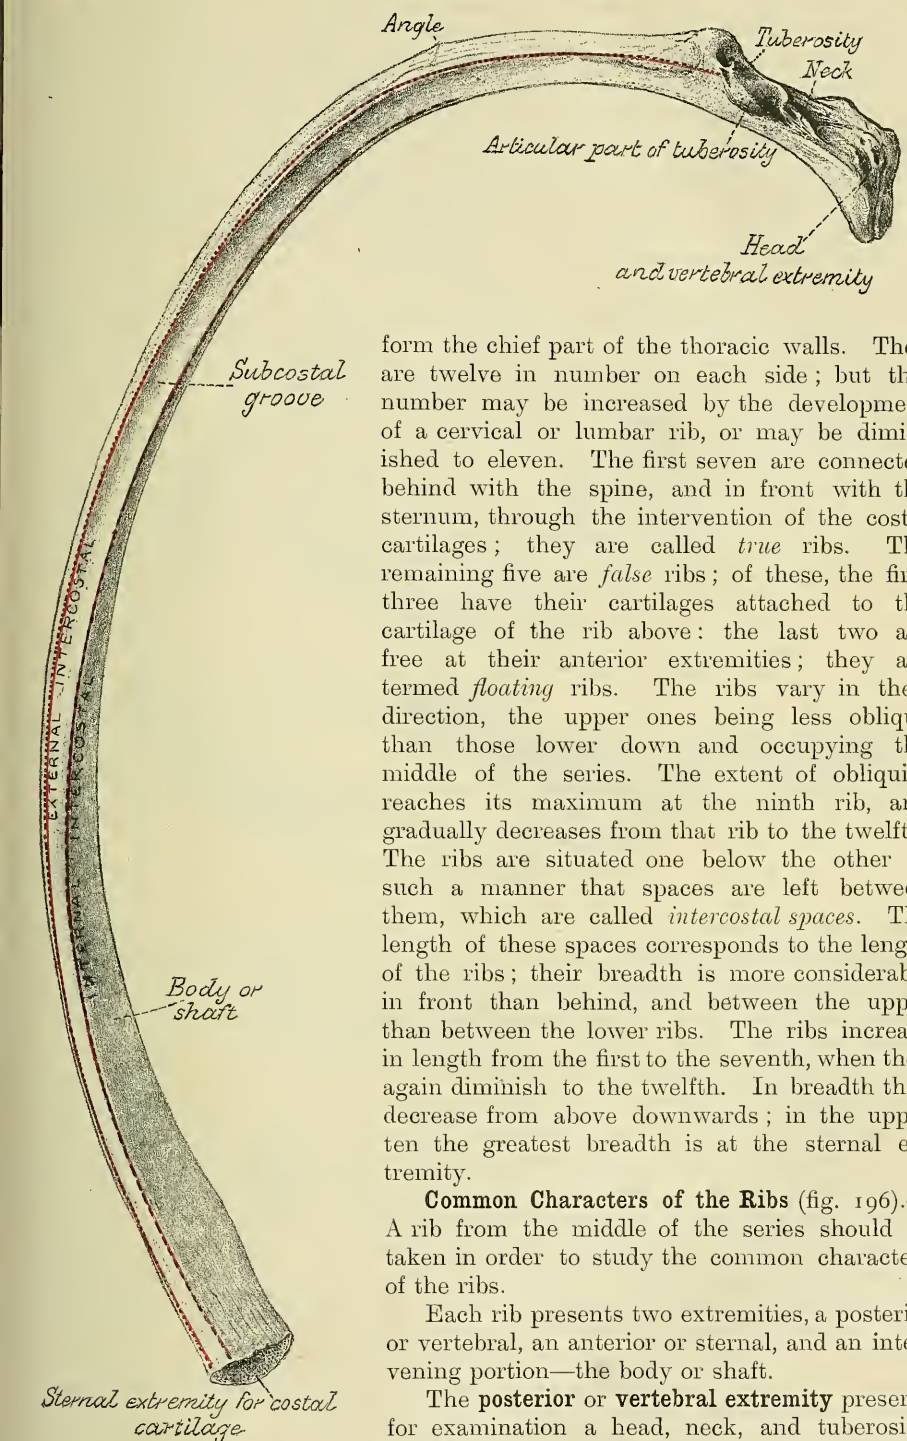
Articulations. — With the clavicles and seven costal cartilages on each side.

Attachment of Muscles. —To nine pairs and one single muscle : the Pectoralis major, Sterno-cleido-mastoid, Sterno-hyoid, Sterno-thyroid, Triangularis sterni, the aponeuroses of the Obliquus externus, Obliquus internus, Transversalis, and Rectus muscles, and Diaphragm.

The Ribs

The **Ribs** are elastic arches of bone, which

Fig. 196.—A central rib of left side.



form the chief part of the thoracic walls. They are twelve in number on each side; but this number may be increased by the development of a cervical or lumbar rib, or may be diminished to eleven. The first seven are connected behind with the spine, and in front with the sternum, through the intervention of the costal cartilages; they are called *true* ribs. The remaining five are *false* ribs; of these, the first three have their cartilages attached to the cartilage of the rib above: the last two are free at their anterior extremities; they are termed *floating* ribs. The ribs vary in their direction, the upper ones being less oblique than those lower down and occupying the middle of the series. The extent of obliquity reaches its maximum at the ninth rib, and gradually decreases from that rib to the twelfth. The ribs are situated one below the other in such a manner that spaces are left between them, which are called *intercostal spaces*. The length of these spaces corresponds to the length of the ribs; their breadth is more considerable in front than behind, and between the upper than between the lower ribs. The ribs increase in length from the first to the seventh, when they again diminish to the twelfth. In breadth they decrease from above downwards; in the upper ten the greatest breadth is at the sternal extremity.

Common Characters of the Ribs (fig. 196).—A rib from the middle of the series should be taken in order to study the common characters of the ribs.

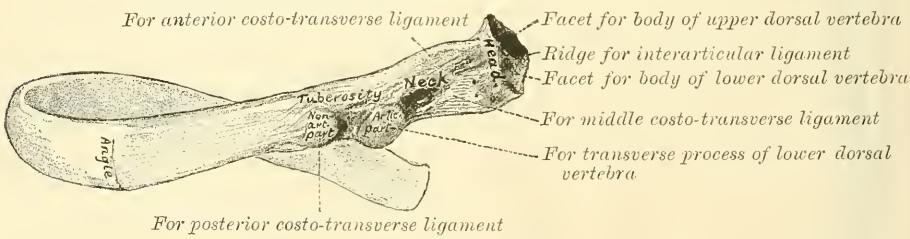
Each rib presents two extremities, a posterior or vertebral, an anterior or sternal, and an intervening portion—the body or shaft.

The **posterior** or **vertebral extremity** presents for examination a head, neck, and tuberosity. The **head** (fig. 197) is marked by a kidney-shaped articular surface, divided by a horizontal ridge into two facets for articulation with the costal cavity formed by the junction of the bodies of two contiguous dorsal vertebræ; the upper facet is small, the inferior one of larger size; the ridge separating them serves for the attachment of the interarticular ligament.

The **neck** is that flattened portion of the rib which extends outwards from the head; it is about an inch long, and is placed in front of the transverse process of the lower of the two vertebræ with which the head articulates. Its *anterior surface* is flat and smooth, its *posterior* rough, for the attachment of the middle costo-transverse ligament, and perforated by numerous foramina, the direction of which is less constant than those found on the inner surface of the shaft. Of its two borders the *superior* presents a rough crest for the attachment of the anterior costo-transverse ligament; its *inferior border* is rounded. On the posterior surface of the neck, just where it joins the shaft, and nearer the lower than the upper border, is an eminence—the **tuberosity,** or **tubercle**; it consists of an articular and a non-articular portion. The *articular portion*, the more internal and inferior of the two, presents a small, oval surface for articulation with the extremity of the transverse process of the lower of the two vertebræ to which the head is connected. The *non-articular portion* is a rough elevation, which affords attachment to the posterior costo-transverse ligament. The tubercle is much more prominent in the upper than in the lower ribs.

The **shaft** is thin and flat, so as to present two surfaces, an external and an internal; and two borders, a superior and an inferior. The *external surface* is convex, smooth, and marked, at its back part, a little in front of the tuberosity, by a prominent line, directed obliquely from above downwards and outwards; this gives attachment to a tendon of the Ilio-costalis muscle, or of one of its accessory portions, and is called the *angle*. At this point the rib is bent in two

Fig. 197.—Vertebral extremity of a rib. External surface.



directions. If the rib is laid upon its lower border, it will be seen that the portion of the shaft in front of the angle rests upon this border, while the portion of the shaft behind the angle is bent inwards and at the same time tilted upwards. The interval between the angle and the tuberosity increases gradually from the second to the tenth rib. The portion of bone between these two parts is rounded, rough, and irregular, and serves for the attachment of the Longissimus dorsi muscle. The portion of bone between the tubercle and sternal extremity is also slightly twisted upon its own axis, the external surface looking downwards behind the angle, a little upwards in front of it. This surface presents, towards its sternal extremity, an oblique line, the *anterior angle*. The *internal surface* is concave, smooth, directed a little upwards behind the angle, a little downwards in front of it. This surface is marked by a ridge which commences at the lower extremity of the head; it is strongly marked as far as the inner side of the angle, and gradually becomes lost at the junction of the anterior with the middle third of the bone. The interval between it and the inferior border presents a groove, *subcostal*, for the intercostal vessels and nerve. At the back part of the bone, this groove belongs to the inferior border, but just in front of the angle, where it is deepest and broadest, it corresponds to the internal surface. The superior edge of the groove is rounded; it serves for the attachment of the Internal intercostal muscle. The inferior edge corresponds to the lower margin of the rib, and gives attachment to the External intercostal. Within the groove are seen the orifices of numerous small foramina, which traverse the wall of the shaft obliquely from before backwards. The *superior border*, thick and rounded, is marked by

an external and an internal lip, more distinct behind than in front; they serve for the attachment of the External and Internal intercostal muscles. The *inferior border*, thin and sharp, has attached to it the External intercostal muscle. The **anterior** or **sternal extremity** is flattened, and presents a porous, oval, concave depression, into which the costal cartilage is received.

Peculiar Ribs

The ribs which require especial consideration are five in number—viz. the first, second, tenth, eleventh, and twelfth.

Peculiar ribs.

Fig. 198.

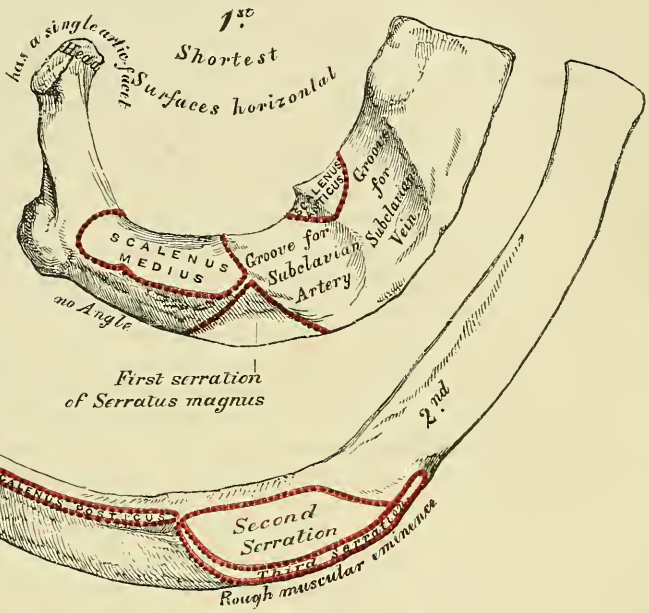


Fig. 199.

Angle slightly marked and close to tuberosity

Fig. 200.

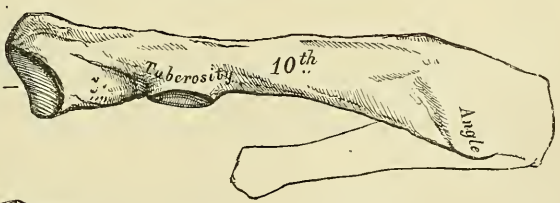

Fig. 201.

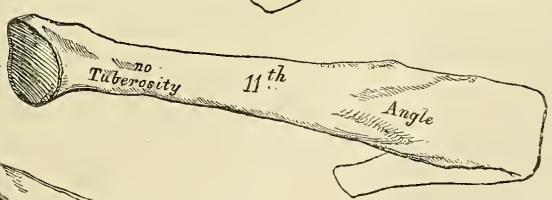

Fig. 202.

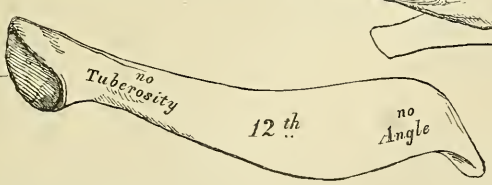

The **first rib** (fig. 198) is one of the shortest and the most curved of all the ribs; it is broad and flat, its surfaces looking upwards and downwards, and its borders inwards and outwards. The *head* is of small size, rounded, and presents only a single articular facet for articulation with the body of the first dorsal

vertebra. The *neck* is narrow and rounded. The *tuberosity*, thick and prominent, rests on the outer border. There is no angle, but in this situation the rib is slightly bent, with the convexity of the bend upwards, so that the head of the bone is directed downwards. The *upper surface* of the shaft is marked by two shallow depressions, separated by a small rough surface for the attachment of the Scalenus anticus muscle—the groove in front of it transmitting the subclavian vein, that behind it the subclavian artery. Between the groove for the subclavian artery and the tuberosity is a rough surface for the attachment of the Scalenus medius muscle. The *under surface* is smooth, and destitute of the groove observed on the other ribs. The *outer border* is convex, thick, and rounded, and at its posterior part gives attachment to the first serration of the Serratus magnus; the *inner* is concave, thin, and sharp, and marked about its centre by the commencement of the rough surface for the Scalenus anticus. The *anterior extremity* is larger and thicker than any of the other ribs.

The **second rib** (fig. 199) is much longer than the first, but bears a very considerable resemblance to it in the direction of its curvature. The non-articular portion of the tuberosity is occasionally only slightly marked. The *angle* is slight, and situated close to the tuberosity, and the shaft is not twisted, so that both ends touch any plane surface upon which it may be laid; but there is a similar though slighter bend, with its convexity upwards, to that found in the first rib. The shaft is not horizontal, like that of the first rib; its *outer surface*, which is convex, looking upwards and a little outwards. It presents, near the middle, a rough eminence for the attachment of the second and third digitations of the Serratus magnus; behind and above which is attached the Scalenus posticus. The *inner surface*, smooth and concave, is directed downwards and a little inwards: it presents a short groove towards its posterior part.

The **tenth rib** (fig. 200) has only a single articular facet on its head.

The **eleventh** and **twelfth ribs** (figs. 201 and 202) have each a single articular facet on the head, which is of rather large size; they have no neck or tuberosity, and are pointed at the extremity. The eleventh has a slight angle and a shallow groove on the lower border. The twelfth has neither, and is much shorter than the eleventh, and the head has a slight inclination downwards.

Structure.—The ribs consist of cancellous tissue, enclosed in a thin, compact layer.

Development.—Each rib, with the exception of the last two, is developed by *three* centres: one for the shaft, one for the head, and one for the tubercle. The last two have only *two* centres, that for the tubercle being wanting. Ossification commences in the shaft of the ribs at a very early period, before its appearance in the vertebræ. The epiphysis of the head, which is of a slightly angular shape, and that for the tubercle, of a lenticular form, make their appearance between the sixteenth and twentieth years, and are not united to the rest of the bone until about the twenty-fifth year.

Attachment of Muscles.—To nineteen: the Internal and External intercostals, Scalenus anticus, Scalenus medius, Scalenus posticus, Pectoralis minor, Serratus magnus, Obliquus externus, Quadratus lumborum, Diaphragm, Latissimus dorsi, Serratus posticus superior, Serratus posticus inferior, Ilio-costalis, Musculus accessorius ad ilio-costalem, Longissimus dorsi, Cervicalis ascendens, Levatores costarum, and Infra-costales.

The Costal Cartilages

The **Costal Cartilages** (fig. 190, p. 212) are bars of white, elastic hyaline cartilage, which serve to prolong the ribs forward to the front of the chest, and contribute very materially to the elasticity of its walls. The first seven are connected with the sternum, the next three with the lower border of the cartilage of the preceding rib. The cartilages of the last two ribs, which have pointed extremities, float freely in the walls of the abdomen. Like the ribs, the costal

cartilages vary in their length, breadth, and direction. They increase in length from the first to the seventh, then gradually diminish to the last. They diminish in breadth, as well as the intervals between them, from the first to the last. They are broad at their attachment to the ribs, and taper towards their sternal extremities, excepting the first two, which are of the same breadth throughout, and the sixth, seventh, and eighth, which are enlarged where their margins are in contact. In direction they also vary: the first descends a little, the second is horizontal, the third ascends slightly, whilst all the rest follow the course of the ribs for a short extent, and then ascend to the sternum or preceding cartilage. Each costal cartilage presents two surfaces, two borders, and two extremities. The *anterior surface* is convex, and looks forwards and upwards: that of the first gives attachment to the costo-clavicular ligament and the Subclavius muscle; that of the second, third, fourth, fifth, and sixth, at their sternal ends, to the Pectoralis major.* The others are covered by, and give partial attachment to, some of the great flat muscles of the abdomen. The *posterior surface* is concave, and directed backwards and downwards, the first giving attachment to the Sterno-thyroid, and the six or seven inferior ones affording attachment to the Transversalis muscle and the Diaphragm. Of the two borders, the *superior* is concave, the *inferior* convex: they afford attachment to the Intercostal muscles, the upper border of the sixth giving attachment to the Pectoralis major muscle. The contiguous borders of the sixth, seventh, and eighth, and sometimes the ninth and tenth, costal cartilages present small, smooth, oblong-shaped facets at the points where they articulate. Of the two extremities, the *outer* one is continuous with the osseous tissue of the rib to which it belongs. The *inner* extremity of the first is continuous with the sternum; the six succeeding ones have rounded extremities, which are received into shallow concavities on the lateral margins of the sternum. The inner extremities of the eighth, ninth, and tenth costal cartilages are pointed, and are connected with the cartilage above. Those of the eleventh and twelfth are free and pointed.

The costal cartilages are most elastic in youth, those of the false ribs being more so than the true. In old age they become of a deep yellow colour, and are prone to calcify.

Attachment of Muscles.—To nine: the Subclavius, Sterno-thyroid, Pectoralis major, Internal oblique, Transversalis, Rectus, Diaphragm, Triangularis sterni, and Internal intercostals.

Surface Form.—The bones of the chest are to a very considerable extent covered by muscles, so that in the strongly-developed muscular subject they are for the most part concealed. In the emaciated subject, on the other hand, the ribs, especially in the lower and lateral region, stand out as prominent ridges with the sunken, intercostal spaces between them.

In the middle line, in front, the superficial surface of the sternum is to be felt throughout its entire length, at the bottom of a deep median furrow situated between the two great pectoral muscles and called the *sternal furrow*. These muscles overlap the anterior surface somewhat, so that the whole of the sternum in its entire width is not subcutaneous, and this overlapping is greater opposite the centre of the bone than above and below, so that the furrow is wide at its upper and lower part, but narrower in the middle. The centre of the upper border of the sternum is visible, constituting the presternal notch, but the lateral parts of this border are obscured by the tendinous origins of the Sterno-mastoid muscles, which present themselves as oblique tendinous cords, which narrow and deepen the notch. Lower down on the subcutaneous surface a well-defined transverse ridge is always to be felt. This denotes the line of junction of the manubrium and body of the bone and is a useful guide to the second costal cartilage, and thus to the identity of any given rib. The second rib being found, through its costal cartilage, it is easy to count downwards and find any other. From the middle of the bone the furrow spreads out, and, exposing more of the surface of the body of the sternum, terminates below in a sudden depression, the *infra-sternal depression* or *pit of the stomach* (*scrobiculus cordis*), which corresponds to the ensiform cartilage. This depression lies between the cartilages of the seventh rib, and in it the ensiform cartilage may be felt. The sternum in its vertical diameter presents a general convexity forwards, the most prominent point of which is at the joint between the manubrium and gladiolus.

* The first and seventh also, occasionally, give origin to the same muscle.

On each side of the sternum the costal cartilages and ribs on the front of the chest are partially obscured by the great pectoral muscle; through which, however, they are to be felt as ridges, with depressed intervals between them, corresponding to the intercostal spaces. Of these spaces, the one between the second and third ribs is the widest, the next two somewhat narrower, and the remainder, with the exception of the last two, comparatively narrow.

The lower border of the Pectoralis major muscle corresponds to the fifth rib, and below this, on the front of the chest, the broad, flat outline of the ribs, as they begin to ascend, and the more rounded outline of the costal cartilages, are often visible. The lower boundary of the front of the thorax, the *abdomino-thoracic arch*, which is most plainly seen by arching the body backwards, is formed by the ensiform cartilage and the cartilages of the seventh, eighth, ninth, and tenth ribs, and the extremities of the eleventh and twelfth ribs or their cartilages.

On each side of the chest, from the axilla downwards, the flattened external surfaces of the ribs may be defined in the form of oblique ridges, separated by depressions corresponding to the intercostal spaces. They are, however, covered by muscles, which obscure their outline to a certain extent in the strongly developed. Nevertheless, the ribs, with the exception of the first, can generally be followed over the front and sides of the chest without difficulty. The first rib, being almost completely covered by the clavicle and scapula, can only be distinguished in a small portion of its extent. At the back, the angles of the ribs form a slightly-marked oblique line, on each side of and some distance from the vertebral spines. This line diverges somewhat as it descends, and external to it is a broad, convex surface, caused by the projection of the ribs beyond their angles. Over this surface, except where covered by the scapula, the individual ribs can be distinguished.

Surgical Anatomy.—Malformations of the sternum present nothing of surgical importance beyond the fact that abscesses of the mediastinum may sometimes escape through the sternal foramen. Fracture of the sternum is by no means common, owing, no doubt, to the elasticity of the ribs and their cartilages which support it like so many springs. When broken, it is frequently associated with fracture of the spine, and may be caused by forcibly bending the body either backwards; or forwards until the chin becomes impacted against the top of the sternum. It may also be fractured by direct violence or by muscular action. The fracture usually occurs in the upper half of the body of the bone. Dislocation of the gladiolus from the manubrium also takes place, and is sometimes described as a fracture.

The bone being subcutaneous is frequently the seat of gummatous tumours and not uncommonly is affected with caries. Occasionally the bone, and especially its ensiform appendix, becomes altered in shape and driven inwards by the pressure, in workmen, of tools against their chest.

The ribs are frequently broken, though from their connections and shape they are able to withstand great force, yielding under the injury and recovering themselves like a spring. The middle of the series are the ones most liable to fracture. The first and to a less extent the second, being protected by the clavicle, are rarely fractured; and the eleventh and twelfth on account of their loose and floating condition enjoy a like immunity. The fracture generally occurs from indirect violence, from forcible compression of the chest wall, and the bone then gives way at its weakest part, i.e. just in front of the angle. But the ribs may also be broken by direct violence, when the bone gives way and is driven inwards at the point struck, or by muscular action. It seems probable, however, that in these latter cases the bone has undergone some atrophic changes. Fracture of the ribs is frequently complicated with some injury to the viscera contained within the thorax or upper part of the abdominal cavity, and this is most likely to occur in fractures from direct violence.

Fracture of the costal cartilages may also take place, though it is a comparatively rare injury.

The thorax is frequently found to be altered in shape in certain diseases.

The *rickety* thorax is caused chiefly by atmospheric pressure. The balance between the air on the inside of the chest and the outside during some stage of respiration is not equal, the preponderance being in favour of the air outside, and this, acting on the softened ribs, causes them to be forced in at the junction of the cartilages with the bones, which is the weakest part. In consequence of this the sternum projects forwards, with a deep depression on either side caused by the sinking in of the softened ribs. The depression is less on the left side, on account of the ribs being supported by the heart. The condition is known as 'pigeon-breast.' The lower ribs, however, are not involved in this deformity, as they are prevented from falling in by the presence of the stomach, liver, and spleen. And when the liver and spleen are enlarged, as they sometimes are in rickets, the lower ribs may be pushed outwards: this causes a transverse constriction just above the costal arch. The anterior extremities of the ribs are usually enlarged in rickets, giving rise to what has been termed the 'rickety rosary.' The *phthisical chest* is often long and narrow, flattened from before backwards, and with great obliquity of the ribs and projection of the scapulæ. In *pulmonary emphysema* the chest is enlarged in all its diameters, and presents on section an almost circular outline. It has received the name of the 'barrel-shaped chest.' In severe cases of *lateral curvature of the spine*, the thorax

becomes much distorted. In consequence of the rotation of the bodies of the vertebræ, which takes place in this disease, the ribs opposite the convexity of the dorsal curve become extremely convex behind, being thrown out and bulging, and at the same time flattened in front, so that the two ends of the same rib are almost parallel. Coincident with this the ribs on the opposite side, on the concavity of the curve, are sunk and depressed behind, and bulging and convex in front. In addition to this the ribs become occasionally welded together by bony material.

The ribs are frequently the seat of necrosis leading to abscesses and sinuses, which may burrow to a considerable extent over the wall of the chest. The only special anatomical point in connection with these is that care must be taken in dealing with them, that the intercostal space is not punctured and the pleural cavity opened or the intercostal vessels wounded.

In cases of empyema the chest requires opening to evacuate the pus. There is considerable difference of opinion as to the best position to do this. Probably the best place in most cases will be found to be between the fifth and sixth ribs, in or a little in front of the mid-axillary line. This is the last part of the cavity to be closed by the expansion of the lung; it is not thickly covered by soft parts; the space between the two ribs is sufficiently great to allow of the introduction of a fair-sized drainage tube. and the opening is in a dependent position, when the patient is confined to bed, as he usually inclines towards the affected side, so as to allow the sound lung the freest possible play, and so permits of efficient drainage.

OF THE EXTREMITIES

The extremities, or limbs, are those long, jointed appendages of the body which are connected to the trunk by one end, and free in the rest of their extent. They are *four* in number: an *upper* or *thoracic pair*, connected with the thorax through the intervention of the shoulder, and subservient mainly to prehension; and a *lower pair*, connected with the pelvis, intended for support and locomotion. Both pairs of limbs are constructed after one common type, so that they present numerous analogies; while, at the same time, certain differences are observed in each, dependent on the peculiar offices they have to perform.

The bones by which the upper and lower limbs are attached to the trunk are named respectively the *shoulder* and *pelvic girdles*, and they are constructed on the same general type, though presenting certain modifications relating to the different uses to which the upper and lower limbs are respectively applied. The *shoulder girdle* is formed by the scapula and clavicle, and is imperfect in front and behind. In front, however, the girdle is completed by the upper end of the sternum, with which the inner extremities of the clavicle articulate. Behind, the girdle is widely imperfect, and the scapula is connected to the trunk by muscles only. The *pelvic girdle* is formed by the innominate bones, and is completed in front, through the symphysis pubis, at which the two innominate bones articulate with each other. It is imperfect behind, but the intervening gap is filled in by the upper part of the sacrum. The pelvic girdle therefore presents, with the sacrum, a complete ring, comparatively fixed, and presenting an arched form which confers upon it a solidity manifestly intended for the support of the trunk, and in marked contrast to the lightness and mobility of the shoulder girdle.

With regard to the morphology of these girdles, the blade of the scapula is generally believed to correspond to the ilium: but with regard to the clavicles there is some difference of opinion; formerly it was believed that they corresponded to the ossa pubis meeting at the symphysis, but it is now generally taught that the clavicle has no homologue in the pelvic girdle, and that the os pubis and ischium are represented by the small coracoid process in man and most mammals.

Of the Upper Extremity

The bones of the upper extremity consist of those of the shoulder girdle, of the arm, the forearm, and the hand. The shoulder girdle consists of two bones, the clavicle and the scapula.

The Clavicle

The **Clavicle** (clavis, *a key*), or collar-bone, forms the anterior portion of the shoulder girdle. It is a long bone, curved somewhat like the italic letter *f*, and placed nearly horizontally at the upper and anterior part of the thorax, immediately above the first rib. It articulates by its inner extremity with the upper border of the sternum, and by its outer extremity with the acromion process of the scapula; serving to sustain the upper extremity in the various positions which it assumes, whilst, at the same time, it allows of great latitude of motion in the arm.* It presents a double curvature, when looked at in front; the convexity being forwards at the sternal end, and the concavity at the scapular end. Its outer third is flattened from above downwards, and extends, in the natural position of the bone, from a point opposite the coracoid process to the acromion. Its inner two-thirds are of a cylindrical form, and extend from the sternum to a point opposite the coracoid process of the scapula.

External or Flattened Portion.—The *outer third* is flattened from above downwards, so as to present two surfaces, an upper and a lower; and two borders, an anterior and a posterior. The *upper surface* is flattened, rough, marked by impressions for the attachment of the Deltoid in front, and the Trapezius behind; between these two impressions, externally, a small portion of the bone is subcutaneous. The *under surface* is flattened. At its posterior border, a little external to the point where the prismatic joins with the flattened portion, is a rough eminence, the *conoid tubercle*; this, in the natural position of the bone, surmounts the coracoid process of the scapula, and gives attachment to the conoid ligament. From this tubercle, an oblique line, occasionally a depression, passes forwards and outwards to near the outer end of the anterior border; it is called the *oblique line*, and affords attachment to the trapezoid ligament. The *anterior border* is concave, thin, and rough; and gives attachment to the Deltoid; it occasionally presents, at its inner end, at the commencement of the deltoid impression, a tubercle, the *deltoid tubercle*, which is sometimes to be felt in the living subject. The *posterior border* is convex, rough, broader than the anterior, and gives attachment to the Trapezius.

Internal or Cylindrical Portion.—The cylindrical portion forms the *inner two-thirds* of the bone. It is curved so as to be convex in front, concave behind, and is marked by three borders, separating three surfaces. The *anterior border* is continuous with the anterior margin of the flat portion. At its commencement it is smooth, and corresponds to the interval between the attachment of the Pectoralis major and Deltoid muscles; at the inner half of the clavicle it forms the lower boundary of an elliptical space for the attachment of the clavicular portion of the Pectoralis major, and approaches the posterior border of the bone. The *superior border* is continuous with the posterior margin of the flat portion, and separates the anterior from the posterior surface. At its commencement it is smooth and rounded, becomes rough towards the inner third for the attachment of the Sterno-mastoid muscle, and terminates at the upper angle of the sternal extremity. The *posterior* or *subclavian border* separates the posterior from the inferior surface, and extends from the conoid tubercle to the rhomboid impression. It forms the posterior boundary of the groove for the Subclavius muscle, and gives attachment to a layer of cervical fascia, covering the Omo-hyoid muscle. The *anterior surface* is included between the superior and anterior borders. It is directed forwards and a little upwards at the sternal end, outwards and still more upwards at the acromial extremity, where it becomes

* The clavicle acts especially as a fulcrum to enable the muscles to give lateral motion to the arm. It is accordingly absent in those animals whose fore limbs are used only for progression, but is present for the most part in those animals whose anterior extremities are clawed and used for prehension, though in some of them—as, for instance, in a large number of the carnivora—it is merely a rudimentary bone suspended among the muscles, and not articulating either with the scapula or sternum.

continuous with the upper surface of the flat portion. Externally, it is smooth, convex, nearly subcutaneous, being covered only by the Platysma; but, corresponding to the inner half of the bone, it is divided by a more or less prominent line into two parts: a lower portion, elliptical in form, rough, and slightly convex, for the attachment of the Pectoralis major; and an upper part, which is rough, for the attachment of the Sterno-cleido-mastoid. Between the two muscular impressions is a small, subcutaneous interval. The *posterior* or *cervical surface* is smooth, flat, and looks backwards towards the root of the neck. It is limited, above, by the superior border; below, by the subclavian border; internally, by the margin of the sternal extremity; externally, it is continuous with the posterior border of the flat portion. It is concave from within outwards, and is in relation, by its lower part, with the suprascapular vessels. This surface, at about the junction of the inner and outer curves, is also in close relation with the brachial plexus and subclavian vessels. It gives attachment, near the sternal extremity, to part of the Sterno-hyoid muscle; and presents, at or near the middle, a

FIG. 203.—Left clavicle. Superior surface.

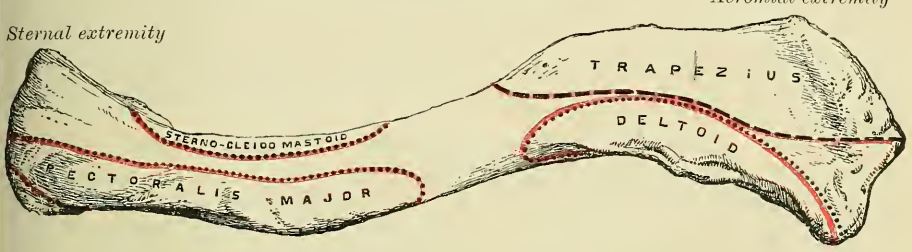

FIG. 204.—Left clavicle. Inferior surface.

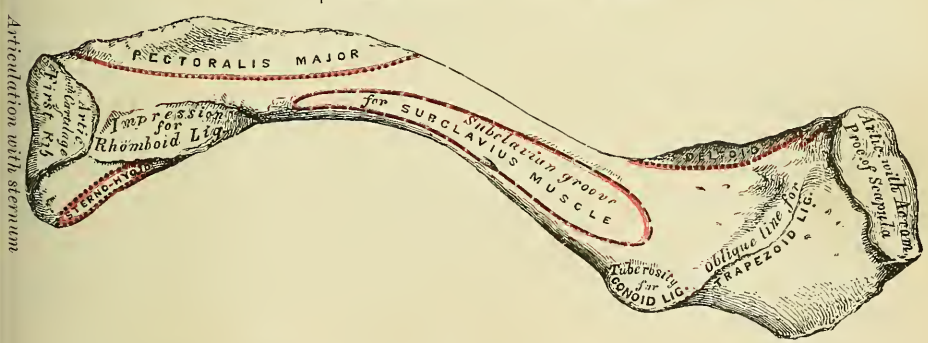


foramen, directed obliquely outwards, which transmits the chief nutrient artery of the bone. Sometimes there are two foramina on the posterior surface, or one on the posterior, the other on the inferior surface. The *inferior* or *subclavian surface* is bounded, in front, by the anterior border; behind, by the subclavian border. It is narrow internally, but gradually increases in width externally, and is continuous with the under surface of the flat portion. Commencing at the sternal extremity may be seen a small facet for articulation with the cartilage of the first rib. This is continuous with the articular surface at the sternal end of the bone. External to this is a broad, rough impression, the *rhomboid*, rather more than an inch in length, for the attachment of the costo-clavicular (rhomboid) ligament. The remaining part of this surface is occupied by a longitudinal groove, the *subclavian groove*, broad and smooth externally, narrow and more uneven internally; it gives attachment to the Subclavius muscle, and, by its anterior margin, to the costo-coracoid membrane. Not unfrequently this groove is subdivided into two parts by a longitudinal line, which gives attachment to the intermuscular septum of the Subclavius muscle.

The **internal** or **sternal extremity** of the clavicle is triangular in form, directed inwards, and a little downwards and forwards; and presents an articular facet, concave from before backwards, convex from above downwards, which articulates with the sternum through the intervention of an interarticular fibro-cartilage; the circumference of the articular surface is rough, for the attachment of numerous ligaments. The posterior border of this surface is prolonged backwards so as to increase the size of the articular facet; the upper border gives attachment to the interarticular fibro-cartilage, and the lower border is continuous with the costal facet on the inner end of the inferior or subclavian surface, which articulates with the cartilage of the first rib.

The **outer** or **acromial extremity**, directed outwards and forwards, presents a small, flattened, oval facet, which looks obliquely downwards, for articulation with the acromion process of the scapula. The circumference of the articular facet is rough, especially above, for the attachment of the acromio-clavicular ligaments.

Peculiarities of the Bone in the Sexes and in Individuals.—In the female, the clavicle is generally shorter, thinner, less curved, and smoother than in the male. In these persons who perform considerable manual labour, which brings into constant action the muscles connected with this bone, it becomes thicker and more curved, its ridges for muscular attachment become prominently marked, and its sternal end of a prismatic form. The right clavicle is generally longer, thicker, and rougher than the left.

Structure.—The shaft, as well as the extremities, consists of cancellous tissue, invested in a compact layer much thicker in the middle than at either end. The clavicle is highly elastic, by reason of its curves. From the experiments of Mr. Ward, it has been shown that it possesses sufficient longitudinal elastic force to project its own weight nearly two feet on a level surface, when a smart blow is struck on it; and sufficient transverse elastic force, opposite the centre of its anterior convexity, to throw its own weight about a foot. This extent of elastic power must serve to moderate very considerably the effect of concussions received upon the point of the shoulder.

Development.—By *two* centres: one for the shaft, and one for the sternal extremity. The centre for the shaft appears very early, before any other bone; according to Béclard, as early as the thirtieth day. The centre for the sternal end makes its appearance about the eighteenth or twentieth year, and unites with the rest of the bone about the twenty-fifth year.

Articulations.—With the sternum, scapula, and cartilage of the first rib.

Attachment of Muscles.—To six: the Sterno-cleido-mastoid, Trapezius, Pectoralis major, Deltoid, Subclavius, and Sterno-hyoid.

Surface Form.—The clavicle can be felt throughout its entire length, even in persons who are very fat. Commencing at the inner end, the enlarged sternal extremity, where the bone projects above the upper margin of the sternum, can be felt, forming with the sternum and the rounded tendon of the Sterno-mastoid a V-shaped notch, the *presternal notch*. Passing outwards, the shaft of the bone can be felt immediately under the skin, with its convexity forwards in the inner two-thirds, the surface partially obscured above and below by the attachments of the Sterno-mastoid and Pectoralis major muscles. In the outer third it forms a gentle curve backwards, and terminates at the outer end in a somewhat enlarged extremity which articulates with the acromial process of the scapula. The direction of the clavicle is almost, if not quite, horizontal when the arm is lying quietly by the side, though in well-developed subjects it may incline a little upwards at its outer end. Its direction is, however, very changeable with the varying movements of the shoulder-joint.

Surgical Anatomy.—The clavicle is the most frequently broken of any single bone in the body. This is due to the fact that it is much exposed to violence, and is the only bony connection between the upper limb and the trunk. The bone, moreover, is slender, and is very superficial. The bone may be broken by direct or indirect violence, or by muscular action. The most common cause is, however, from indirect violence, and the bone then gives way at the junction of the outer with the inner two-thirds of the bone; that is to say, at the junction of the two curves, for this is the weakest part of the bone. The fracture is generally oblique, and the displacement of the fragments is inwards, away

from the surface of the body, hence compound fracture of the clavicle is of rare occurrence. Beneath the bone the main vessels of the upper limb and the great nerve-cords of the brachial plexus lie on the first rib and are liable to be wounded in fracture; especially in fracture from direct violence, when the force of the blow drives the broken ends inwards. Fortunately the subclavius muscle is interposed between these structures and the clavicle, and this often protects them from injury.

The clavicle is not uncommonly the seat of sarcomatous tumours, rendering the operation of excision of the entire bone necessary. This is an operation of considerable difficulty and danger. It is best performed by exposing the bone freely, disarticulating at the acromial end, and turning it inwards. The removal of the outer part is comparatively easy, but resection of the inner part is fraught with difficulty, the main danger being the risk of wounding the great veins which are in relation with its under surface.

The Scapula

The **Scapula** (*σκαπάνη, a spade*) forms the back part of the shoulder girdle. It is a large, flat bone, triangular in shape, situated at the posterior aspect and side of the thorax, between the second and seventh or sometimes the eighth ribs, its posterior border or base being about an inch from, and nearly, but not quite parallel with, the spinous processes of the vertebræ, so that it is rather closer to them above than below. It presents for examination two surfaces, three borders, and three angles.

The **anterior surface**, or **venter** (fig. 205), presents a broad concavity, the *subscapular fossa*. It is marked, in the posterior two-thirds, by several oblique ridges, which pass from behind obliquely outwards and upwards; the anterior third is smooth. The oblique ridges give attachment to the tendinous intersections, and the surfaces between them to the fleshy fibres, of the Subscapularis muscle. The anterior third of the fossa, which is smooth, is covered by, but does not afford attachment to, the fibres of this muscle. The venter is separated from the posterior border by a smooth, triangular margin at the superior and inferior angles, and in the interval between these by a narrow edge which is often deficient. This marginal surface affords attachment throughout its entire extent to the Serratus magnus muscle. The subscapular fossa presents a transverse depression at its upper part, where the bone appears to be bent on itself, forming a considerable angle, called the *subscapular angle*, thus giving greater strength to the body of the bone from its arched form; while the summit of the arch serves to support the spine and acromion process. It is in this situation that the fossa is deepest; so that the thickest part of the Subscapularis muscle lies in a line perpendicular to the plane of the glenoid cavity, and must consequently operate most effectively on the head of the humerus, which is contained in that cavity.

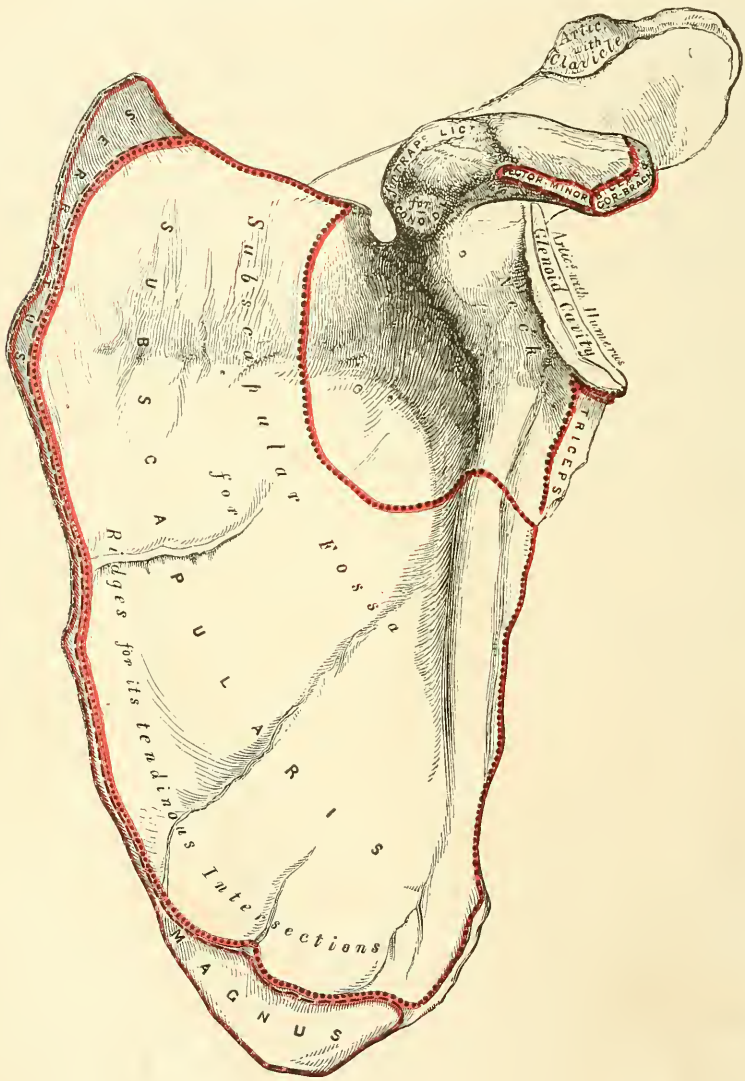
The **posterior surface**, or **dorsum** (fig. 206), is arched from above downwards, alternately concave and convex from side to side. It is subdivided unequally into two parts by the *spine*; the portion above the spine is called the *supraspinous fossa*, and that below it the *infraspinous fossa*.

The *supraspinous fossa*, the smaller of the two, is concave, smooth, and broader at the vertebral than at the humeral extremity. It affords attachment by its inner two-thirds to the Supraspinatus muscle.

The *infraspinous fossa* is much larger than the preceding; towards its vertebral margin a shallow concavity is seen at its upper part; its centre presents a prominent convexity, whilst towards the axillary border is a deep groove which runs from the upper towards the lower part. The inner two-thirds of this surface affords attachment to the Infraspinatus muscle; the outer third is only covered by it, without giving origin to its fibres. This surface is separated from the axillary border by an elevated ridge, which runs from the lower part of the glenoid cavity, downwards and backwards to the posterior border, about an inch above the inferior angle. The ridge serves for the attachment of a strong aponeurosis, which separates the Infraspinatus from the two Teres muscles. The surface of bone between this line and the axillary border is narrow in the

upper two-thirds of its extent, and traversed near its centre by a groove for the passage of the dorsalis scapulæ vessels ; it affords attachment to the Teres minor. Its lower third presents a broader, somewhat triangular surface, which gives origin to the Teres major, and over which the Latissimus dorsi glides ; sometimes the latter muscle takes origin by a few fibres from this part. The broad and narrow portions of bone above alluded to are separated by an oblique line, which runs from the axillary border, downwards and backwards, to meet the elevated ridge : to it is attached the aponeurosis separating the two Teres muscles from each other.

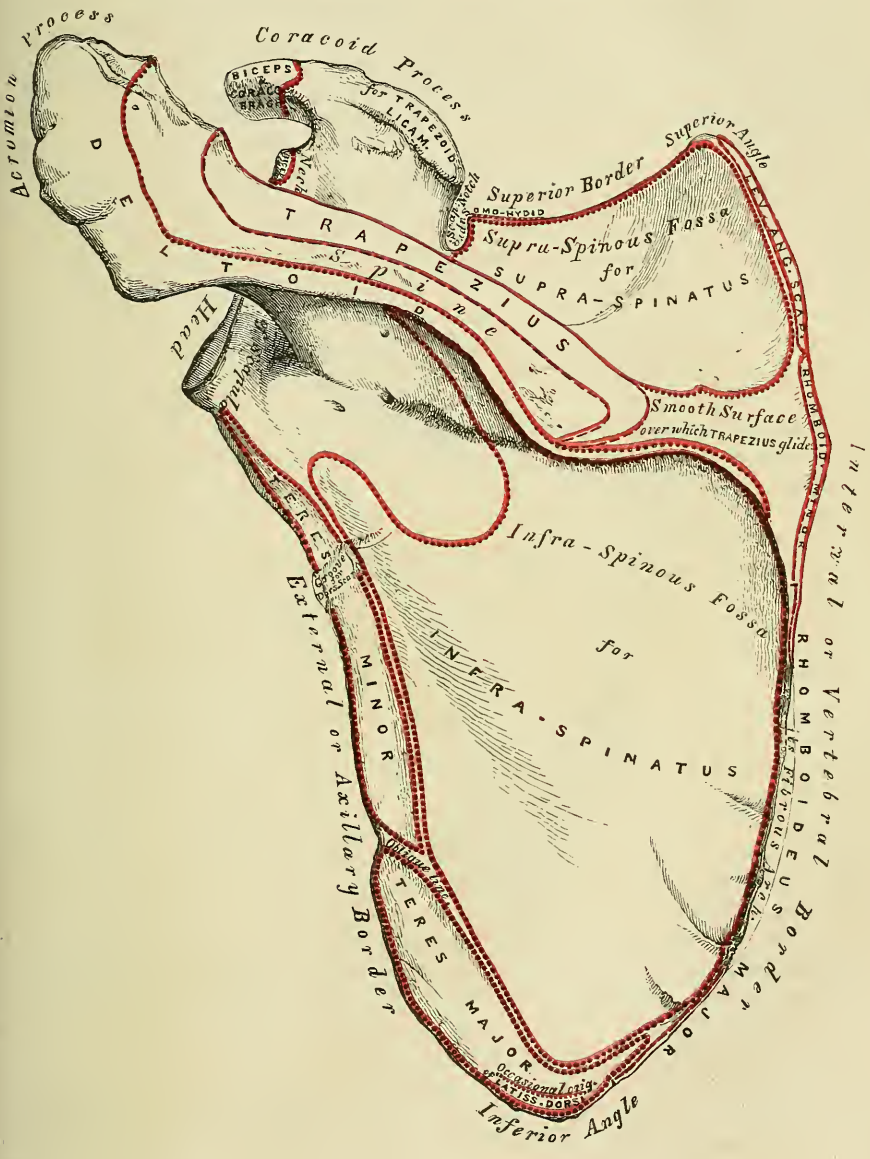
Fig. 205.—Left scapula. Anterior surface, or venter.



The **Spine** is a prominent plate of bone, which crosses obliquely the inner four-fifths of the dorsum of the scapula at its upper part, and separates the supra- from the infra-spinous fossa : it commences at the vertebral border by a smooth, triangular surface over which the Trapezius glides, separated from the bone by a bursa ; and, gradually becoming more elevated as it passes forwards, terminates in the acromion process, which overhangs the shoulder-joint. The spine is triangular, and flattened from above downwards, its apex corresponding

to the posterior border, its base (which is directed outwards) to the neck of the scapula. It presents two surfaces and three borders. Its *superior surface* is concave, assists in forming the supraspinous fossa, and affords attachment to part of the Supraspinatus muscle. Its *inferior surface* forms part of the infraspinous fossa, gives origin to part of the Infraspinatus muscle, and presents near its centre the orifice of a nutrient canal. Of the three borders, the *anterior* is

FIG. 206.—Left scapula. Posterior surface, or dorsum.



attached to the dorsum of the bone; the *posterior*, or *crest of the spine*, is broad, and presents two lips and an intervening rough interval. To the superior lip is attached the Trapezius, to the extent shown in the figure. A rough tubercle is generally seen occupying that portion of the spine which receives the insertion of the middle and inferior fibres of this muscle. To the inferior lip, throughout its whole length, is attached the Deltoid. The interval between the lips is also partly covered by the fibres of these muscles. The *external border*, or *base*, the

shortest of the three, is slightly concave, its edge thick and round, continuous above with the under surface of the acromion process, below with the neck of the scapula. The narrow portion of bone external to this border, and separating it from the glenoid cavity, is called the *great scapular notch*, and serves to connect the supra- and infra-spinous fossæ.

The **Acromion Process**, so called from forming the summit of the shoulder (*ἄκρον*, a *summit*; *ὦμος*, *the shoulder*), is a large and somewhat triangular process, flattened from behind forwards, directed at first a little outwards, and then curving forwards and upwards, so as to overhang the glenoid cavity. Its *upper surface*, directed upwards, backwards, and outwards, is convex, rough, and gives attachment to some fibres of the Deltoid, and in the rest of its extent it is subcutaneous. Its *under surface* is smooth and concave. Its *outer border* is thick and irregular, and presents three or four tubercles for the tendinous origins of the Deltoid muscle. Its *inner margin*, shorter than the outer, is concave, gives attachment to a portion of the Trapezius muscle, and presents about its centre a small, oval surface for articulation with the acromial end of the clavicle. Its *apex*, which corresponds to the point of meeting of these two borders in front, is thin, and has attached to it the coraco-acromial ligament.

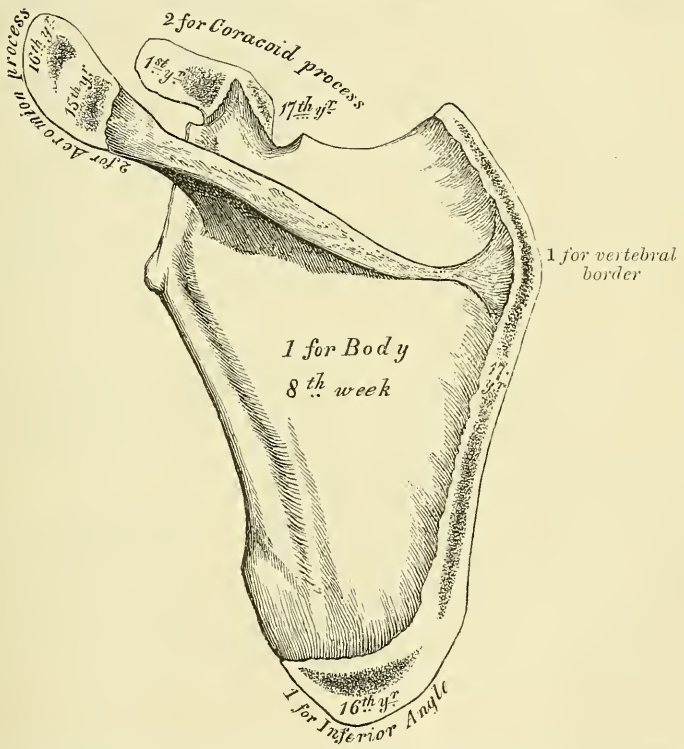
Of the three borders or costæ of the scapula, the *superior* is the shortest and thinnest; it is concave, terminating at its inner extremity at the superior angle, at its outer extremity at the coracoid process. At its outer part is a deep, semicircular notch, the *suprascapular*, formed partly by the base of the coracoid process. This notch is converted into a foramen by the transverse ligament, and serves for the passage of the suprascapular nerve. The adjacent margin of the superior border affords attachment to the Omo-hyoid muscle. The *external*, or *axillary*, *border* is the thickest of the three. It commences above at the lower margin of the glenoid cavity, and inclines obliquely downwards and backwards to the inferior angle. Immediately below the glenoid cavity is a rough impression (the *infra-glenoid tubercle*), about an inch in length, which affords attachment to the long head of the Triceps muscle; to this succeeds a longitudinal groove, which extends as far as its lower third, and affords origin to part of the Subscapularis muscle. The inferior third of this border, which is thin and sharp, serves for the attachment of a few fibres of the Teres major behind and of the Subscapularis in front. The *internal*, or *vertebral*, *border*, also named the *base*, is the longest of the three, and extends from the superior to the inferior angle of the bone. It is arched, intermediate in thickness between the superior and the external borders, and the portion of it above the spine is bent considerably outwards, so as to form an obtuse angle with the lower part. The vertebral border presents an anterior lip, a posterior lip, and an intermediate space. The *anterior lip* affords attachment to the Serratus magnus; the *posterior lip*, to the Supraspinatus above the spine, the Infraspinatus below; the interval between the two lips, to the Levator anguli scapulæ above the triangular surface at the commencement of the spine, the Rhomboideus minor to the edge of that surface; the Rhomboideus major being attached by means of a fibrous arch, connected above to the lower part of the triangular surface at the base of the spine, and below to the lower part of the posterior border.

Of the three angles, the *superior*, formed by the junction of the superior and internal borders, is thin, smooth, rounded, somewhat inclined outwards, and gives attachment to a few fibres of the Levator anguli scapulæ muscle. The *inferior* angle, thick and rough, is formed by the union of the vertebral and axillary borders, its outer surface affording attachment to the Teres major and occasionally a few fibres of the Latissimus dorsi. The *anterior* angle is the thickest part of the bone, and forms what is called the *head* of the scapula. The head presents a shallow, pyriform, articular surface, the *glenoid cavity* (*γλήνη*, *a socket*), whose longest diameter is from above downwards, and its direction outwards and forwards. It is broader below than above; at its apex is a slight impression (the *supra-glenoid tubercle*), to which is attached the long tendon of

the Biceps muscle. It is covered with cartilage in the recent state; and its margins, slightly raised, give attachment to a fibro-cartilaginous structure, the *glenoid ligament*, by which its cavity is deepened. The *neck* of the scapula is the slightly depressed surface which surrounds the head; it is more distinct on the posterior than on the anterior surface, and below than above. In the latter situation it has, arising from it, a thick prominence, the coracoid process.

The **Coracoid Process**, so called from its fancied resemblance to a crow's beak (*κόραξ, a crow*), is a thick, curved process of bone, which arises by a broad base from the upper part of the neck of the scapula; it is directed at first upwards and inwards; then, becoming smaller, it changes its direction, and passes forwards and outwards. The ascending portion, flattened from before backwards, presents in front a smooth, concave surface, over which passes the Subscapularis muscle. The horizontal portion is flattened from above downwards; its upper

Fig. 207.—Plan of the development of the scapula. By seven centres.



The epiphyses (except one for the coracoid process) appear from fifteen to seventeen years, and unite between twenty-two and twenty-five years of age.

surface is convex and irregular, and gives attachment to the Pectoralis minor; its under surface is smooth; its inner border is rough, and gives attachment to the Pectoralis minor; its outer border is also rough for the coraco-acromial ligament, while the apex is embraced by the conjoined tendon of origin of the short head of the Biceps and of the Coraco-brachialis and gives attachment to the costo-coracoid ligament. At the inner side of the root of the coracoid process is a rough impression for the attachment of the conoid ligament; and running from it obliquely forwards and outwards, on the upper surface of the horizontal portion, an elevated ridge for the attachment of the trapezoid ligament.

Structure.—In the head, processes, and all the thickened parts of the bone, the scapula is composed of cancellous tissue, while in the rest of its extent it is

composed of a thin layer of dense, compact tissue. The centre and upper part of the dorsum, but especially the former, are usually so thin as to be semi-transparent; occasionally the bone is found wanting in this situation, and the adjacent muscles come into contact.

Development (fig. 207).—By *seven* centres; one for the body, two for the coracoid process, two for the acromion, one for the vertebral border, and one for the inferior angle.

Ossification of the body of the scapula commences about the second month of fœtal life, by the formation of an irregular quadrilateral plate of bone, immediately behind the glenoid cavity. This plate extends itself so as to form the chief part of the bone, the spine growing up from its posterior surface about the third month. At birth, the chief part of the scapula is osseous, only the coracoid and acromion processes, the posterior border, and inferior angle being cartilaginous. About the first year after birth, ossification takes place in the middle of the coracoid process, which usually becomes joined with the rest of the bone at the time when the other centres make their appearance. Between the fifteenth and seventeenth years, ossification of the remaining centres takes place in quick succession, and in the following order: first, near the base of the acromion and in the root of the coracoid process, the latter appearing in the form of a broad scale; secondly, in the inferior angle and contiguous part of the posterior border; thirdly, near the extremity of the acromion; fourthly, in the posterior border. The acromion process, besides being formed of two separate nuclei, has its base formed by an extension into it of the centre of ossification which belongs to the spine, the extent of which varies in different cases. The two separate nuclei unite, and then join with the extension carried in from the spine. These various epiphyses become joined to the bone between the ages of twenty-two and twenty-five years. Sometimes failure of union between the acromion process and spine occurs, the junction being effected by fibrous tissue, or by an imperfect articulation; in some cases of supposed fracture of the acromion with ligamentous union, it is probable that the detached segment was never united to the rest of the bone. Very often, in addition to these, a minute epiphysis appears at the margin of the glenoid cavity.

Articulations.—With the humerus and clavicle.

Attachment of Muscles.—To seventeen: to the anterior surface, the Subscapularis; posterior surface, Supraspinatus, Infraspinatus; spine, Trapezius, Deltoid; superior border, Omo-hyoid; vertebral border, Serratus magnus, Levator anguli scapulæ, Rhomboideus minor and major; axillary border, Triceps, Teres minor, Teres major; glenoid cavity, long head of the Biceps; coracoid process, short head of the Biceps, Coraco-brachialis, Pectoralis minor; and to the inferior angle occasionally a few fibres of the Latissimus dorsi.

Surface Form.—The only parts of the scapula which are truly subcutaneous are the spine and acromion process, but, in addition to these, the coracoid process, the internal or vertebral border and inferior angle, and, to a less extent, the axillary border, may be defined. The acromion process and spine of the scapula are easily felt throughout their entire length, forming, with the clavicle, the arch of the shoulder. The acromion can be ascertained to be connected to the clavicle at the acromio-clavicular joint by running the finger along it, its position being often indicated by an irregularity or bony outgrowth from the clavicle close to the joint. The acromion can be felt forming the point of the shoulder, and from this can be traced backwards to join the spine of the scapula. The place of junction is usually denoted by a prominence, which is sometimes called the angle. From here the spine can be felt as a prominent ridge of bone, marked on the surface as an oblique depression, which becomes less and less distinct and terminates a little external to the spinous processes of the vertebræ. Its termination is usually indicated by a slight dimple in the skin, on a level with the interval between the third and fourth dorsal spines. Below this point the vertebral border of the scapula may be traced, running downwards and outwards, and thus diverging from the vertebral spines, to the inferior angle of the bone, which can be recognised, although covered by the Latissimus dorsi muscle. From this angle the axillary border can usually be traced through its thick muscular covering, forming, with the muscles, the posterior fold of the axilla. The coracoid process may be felt about an inch below the junction of the middle and outer third of the clavicle. Its

position is indicated on the surface of the body by a slight depression, which corresponds to the interval between the Pectoralis major and Deltoid muscles. When the arms are hanging by the side, the upper angle of the scapula corresponds to the upper border of the second rib or the interval between the first and second dorsal spines, the inferior angle to the upper border of the eighth rib or the interval between the seventh and eighth dorsal spines.

Surgical Anatomy.—Fractures of the body of the scapula are rare, owing to the mobility of the bone, the thick layer of muscles by which it is encased on both surfaces, and the elasticity of the ribs on which it rests. Fracture of the neck of the bone is also uncommon. The most frequent course of the fracture is from the suprascapular notch to the infra-glenoid tubercle, and it derives its principal interest from its simulation to a subglenoid dislocation of the humerus. The diagnosis can be made by noting the alteration in the position of the coracoid process. A fracture of the neck external to and not including the coracoid process is said to occur, but it is exceedingly doubtful whether such an accident ever takes place. The acromion process is more frequently broken than any other part of the bone, and there is sometimes, in young subjects, a separation of the epiphysis. It is believed that many of the cases of supposed fracture of the acromion, with fibrous union, which have been found on post-mortem examination are really cases of imperfectly united epiphysis. Sir Astley Cooper believed that most fractures of this bone united by fibrous tissue, and the cause of this mode of union was the difficulty there was in keeping the fractured ends in constant apposition. The coracoid process is occasionally broken off, either from direct violence or, perhaps rarely, from muscular action.

Tumours of various kinds grow from the scapula. Of the innocent form of tumours probably the osteomata are the most common. When this grows from the venter of the scapula, as it sometimes does, it is of the compact variety, such as usually grows from membrane-formed bones, as the bones of the skull. This would appear to afford evidence that this portion of the bone is formed from membrane, and not like the rest of the bone from cartilage. Sarcomatous tumours sometimes grow from the scapula and may necessitate removal of the bone, with or without amputation of the upper limb. The bone may be excised by a T incision, and the flaps being reflected, the removal is commenced from the posterior or vertebral border, so that the subscapular vessels which lie along the axillary border are among the last structures divided, and can be at once secured.

The Humerus

The **Humerus** is the longest and largest bone of the upper extremity; it presents for examination a shaft and two extremities.

The **Upper Extremity** is the largest part of the bone; it presents a rounded *head*, joined to the shaft by a constricted portion, called the *neck*, and two other eminences, the *greater* and *lesser tuberosities* (fig. 208).

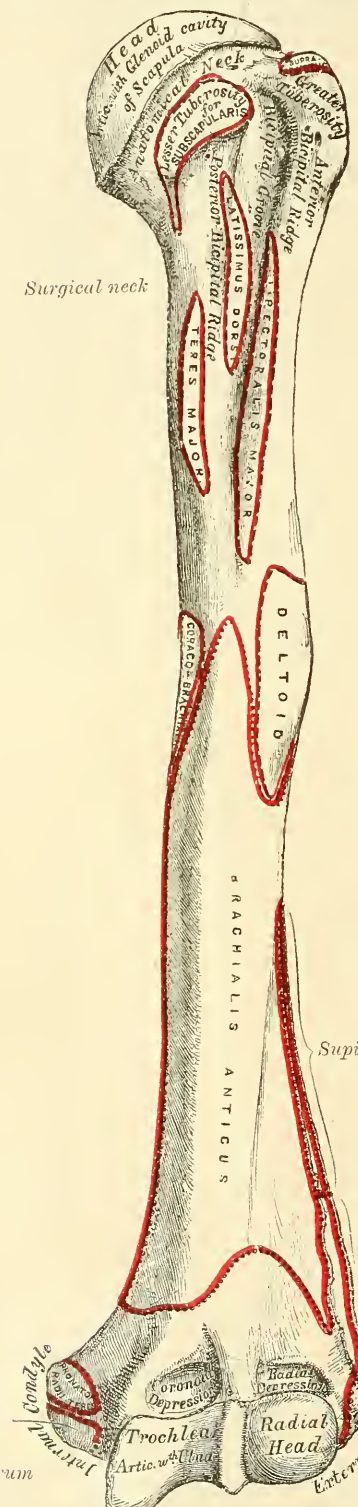
The **head**, nearly hemispherical in form,* is directed upwards, inwards, and a little backwards, and articulates with the glenoid cavity of the scapula; its surface is smooth, and coated with cartilage in the recent state. The circumference of its articular surface is slightly constricted, and is termed the *anatomical neck*, in contradistinction to the constriction which exists below the tuberosities. The latter is called the *surgical neck*, from its being most frequently the seat of fracture. It should be remembered, however, that fracture of the *anatomical neck* does sometimes, though rarely, occur.

The **anatomical neck** is obliquely directed, forming an obtuse angle with the shaft. It is more distinctly marked in the lower half of its circumference than in the upper half, where it presents a narrow groove, separating the head from the tuberosities. Its circumference affords attachment to the capsular ligament, and is perforated by numerous vascular foramina.

The **greater tuberosity** is situated on the outer side of the head and lesser tuberosity. Its upper surface is rounded and marked by three flat facets, separated by two slight ridges: the superior facet gives attachment to the tendon of the Supraspinatus; the middle one to the Infraspinatus; the inferior facet, and the shaft of the bone below it, to the Teres minor. The outer surface of

* Though the head is nearly hemispherical in form, its margin, as Sir G. Humphry has shown, is by no means a true circle. Its greatest measurement is, from the top of the bicipital groove in a direction downwards, inwards, and backwards. Hence it follows that the greatest elevation of the arm can be obtained by rolling the articular surface in this direction—that is to say, obliquely upwards, outwards, and forwards.

FIG. 208.—Left humerus. Anterior view.



the great tuberosity is convex, rough, and continuous with the outer side of the shaft.

The **lesser tuberosity** is more prominent, although smaller, than the greater: it is situated in front of the head, and is directed inwards and forwards. Its summit presents a prominent facet for the insertion of the tendon of the Subscapularis muscle. The tuberosities are separated from one another by a deep groove, the *bicipital groove*, so called from its lodging the long tendon of the Biceps muscle, with which runs a branch of the anterior circumflex artery. It commences above between the two tuberosities, passes obliquely downwards and a little inwards, and terminates at the junction of the upper with the middle third of the bone. It is deep and narrow at the commencement, and becomes shallow and a little broader as it descends. Its borders are called, respectively, the anterior and posterior *bicipital ridges*, and form the upper part of the anterior and internal borders of the shaft of the bone. In the recent state it is covered with a thin layer of cartilage, lined by a prolongation of the synovial membrane of the shoulder-joint, and receives the tendon of insertion of the Latissimus dorsi muscle.

The **Shaft** of the humerus is almost cylindrical in the upper half of its extent, prismatic and flattened below, and presents three borders and three surfaces for examination.

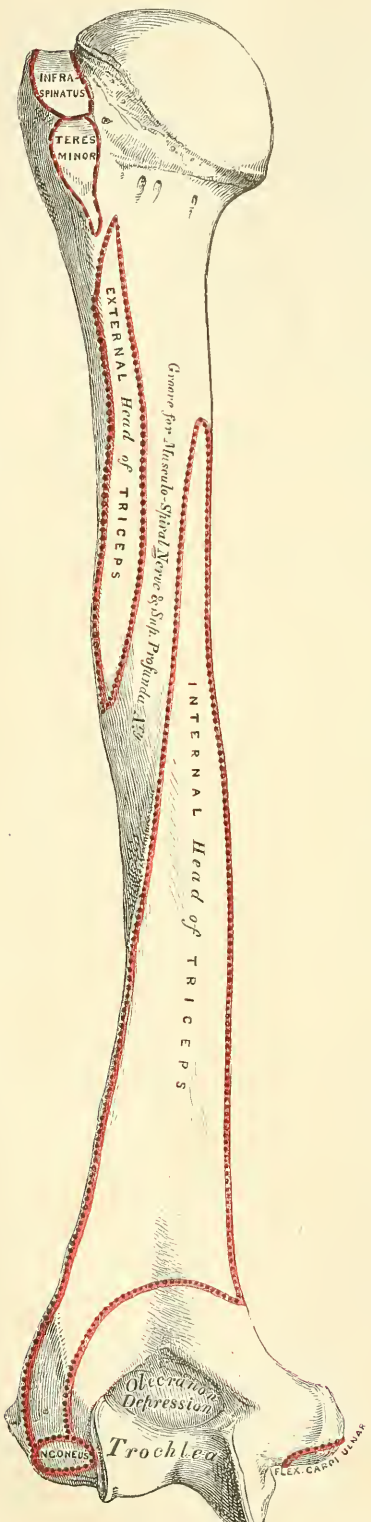
The **anterior border** runs from the front of the great tuberosity above to the coronoid depression below, separating the internal from the external surface. Its upper part is very prominent and rough, and forms the outer lip of the bicipital groove. It is sometimes called the *anterior bicipital ridge*, and serves for the attachment of the tendon of the Pectoralis major. About its centre it forms the anterior boundary of the rough deltoid impression; below, it is smooth and rounded, affording attachment to the Brachialis anticus.

The **external border** runs from the back part of the greater tuberosity to the external condyle, and separates the external from the posterior surface. It is rounded and indistinctly marked in its upper half, serving for the attachment of the lower part of the insertion of the Teres minor, and below this of the external head of the Triceps muscle; its centre is traversed by a broad but shallow, oblique depression, the *musculo-spiral groove*; its lower part is marked by a prominent, rough margin, a little curved from behind forwards, the *external condyloid ridge*, which presents an anterior lip for the attachment of the Supinator longus above, and Extensor carpi radialis longior below, a posterior lip for the Triceps, and an interstice for the attachment of the external intermuscular septum.

The **internal border** extends from the lesser tuberosity to the internal condyle. Its upper third is marked by a prominent ridge, forming the posterior lip of the bicipital groove, and gives attachment to the tendon of the Teres major. About its centre is a rough ridge for the attachment of the Coraco-brachialis, and just below this is seen the entrance of the nutrient canal, directed downwards. Sometimes there is a second canal situated at the commencement of the musculo-spiral groove for a nutrient artery derived from the superior profunda branch of the brachial artery. The inferior third of this border is raised into a slight ridge, the *internal condyloid ridge*, which becomes very prominent below; it presents an anterior lip for the attachment of the Brachialis anticus, a posterior lip for the internal head of the Triceps, and an intermediate space for the internal intermuscular septum.

The **external surface** is directed outwards above, where it is smooth, rounded, and covered by the Deltoid muscle; forwards and outwards below, where it is slightly concave from above downwards, and gives origin to part of the Brachialis anticus muscle. About the middle of this surface is seen a rough, triangular impression for the insertion of the Deltoid muscle; and below it the musculo-spiral groove, directed obliquely from behind, forwards, and downwards, and transmitting the musculo-spiral nerve and superior profunda artery.

Fig. 209.—Left humerus. Posterior surface.



The **internal surface**, less extensive than the external, is directed inwards above, forwards and inwards below; at its upper part it is narrow, and forms the floor of the bicipital groove: to it is attached the Latissimus dorsi. The middle part of this surface is slightly rough for the attachment of some of the fibres of the tendon of insertion of the Coraco-brachialis; its lower part is smooth, concave, and gives attachment to the Brachialis anticus muscle.*

The **posterior surface** (fig. 209) appears somewhat twisted, so that its upper part is directed a little inwards, its lower part backwards and a little outwards. Nearly the whole of this surface is covered by the external and internal heads of the Triceps, the former of which is attached to its upper and outer part, the latter to its inner and back part, the two being separated by the musculo-spiral groove.

The **Lower Extremity** is flattened from before backwards, and curved slightly forwards; it terminates below in a broad, articular surface, which is divided into two parts by a slight ridge. Projecting on either side are the external and internal condyles (*epicondyles*). The articular surface extends a little lower than the condyles, and is curved slightly forwards, so as to occupy the more ante-

* A small, hook-shaped process of bone, varying from $\frac{1}{10}$ to $\frac{3}{4}$ of an inch in length, is not unfrequently found projecting from the inner surface of the shaft of the humerus two inches above the internal condyle. It is curved downwards, forwards, and inwards, and its pointed extremity is connected to the internal border, just above the inner condyle, by a ligament or fibrous band, completing an arch, through which the median nerve and brachial artery pass, when these structures deviate from their usual course. Sometimes the nerve alone is transmitted through it, or the nerve may be accompanied by the ulnar artery, in cases of high division of the brachial. A well-marked groove is usually found behind the process, in which the nerve and artery are lodged. This space is analogous to the supra condyloid foramen in many animals, and probably serves in them to protect the nerve and artery from compression during the contraction of the muscles in this region. A detailed account of this process is given by Dr. Struthers, in his *Anatomical and Physiological Observations*, p. 202. An accessory portion of the Coraco-brachialis muscle is frequently connected with this process, according to Mr. J. Wood, *Journal of Anat. and Phys.* No. 1, Nov. 1866, p. 47.

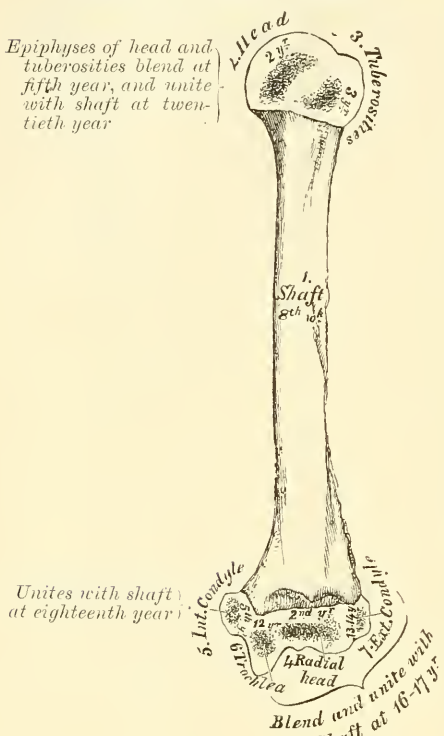
rior part of the bone; its greatest breadth is in the transverse diameter, and it is obliquely directed, so that its inner extremity occupies a lower level than the outer. The outer portion of the articular surface presents a smooth, rounded eminence, which has received the name of the *capitellum*, or *radial head* of the humerus; it articulates with the cup-shaped depression on the head of the radius, and is limited to the front and lower part of the bone, not extending as far back as the other portion of the articular surface. On the inner side of this eminence is a shallow groove, in which is received the inner margin of the head of the radius. Above the front part of the capitellum is seen a slight depression, which receives the anterior border of the head of the radius, when the fore-arm is flexed. The inner portion of the articular surface, the *trochlear*, presents a deep depression between two well-marked borders. This surface is convex from before backwards, concave from side to side, and occupies the anterior, lower, and posterior parts of the bone. The external border, less prominent than the internal, corresponds to the interval between the radius and the ulna. The internal border is thicker, more prominent, and consequently of greater length, than the external. The grooved portion of the articular surface fits accurately within the greater sigmoid cavity of the ulna; it is broader and deeper on the posterior than on the anterior aspect of the bone, and is inclined obliquely from behind forwards, and from without inwards. Above the front part of the trochlear surface is seen a smaller depression, the *coronoid fossa*, which receives the coronoid process of the ulna during flexion of the fore-arm. Above the back part of the trochlear surface is a deep, triangular depression, the *olecranon fossa*, in which is received the summit of the olecranon process in extension of the forearm. These fossæ are separated from one another by a thin, transparent lamina of bone, which is sometimes perforated, forming the *supratrochlear foramen*; their upper margins afford attachment to the anterior and posterior ligaments of the elbow-joint, and they are lined, in the recent state, by the synovial membrane of this articulation. The articular surfaces, in the recent state, are covered with a thin layer of cartilage. The external condyle (*radial epicondyle*) is a small, tubercular eminence, less prominent than the internal, curved a little forwards, and giving attachment to the external lateral ligament of the elbow-joint, and to a tendon common to the origin of some of the extensor and supinator muscles. The internal condyle (*ulnar epicondyle*), larger and more prominent than the external, is directed a little backwards: it gives attachment to the internal lateral ligament, to the Pronator radii teres, and to a tendon common to the origin of some of the flexor muscles of the forearm. The ulnar nerve runs in a groove at the back of the internal condyle, or between it and the olecranon process. These eminences are directly continuous above with the external and internal borders—i.e. the external and internal condyloid ridges. The great prominence of the inner one renders it more liable to fracture.

Structure.—The extremities consist of cancellous tissue, covered with a thin, compact layer; the shaft is composed of a cylinder of compact tissue, thicker at the centre than at the extremities, and hollowed out by a large medullary canal, which extends along its whole length.

Development.—By *seven*, or occasionally *eight* centres (fig. 210): one for the shaft, one for the head, one for the tuberosities, one for the radial head, one for the trochlear portion of the articular surface, and one for each condyle. The nucleus for the shaft appears near the centre of the bone in the eighth week, and soon extends towards the extremities. At birth the humerus is ossified nearly in its whole length, the extremities remaining cartilaginous. During the first year, sometimes earlier, ossification commences in the head of the bone, and during the third year the centre for the tuberosities makes its appearance, usually by a single ossific point, but sometimes, according to Béclard, by one for each tuberosity, that for the lesser being small, and not appearing until the fifth year. By the sixth year the centres for the head and tuberosities have enlarged and become joined, so as to form a single large epiphysis.

The lower end of the humerus is developed in the following manner:—At the end of the second year ossification commences in the radial portion of the articular surface, and from this point extends inwards, so as to form the chief part of the articular end of the bone, the centre for the inner part of the articular surface not appearing until about the age of twelve. Ossification commences in the internal condyle about the fifth year, and in the external one not until about the thirteenth or fourteenth year. About sixteen or seventeen years, the outer condyle and both portions of the articulating surface (having already joined) unite with the shaft; at eighteen years the inner condyle becomes joined, whilst the upper epiphysis, although the first formed, is not united until about the twentieth year.

FIG. 210.—Plan of the development of the humerus. By seven centres.



Articulations.—With the glenoid cavity of the scapula, and with the ulna and radius.

Attachment of Muscles.—To twenty-four: to the greater tuberosity, the Supraspinatus, Infraspinatus, and Teres minor; to the lesser tuberosity, the Subscapularis; to the anterior bicipital ridge, the Pectoralis major; to the posterior bicipital ridge, the Teres major; to the bicipital groove, the Latissimus dorsi; to the shaft, the Deltoid, Coraco-brachialis, Brachialis anticus, external and internal heads of the Triceps; to the internal condyle, the Pronator radii teres, and common tendon of the Flexor carpi radialis, Palmaris longus, Flexor sublimis digitorum, and Flexor carpi ulnaris; to the external condyloid ridge, the Supinator longus, and Extensor carpi radialis longior; to the external condyle, the common tendon of the Extensor carpi radialis brevior, Extensor communis digitorum, Extensor minimi digiti, Extensor carpi ulnaris, and Supinator brevis; to the back of the external condyle, the Anconeus.

Surface Form.—The humerus is almost entirely clothed by the muscles which surround it, and the only parts of this bone which are strictly subcutaneous are small portions of the internal and external condyles. In addition to these, the tuberosities and a part of the head of the bone can be felt under the skin and muscles by which they are covered. Of these the greater tuberosity forms the most prominent bony point of the shoulder, extending beyond the acromion process and covered by the Deltoid muscle. It influences materially the surface form of the shoulder. It is best felt while the arm is lying loosely by the side; if the arm be raised, it recedes from under the finger. The lesser tuberosity, directed forwards and inwards, is to be felt to the inner side of the greater tuberosity, just below the acromio-clavicular joint. Between the two tuberosities lies the bicipital groove. This can be defined by placing the finger, and making firm pressure, just internal to the greater tuberosity; then, by rotating the humerus, the groove will be felt to pass under the finger as the bone is rotated. With the arm abducted from the side, by pressing deeply in the axilla, the lower part of the head of the bone is to be felt. On each side of the elbow-joint, and just above it, the internal and external condyles of the bone are to be felt. Of these the internal is the more prominent, but the ridge passing upwards from it, the internal condyloid ridge, is much less marked than the external, and, as a rule, is not to be felt. Occasionally, however, we find along this border the hook-shaped process mentioned above. The external condyle is most plainly to be seen during semiflexion of the forearm, and its position is indicated by a depression between the attachment of

the adjacent muscles. From it is to be felt a strong bony ridge running up the outer border of the shaft of the bone. This is the external condyloid ridge; it is concave forwards, and corresponds with the curved direction of the lower extremity of the humerus.

Surgical Anatomy.—There are several points of surgical interest connected with the humerus. First, as regards its development. The upper end, though the first to ossify, is the last to join the shaft, and the length of the bone is mainly due to growth from this upper epiphysis. Hence, in cases of amputation of the arm in young subjects, the humerus continues to grow considerably, and the end of the bone which immediately after the operation was covered with a thick cushion of soft tissue begins to project, thinning the soft parts and rendering the stump conical. This may necessitate the removal of a couple of inches or so of the bone, and even after this operation a recurrence of the conical stump may take place.

There are several points of surgical interest in connection with fractures. First, as regards their causation; the bone may be broken by direct or indirect violence like the other long bones, but, in addition to this, it is probably more frequently fractured by muscular action than any other of this class of bone in the body. It is usually the shaft, just below the insertion of the deltoid, which is thus broken. I have seen the accident happen from throwing a stone, and in an apparently healthy adult from cutting a piece of hard 'cake tobacco' on a table. In this latter case there was no disease of the bone that could be discovered. Fractures of the upper end may take place through the anatomical neck, through the surgical neck, or separation of the greater tuberosity may occur. Fracture of the anatomical neck is a very rare accident; in fact, it is doubted by some whether it ever occurs. These fractures are usually considered to be intracapsular, but they are probably partly within and partly without the capsule, as the lower part of the capsule is inserted some little distance below the anatomical neck, while the upper part is attached to it. They may be impacted or non-impacted. In most cases there is little or no displacement on account of the capsule, in whole or in part, remaining attached to the lower fragment. But occasionally a very remarkable alteration in position takes place; the upper fragment turns on its own axis, so that the cartilaginous surface of the head rests against the upper end of the lower fragment. When the fractured end is entirely separated from all its surroundings, its vascular supply must be entirely cut off, and one would expect it, theoretically, to necrose. But this must be exceedingly rare, for Gurlt was unable to find a single authenticated case recorded. Separation of the upper epiphysis of the humerus sometimes occurs in the young subject, and is marked by a characteristic deformity, by which the lesion may be at once recognised. This consists in the presence of an abrupt projection at the front of the joint some short distance below the coracoid process, caused by the upper end of the lower fragment. In fractures of the shaft of the humerus the lesion may take place at any point, but appears to be more common in the lower than the upper part of the bone. The points of interest in connection with these fractures are (1) that the musculo-spiral nerve may be injured as it lies in the groove on the bone, or may become involved in the callus which is subsequently thrown out; and (2) the frequency of non-union. This is believed to be more common in the humerus than in any other bone, and various causes have been assigned for it. It would seem most probably to be due to the difficulty that there is in fixing the shoulder-joint and the upper fragment, and possibly the elbow-joint and lower fragment also. Other causes which have been assigned for the non-union are: (1) that in attempting passive motion of the elbow-joint to overcome any rigidity which may exist, the movement does not take place at the articulation but at the seat of fracture; or that the patient, in consequence of the rigidity of the elbow, in attempting to flex or extend the forearm, moves the fragment and not the joint. (2) The presence of small portions of muscular tissue between the broken ends. (3) Want of support to the elbow, so that the weight of the arm tends to drag the lower fragment away from the upper. An important distinction to make in fractures of the lower end of the humerus, is between those that involve the joint and those which do not; the former are always serious, as they may lead to impairment of the utility of the limb. They include the T-shaped fracture and oblique fractures which involve the articular surface. The fractures which do not involve the joint are the transverse above the condyles, and detachment of one or other condyle.

Under the head of separation of the epiphysis two separate injuries have been described. One where the whole of the four ossific centres which form the lower extremity of the bone are separated from the shaft; and secondly, where the articular portion is alone separated, the two condyles remaining attached to the shaft of the bone. The epiphysial line between the shaft and lower end runs across the bone just above the tips of the condyles, a point to be borne in mind in performing the operation of excision.

Tumours originating from the humerus are of frequent occurrence. A not uncommon place for a chondroma to grow from is the shaft of the bone somewhere in the neighbourhood of the insertion of the deltoid. Sarcomata frequently grow from this bone.

The **Forearm** is that portion of the upper extremity which is situated between the elbow and wrist. It is composed of two bones, the ulna and the radius.

The Ulna

The **Ulna** (figs. 211, 212), so called from its forming the elbow (ὠλένη), is a long bone, prismatic in form, placed at the inner side of the forearm, parallel with the radius. It is the larger and longer of the two bones. Its upper extremity, of great thickness and strength, forms a large part of the articulation of the elbow-joint; it diminishes in size from above downwards, its lower extremity being very small, and excluded from the wrist-joint by the interposition of an interarticular fibro-cartilage. It is divisible into a shaft and two extremities.

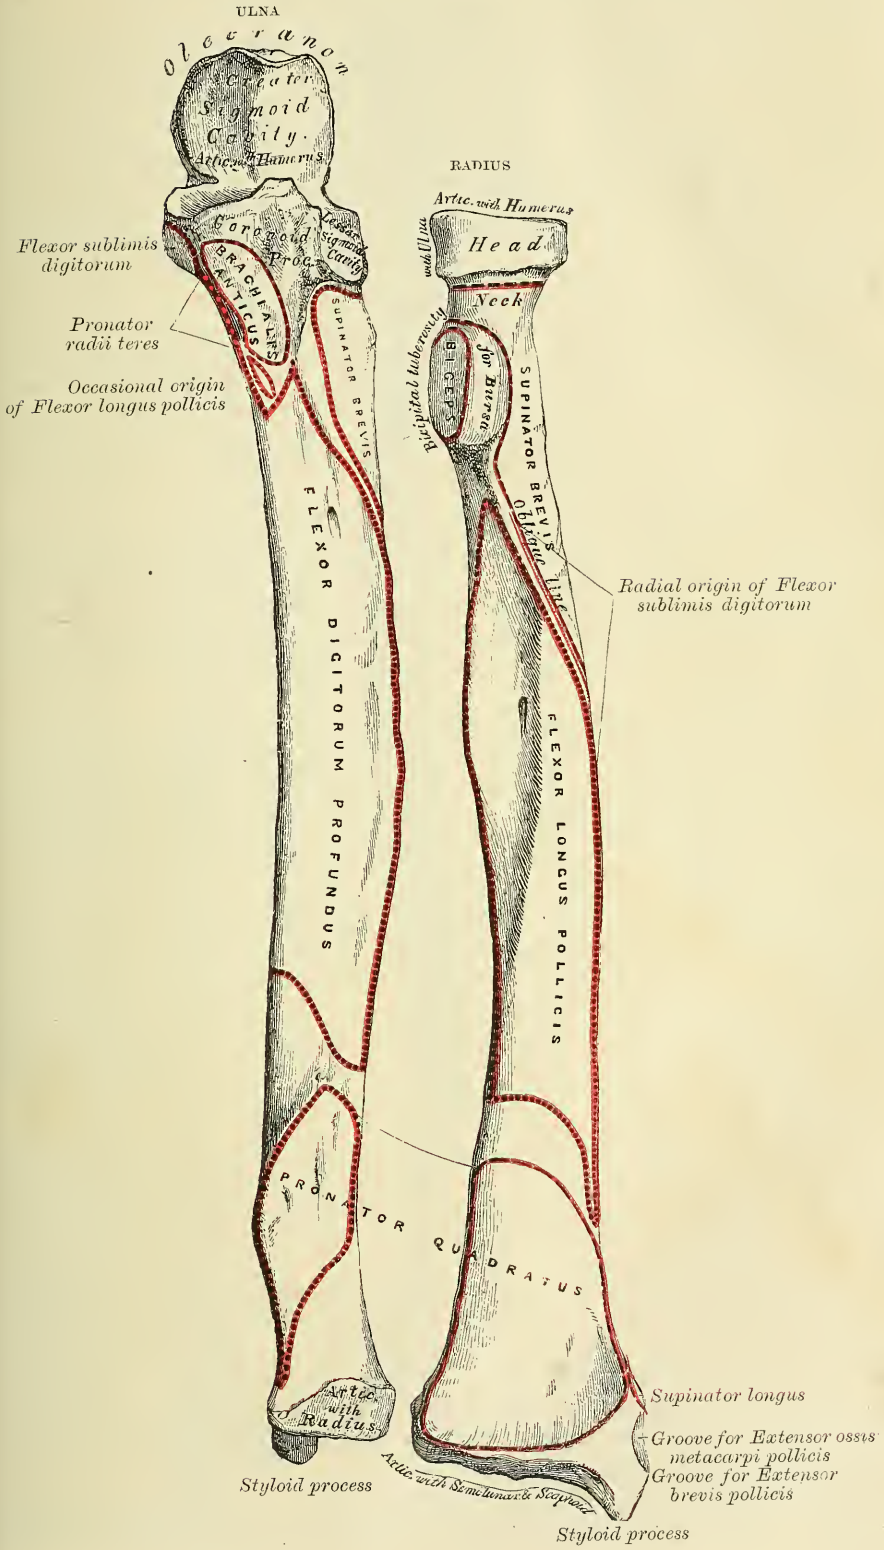
The **Upper Extremity**, the strongest part of the bone, presents for examination two large, curved processes, the Olecranon process and the Coronoid process; and two concave, articular cavities, the greater and lesser sigmoid cavities.

The **Olecranon Process** (ὠλένη, elbow; κρανίον, head) is a large, thick, curved eminence, situated at the upper and back part of the ulna. It is curved forwards at the summit so as to present a prominent tip, its base being contracted where it joins the shaft. This is the narrowest part of the upper end of the ulna, and, consequently, the most usual seat of fracture. The posterior surface of the olecranon, directed backwards, is triangular, smooth, subcutaneous, and covered by a bursa. Its upper surface is of quadrilateral form, marked behind by a rough impression for the attachment of the Triceps muscle; and in front, near the margin, by a slight transverse groove for the attachment of part of the posterior ligament of the elbow-joint. Its anterior surface is smooth, concave, covered with cartilage in the recent state, and forms the upper and back part of the great sigmoid cavity. The lateral borders present a continuation of the same groove that was seen on the margin of the superior surface; they serve for the attachment of ligaments—viz. the back part of the internal lateral ligament internally, the posterior ligament externally. To the inner border is also attached a part of the Flexor carpi ulnaris; while to the outer border is attached the Anconeus.

The **Coronoid Process** (κορώνη, *anything hooked like a crow's beak*) is a triangular eminence of bone which projects horizontally forwards from the upper and front part of the ulna, forming the lower part of the great sigmoid cavity. Its base is continuous with the shaft, and of considerable strength; so much so that fracture of it is an accident of rare occurrence. Its apex is pointed, slightly curved upwards, and received into the coronoid depression of the humerus in flexion of the forearm. Its upper surface is smooth, concave, and forms the lower part of the greater sigmoid cavity. The under surface is concave, and marked internally by a rough impression for the insertion of the Brachialis anticus. At the junction of this surface with the shaft is a rough eminence, the *tubercle of the ulna*, for the attachment of the oblique ligament. Its outer surface presents a narrow, oblong, articular depression, the *lesser sigmoid* cavity. The inner surface, by its prominent, free margin, serves for the attachment of part of the internal lateral ligament. At the front part of this surface is a small, rounded eminence for the attachment of one head of the Flexor sublimis digitorum; behind the eminence, a depression for part of the origin of the Flexor profundus digitorum; and, descending from the eminence, a ridge, which gives attachment to one end of the Pronator radii teres. Generally, the Flexor longus pollicis arises from the lower part of the coronoid process by a rounded bundle of muscular fibres.

The **Greater Sigmoid Cavity**, so called from its resemblance to the old shape of the Greek letter Σ, is a semilunar depression of large size, formed by the olecranon and coronoid processes, and serving for articulation with the trochlear surface of the humerus. About the middle of either lateral border of this cavity is a notch, which contracts it somewhat, and serves to indicate the junction of the two processes of which it is formed. The cavity is concave from above downwards, and divided into two lateral parts by a smooth, elevated ridge which runs from the summit of the olecranon to the tip of the coronoid process. Of these

FIG. 211.—Bones of the left forearm. Anterior surface.



two portions, the internal is the larger, and is slightly concave transversely; the external portion is convex above, slightly concave below. The articular surface, in the recent state, is covered with a thin layer of cartilage.

The **Lesser Sigmoid Cavity** is a narrow, oblong, articular depression, placed on the outer side of the coronoid process, and receives the lateral articular surface of the head of the radius. It is concave from before backwards; and its extremities, which are prominent, serve for the attachment of the orbicular ligament. In the recent state, it is covered with a thin layer of cartilage.

The **Shaft**, at its upper part, is prismatic in form, and curved from behind forwards, and from without inwards, so as to be convex behind and externally; its central part is quite straight; its lower part rounded, smooth, and bent a little outwards; it tapers gradually from above downwards, and presents for examination three borders, and three surfaces.

The **anterior border** commences above at the prominent inner angle of the coronoid process, and terminates below in front of the styloid process. It is well marked above, smooth and rounded in the middle of its extent, and affords attachment to the Flexor profundus digitorum: its lower fourth, marked off from the rest of the border by the commencement of an oblique ridge on the anterior surface, serves for the attachment of the Pronator quadratus. It separates the anterior from the internal surface.

The **posterior border** commences above at the apex of the triangular subcutaneous surface at the back part of the olecranon, and terminates below at the back part of the styloid process; it is well marked in the upper three-fourths, and gives attachment to an aponeurosis common to the Flexor carpi ulnaris, the Extensor carpi ulnaris, and the Flexor profundus digitorum muscles; its lower fourth is smooth and rounded. This border separates the internal from the posterior surface.

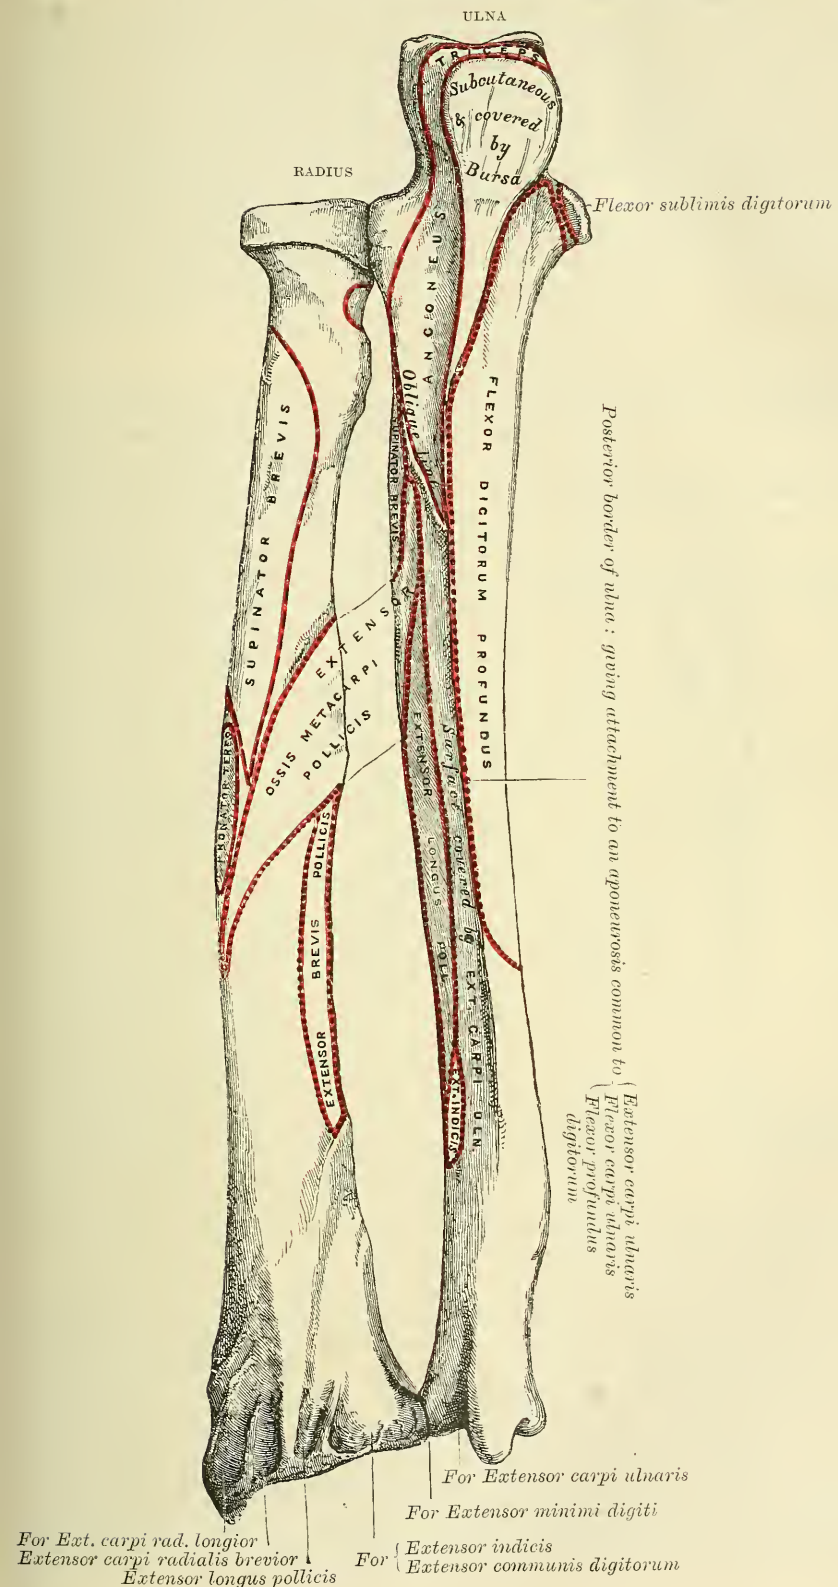
The **external** or **interosseous border** commences above by two lines, which converge one from each extremity of the lesser sigmoid cavity, enclosing between them a triangular space for the attachment of part of the Supinator brevis, and terminates below at the middle of the head of the ulna. Its two middle fourths are very prominent, its lower fourth is smooth and rounded. This border gives attachment to the interosseous membrane, except along its upper fourth, and separates the anterior from the posterior surface.

The **anterior surface**, much broader above than below, is concave in the upper three-fourths of its extent, and affords attachment to the Flexor profundus digitorum; its lower fourth, also concave, to the Pronator quadratus. The lower fourth is separated from the remaining portion of the bone by a prominent ridge, directed obliquely from above downwards and inwards; this ridge (the *oblique* or *Pronator ridge*) marks the extent of attachment of the Pronator quadratus above. At the junction of the upper with the middle third of the bone is the nutrient canal, directed obliquely upwards and inwards.

The **posterior surface**, directed backwards and outwards, is broad and concave above, somewhat narrower and convex in the middle of its course, narrow, smooth, and rounded below. It presents, above, an oblique ridge, which runs from the posterior extremity of the lesser sigmoid cavity, downwards to the posterior border; the triangular surface above this ridge receives the insertion of the Anconeus muscle, whilst the ridge itself affords attachment to the Supinator brevis. The surface of bone below this is subdivided by a longitudinal ridge, sometimes called the *perpendicular line*, into two parts: the internal part is smooth, concave, and is covered by the Extensor carpi ulnaris; the external portion, wider and rougher, gives attachment from above downwards to part of the Supinator brevis, the Extensor ossis metacarpi pollicis, the Extensor longus pollicis, and the Extensor indicis muscles.

The **internal surface** is broad and concave above, narrow and convex below. It gives attachment by its upper three-fourths to the Flexor profundus digitorum muscle: its lower fourth is subcutaneous

Fig. 212.—Bones of the left forearm. Posterior surface.



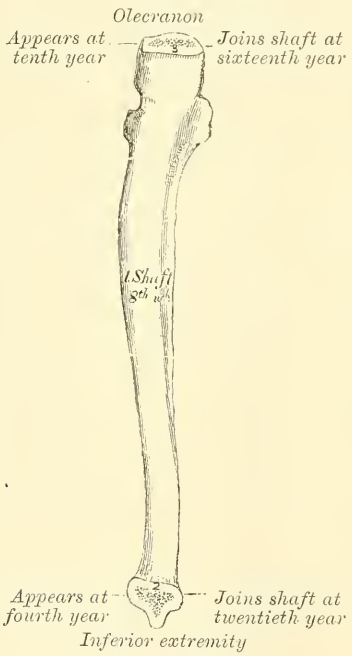
R

The **Lower Extremity** of the ulna is of small size, and excluded from the articulation of the wrist-joint. It presents for examination two eminences, the outer and larger of which is a rounded, articular eminence, termed the *head* of the ulna; the inner, narrower and more projecting, is a non-articular eminence, the *styloid process*. The *head* presents an articular facet, part of which, of an oval form, is directed downwards, and articulates with the upper surface of the interarticular fibro-cartilage which separates it from the wrist-joint; the remaining portion, directed outwards, is narrow, convex, and received into the sigmoid cavity of the radius. The *styloid process* projects from the inner and back part of the bone, and descends a little lower than the head, terminating in a rounded summit, which affords attachment to the internal lateral ligament of the wrist. The head is separated from the styloid process by a depression for the attachment of the triangular interarticular fibro-cartilage; and behind, by a shallow groove for the passage of the tendon of the Extensor carpi ulnaris.

Structure.—Similar to that of the other long bones.

Development.—By *three* centres: one for the shaft, one for the inferior extremity, and one for the olecranon (fig. 213). Ossification commences near the middle of the shaft about the eighth week, and soon extends through the greater part of the bone. At birth the ends are cartilaginous. About the fourth year, a separate osseous nucleus appears in the middle of the head, which soon extends into the styloid process. About the tenth year, ossific matter appears in the olecranon near its extremity, the chief part of this process being formed from an extension of the shaft of the bone into it. At about the sixteenth year, the upper epiphysis becomes joined, and at about the twentieth year the lower one.

Fig. 213.—Plan of the development of the ulna. By three centres.



Articulations.—With the humerus and radius.

Attachment of Muscles.—To fourteen: to the olecranon, the Triceps, Anconeus, and one head of the Flexor carpi ulnaris. To the coronoid process, the Brachialis anticus, Pronator radii teres, Flexor sublimis digitorum, and Flexor profundus digitorum; generally also the Flexor longus pollicis. To the shaft, the Flexor profundus digitorum, Pronator quadratus, Flexor carpi ulnaris, Extensor carpi ulnaris, Anconeus, Supinator brevis, Extensor ossis metacarpi pollicis, Extensor longus pollicis, and Extensor indicis.

Surface Form.—The most prominent part of the ulna on the surface of the body is the olecranon process, which can always be felt at the back of the elbow-joint. When the forearm is flexed, the upper triangular surface can be felt, directed backwards; during extension it recedes into the olecranon fossa, and the contracting fibres of the Triceps prevent its being perceived. At the back of the olecranon is the smooth, triangular, subcutaneous surface, which below is continuous with the posterior border of the shaft of the bone; this is to be felt in every position of the joint. During extension, the upper border of the olecranon is slightly above the level of the internal condyle, and the process itself is nearer to this condyle than the outer one. Running down the back of the forearm, from the apex of the triangular surface which forms the posterior surface of the olecranon, is a prominent ridge of bone, the posterior border of the ulna. This is to be felt throughout the entire length of the shaft of the bone, from the olecranon above to the styloid process below. As it passes down the forearm it pursues a sinuous course and inclines to the

inner side, so that, though it is situated in the middle of the back of the limb above, it is on the inner side of the wrist at its termination. It becomes rounded off in its lower third, and may be traced below to the small, subcutaneous surface of the styloid process. Internal to this border the lower fourth of the internal surface is to be felt. The styloid process is to be felt as a prominent tubercle of bone, continuous above with the posterior subcutaneous border of the ulna, and terminating below in a blunt apex, which lies a little internal, and behind, but on a level with, the wrist-joint. The styloid process is best felt when the hand is in the same line as the bones of the forearm, and in a position midway between supination and pronation. If the forearm is pronated while the finger is placed on the process, it will be felt to recede, and another prominence of bone will appear just external and above it. This is the head of the ulna, which articulates with the lower end of the radius and the triangular interarticular fibro-cartilage, and now projects between the tendons of the Extensor carpi ulnaris and the Extensor minimi digiti muscles.

The Radius

The **Radius** (radius, *a ray*, or *spoke of a wheel*) is situated on the outer side of the forearm, lying side by side with the ulna, which exceeds it in length and size (figs. 211, 212). Its upper end is small, and forms only a small part of the elbow-joint; but its lower end is large, and forms the chief part of the wrist. It is one of the long bones, prismatic in form, slightly curved longitudinally, and, like other long bones, has a shaft and two extremities.

The **Upper Extremity** presents a head, neck, and tuberosity. The *head* is of a cylindrical form, depressed on its upper surface into a shallow cup which articulates with the capitellum or radial head of the humerus. In the recent state it is covered with a layer of cartilage, which is thinnest at its centre. Around the circumference of the head is a smooth, articular surface, broad internally where it articulates with the lesser sigmoid cavity of the ulna; narrow in the rest of its circumference, where it rotates within the orbicular ligament. It is coated with cartilage in the recent state. The head is supported on a round, smooth, and constricted portion of bone, called the *neck*, which presents, behind, a slight ridge, for the attachment of part of the Supinator brevis. Beneath the neck, at the inner and front aspect of the bone, is a rough eminence, the *bicipital tuberosity*. Its surface is divided into two parts by a vertical line—a posterior, rough portion, for the insertion of the tendon of the Biceps muscle; and an anterior, smooth portion, on which a bursa is interposed between the tendon and the bone.

The **Shaft** of the bone is prismoid in form, narrower above than below, and slightly curved, so as to be convex outwards. It presents three surfaces, separated by three borders.

The **anterior border** extends from the lower part of the tuberosity above, to the anterior part of the base of the styloid process below. It separates the anterior from the external surface. Its upper third is very prominent; and from its oblique direction, downwards and outwards, has received the name of the *oblique line of the radius*. It gives attachment, externally, to the Supinator brevis; internally, to the Flexor longus pollicis, and between these to the Flexor sublimis digitorum. The middle third of the anterior border is indistinct and rounded. Its lower fourth is sharp, prominent, affords attachment to the Pronator quadratus, and terminates in a small tubercle, into which is inserted the tendon of the Supinator longus.

The **posterior border** commences above, at the back part of the neck of the radius, and terminates below, at the posterior part of the base of the styloid process; it separates the posterior from the external surface. It is indistinct above and below, but well marked in the middle third of the bone.

The **internal** or **interosseous border** commences above, at the back part of the tuberosity, where it is rounded and indistinct, becomes sharp and prominent as it descends, and at its lower part divides into two ridges, which descend to the anterior and posterior margins of the sigmoid cavity. This border separates the

anterior from the posterior surface, and has the interosseous membrane attached to it throughout the greater part of its extent.

The **anterior surface** is narrow and concave for its upper three-fourths, and gives attachment to the Flexor longus pollicis muscle ; it is broad and flat for its lower fourth, and gives attachment to the Pronator quadratus. A prominent ridge limits the attachment of the Pronator quadratus below, and between this and the inferior border is a triangular rough surface for the attachment of the anterior ligament of the wrist-joint. At the junction of the upper and middle third of this surface is the nutrient foramen, which is directed obliquely upwards.

The **posterior surface** is rounded, convex, and smooth in the upper third of its extent, and covered by the Supinator brevis muscle. Its middle third is broad, slightly concave, and gives attachment to the Extensor ossis metacarpi pollicis above, the Extensor brevis pollicis below. Its lower third is broad, convex, and covered by the tendons of the muscles, which subsequently run in the grooves on the lower end of the bone.

The **external surface** is rounded and convex throughout its entire extent. Its upper third gives attachment to the Supinator brevis muscle. About its centre is seen a rough ridge, for the insertion of the Pronator radii teres muscle. Its lower part is narrow, and covered by the tendons of the Extensor ossis metacarpi pollicis and Extensor brevis pollicis muscles.

The **Lower Extremity** of the radius is large, of quadrilateral form, and provided with two articular surfaces—one at the extremity, for articulation with the carpus, and one at the inner side of the bone, for articulation with the ulna. The carpal articular surface is of triangular form, concave, smooth, and divided by a slight antero-posterior ridge into two parts. Of these, the external is large, of a triangular form, and articulates with the scaphoid bone ; the inner, smaller and quadrilateral, articulates with the semilunar. The articular surface for the ulna is called the *sigmoid cavity* of the radius ; it is narrow, concave, smooth, and articulates with the head of the ulna. The circumference of this end of the bone presents three surfaces—an anterior, external, and posterior. The *anterior surface*, rough and irregular, affords attachment to the anterior ligament of the wrist-joint. The *external surface* is prolonged obliquely downwards into a strong, conical projection, the *styloid process*, which gives attachment by its base to the tendon of the Supinator longus, and by its apex to the external lateral ligament of the wrist-joint. The outer surface of this process is marked by a flat groove, which runs obliquely downwards and forwards, and gives passage to the tendons of the Extensor ossis metacarpi pollicis, and the Extensor brevis pollicis. The *posterior surface* is convex, affords attachment to the posterior ligament of the wrist, and is marked by three grooves. Proceeding from without inwards, the first groove is broad, but shallow, and subdivided into two by a slightly elevated ridge : the outer of these two transmits the tendon of the Extensor carpi radialis longior, the inner the tendon of the Extensor carpi radialis brevior. The second, which is near the centre of the bone, is a deep but narrow groove, bounded on its outer side by a sharply defined ridge ; it is directed obliquely from above, downwards and outwards, and transmits the tendon of the Extensor longus pollicis. The third, lying most internally, is a broad groove, for the passage of the tendons of the Extensor indicis and Extensor communis digitorum.

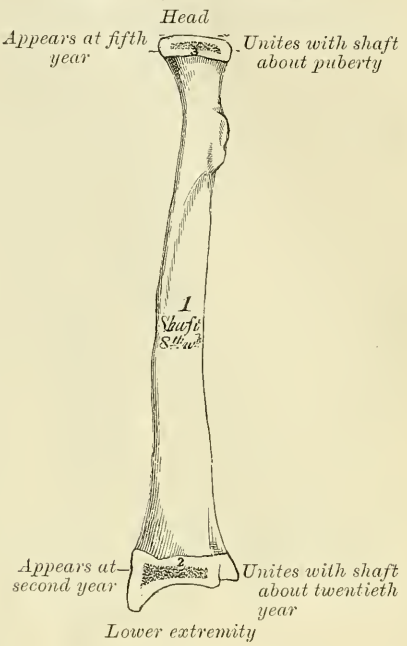
Structure.—Similar to that of the other long bones.

Development (fig. 214).—By *three* centres : one for the shaft, and one for each extremity. That for the shaft makes its appearance near the centre of the bone, soon after the development of the humerus commences. At birth the shaft is ossified, but the ends of the bone are cartilaginous. About the end of the second year, ossification commences in the lower epiphysis ; and about the fifth year, in the upper one. At the age of seventeen or eighteen the upper epiphysis becomes joined to the shaft ; the lower epiphysis becoming united about the twentieth year.

Articulations.—With four bones: the humerus, ulna, scaphoid, and semilunar.

Attachment of Muscles.—To nine; to the tuberosity, the Biceps; to the oblique ridge, the Supinator brevis, Flexor sublimis digitorum, and Flexor longus pollicis; to the shaft (its anterior surface), the Flexor longus pollicis and Pronator quadratus; (its posterior surface), the Extensor ossis metacarpi pollicis and Extensor brevis pollicis; (its outer surface), the Pronator radii teres; and to the styloid process, the Supinator longus.

Fig. 214.—Plan of the development of the radius. By three centres.



Surface Form.—Just below, and a little in front of, the posterior surface of the external condyle a part of the head of the radius may be felt, covered by the orbicular and external lateral ligaments. There is in this situation a little dimple in the skin, which is most visible when the arm is extended, and which marks the position of the head of the bone. If the finger is placed on this dimple, and the forearm pronated and supinated, the head of the bone will be distinctly perceived rotating in the lesser sigmoid cavity. The upper half of the shaft of the radius cannot be felt, as it is surrounded by the fleshy bellies of the muscles arising from the external condyle. The lower half of the shaft can be readily examined, though covered by tendons and muscles and not strictly subcutaneous. If traced downwards, the shaft will be felt to terminate in a lozenge-shaped, convex surface on the outer side of the base of the styloid process. This is the only subcutaneous part of the bone, and from its lower extremity the apex of the styloid process will be felt bending inwards towards the wrist. About the middle of the posterior aspect of the lower extremity of the bone is a well-marked ridge, best perceived when the hand is slightly flexed on the wrist. It bounds the oblique groove on the posterior surface of the bone, through which the tendon of the Extensor longus pollicis runs, and serves to keep that tendon in its place.

Surgical Anatomy.—The two bones of the forearm are more often broken together, than is either the radius or ulna separately. It is therefore convenient to consider the fractures of these two bones together in the first instance and subsequently to mention the principal fractures which take place in each bone individually. These fractures may be produced by either direct or indirect violence, though more commonly by direct violence. When indirect force is applied to the forearm the radius generally alone gives way, though both bones may suffer. The fracture from indirect force generally takes place somewhere about the middle of the bones, fracture from direct violence may occur at any part, more often, however, in the lower half of the bone. The fracture is usually transverse, but may be more or less oblique. A point of interest in connection with these fractures is the tendency that there is for the two bones to unite across the interosseous membrane; the limb should therefore be put up in a position midway between supination and pronation, which is not only the most comfortable position, but also separates the bones most widely from each other and therefore diminishes the risk of the bones becoming united across the interosseous membrane. The splints, anterior and posterior, which are applied in these cases should be rather wider than the limb, so as to prevent any lateral pressure on the bones. For in these cases there is a greater liability to gangrene from the pressure of the splints than in other parts of the body. This is no doubt due principally to two causes: (1) the flexion of the forearm compressing to a certain extent the brachial artery and retarding the flow of blood to the limb; and (2) the superficial position of the two main arteries of the forearm in a part of their course, and their liability to be compressed by the splints. The special fractures of the ulna are:—(1) fracture of the olecranon. This may be caused by direct violence, falls on the elbow with the forearm flexed, or by muscular action by the sudden contraction of the Triceps. The most common place for the fracture to occur is at the constricted portion where the olecranon joins the shaft of the bone, and the fracture may be either transverse or oblique; but any part may be broken, even a thin shell may

be torn off. Fractures from direct violence are occasionally comminuted. The displacement is sometimes very slight, owing to the fibrous structures around the process not being torn. (2) Fracture of the coronoid process sometimes occurs as a complication of dislocation backwards of the bones of the forearm, but it is doubtful if it ever occurs as an uncomplicated injury. (3) Fractures of the shaft of the ulna may occur at any part, but usually take place at the middle of the bone or a little below it. They are almost always the result of direct violence. (4) The styloid process may be knocked off by direct violence. Fractures of the radius consist of (1) fracture of the head of the bone; this generally occurs in conjunction with some other lesion, but may occur as an uncomplicated injury. (2) Fracture of the neck may also take place, but is generally complicated with other injury. (3) Fractures of the shaft of the radius are very common, and may take place at any part of the bone. They may take place from either direct or indirect violence. In fractures of the upper third of the shaft of the bone, that is to say, above the insertion of the Pronator radii teres, the displacement is very great. The upper fragment is strongly supinated by the Biceps and Supinator brevis, and flexed by the Biceps; whilst the lower fragment is pronated and drawn towards the ulna by the two pronators. If such a fracture is put up in the ordinary position, midway between supination and pronation, the fracture will unite with the upper fragment in a position of supination, and the lower one in the mid position, and thus considerable impairment of the movements of the hand result. The limb should be put up with the forearm supinated. (4) The most important fracture of the radius is that of the lower end (Colles's fracture). The fracture is transverse, and generally takes place about an inch from the lower extremity. It is caused by falls on the palm of the hand, and is an injury of advanced life, occurring more frequently in the female than the male. In consequence of the manner in which the fracture is caused, the upper fragment becomes driven into the lower, and impaction is the result; or else the lower fragment becomes split up into two or more pieces, so that no fixation occurs. Separation of the lower epiphysis of the radius may take place in the young. This injury and Colles's fracture may be distinguished from other injuries in this neighbourhood—especially dislocation, with which it is liable to be confounded—by observing the relative positions of the styloid processes of the ulna and radius. In the natural condition of parts, with the arm hanging by the side, the styloid process of the radius is on a lower level than that of the ulna, that is to say, nearer the ground. After fracture or separation of the epiphysis this process is on the same or higher level than that of the ulna, whereas it would be unaltered in position in dislocation.

THE HAND

The skeleton of the Hand is subdivided into three segments—the Carpus or wrist bones; the Metacarpus or bones of the palm; and the Phalanges or bones of the fingers.

THE CARPUS

The bones of the **Carpus** (*καρπός, the wrist*), eight in number, are arranged in two rows. Those of the upper row, enumerated from the radial to the ulnar side, are the scaphoid, semilunar, cuneiform, and pisiform; those of the lower row, enumerated in the same order, are the trapezium, trapezoid, os magnum, and unciform.

Common Characters of the Carpal Bones

Each bone (excepting the pisiform) presents six surfaces. Of these the *anterior* or *palmar* and the *posterior* or *dorsal* are rough, for ligamentous attachment; the dorsal surface being the broader, except in the scaphoid and semilunar. The *superior* or *proximal* and *inferior* or *distal* are articular, the superior generally convex, the inferior concave; and the *internal* and *external* are also articular when in contact with contiguous bones, otherwise rough and tubercular. The structure in all is similar, consisting of cancellous tissue enclosed in a layer of compact bone. Each bone is also developed from a single centre of ossification.

Bones of the Upper Row

Scaphoid (fig. 217)

The **Scaphoid** is the largest bone of the first row. It has received its name from its fancied resemblance to a boat, being broad at one end, and

FIG. 215.—Bones of the left hand. Dorsal surface.

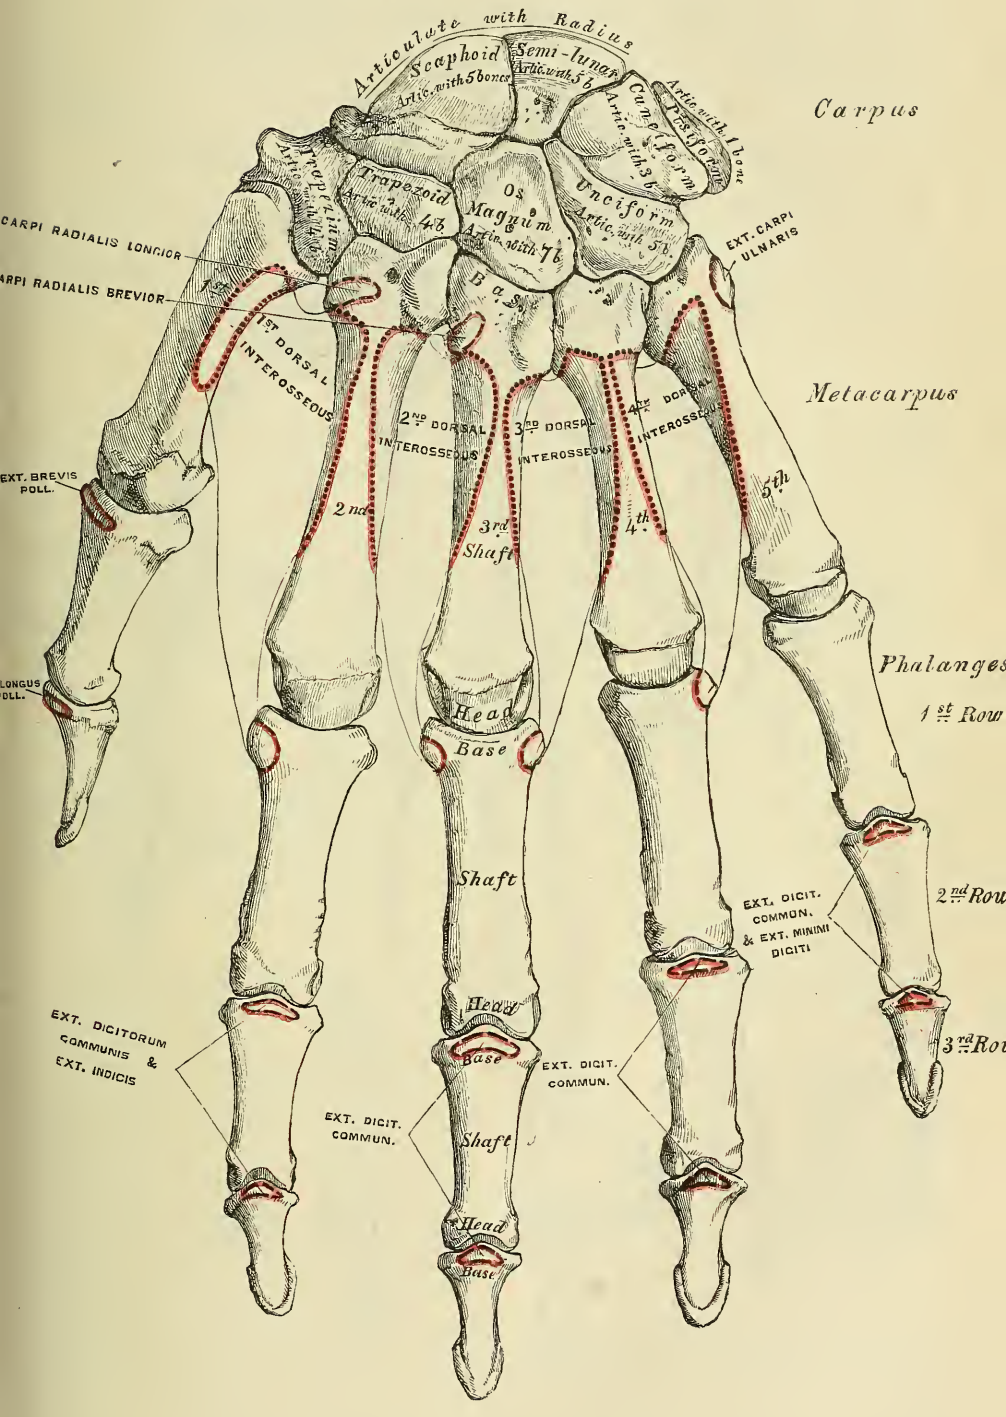


FIG. 216.—Bones of the left hand. Palmar surface.

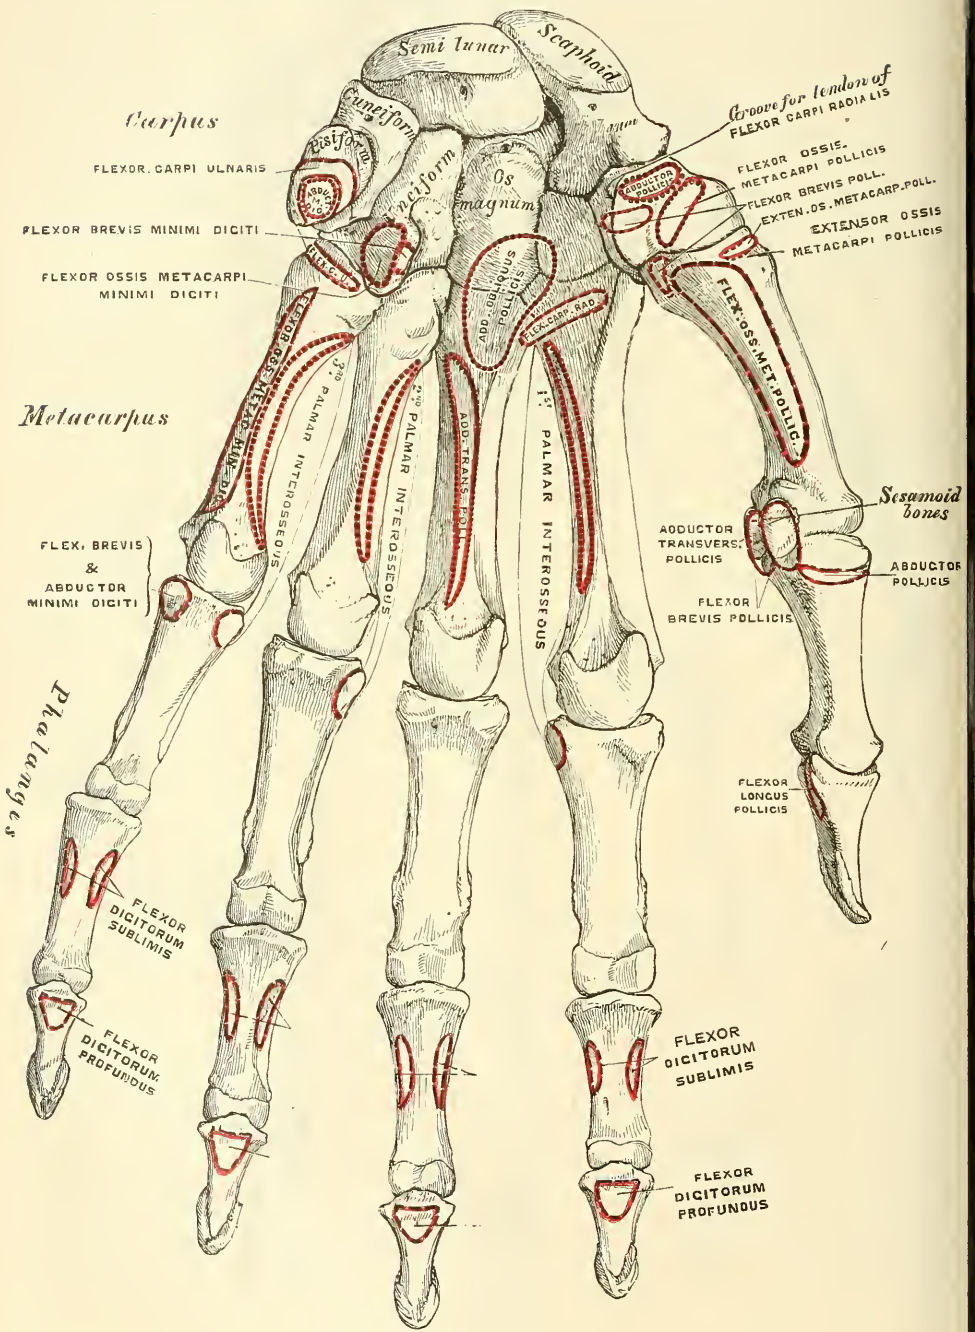
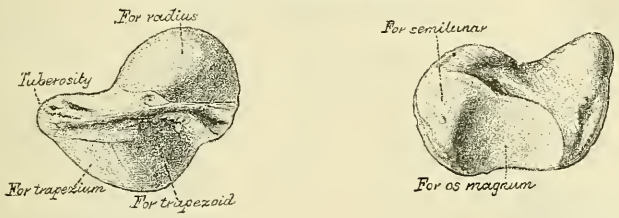


narrowed, like a prow, at the opposite (σκάφη, *a boat*; εἶδος, *like*). It is situated at the upper and outer part of the carpus, its long axis being from above downwards, outwards, and forwards. The *superior surface* is convex, smooth, of triangular shape, and articulates with the lower end of the radius. The *inferior surface*, directed downwards, outwards, and backwards, is smooth, convex, also triangular, and divided by a slight ridge into two parts, the external of which articulates with the trapezium, the inner with the trapezoid. The *posterior* or *dorsal surface* presents a narrow, rough groove, which runs the entire breadth of

Fig. 217.—The left scaphoid.



the bone, and serves for the attachment of ligaments. The *anterior* or *palmar surface* is concave above, and elevated at its lower and outer part into a prominent, rounded tubercle, which projects forwards from the front of the carpus and gives attachment to the anterior annular ligament of the wrist and sometimes a few fibres of the Abductor pollicis. The *external surface* is rough and narrow, and gives attachment to the external lateral ligament of the wrist. The *internal surface* presents two articular facets; of these, the superior or smaller one is flattened, of semilunar form, and articulates with the semilunar; the inferior or larger is concave, forming, with the semilunar bone, a concavity for the head of the os magnum.

To ascertain to which side the bone belongs, hold it with the superior or radial, convex, articular surface upwards, and the posterior surface—i.e. the narrow, non-articular, grooved surface—towards you. The tubercle on the outer surface points to the side to which the bone belongs.*

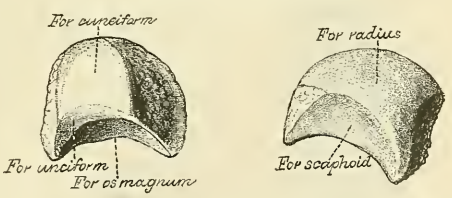
Articulations.—With five bones: the radius above, trapezium and trapezoid below, os magnum and semilunar internally.

Attachment of Muscles.—Occasionally a few fibres of the Abductor pollicis.

Semilunar (fig. 218)

The **Semilunar** bone may be distinguished by its deep concavity and crescentic outline (*semi*, half; *luna*, moon). It is situated in the centre of the upper row of the carpus, between the scaphoid and cuneiform. The *superior surface*, convex, smooth, and bounded by four edges, articulates with the radius. The *inferior surface* is deeply concave, and of greater extent from before backwards than transversely: it articulates with the head of the os magnum, and, by a long, narrow facet (separated by a ridge from the general surface), with the unciform bone. The *anterior* or *palmar* and *posterior* or *dorsal surfaces* are rough, for the attachment of ligaments, the former being the broader, and of somewhat rounded form. The *external surface* presents a narrow, flattened,

Fig. 218.—The left semilunar.



* In these directions each bone is supposed to be placed in its natural position—that is, such a position as it would occupy when the arm is hanging by the side, the forearm in a position of supination, the thumb being directed outwards and the palm of the hand looking forwards.

semilunar facet for articulation with the scaphoid. The *internal surface* is marked by a smooth, quadrilateral facet, for articulation with the cuneiform.

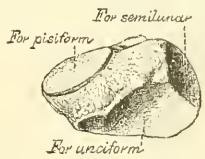
Hold it with the convex articular surface for the radius upwards, and the narrowest non-articular surface towards you. The semilunar facet for the scaphoid will be on the side to which the bone belongs.

Articulations.—With five bones: the radius above, os magnum and unciform below, scaphoid and cuneiform on either side.

Cuneiform (fig. 219)

The **Cuneiform** (cuneus, *a wedge*; forma, *likeness*) may be distinguished by its pyramidal shape (*os pyramidal*), and by its having an oval, isolated facet for articulation with the pisiform bone. It is situated at the upper and inner side of the carpus. The *superior surface* presents an internal, rough, non-articular portion, and an external or articular portion, which is convex, smooth, and articulates with the triangular interarticular fibro-cartilage of the wrist. The *inferior surface*, directed outwards, is concave, sinuously curved, and smooth for articulation with the unciform. The *posterior* or *dorsal surface* is rough, for the attachment of ligaments. The *anterior* or *palmar surface* presents, at its inner side, an oval facet, for articulation with the pisiform; and is rough externally, for ligamentous attachment. The *external surface*, the base of the pyramid, is marked by a flat, quadrilateral, smooth facet, for articulation with the semilunar. The *internal surface*, the summit of the pyramid, is pointed and roughened, for the attachment of the internal lateral ligament of the wrist.

Fig. 219.—The left cuneiform.



Hold the bone with the surface supporting the pisiform facet away from you, and the concavo-convex surface for the unciform downwards. The base of the wedge (i.e. the broad end of the bone) will be on the side to which it belongs.

Articulations.—With three bones: the semilunar externally, the pisiform in front, the unciform below; and with the triangular, interarticular fibro-cartilage which separates it from the lower end of the ulna.

Pisiform (fig. 220)

The **Pisiform** (pisum, *a pea*; forma, *likeness*) may be known by its small size, and by its presenting a single articular facet. It is situated on a plane anterior to the other bones of the carpus; it is spheroidal in form, with its long diameter directed vertically. Its *posterior* surface presents a smooth, oval facet, for articulation with the cuneiform: this facet approaches the superior, but not the inferior, border of the bone. The *anterior* or *palmar surface* is rounded and rough, and gives attachment to the anterior annular ligament and to the Flexor carpi ulnaris and Abductor minimi digiti muscles. The *outer* and *inner surfaces* are also rough, the former being concave, the latter usually convex.

Fig. 220.—The left pisiform.

Hold the bone with the posterior surface—that which presents the articular facet—towards you, in such a manner that the faceted portion of the surface is uppermost. The outer, concave surface will point to the side to which it belongs.

Articulations.—With one bone, the cuneiform.

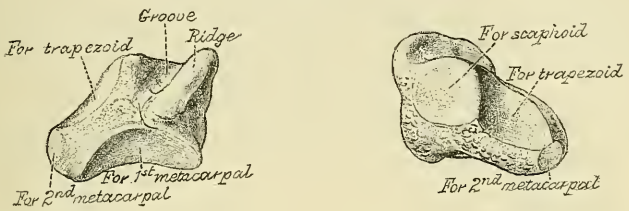
Attachment of Muscles.—To two: the Flexor carpi ulnaris and Abductor minimi digiti; and to the anterior annular ligament.

Bones of the Lower Row

Trapezium (fig. 221)

The **Trapezium** (*τράπεζα, a table*) is of very irregular form. It may be distinguished by a deep groove, for the tendon of the Flexor carpi radialis muscle. It is situated at the external and inferior part of the carpus, between the scaphoid and first metacarpal bone. The *superior surface*, concave and smooth, is directed upwards and inwards, and articulates with the scaphoid. The *inferior surface*, directed downwards and inwards, is oval, concave from side to side, convex from before backwards, so as to form a saddle-shaped surface, for articulation with

Fig. 221.—The left trapezium.



the base of the first metacarpal bone. The *anterior* or *palmar surface* is narrow and rough. At its upper part is a deep groove, running from above obliquely downwards and inwards: it transmits the tendon of the Flexor carpi radialis, and is bounded externally by a prominent ridge, the oblique ridge of the trapezium. This surface gives attachment to the Abductor pollicis, Flexor ossis metacarpi pollicis, and Flexor brevis pollicis muscles, and the anterior annular ligament. The *posterior* or *dorsal surface* is rough. The *external surface* is also broad and rough, for the attachment of ligaments. The *internal surface* presents two articular facets: the upper one, large and concave, articulates with the trapezoid; the lower one, narrow and flattened, with the base of the second metacarpal bone.

Hold the bone with the saddle-shaped surface downwards and the grooved surface away from you. The prominent, rough, non-articular surface points to the side to which the bone belongs.

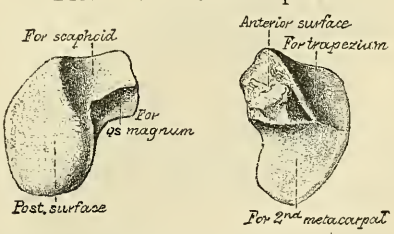
Articulations.—With four bones: the scaphoid above, the trapezoid and second metacarpal bones internally, the first metacarpal below.

Attachment of Muscles.—Abductor pollicis, Flexor ossis metacarpi pollicis, and part of the Flexor brevis pollicis.

Trapezoid (fig. 222)

The **Trapezoid** is the smallest bone in the second row. It may be known by its wedge-shaped form, the broad end of the wedge forming the dorsal, the narrow end the palmar, surface; and by its having four articular surfaces touching each other, and separated by sharp edges. The *superior surface*, quadrilateral in form, smooth, and slightly concave, articulates with the scaphoid. The *inferior surface* articulates with the upper end of the second metacarpal bone; it is convex from side to side, concave from before backwards, and subdivided, by an elevated ridge, into two unequal lateral facets. The *posterior* or *dorsal* and *anterior* or *palmar surfaces* are rough, for the attachment of ligaments, the former being the larger of the two. The *external*

Fig. 222.—The left trapezoid.



surface, convex and smooth, articulates with the trapezium. The *internal surface* is concave and smooth in front, for articulation with the os magnum ; rough behind, for the attachment of an interosseous ligament.

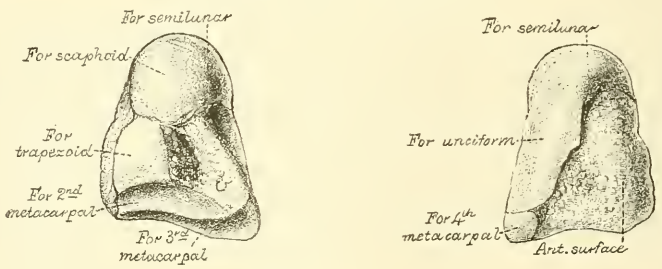
Hold the bone with the larger, non-articular surface towards you, and the smooth, quadrilateral articular surface upwards. The convex, articular surface will point to the side to which the bone belongs.*

Articulations.—With four bones : the scaphoid above, second metacarpal bone below, trapezium externally, os magnum internally.

Os Magnum (fig. 223)

The **Os Magnum** is the largest bone of the carpus, and occupies the centre of the wrist. It presents, above, a rounded portion or head, which is received into the concavity formed by the scaphoid and semilunar bones; a constricted portion or neck; and, below this, the body. The *superior surface* is rounded, smooth, and articulates with the semilunar. The *inferior surface* is divided by two ridges into three facets, for articulation with the second, third, and fourth metacarpal bones, that for the third (the middle facet) being the largest of the three. The *posterior* or *dorsal surface* is broad and rough ; the *anterior* or *palmar*, narrow,

Fig. 223.—The left os magnum.



rounded, and also rough, for the attachment of ligaments and a part of the Adductor obliquus pollicis. The *external surface* articulates with the trapezoid by a small facet at its anterior inferior angle, behind which is a rough depression for the attachment of an interosseous ligament. Above this is a deep and rough groove, which forms part of the neck, and serves for the attachment of ligaments, bounded superiorly by a smooth, convex surface, for articulation with the scaphoid. The *internal surface* articulates with the unciform by a smooth, concave, oblong facet, which occupies its posterior and superior parts ; and is rough in front, for the attachment of an interosseous ligament.

Hold the bone with the broader, non-articular surface towards you, and the head upwards. The small, articular facet at the anterior inferior angle of the external surface will point to the side to which the bone belongs.

Articulations.—With seven bones : the scaphoid and semilunar above ; the second, third, and fourth metacarpal below ; the trapezoid on the radial side ; and the unciform on the ulnar side.

Attachment of Muscles.—Part of the Adductor obliquus pollicis.

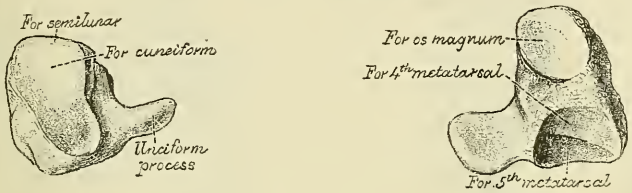
Unciform (fig. 224)

The **Unciform** (uncus, *a hook* ; forma, *likeness*) may be readily distinguished by its wedge-shaped form, and the hook-like process that projects from its palmar surface. It is situated at the inner and lower angle of the carpus, with its base

* Occasionally in a badly marked bone there is some difficulty in ascertaining to which side the bone belongs ; the following method will sometimes be found useful. Hold the bone with its broader, non-articular surface upwards, so that its sloping border is directed towards you. The border will slope to the side to which the bone belongs.

downwards, resting on the two inner metacarpal bones, and its apex directed upwards and outwards. The *superior surface*, the apex of the wedge, is narrow, convex, smooth, and articulates with the semilunar. The *inferior surface* articulates with the fourth and fifth metacarpal bones, the concave surface for each being separated by a ridge, which runs from before backwards. The *posterior* or *dorsal surface* is triangular and rough, for ligamentous attachment. The *anterior* or *palmar surface* presents, at its lower and inner side, a curved, hook-like process of bone, the *unciform process*, directed from the palmar surface forwards and outwards. It gives attachment, by its apex, to the annular ligament and the Flexor carpi ulnaris; by its inner surface to the Flexor brevis minimi digiti and the Flexor ossis metacarpi minimi digiti; and is grooved on its outer side, for the passage of the Flexor tendons into the palm of the hand. This is one of the four eminences on the front of the carpus to which the anterior annular ligament is attached; the others being the pisiform internally, the oblique ridge of the trapezium and the tuberosity of the scaphoid externally. The *internal surface* articulates with the cuneiform by an oblong facet, cut obliquely from above, down-

Fig. 224.—The left unciform.



wards and inwards. The *external surface* articulates with the os magnum by its upper and posterior part, the remaining portion being rough, for the attachment of ligaments.

Hold the bone with the hooked process away from you, and the articular surface, divided into two parts for the metacarpal bones, downwards. The concavity of the process will be on the side to which the bone belongs.

Articulations.—With five bones: the semilunar above, the fourth and fifth metacarpal below, the cuneiform internally, the os magnum externally.

Attachment of Muscles.—To three: the Flexor brevis minimi digiti, the Flexor ossis metacarpi minimi digiti, the Flexor carpi ulnaris.

THE METACARPUS

The **Metacarpal Bones** are five in number: they are long cylindrical bones, presenting for examination a shaft and two extremities.

Common Characters of the Metacarpal Bones

The **shaft** is prismoid in form, and curved longitudinally, so as to be convex in the longitudinal direction behind, concave in front. It presents three surfaces: two lateral and one posterior. The *lateral surfaces* are concave, for the attachment of the Interossei muscles, and separated from one another by a prominent ridge. The *posterior* or *dorsal surface* presents in its distal half a smooth, triangular, flattened area which is covered, in the recent state, by the tendons of the Extensor muscles. This triangular surface is bounded by two lines, which commence in small tubercles situated on the dorsal aspect of either side of the digital extremity, and, running backwards, converge to meet together a little behind the centre of the bone and form a ridge which runs along the rest of the dorsal surface to the carpal extremity. This ridge separates two lateral, sloping surfaces for the attachment of the Dorsal interossei muscles.* To the tubercles

* By these sloping surfaces the metacarpal bones of the hand may be at once differentiated from the metatarsal bones of the foot.

on the digital extremities are attached the lateral ligaments of the metacarpo-phalangeal joints.

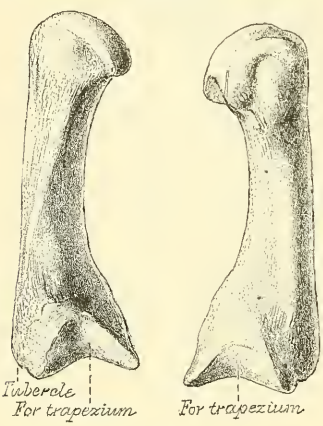
The **carpal extremity,** or **base,** is of a cuboidal form, and broader behind than in front : it articulates above with the carpus, and on each side with the adjoining metacarpal bones ; its *dorsal* and *palmar surfaces* are rough, for the attachment of tendons and ligaments.

The **digital extremity,** or **head,** presents an oblong surface, flattened at each side ; it articulates with the proximal phalanx ; it is broader, and extends farther forwards, on the palmar than on the dorsal aspect. It is longer in the antero-posterior than in the transverse diameter. On either side of the head is a tubercle for the attachment of the lateral ligament of the metacarpo-phalangeal joint. The *posterior surface,* broad and flat, supports the Extensor tendons ; the *anterior surface* is grooved in the middle line for the passage of the Flexor tendons and marked on each side by an articular eminence continuous with the terminal articular surface.

Peculiar Characters of the Metacarpal Bones

The **metacarpal bone of the thumb** (fig. 225) is shorter and wider than the rest, diverges to a greater degree from the carpus, and its *palmar surface* is directed inwards towards the palm. The *shaft* is flattened and broad on its dorsal aspect, and does not present the ridge which is found on the other metacarpal bones ; it is concave from before backwards, on its palmar surface. The *carpal extremity,* or *base,* presents a concavo-convex surface, for articulation with the trapezium ; it has no lateral facets, but presents externally a tubercle for the insertion of the Extensor ossis metacarpi pollicis. The *digital extremity* is less convex than that of the other metacarpal bones, broader from side to side than from before backwards. It presents on its palmar aspect two distinct articular eminences for the two sesamoid bones in the tendons of the Flexor brevis pollicis ; the outer one being the larger of the two.

Fig. 225.—The first metacarpal. (Left.)



The side to which this bone belongs may be known by holding it in the position it occupies in the hand, with the carpal extremity upwards and the dorsal surface backwards ; the tubercle for the Extensor ossis metacarpi pollicis will point to the side to which it belongs.

Attachment of Muscles.—To four : the Flexor ossis metacarpi pollicis, the Extensor ossis metacarpi pollicis, the Flexor brevis pollicis, and the First dorsal interosseous.

The **metacarpal bone of the index finger** (fig. 226) is the longest, and its base the largest, of the other four. Its *carpal extremity* is prolonged upwards and inwards, forming a prominent ridge. The dorsal and palmar surfaces of this extremity are rough, for the attachment of tendons and ligaments. It presents four articular facets : three on the upper aspect of the base ; the middle one of the three is the largest, concave from side to side, convex from before backwards, for articulation with the trapezoid ; the external one is a small, flat, quadrilateral facet, for articulation with the trapezium ; the internal one on the summit of the ridge is long and narrow, for articulation with the os magnum. The fourth facet is on the inner or ulnar side of the extremity of the bone, and is for articulation with the third metacarpal bone.

The side to which this bone belongs is indicated by the absence of the lateral

facet on the outer (radial) side of its base, so that if the bone is placed with its base towards the student, and the palmar surface upwards, the side on which there is no lateral facet will be that to which it belongs.

Attachment of Muscles.—To six: Flexor carpi radialis, Extensor carpi radialis longior, Adductor obliquus pollicis, First and Second dorsal interosseous, and First palmar interosseous.

The **metacarpal bone of the middle finger** (fig. 227) is a little smaller than the preceding; it presents a pyramidal eminence (the styloid process) on the radial side of its base (dorsal aspect), which extends upwards behind the os magnum; immediately below this, on the dorsal aspect, is a rough surface for the attachment of the Extensor carpi radialis brevior. The carpal, articular facet is concave behind, flat in front, and articulates with the os magnum. On the radial side is a smooth, concave facet for articulation with the second metacarpal bone, and on the ulnar side two small, oval facets, for articulation with the fourth metacarpal.

Fig. 226.—The second metacarpal. (Left.)

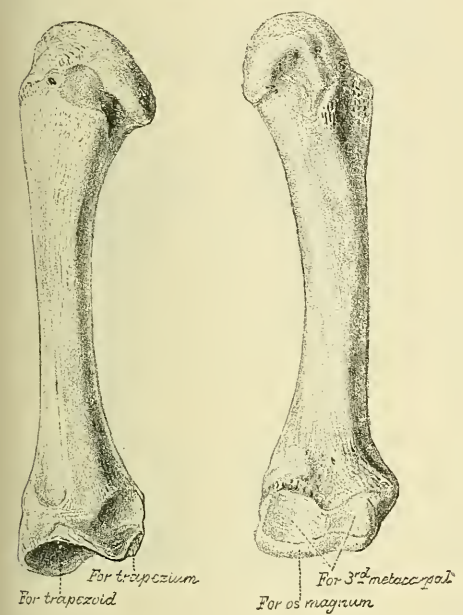


Fig. 227.—The third metacarpal. (Left.)

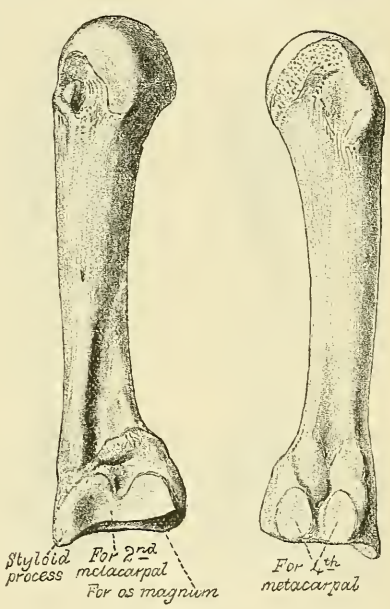

The side to which this bone belongs is easily recognised by the styloid process on the radial side of its base. With the palmar surface uppermost, and the base towards the student, this process points towards the side to which the bone belongs.

Attachment of Muscles.—To six: Extensor carpi radialis brevior, Flexor carpi radialis, Adductor transversus pollicis, Adductor obliquus pollicis, and Second and Third dorsal interosseous.

The **metacarpal bone of the ring-finger** (fig. 228) is shorter and smaller than the preceding, and its base small and quadrilateral; the carpal surface of the base presenting two facets, for articulation with the unciform and os magnum. On the radial side are two oval facets, for articulation with the third metacarpal bone; and on the ulnar side, a single concave facet, for the fifth metacarpal.

If this bone is placed with the base towards the student, and the palmar surface upwards, the radial side of the base, which has two facets for articulation with the third metacarpal bone, will be on the side to which it belongs. If, as sometimes happens in badly marked bones, one of these facets is indistinguishable, the side may be known by selecting the surface on which the larger

articular facet is present. This facet is for the fifth metacarpal bone, and would therefore be situated on the ulnar side—that is, the one to which the bone does *not* belong.

Attachment of Muscles.—To three : the Third and Fourth dorsal and Second palmar interosseous.

The **metacarpal bone of the little finger** (fig. 229) presents on its base one facet, which is concavo-convex, and which articulates with the unciform bone, and one lateral, articular facet, which articulates with the fourth metacarpal bone. On its ulnar side is a prominent tubercle, for the insertion of the tendon of the Extensor carpi ulnaris. The dorsal surface of the shaft is marked by an oblique ridge, which extends from near the ulnar side of the upper extremity to the radial side of the lower. The outer division of this surface serves for the attachment of the Fourth dorsal interosseous muscle ; the inner division is smooth, and covered by the Extensor tendons of the little finger.

If this bone is placed with its base towards the student, and its palmar surface upwards, the side of the head which has a lateral facet will be that to which the bone belongs.

Fig. 228.—The fourth metacarpal. (Left.)

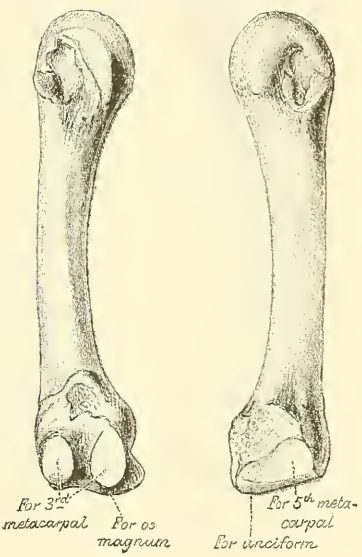

Fig. 229.—The fifth metacarpal. (Left.)

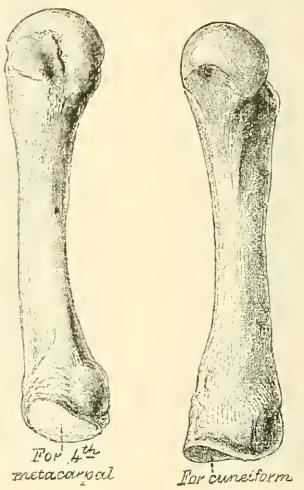


Attachment of Muscles.—To five : the Extensor carpi ulnaris, Flexor carpi ulnaris, Flexor ossis metacarpi minimi digiti, Fourth dorsal, and Third palmar interosseous.

Articulations.—Besides the phalangeal articulations, the first metacarpal bone articulates with the trapezium ; the second with the trapezium, trapezoid, os magnum, and third metacarpal bones ; the third with the os magnum, and second and fourth metacarpal bones ; the fourth with the os magnum, unciform, and third and fifth metacarpal bones ; and the fifth with the unciform and fourth metacarpal.

The *first* has no lateral facets on its carpal extremity ; the *second* has no lateral facet on its radial side, but one on its ulnar side ; the third has one on its radial and two on its ulnar side ; the fourth has two on its radial and one on its ulnar side ; and the fifth has only one on its radial side.

PHALANGES

The **Phalanges** (*internodia*) are the bones of the fingers ; they are fourteen in number, three for each finger, and two for the thumb. They are long bones,

and present for examination a shaft and two extremities. The *shaft* tapers from above downwards, is convex posteriorly, concave in front from above downwards, flat from side to side, and marked laterally by rough ridges, which give attachment to the fibrous sheaths of the Flexor tendons. The *metacarpal extremity* or *base*, in the first row presents an oval, concave, articular surface, broader from side to side than from before backwards; and the same extremity in the other two rows, a double concavity, separated by a longitudinal median ridge, extending from before backwards. The *digital extremities* are smaller than the others, and terminate, in the first and second rows, in two small, lateral condyles, separated by a slight groove; the articular surface being prolonged farther forwards on the palmar than on the dorsal surface, especially in the first row.

The **Ungual Phalanges** are convex on their dorsal, flat on their palmar surfaces; they are recognised by their small size, and by a roughened, elevated surface of a horseshoe form on the palmar aspect of their ungual extremity, which serves to support the sensitive pulp of the finger.

Articulations.—The first row with the metacarpal bones and the second row of phalanges; the second row with the first and third; the third with the second row.

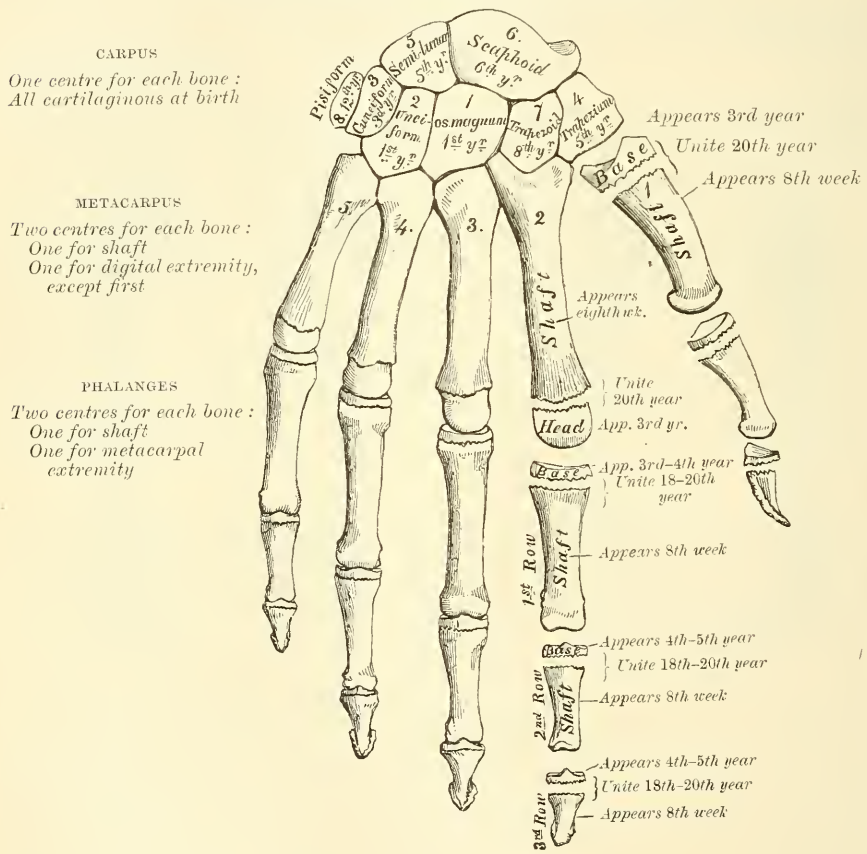
Attachment of Muscles.—To the base of the first phalanx of the thumb, five muscles: the Extensor brevis pollicis, Flexor brevis pollicis, Abductor pollicis, Adductor transversus and obliquus pollicis. To the second phalanx, two: the Flexor longus pollicis and the Extensor longus pollicis. To the base of the first phalanx of the index finger, the First dorsal and the First palmar interosseous; to that of the middle finger, the Second and Third dorsal interosseous; to that of the ring-finger, the Fourth dorsal and the Second palmar interosseous; and to that of the little finger, the Third palmar interosseous, the Flexor brevis minimi digiti, and Abductor minimi digiti. To the second phalanges, the Flexor sublimis digitorum, Extensor communis digitorum, and, in addition, the Extensor indicis to the index finger, the Extensor minimi digiti to the little finger. To the third phalanges, the Flexor profundus digitorum and Extensor communis digitorum.

Surface Form.—On the front of the wrist are two subcutaneous eminences, one on the radial side, the larger and flatter, due to the tuberosity of the scaphoid and the ridge on the trapezium; the other, on the ulnar side, caused by the pisiform bone. The tubercle of the scaphoid is to be felt just below and in front of the apex of the styloid process of the radius. It is best perceived by extending the hand on the forearm. Immediately below is to be felt another prominence, better marked than the tubercle; this is the ridge on the trapezium, which gives attachment to some of the short muscles of the thumb. On the inner side of the front of the wrist the pisiform bone is to be felt, forming a small but prominent projection in this situation. It is some distance below the styloid process of the ulna, and may be said to be just below the level of the styloid process of the radius. The rest of the front of the carpus is covered by tendons and the annular ligament, and entirely concealed. with the exception of the hooked process of the unciform, which can only be made out with difficulty. The back of the carpus is convex and covered by the Extensor tendons, so that none of the posterior surfaces of the bones are to be felt, with the exception of the cuneiform on the inner side. Below the carpus the dorsal surface of the metacarpal bones except the fifth are covered by tendons, and are scarcely visible except in very thin hands. The dorsal surface of the fifth is, however, subcutaneous throughout almost its whole length, and is plainly to be perceived and felt. In addition to this, slightly external to the middle line of the hand, is a prominence, frequently well marked, but occasionally indistinct, formed by the base of the metacarpal of the middle finger. The heads of the metacarpal bones are plainly to be felt and seen, rounded in contour and standing out in bold relief under the skin, when the fist is clenched. It should be borne in mind that when the fingers are flexed on the hand, the articular surfaces of the first phalanges glide off the heads of the metacarpal bones on to their anterior surfaces; so that the heads of these bones form the prominence of the knuckles and receive the force of any blow which may be given. The head of the third metacarpal bone is the most prominent, and receives the greater part of the shock of the blow. This bone articulates with the os magnum, so that the concussion is carried through this bone to the scaphoid and semilunar, with which the head of the os magnum articulates, and by these bones is transferred to the radius, along which it may be carried to the capitellum of the humerus. The enlarged extremities of the phalanges are to be plainly felt: they form

the joints of the fingers. When the digits are bent, the proximal phalanges of the joints form prominences, which in the joint between the first and second phalanges is slightly hollowed, in accordance with the grooved shape of their articular surfaces, whilst in the last row the prominence is flattened and square-shaped. In the palm of the hand the four inner metacarpal bones are covered by muscles, tendons, and the palmar fascia, and no part of them but their heads is to be distinguished. With regard to the thumb, on the dorsal aspect, the base of the metacarpal bone forms a prominence, below the styloid process of the radius; the shaft is to be felt, covered by tendons, terminating at its head in a flattened prominence, in front of which can be felt the sesamoid bones.

Surgical Anatomy.—The carpal bones are little liable to fracture, except from extreme violence, when the parts are so comminuted as to necessitate amputation. Occasionally they are the seat of tuberculous disease. The metacarpal bones and the phalanges are not unfrequently broken from direct violence. The first metacarpal bone is the one most commonly fractured, then the second, the fourth and the fifth, the third being the one least frequently broken. There are two diseases of the metacarpal bones and phalanges which

Fig. 230.—Plan of the development of the hand.



require special mention on account of the frequency of their occurrence. One is tuberculous dactylitis, consisting in a deposit of tuberculous material in the medullary canal, expansion of the bone, with subsequent caseation and resulting necrosis. The other is chondroma, which is perhaps more frequently found in connection with the metacarpal bones and phalanges than with any other bones. The tumours are commonly multiple, and may spring either from the medullary canal, or from the periosteum.

Development of the Bones of the Hand

The **Carpal Bones** are each developed by a *single* centre. At birth, they are all cartilaginous. Ossification proceeds in the following order (fig. 230): In the os magnum and unciform an ossific point appears during the first year, the former preceding the latter; in the cuneiform, at the third year; in the trapezium

and semilunar, at the fifth year, the former preceding the latter; in the scaphoid, at the sixth year; in the trapezoid, during the eighth year; and in the pisiform, about the twelfth year.

The **Metacarpal Bones** are each developed by *two* centres: one for the shaft, and one for the digital extremity, for the four inner metacarpal bones; one for the shaft, and one for the base, for the metacarpal bone of the thumb, which in this respect resembles the phalanges.* Ossification commences in the centre of the shaft about the eighth or ninth week, and gradually proceeds to either end of the bone; about the third year the digital extremities of the four inner metacarpal bones, and the base of the first metacarpal, begin to ossify, and they unite about the twentieth year.

The **Phalanges** are each developed by *two* centres: one for the shaft, and one for the base. Ossification commences in the shaft, in all three rows, at about the eighth week, and gradually involves the whole of the bone excepting the upper extremity. Ossification of the base commences in the first row between the third and fourth years, and a year later in those of the second and third rows. The two centres become united, in each row, between the eighteenth and twentieth years.

In the ungual phalanges the centre for the shaft appears at the distal extremity of the phalanx, instead of at the middle of the shaft as is the case with the other phalanges.

Of the Lower Extremity

The **Lower Extremity** consists of three segments, the *thigh*, *leg*, and *foot*, which correspond to the *arm*, *forearm*, and *hand* in the upper extremity. It is connected to the trunk through the os innominatum, or hip-bone, which forms the pelvic girdle.

The Os Innominatum

The **Os Innominatum** (in, *not*; nomino, *I name*), or *nameless bone*, so called from bearing no resemblance to any known object, is a large, irregularly shaped, flat bone, constricted in the centre and expanded above and below. With its fellow of the opposite side, it forms the sides and anterior wall of the pelvic cavity. In young subjects it consists of three separate parts, which meet and form the large, cup-like cavity situated near the middle of the outer surface of the bone: and, although in the adult these have become united, it is usual to describe the bone as divisible into three portions—the ilium, the ischium, and the os pubis.

The **ilium**, so called from its supporting the flank (*ilia*), is the superior, broad and expanded portion which runs upwards from the upper and back part of the acetabulum, and forms the prominence of the hip.

The **ischium** (*ἰσχίον, the hip*) is the inferior and strongest portion of the bone; it proceeds downwards from the acetabulum, expands into a large tuberosity, and then, curving upwards, forms, with the descending ramus of the os pubis, a large aperture, the obturator foramen.

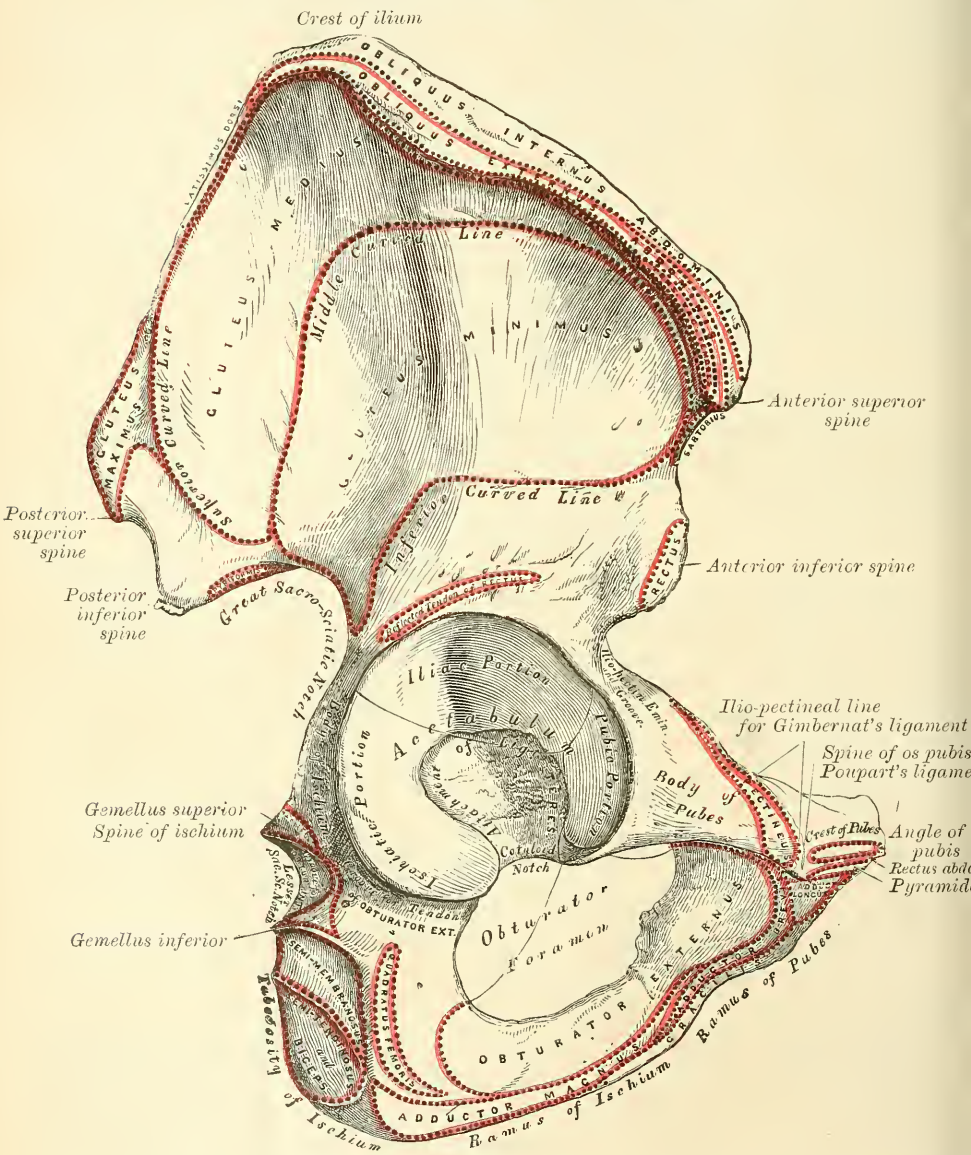
The **os pubis** is that portion which extends inwards from the inner side of the acetabulum for about two inches, then makes a sudden bend, and descends for about one inch: it forms the front of the pelvis, supports the external organs of generation, and has received its name from the skin over it being covered with hair.

The **Ilium** presents for examination two surfaces—an external and an internal—a crest, and two borders—an anterior and a posterior.

* Allen Thomson has demonstrated the fact that the first metacarpal bone is often developed from three centres; that is to say, there is a separate nucleus for the distal end, forming a distinct epiphysis visible at the age of seven or eight years. He also states that there are traces of a proximal epiphysis in the second metacarpal bone. *Journal of Anatomy*, 1869.

External Surface or Dorsum of the Ilium (fig. 231).—The back part of this surface is directed backwards, downwards, and outwards; its front part forwards, downwards, and outwards. It is smooth, convex in front, deeply concave behind; bounded above by the crest, below by the upper border of the acetabulum; in front and behind, by the anterior and posterior borders. This surface is crossed in an arched direction by three semicircular lines—the superior, middle, and inferior curved lines. The superior curved line, the shortest

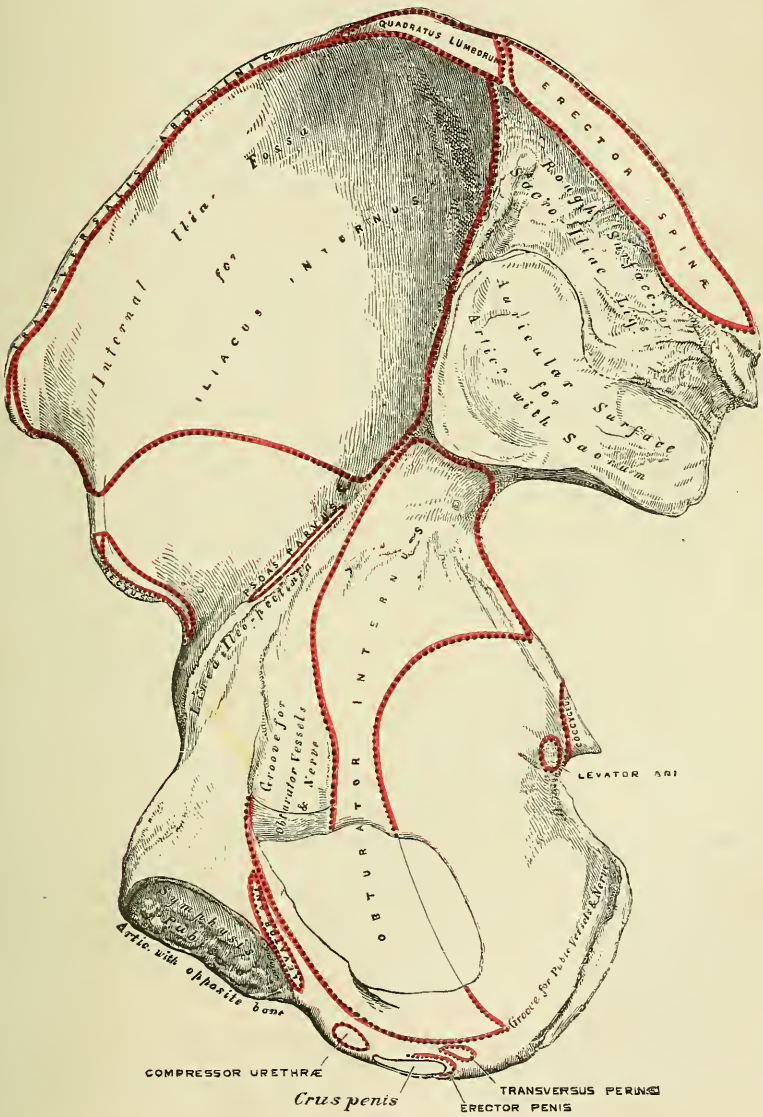
Fig. 231.—Right os innominatum. External surface.



of the three, commences at the crest, about two inches in front of its posterior extremity; it is at first distinctly marked, but as it passes downwards and outwards to the upper part of the great sacro-sciatic notch, where it terminates, it becomes less marked, and is often altogether lost. Behind this line is a narrow semilunar surface, the upper part of which is rough and affords attachment to part of the Gluteus maximus; the lower part is smooth and has no muscular fibres attached to it. The middle curved line, the longest of the three, com-

mences at the crest, about an inch behind its anterior extremity, and, taking a curved direction downwards and backwards, terminates at the upper part of the great sacro-sciatic notch. The space between the superior and middle curved lines and the crest is concave, and affords attachment to the Gluteus medius muscle. Near the central part of this line may often be observed the orifice of a nutrient foramen. The inferior curved line, the least distinct of the three, commences in front at the notch on the anterior border, and, taking a

Fig. 232.—Right os innominatum. Internal surface.



curved direction backwards and downwards, terminates at the middle of the great sacro-sciatic notch. The surface of bone included between the middle and inferior curved lines is concave from above downwards, convex from before backwards, and affords attachment to the Gluteus minimus muscle. Beneath the inferior curved line, and corresponding to the upper part of the acetabulum, is a roughened surface (sometimes a depression), to which is attached the reflected tendon of the Rectus femoris muscle.

The **Internal Surface** (fig. 232) of the ilium is bounded above by the crest;

below it is continuous with the pelvic surfaces of the os pubis and ischium, a faint line only indicating the place of union; and before and behind it is bounded by the anterior and posterior borders. It presents anteriorly a large, smooth, concave surface, called the *internal iliac fossa*, or *venter of the ilium*, which lodges the Iliacus muscle, and presents at its lower part the orifice of a nutrient canal; and below this a smooth, rounded border, the *linea ilio-pectinea*, which separates the iliac fossa from that portion of the internal surface which enters into the formation of the true pelvis, and which gives attachment to part of the Obturator internus muscle. Behind the iliac fossa is a rough surface, divided into two portions, an anterior and a posterior. The anterior or auricular portion, so called from its resemblance in shape to the ear, is coated with cartilage in the recent state, and articulates with a surface of similar shape on the side of the sacrum. The posterior portion is rough, for the attachment of the posterior sacro-iliac ligaments and for a part of the origin of the Erector spinæ.

The **crest** of the ilium is convex in its general outline and sinuously curved, being concave inwards in front, concave outwards behind. It is longer in the female than in the male, very thick behind, and thinner at the centre than at the extremities. It terminates at either end in a prominent eminence, the *anterior superior* and *posterior superior spinous process*. The surface of the crest is broad, and divided into an external lip, an internal lip, and an intermediate space. To the external lip is attached the Tensor vaginæ femoris, Obliquus externus abdominis, and Latissimus dorsi, and by its whole length the fascia lata; to the space between the lips, the Internal oblique; to the internal lip, the Transversalis, Quadratus lumborum, and Erector spinæ, the Iliacus, and the fascia iliaca.

The **anterior border** of the ilium is concave. It presents two projections, separated by a notch. Of these, the uppermost, situated at the junction of the crest and anterior border, is called the *anterior superior spinous process* of the ilium, the outer border of which gives attachment to the fascia lata, and the origin of the Tensor vaginæ femoris; its inner border, to the Iliacus; whilst its extremity affords attachment to Poupart's ligament and the origin of the Sartorius. Beneath this eminence is a notch which gives attachment to the Sartorius muscle, and across which passes the external cutaneous nerve. Below the notch is the *anterior inferior spinous process*, which terminates in the upper lip of the acetabulum; it gives attachment to the straight tendon of the Rectus femoris muscle and the ilio-femoral ligament. On the inner side of the anterior inferior spinous process is a broad, shallow groove, over which passes the Iliacus muscle. This groove is bounded internally by an eminence, the *ilio-pectineal*, which marks the point of union of the ilium and os pubis.

The **posterior border** of the ilium, shorter than the anterior, also presents two projections separated by a notch, the *posterior superior* and the *posterior inferior spinous processes*. The former corresponds with that portion of the posterior surface of the ilium which serves for the attachment of the oblique portion of the sacro-iliac ligaments and the Multifidus spinæ; the latter to the auricular portion which articulates with the sacrum. Below the posterior inferior spinous process is a deep notch, the *great sacro-sciatic*.

The **Ischium** forms the lower and back part of the os innominatum. It is divisible into a thick and solid portion, the *body*; a large, rough eminence, on which the body rests in sitting, the *tuberosity*; and a thin, ascending part, the *ramus*.

The **body**, somewhat triangular in form, presents three surfaces, external, internal, and posterior; and three borders, external, internal, and posterior. The *external surface* corresponds to that portion of the acetabulum formed by the ischium; it is smooth and concave, and forms a little more than two-fifths of the acetabular cavity; its outer margin is bounded by a prominent rim or lip, the external border, to which the cotyloid fibro-cartilage is attached. Below the acetabulum, between it and the tuberosity, is a deep groove, along which the tendon of the Obturator externus muscle runs, as it passes outwards to be inserted

into the digital fossa of the femur. The *internal surface* is smooth, concave, and enters into the formation of the lateral boundary of the true pelvic cavity. This surface is perforated by two or three large, vascular foramina, and affords attachment to part of the Obturator internus muscle. The *posterior surface* is quadrilateral in form, broad and smooth. Below, where it joins the tuberosity, it presents a groove continuous with that on the external surface, for the tendon of the Obturator externus muscle. The lower edge of this groove is formed by the tuberosity of the ischium, and affords attachment to the Gemellus inferior muscle. This surface is limited, in front, by the margin of the acetabulum; behind, by the posterior border; it supports the Pyriformis, the two Gemelli, and the Obturator internus muscles, in their passage outwards to the great trochanter. The *external border* forms the prominent rim of the acetabulum, and separates the posterior from the external surface. To it is attached the cotyloid fibro-cartilage. The *internal border* is thin, and forms the outer circumference of the obturator foramen. The *posterior border* of the body of the ischium presents, a little below the centre, a thin and pointed triangular eminence, the *spine of the ischium*, more or less elongated in different subjects; its external surface gives attachment to the Gemellus superior, its internal surface to the Coccygeus and Levator ani; whilst to the pointed extremity is connected the lesser sacro-sciatic ligament. Above the spine is a notch of large size, the *great sacro-sciatic*, converted into a foramen by the lesser sacro-sciatic ligament; it transmits the Pyriformis muscle, the gluteal vessels and superior gluteal nerve, the sciatic vessels, the greater and lesser sciatic nerves, the internal pudic vessels and nerve, and muscular branches from the sacral plexus. Of these, the gluteal vessels and superior gluteal nerve pass out above the Pyriformis muscle, the other structures below it. Below the spine is a smaller notch, the *lesser sacro-sciatic*; it is smooth, coated in the recent state with cartilage, the surface of which presents numerous markings corresponding to the subdivisions of the tendon of the Obturator internus, which winds over it. It is converted into a foramen by the sacro-sciatic ligaments, and transmits the tendon of the Obturator internus, the nerve which supplies that muscle, and the internal pudic vessels and nerve.

The **tuberosity** presents for examination three surfaces: external, internal, and inferior. The *external surface* is quadrilateral in shape and rough for the attachment of muscles. It is bounded above by the groove for the tendon of the Obturator externus; in front it is limited by the posterior margin of the obturator foramen, and below it is continuous with the ramus of the bone; behind, it is bounded by a prominent margin which separates it from the inferior surface. In front of this margin the surface gives attachment to the Quadratus femoris, and anterior to this to some of the fibres of origin of the Obturator externus. The lower part of the surface gives origin to part of the Adductor magnus. The *internal surface* forms part of the bony wall of the true pelvis. In front, it is limited by the posterior margin of the obturator foramen. Behind, it is bounded by a sharp ridge, for the attachment of a falciform prolongation of the great sacro-sciatic ligament; it present a groove on the inner side of this for the lodgment of the internal pudic vessels and nerve; and, more anteriorly, has attached the Transversus perinæi and Erector penis muscles. The *inferior surface* is divided into two portions: an anterior, rough, somewhat triangular part, and a posterior, smooth, quadrilateral portion. The anterior surface is subdivided by a prominent vertical ridge, passing from base to apex, into two parts; the outer one gives attachment to the Adductor magnus, the inner to the great sacro-sciatic ligament. The posterior portion is subdivided into two facets by an oblique ridge, which runs forwards and outwards; from the upper and outer facet arises the Semi-membranosus; from the lower and inner, the Biceps and Semi-tendinosus.

The **ramus**, or **ascending ramus**, is the thin, flattened part of the ischium, which ascends from the tuberosity upwards and inwards, and joins the ramus of the os

pubis—their point of junction being indicated in the adult by a rough line. The outer surface of the ramus is rough, for the attachment of the Obturator externus muscle, and also some fibres of the Adductor magnus; its inner surface forms part of the anterior wall of the pelvis. Its inner border is thick, rough, slightly everted, forms part of the outlet of the pelvis, and presents two ridges and an intervening space. The ridges are continuous with similar ones on the descending ramus of the os pubis: to the outer one is attached the deep layer of the superficial perineal fascia, and to the inner the anterior layer of the triangular ligament of the perinæum. If these two ridges are traced downwards, they will be found to join with each other just behind the point of origin of the Transversus perinæi muscle; here the two layers of fascia are continuous behind the posterior border of the muscle. To the intervening space, just in front of the point of junction of the ridges, is attached the Transversus perinæi muscle, and in front of this a portion of the crus penis vel clitoridis and the Erector penis vel clitoridis muscle. Its outer border is thin and sharp, and forms part of the inner margin of the obturator foramen.

The **Os Pubis** forms the anterior part of the os innominatum, and, with the bone of the opposite side, forms the front boundary of the true pelvic cavity. It is divisible into a body, an ascending and a descending ramus.

The **body** is somewhat quadrilateral in shape, and presents for examination two surfaces and three borders. The *anterior surface* is rough, directed forwards and outwards, and serves for the attachment of various muscles. To the upper and inner angle, immediately below the crest, is attached the Adductor longus; lower down, from without inwards, are attached the Obturator externus, the Adductor brevis, and the upper part of the Gracilis. The *posterior surface*, convex from above downwards, concave from side to side, is smooth, and forms part of the anterior wall of the pelvis. It gives attachment to the Levator ani, Obturator internus, a few muscular fibres prolonged from the bladder, and the pubo-prostatic ligaments. The *upper border* presents for examination a prominent tubercle, which projects forwards and is called the *spine*; to it is attached the outer pillar of the external abdominal ring and Poupart's ligament. Passing outwards from this is a prominent ridge, forming part of the *ilio-pectineal line* which, running outwards, marks the brim of the true pelvis: to it is attached a portion of the conjoined tendon of the Internal oblique and Transversalis muscles, Gimbernat's ligament and the triangular ligament of the abdomen. Internal to the spine of the os pubis is the *crest*, which extends from this process to the inner extremity of the bone. It affords attachment, anteriorly, to the conjoined tendon of the Internal oblique and Transversalis; and posteriorly, to the Rectus and Pyramidalis muscles. The point of junction of the crest with the inner border of the bone is called the *angle*; to it, as well as to the symphysis, is attached the internal pillar of the external abdominal ring. The *internal border* is the symphysis; it is oval, covered by eight or nine transverse ridges, or a series of nipple-like processes arranged in rows, separated by grooves; they serve for the attachment of a thin layer of cartilage, placed between it and the central fibro-cartilage. The *outer border* presents a sharp margin, which forms part of the circumference of the obturator foramen and affords attachment to the obturator membrane.

The **ascending** or **superior ramus** extends from the body to the point of junction of the os pubis with the ilium, and forms the upper part of the circumference of the obturator foramen. It presents for examination a superior, inferior, and posterior surface, and an outer extremity. The *superior surface* presents a continuation of the ilio-pectineal line, already mentioned as commencing on the body of the bone. In front of this ridge, the surface of bone is triangular in form, wider externally than internally, smooth, and affords attachment to the Pectineus muscle. The surface is bounded externally by a rough eminence, the *ilio-pectineal*, which serves to indicate the point of junction of the ilium and os pubis, and gives attachment to the Psoas parvus, when this muscle is present. The

triangular surface for the Pectineus muscle is bounded below by a prominent ridge, the *obturator crest*, which extends from the margin of the acetabulum, at the anterior extremity of the cotyloid notch, to the spine of the os pubis. The *inferior surface* forms the upper boundary of the obturator foramen, and presents, externally, a broad and deep, oblique groove, for the passage of the obturator vessels and nerve; and internally, a sharp margin which forms part of the circumference of the obturator foramen, and to which the obturator membrane is attached. The *posterior surface* forms part of the anterior boundary of the true pelvis. It is smooth, convex from above downwards, and affords attachment to the upper fibres of the Obturator internus. The *outer extremity*, the thickest part of the ramus, forms one-fifth of the cavity of the acetabulum.

The **descending** or **inferior ramus** of the os pubis is thin and flattened. It passes outwards and downwards, becoming narrower as it descends and joins with the ramus of the ischium. Its *anterior surface* is rough, for the attachment of muscles—the Gracilis along its inner border; a portion of the Obturator externus where it enters into the formation of the foramen of that name; and between these two muscles, the Adductores brevis and magnus from within outwards. The *posterior surface* is smooth, and gives attachment to the Obturator internus, and, close to the inner margin, to the Compressor urethræ. The *inner border* is thick, rough, and everted, especially in females. It presents two ridges, separated by an intervening space. The ridges extend downwards, and are continuous with similar ridges on the ascending ramus of the ischium; to the external one is attached the deep layer of the superficial perineal fascia, and to the internal one the anterior layer of the triangular ligament of the perinæum. The *outer border* is thin and sharp, forms part of the circumference of the obturator foramen, and gives attachment to the obturator membrane.

The **cotyloid cavity**, or **acetabulum**, is a deep, cup-shaped, hemispherical depression, directed downwards, outwards, and forwards; formed internally by the os pubis, above by the ilium, behind and below by the ischium; a little less than two-fifths being formed by the ilium, a little more than two-fifths by the ischium, and the remaining fifth by the pubic bone. It is bounded by a prominent, uneven rim, which is thick and strong above, and serves for the attachment of a fibro-cartilaginous structure which contracts its orifice, and deepens the surface for articulation. It presents, on its inner side, a deep notch, the *cotyloid notch*, which is continuous with a circular depression, the *fossa acetabuli*, at the bottom of the cavity: this depression is perforated by numerous apertures, lodges a mass of fat, and its margins, as well as those of the notch, serve for the attachment of the ligamentum teres. The notch is converted, in the natural state, into a foramen by a dense ligamentous band which passes across it. Through this foramen the nutrient vessels and nerves enter the joint.

The **obturator** or **thyroid foramen** is a large aperture, situated between the ischium and os pubis. In the male it is large, of an oval form, its longest diameter being obliquely from above downwards; in the female it is smaller, and more triangular. It is bounded by a thin, uneven margin, to which a strong membrane is attached; and presents, at its upper and outer part, a deep groove, which runs from the pelvis obliquely forwards, inwards, and downwards. This groove is converted into a foramen by the obturator membrane, and transmits the obturator vessels and nerve.

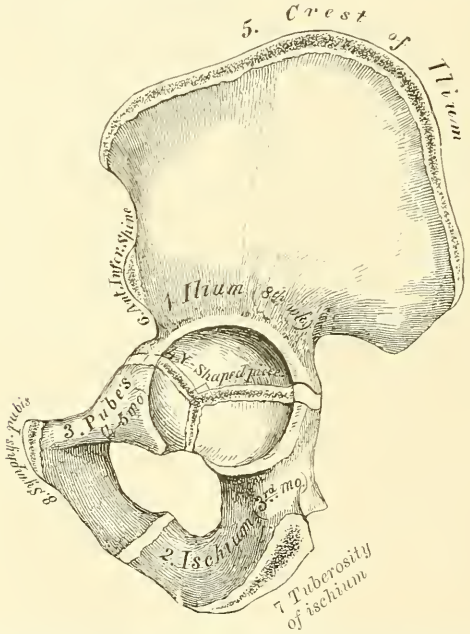
Structure.—This bone consists of much cancellous tissue, especially where it is thick, enclosed between two layers of dense, compact tissue. In the thinner parts of the bone, as at the bottom of the acetabulum and centre of the iliac fossa, it is usually semi-transparent, and composed entirely of compact tissue.

Development (fig. 233).—By *eight* centres: three primary—one for the ilium, one for the ischium, and one for the os pubis; and *five* secondary—one for the crest of the ilium, one for the anterior inferior spinous process (said to occur more frequently in the male than the female), one for the tuberosity of the ischium, one for the symphysis pubis (more frequent in the female than the

male), and one for the Y-shaped piece at the bottom of the acetabulum. These various centres appear in the following order: First, in the ilium, at the lower part of the bone, immediately above the sciatic notch, at about the eighth or ninth week; secondly, in the body of the ischium, at about the third month of fœtal life; thirdly, in the body of the os pubis, between the fourth and fifth months. At birth, the three primary centres are quite separate, the crest, the bottom of the acetabulum, and the rami of the ischium and pubes being still cartilaginous. At about the seventh or eighth year, the rami of the os pubis and ischium are almost completely ossified. About the thirteenth or fourteenth year, the three divisions of the bone have extended their growth into the bottom of the acetabulum, being separated from each other by a Y-shaped portion of cartilage, which now presents traces of ossification, often by two or more centres. The ilium and ischium then become joined, and lastly the os pubis, through the intervention of this Y-shaped portion. At about the age of puberty, ossification

Fig. 233.—Plan of the development of the os innominatum.

By eight centres { *Three primary (Ilium, Ischium, and Os Pubis)* / *Five secondary*



The three primary centres unite through Y-shaped piece about puberty. Epiphyses appear about puberty, and unite about 25th year

takes place in each of the remaining portions, and they become joined to the rest of the bone about the twenty-fifth year.

Articulations.—With its fellow of the opposite side, the sacrum and femur.

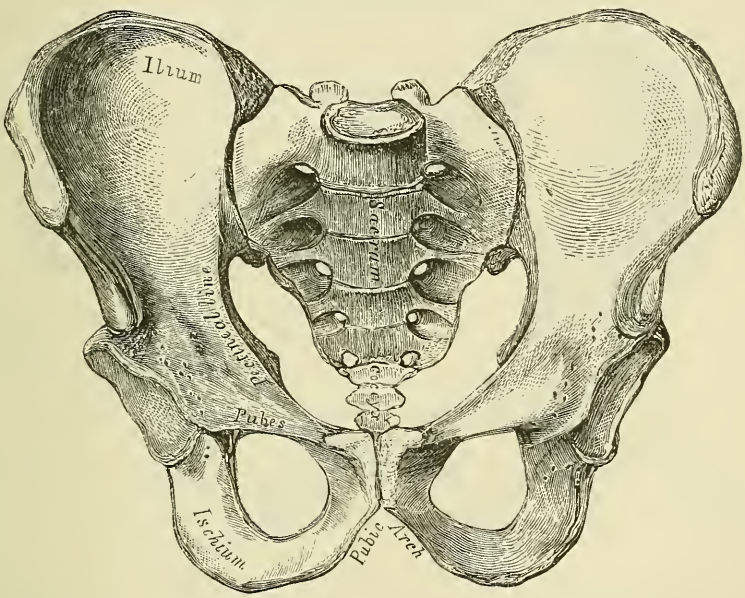
Attachment of Muscles.—To the *ilium*, sixteen. To the outer lip of the crest, the Tensor vaginæ femoris, Obliquus externus abdominis, and Latissimus dorsi; to the internal lip, the Iliacus, Transversalis, Quadratus lumborum, and Erector spinæ; to the interspace between the lips, the Obliquus internus. To the outer surface of the ilium, the Gluteus maximus, Gluteus medius, Gluteus minimus, reflected tendon of the Rectus; to the upper part of the great sacro-sciatic notch a portion of the Pyriformis; to the internal surface, the Iliacus; to that portion of the internal surface below the linea ilio-pectinea, the Obturator internus; and the Multifidus spinæ to the internal surface of the posterior superior spine; to the anterior border, the Sartorius and straight tendon of the Rectus. To the *ischium*, thirteen. To the outer surface of the ramus, the Obturator externus and Adductor magnus; to the internal surface, the Obturator internus and

Erector penis. To the spine, the Gemellus superior, Levator ani, and Coccygeus. To the tuberosity, the Biceps, Semi-tendinosus, Semi-membranosus, Quadratus femoris, Adductor magnus, Gemellus inferior, Transversus perinæi, Erector penis. To the *os pubis*, sixteen: Obliquus externus, Obliquus internus, Transversalis, Rectus, Pyramidalis, Psoas parvus, Pectineus, Adductor magnus, Adductor longus, Adductor brevis, Gracilis, Obturator externus and internus, Levator ani, Compressor urethræ, and occasionally a few fibres of the Accelerator urinæ.

The Pelvis (figs. 234, 235)

The **Pelvis,** so called from its resemblance to a basin (L. *pelvis*), is stronger and more massively constructed than either the cranial or thoracic cavity; it is a bony ring, interposed between the lower end of the spine, which it supports, and the lower extremities, upon which it rests. It is composed of four bones: the two ossa innominata, which bound it on either side and in front; and the sacrum and coccyx, which complete it behind.

Fig. 234.—Male pelvis (adult).



The pelvis is divided by a plane passing through the prominence of the sacrum, the linea ilio-pectinea, and the upper margin of the symphysis pubis, into the false and true pelvis.

The **false pelvis** is all that expanded portion of the pelvic cavity which is situated above this plane. It is bounded on each side by the ossa ilii; in front it is incomplete, presenting a wide interval between the spinous processes of the ilia on either side, which is filled up in the recent state by the parietes of the abdomen; behind, in the middle line, is a deep notch. This broad, shallow cavity is fitted to support the intestines, and to transmit part of their weight to the anterior wall of the abdomen, and is, in fact, really a portion of the abdominal cavity. The term false pelvis is incorrect, and this space ought more properly to be regarded as part of the hypogastric region of the abdomen.

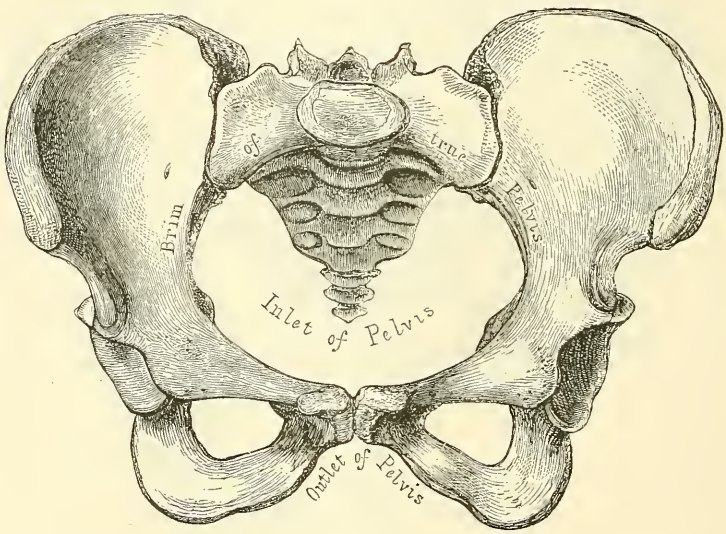
The **true pelvis** is all that part of the pelvic cavity which is situated beneath the plane. It is smaller than the false pelvis, but its walls are more perfect. For convenience of description, it is divided into a superior circumference or inlet, an inferior circumference or outlet, and a cavity.

The **superior circumference** forms the margin or brim of the pelvis, the

included space being called the *inlet*. It is formed by the linea ilio-pectinea, completed in front by the crests of the pubic bones, and behind by the anterior margin of the base of the sacrum and sacro-vertebral angle. The *inlet* of the pelvis is somewhat heart-shaped, obtusely pointed in front, diverging on either side, and encroached upon behind by the projection forwards of the promontory of the sacrum. It has three principal diameters: antero-posterior (sacro-pubic), transverse, and oblique. The antero-posterior extends from the sacro-vertebral angle to the symphysis pubis; its average measurement is four inches in the male, four and three-quarters in the female. The transverse extends across the greatest width of the inlet, from the middle of the brim on one side to the same point on the opposite; its average measurement is four and a half in the male, five and a quarter in the female. The oblique extends from the margin of the pelvis, corresponding to the ilio-pectineal eminence on one side, to the sacro-iliac symphysis on the opposite side; its average measurement is four and a quarter in the male, and five in the female.

The **cavity** of the true pelvis is bounded in front by the symphysis pubis; behind, by the concavity of the sacrum and coccyx, which, curving forwards

Fig. 235.—Female pelvis (adult).



above and below, contracts the inlet and outlet of the canal; and laterally it is bounded by a broad, smooth, quadrangular surface of bone, corresponding to the inner surface of the body of the ischium and that part of the ilium which is below the ilio-pectineal line. The cavity is shallow in front, measuring at the symphysis an inch and a half in depth, three inches and a half in the middle, and four inches and a half posteriorly. From this description, it will be seen that the cavity of the pelvis is a short, curved canal, considerably deeper on its posterior than on its anterior wall, and broader in the middle than at either extremity, from the projection forwards of the sacro-coccygeal column above and below. This cavity contains, in the recent subject, the rectum, bladder, and part of the organs of generation. The rectum is placed at the back of the pelvis, and corresponds to the curve of the sacro-coccygeal column; the bladder in front, behind the symphysis pubis. In the female, the uterus and vagina occupy the interval between these parts.

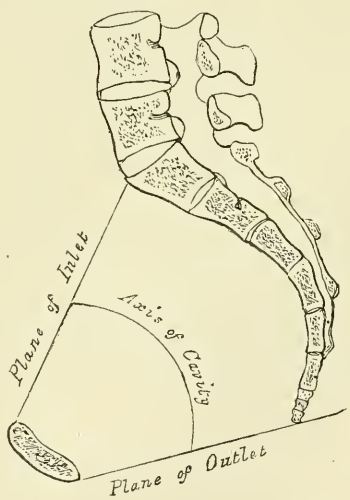
The **lower circumference** of the pelvis is very irregular, and forms what is called the *outlet*. It is bounded by three prominent eminences: one posterior, formed by the point of the coccyx; and one on each side, the tuberosities of the ischia. These eminences are separated by three notches: one in front, the *pubic arch*, formed by the convergence of the rami of the ischia and pubic bones on

each side. The other notches, one on each side, are formed by the sacrum and coccyx behind, the ischium in front, and the ilium above: they are called the *sacro-sciatic notches*; in the natural state they are converted into foramina by the lesser and greater sacro-sciatic ligaments. In the recent state, when the ligaments are *in situ*, the outlet of the pelvis is lozenge-shaped, bounded, in front, by the subpubic ligament and the rami of the ossa pubes and ischia; on each side, by the tuberosities of the ischia; and behind, by the great sacro-sciatic ligaments and the tip of the coccyx.

The diameters of the outlet of the pelvis are two, antero-posterior and transverse. The *antero-posterior* extends from the tip of the coccyx to the lower part of the symphysis pubis; its average measurement is three and a quarter inches in the male and five in the female. The antero-posterior diameter varies with the length of the coccyx, and is capable of increase or diminution, on account of the mobility of that bone. The *transverse* extends from the posterior part of one ischiatic tuberosity to the same point on the opposite side; the average measurement is three and a half inches in the male and four and three-quarters in the female.*

Position of the Pelvis.—In the erect posture, the pelvis is placed obliquely with regard to the trunk of the body: the bony ring, which separates the true from the false pelvis, and which forms the essential part of the pelvis, is placed so as to form an angle of about 60° to 65° with the ground on which we stand. The pelvic surface of the symphysis pubis looks upwards and backwards, the concavity of the sacrum and coccyx downwards and forwards; the base of the sacrum in well-formed female bodies being nearly four inches above the upper border of the symphysis pubis, and the apex of the coccyx a little more than half an inch above its lower border. The obliquity is much greater in the fœtus, and at an early period of life, than in the adult. In consequence of this obliquity of the pelvis, the line of gravity of the head, which passes through the middle of the odontoid process of the axis and through the points of junction of the curves of the vertebral column to the sacro-vertebral angle, descends towards the front of the cavity, so that it bisects a line drawn transversely through the middle of the heads of the thigh-bones. And thus the centre of gravity of the head is placed immediately over the heads of the thigh-bones on which the trunk is supported.

FIG. 236.—Vertical section of the pelvis, with lines indicating the axes of the pelvis.



Axes of the Pelvis (fig. 236).—The plane of the inlet of the true pelvis will be represented by a line drawn from the base of the sacrum to the upper margin of the symphysis pubis. A line carried at right angles with this at its middle, would correspond at one extremity with the umbilicus, and at the other with the middle of the coccyx: the axis of the inlet is therefore directed downwards and

* The measurements of the pelvis given above are, I believe, fairly accurate, but different measurements are given by various authors, no doubt due in a great measure to differences in the physique and stature of the population from whom the measurements have been taken. The accompanying chart has been formulated to show the measurements of the pelvis, which are adopted by many obstetricians.—ED.

	A.P.	Obl.	Tr.
Inlet	4	4½	5
Cavity	4½	4½	4½
Outlet	5	4½	4

backwards. The axis of the outlet, produced upwards, would touch the base of the sacrum, and is therefore directed downwards and forwards. The axis of the cavity is curved like the cavity itself: this curve corresponds to the concavity of the sacrum and coccyx, the extremities being indicated by the central points of the inlet and outlet. A knowledge of the direction of these axes serves to explain the course of the fœtus in its passage through the pelvis during parturition. It is also important to the surgeon, as indicating the direction of the force required in the removal of calculi from the bladder, and as determining the direction in which instruments should be used in operations upon the pelvic viscera.

Differences between the Male and Female Pelvis.—The *female* pelvis, looked at as a whole, is distinguished from the *male* by the bones being more delicate, by its width being greater and its depth smaller. The whole pelvis is less massive, and its bones are lighter and more slender, and its muscular impressions are slightly marked. The iliac fossæ are broad and expanded, and the anterior iliac spines widely separated; hence the greater prominence of the hips. The *inlet* in the female is larger than in the male; it is more nearly circular, and the sacro-vertebral angle projects less forwards. The *cavity* is shallower and wider; the sacrum is shorter and wider, and its lower half forms a greater angle with its upper; the obturator foramina are triangular and smaller in size than in the male. The *outlet* is larger and the coccyx more movable. The spines of the ischia project less inwards. The tuberosities of the ischia and the acetabula are wider apart. The *pubic arch* is wider and more rounded than in the male, where it is an angle rather than an arch; its pillars are somewhat excavated, and sloped from within outwards, so that their inner surfaces look forwards. In consequence of this the width of the fore part of the pelvic outlet is much increased and the passage of the fœtal head facilitated.

The size of the pelvis varies, not only in the two sexes, but also in different members of the same sex. This does not appear to be influenced in any way by the height of the individual. Women of short stature, as a rule, have broad pelves. Occasionally the pelvis is equally contracted in all its dimensions, so much so that all its diameters measure an inch less than the average, and this even in women of average height and otherwise well formed. The principal divergences, however, are found at the inlet, and affect the relation of the antero-posterior to the transverse diameter. Thus we may have a pelvis the inlet of which is elliptical either in a transverse or antero-posterior direction; the transverse diameter in the former, and the antero-posterior in the latter, greatly exceeding the other diameters. Again, the inlet of the pelvis in some instances is seen to be almost circular.

The same differences are found in various races. European women are said to have the most roomy pelves. That of the negress is smaller, circular in shape, and with a narrow pubic arch. The Hottentots and Bushwomen possess the smallest pelves.

In the *fœtus*, and for several years after birth, the pelvis is small in proportion to that of the adult. The cavity is deep, and the projection of the sacro-vertebral angle less marked. The antero-posterior and transverse diameters are nearly equal. *About puberty*, the pelvis in both sexes presents the general characters of the adult male pelvis; but *after puberty* it acquires its proper sexual characters.

Surface Form.—The pelvic bones are so thickly covered with muscles that it is only at certain points that they approach the surface and can be felt through the skin. In front, the anterior superior spinous process is easily to be recognised; a portion of it is subcutaneous, and in thin subjects may be seen to stand out as a prominence at the outer extremity of the fold of the groin. In fat subjects its position is marked by an oblique depression amongst the surrounding fat, at the bottom of which the bony process may be felt. Proceeding upwards and outwards from this process, the crest of the ilium may be traced throughout its whole length, sinuously curved. It is represented, in muscular subjects, on the surface, by a groove or furrow, the *iliac furrow*, caused by the projection of fleshy fibres of the External oblique muscle of the abdomen. It terminates behind in

the posterior superior spinous process, the position of which is indicated by a slight depression on a level with and on each side of the spinous process of the second sacral vertebra. Between the two posterior superior spinous processes, but at a lower level, is to be felt the spinous process of the third sacral vertebra (see page 140). Another part of the bony pelvis which is easily accessible to the touch is the tuberosity of the ischium, situated beneath the gluteal fold, and, when the hip is flexed, easily to be felt, as it is then to a great extent uncovered by muscle. Finally, the spine of the os pubis can always be readily felt, and constitutes an important surgical guide, especially in connection with the subject of hernia. It is nearly in the same horizontal line with the upper edge of the great trochanter. In thin subjects it is very apparent, but in the obese it is obscured by the pubic fat. It can, however, be detected by following up the tendon of origin of the Adductor longus muscle.

Surgical Anatomy.—There is arrest of development in the bones of the pelvis in cases of extroversion of the bladder; the anterior part of the pelvic girdle being deficient, the bodies of the pubic bones imperfectly developed, and the symphysis absent. 'The pubic bones are separated to the extent of from two to four inches, the superior rami shortened and directed forwards, and the obturator foramen diminished in size, narrowed, and turned outwards. The iliac bones are straightened out more than normal. The sacrum is very peculiar. The lateral curve, instead of being concave, is flattened out or even convex, with the ilio-sacral facets turned more outward than normal, while the vertical curve is straightened.' *

Fractures of the pelvis are divided into fractures of the false pelvis and of the true pelvis. Fractures of the false pelvis vary in extent; a small portion of the crest may be broken, or one of the spinous processes may be torn off, and this may be the result of muscular action; or the bone may be extensively comminuted. This latter accident is the result of some crushing violence, and may be complicated with fracture of the true pelvis. These cases may be accompanied by injury to the intestine as it lies in the hollow of the bone, or to the iliac vessels as they course along the margin of the true pelvis. Fractures of the true pelvis generally occur through the ascending ramus of the os pubis and the ascending ramus of the ischium, as this is the weakest part of the bony ring, and may be caused either by crushing violence applied in an antero-posterior direction, when the fracture occurs from direct force, or by compression laterally, when the acetabula are pressed together and the bone gives way in the same place from indirect violence. Occasionally the fracture may be double, occurring on both sides of the body. It is in these cases that injury to the contained viscera is liable to take place, the urethra, the bladder, the rectum, the vagina in the female, the small intestines, and even the uterus, have all been lacerated by a displaced fragment. Fractures of the acetabulum are occasionally met with: either a portion of the rim may be broken off, or a fracture may take place through the bottom of the cavity and the head of the femur driven inwards and project into the pelvic cavity. Separation of the Y-shaped cartilage at the bottom of the acetabulum may also occur in the young subject, separating the bone into its three anatomical portions.

The sacrum is occasionally, but rarely, broken by direct violence—i.e. blows, kicks, or falls on the part. The lesion may be complicated with injury to the nerves of the sacral plexus, leading to paralysis and loss of sensation in the lower extremity, or to incontinence of fæces from paralysis of the sphincter ani.

The pelvic bones often undergo important deformity in rickets, the effect of which in the adult woman may interfere seriously with child-bearing. In consequence of the yielding nature of the bones, the acetabula become approximated, the symphysis is pushed forward, and the antero-posterior diameter lessened. In osteo-malacia also great deformity may occur, the pelvis becoming beak-shaped. The promontory of the sacrum is pushed forward by the weight of the body, and the sides of the pelvis are approximated by the pressure of the two thigh-bones: this gives to the pelvis the peculiar deformity which is characteristic of this disease.

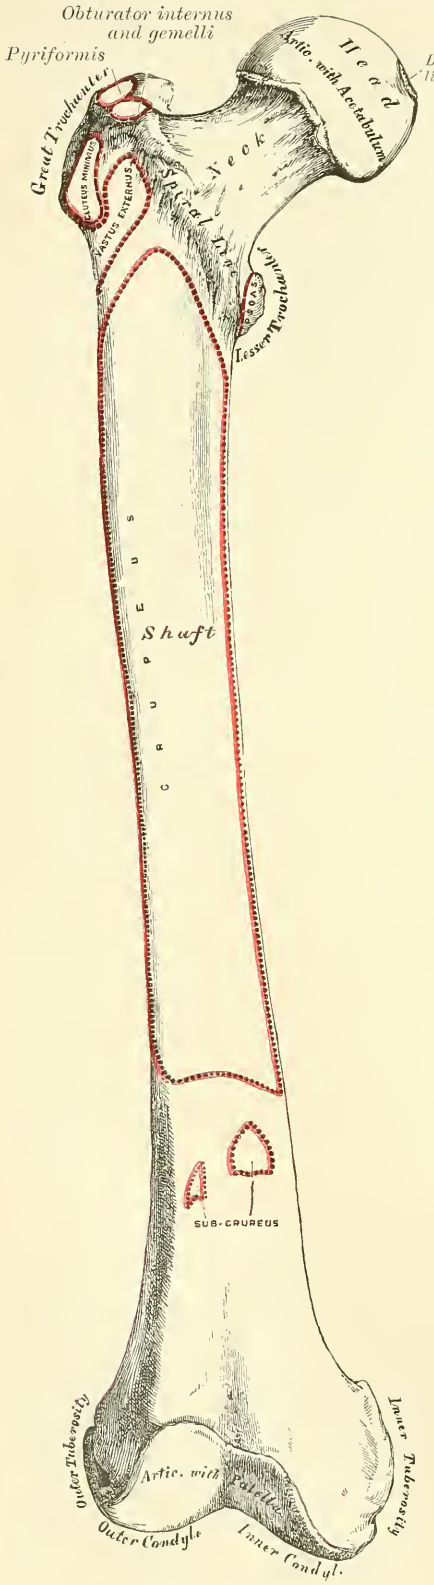
The Femur or Thigh-bone

The **Femur** (femur, *the thigh*) is the longest,† largest, and strongest bone in the skeleton, and almost perfectly cylindrical in the greater part of its extent. In the erect posture it is not vertical, being separated from its fellow above by a considerable interval, which corresponds to the entire breadth of the pelvis, but inclining gradually downwards and inwards, so as to approach its fellow towards its lower part, for the purpose of bringing the knee-joint near the line of gravity of the body. The degree of this inclination varies in different persons, and is greater in the female than the male, on account of the greater breadth of the pelvis. The femur, like other long bones, is divisible into a shaft and two extremities.

* Wood. Heath's *Dictionary of Practical Surgery*, i. 426.

† In a man six feet high, it measures eighteen inches—one-fourth of the whole body.

Fig. 237.—Right femur. Anterior surface.



The **Upper Extremity** presents for examination a head, a neck, and the great and lesser trochanters.

The **head**, which is globular, and forms rather more than a hemisphere, is directed upwards, inwards, and a little forwards, the greater part of its convexity being above and in front. Its surface is smooth, coated with cartilage in the recent state, except at a little behind and below its centre, where there is an ovoid depression, for the attachment of the ligamentum teres. The **neck** is a flattened pyramidal process of bone, which connects the head with the shaft. It varies in length and obliquity at various periods of life, and under different circumstances. The angle is widest in infancy, and becomes lessened during growth, so that at puberty it forms a gentle curve from the axis of the shaft. In the adult it forms an angle of about 130° with the shaft, but varies in inverse proportion to the development of the pelvis and the stature. In consequence of the prominence of the hips and widening of the pelvis in the female, the neck of the thigh-bone forms more nearly a right angle with the shaft than it does in man. It has been stated that the angle diminishes in old age and the direction of the neck becomes horizontal, but this statement is founded on insufficient evidence. Sir George Humphry states that the angle decreases during the period of growth, but after full growth has been attained it does not usually undergo any change, even in old age. He further states that the angle varies considerably in different persons of the same age. It is smaller in short than in long bones, and when the pelvis is wide.* The neck is flattened from before backwards, contracted in the middle, and broader at its outer extremity, where it is connected with the shaft, than at its summit, where it is attached to the head. The vertical diameter of the outer half is increased by the thickening of the lower edge, which slopes downwards to join the shaft at the lesser trochanter, so that the outer half of the neck is flattened from before backwards, and its vertical diameter

* *Journal of Anatomy and Physiology.*

measures one third more than the antero-posterior. The inner half is smaller, and of a more circular shape. The *anterior surface* of the neck is perforated by numerous vascular foramina. The *posterior surface* is smooth, and is broader and more concave than the anterior; it gives attachment to the posterior part of the capsular ligament of the hip-joint, about half an inch above the posterior intertrochanteric line. The *superior border* is short and thick, and terminates externally at the great trochanter; its surface is perforated by large foramina. The *inferior border*, long and narrow, curves a little backwards, to terminate at the lesser trochanter.

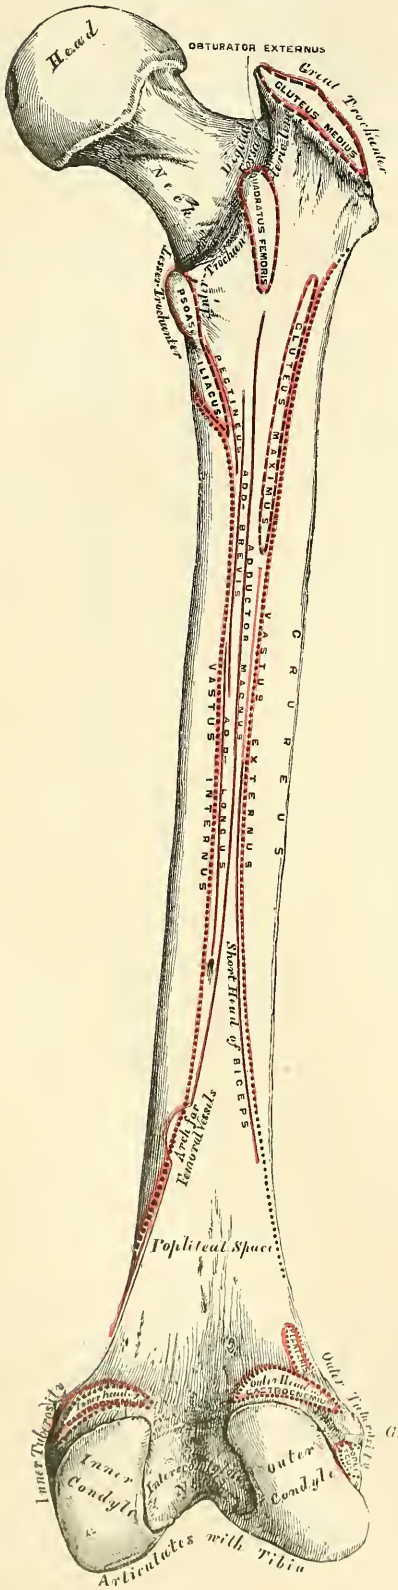
The **Trochanters** (τροχάω, *to run* or *roll*) are prominent processes of bone which afford leverage to the muscles which rotate the thigh on its axis. They are two in number, the great and the lesser.

The **Great Trochanter** is a large, irregular, quadrilateral eminence, situated at the outer side of the neck, at its junction with the upper part of the shaft. It is directed a little outwards and backwards, and, in the adult, is about three-quarters of an inch lower than the head. It presents for examination two surfaces and four borders. The *external surface*, quadrilateral in form, is broad, rough, convex, and marked by a prominent diagonal line, which extends from the posterior superior to the anterior inferior angle; this line serves for the attachment of the tendon of the Gluteus medius. Above the line is a triangular surface, sometimes rough for part of the tendon of the same muscle, sometimes smooth for the interposition of a bursa between that tendon and the bone. Below and behind the diagonal line is a smooth, triangular surface, over which the tendon of the Gluteus maximus muscle plays, a bursa being interposed. The *internal surface* is of much less extent than the external, and presents at its base a deep depression, the *digital* or *trochanteric fossa*, for the attachment of the tendon of the Obturator externus muscle, and in front of this an impression for the attachment of the Obturator internus and Gemelli. The *superior border* is free; it is thick and irregular, and marked near the centre by an impression for the attachment of the Pyriformis. The *inferior border* corresponds to the point of junction of the base of the trochanter with the outer surface of the shaft; it is marked by a rough, prominent, slightly curved ridge, which gives attachment to the upper part of the Vastus externus muscle. The *anterior border* is prominent, somewhat irregular, as well as the surface of bone immediately below it; it affords attachment at its outer part to the Gluteus minimus. The *posterior border* is very prominent, and appears as a free, rounded edge, which forms the back part of the digital fossa.

The **Lesser Trochanter** is a conical eminence, which varies in size in different subjects; it projects from the lower and back part of the base of the neck. Its base is triangular, and connected with the adjacent parts of the bone by three well-marked borders: two of these are above—the *internal* continuous with the lower border of the neck, the *external* with the posterior intertrochanteric line—while the *inferior border* is continuous with the middle division of the linea aspera. Its summit, which is directed inwards and backwards, is rough, and gives insertion to the tendon of the Psoas magnus. The Iliacus is inserted into the shaft below the lesser trochanter, between the Vastus internus in front and the Pectineus behind.

A well-marked prominence, of variable size, which projects from the upper and front part of the neck, at its junction with the great trochanter, is called the *tubercle of the femur*; it is the point of meeting of five muscles: the Gluteus minimus externally, the Vastus externus below, and the tendon of the Obturator internus and Gemelli above. Running obliquely downwards and inwards from the tubercle is the *spiral line* of the femur, or *anterior intertrochanteric line*; it winds round the inner side of the shaft, below the lesser trochanter, and terminates in the linea aspera, about two inches below this eminence. Its upper half is rough, and affords attachment to the capsular ligament of the hip-joint; its lower half is less prominent, and gives attachment to the upper part of the Vastus internus. Running obliquely downwards and inwards from the summit

Fig. 238.—Right femur. Posterior surface.



of the great trochanter on the posterior surface of the neck is a very prominent well-marked ridge, the *posterior intertrochanteric line*. Its upper half forms the posterior border of the great trochanter, and its lower half runs downwards and inwards across the neck of the bone to the upper and back part of the lesser trochanter. A slight ridge sometimes commences about the middle of the posterior intertrochanteric line, and passes vertically downwards for about two inches along the back part of the shaft: it is called the *linea quadrata*, and gives attachment to the Quadratus femoris and a few fibres of the Adductor magnus muscles.*

The **Shaft**, almost cylindrical in form, is a little broader above than in the centre, and somewhat flattened below, from before backwards. It is slightly arched, so as to be convex in front and concave behind, where it is strengthened by a prominent longitudinal ridge, the *linea aspera*. It presents for examination three borders, separating three surfaces. Of the three borders, one, the linea aspera, is posterior; the other two are placed laterally.

The **linea aspera** (fig. 238) is a prominent longitudinal ridge or crest, on the middle third of the bone, presenting an external lip, an internal lip, and a rough intermediate space. Above, the crest is prolonged by three ridges. The most external one is very rough, and is continued almost vertically upwards to the base of the great trochanter. It is sometimes termed the *gluteal ridge*, and gives attachment to part of the Gluteus maximus muscle: its upper part is often elongated into a roughened crest, on which is a more or less well-marked, rounded tubercle, a rudimental third trochanter. The middle ridge, the least distinct, is continued to the base of the trochanter minor; and the internal one is lost above in the spiral line of the femur. Below, the linea aspera is prolonged by two ridges, which enclose between them a triangular

* Generally there is merely a slight thickening about the centre of the intertrochanteric line, marking the point of attachment of the Quadratus femoris. This is termed by some anatomists the *tubercle of the Quadratus*.

space, the *popliteal surface*, upon which rests the popliteal artery. Of these two ridges, the outer one is the more prominent, and descends to the summit of the outer condyle. The inner one is less marked, especially at its upper part, where it is crossed by the femoral artery. It terminates, below, at the summit of the internal condyle, in a small tubercle, the *Adductor tubercle*, which affords attachment to the tendon of the Adductor magnus.

To the inner lip of the linea aspera and its inner prolongation above and below is attached the Vastus internus; and to the outer lip and its outer prolongation above is attached the Vastus externus. The Adductor magnus is attached to the linea aspera, to its outer prolongation above, and its inner prolongation below. Between the Vastus externus and the Adductor magnus are attached two muscles—viz. the Gluteus maximus above and the short head of the Biceps below. Between the Adductor magnus and the Vastus internus four muscles are attached: the Iliacus and Pectineus above (the latter to the middle of the upper divisions); below these, the Adductor brevis and Adductor longus. The linea aspera is perforated a little below its centre by the nutrient canal, which is directed obliquely upwards.

The two *lateral borders* of the femur are only slightly marked, the outer one extending from the anterior inferior angle of the great trochanter to the anterior extremity of the external condyle; the inner one from the spiral line, at a point opposite the trochanter minor, to the anterior extremity of the internal condyle. The internal border marks the limit of attachment of the Crureus muscle internally.

The **anterior surface** includes that portion of the shaft which is situated between the two lateral borders. It is smooth, convex, broader above and below than in the centre, slightly twisted, so that its upper part is directed forwards and a little outwards, its lower part forwards and a little inwards. To the upper three-fourths of this surface the Crureus is attached; the lower fourth is separated from the muscle by the intervention of the synovial membrane of the knee-joint and a bursa, and affords attachment to the Subcrureus to a small extent. The *external surface* includes the portion of bone between the external border and the outer lip of the linea aspera; it is continuous above with the outer surface of the great trochanter, below with the outer surface of the external condyle: to its upper three-fourths is attached the outer portion of the Crureus muscle. The *internal surface* includes the portion of bone between the internal border and the inner lip of the linea aspera; it is continuous above with the lower border of the neck, below with the inner side of the internal condyle: it is covered by the Vastus internus muscle.

The **Lower Extremity**, larger than the upper, is of a cuboid form, flattened from before backwards, and divided into two large eminences, the *condyles* (κόνδυλος, *a knuckle*), by an interval which presents a smooth depression in front called the *trochlea*, and a notch of considerable size behind—the *intercondyloid notch*. The *external condyle* is the more prominent anteriorly, and is the broader both in the antero-posterior and transverse diameters. The *internal condyle* is the narrower, longer, and more prominent inferiorly. This difference in the length of the two condyles is only observed when the bone is perpendicular, and depends upon the obliquity of the thigh-bones, in consequence of their separation above at the articulation with the pelvis. If the femur is held obliquely, the surfaces of the two condyles will be seen to be nearly horizontal. The two condyles are directly continuous in front, and form a smooth trochlear surface, which articulates with the patella. This surface presents a median groove, which extends downwards and backwards to the intercondyloid notch; and two lateral convexities, of which the external is the broader, more prominent, and prolonged farther upwards upon the front of the outer condyle. The external border of this articular surface is also more prominent, and ascends higher than the internal one. The intercondyloid notch lodges the crucial ligaments; it is bounded laterally by the opposed surfaces of the two condyles, and in front by the lower end of the shaft.

Outer Condyle.—The *outer surface* of the external condyle presents, a little behind its centre, an eminence, the *outer tuberosity*; it is less prominent than the inner tuberosity, and gives attachment to the external lateral ligaments of the knee. Immediately beneath it is a groove which commences at a depression a little behind the centre of the lower border of this surface: the front part of this depression gives origin to the Popliteus muscle, the tendon of which is lodged in the groove during flexion of the knee. The groove is smooth, covered with cartilage in the recent state, and runs upwards and backwards to the posterior extremity of the condyle. The *inner surface* of the outer condyle forms one of the lateral boundaries of the intercondyloid notch, and gives attachment, by its posterior part, to the anterior crucial ligament. The *inferior surface* is convex, smooth, and broader than that of the internal condyle. The posterior extremity is convex and smooth: just above the articular surface is a depression for the tendon of the outer head of the Gastrocnemius, above which is the origin of the Plantaris.

Inner Condyle.—The *inner surface* of the inner condyle presents a convex eminence, the *inner tuberosity*, rough, for the attachment of the internal lateral ligament. The *outer side* of the inner condyle forms one of the lateral boundaries of the intercondyloid notch, and gives attachment, by its anterior part, to the posterior crucial ligament. Its *inferior* or *articular surface* is convex, and presents a less extensive surface than the external condyle. Just above the articular surface of the condyle, behind, is a depression for the tendon of origin of the inner head of the Gastrocnemius.

Structure.—The shaft of the femur is a cylinder of compact tissue, hollowed by a large medullary canal. The cylinder is of great thickness and density in the middle third of the shaft, where the bone is narrowest and the medullary canal well formed; but above and below this the cylinder gradually becomes thinner, owing to a separation of the layers of the bone into cancelli, which project into the medullary canal and finally obliterate it, so that the upper and lower ends of the shaft, and the articular extremities more especially, consist of cancellated tissue, invested by a thin compact layer.

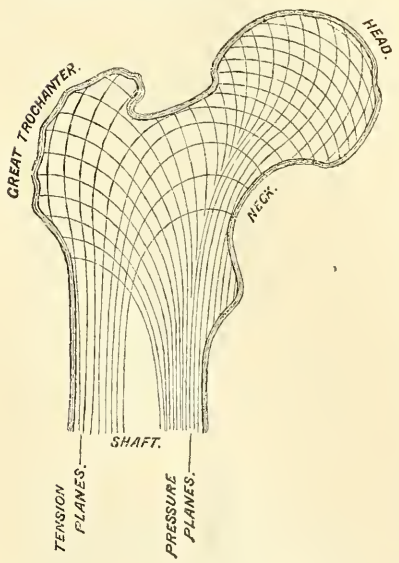


Fig. 239.—Diagram showing the arrangement of the cancelli of the neck of the femur.

The arrangement of the cancelli in the ends of the femur is remarkable. In the upper end they are arranged in two sets. One, starting from the top of the head, the upper surface of the neck, and the great trochanter, converge to the inner circumference of the shaft (fig. 239); these are placed in the direction of greatest pressure, and serve to support the vertical weight of the body. The second set are planes of lamellæ intersecting the former nearly at right angles, and are situated in the line of the greatest tension—that is to say, along the lines in which the muscles and ligaments exert their traction. In the head of the bone these planes are arranged in a curved form, in order to strengthen the bone when exposed to pressure in all directions. In the midst of the cancellous tissue of the neck is a vertical plane of compact bone, the *femoral spur* (*calcar femorale*) which commences at the point where the neck joins the shaft midway between the lesser trochanter and the internal border of the shaft of the bone, and extends in the direction of the digital fossa (fig. 240). This materially strengthens this portion of the bone. Another point in connection with the structure of the neck

of the femur requires mention, especially on account of its influence on the production of fracture in this situation. It will be noticed that a considerable portion of the great trochanter lies behind the level of the posterior surface of the neck; and if a section be made through the trochanter at this level, it will be seen that the posterior wall of the neck is prolonged into the trochanter. This prolongation is termed by Bigelow the 'true neck,' * and forms a thin, dense plate of bone, which passes beneath the posterior intertrochanteric ridge towards the outer surface of the bone.

In the lower end, the cancelli spring on all sides from the inner surface of the cylinder, and descend in a perpendicular direction to the articular surface, the cancelli being strongest and having a more accurately perpendicular course above the condyles. In addition to this, however, horizontal planes of cancellous tissue are to be seen, so that the spongy tissue in this situation presents an appearance of being mapped out into a series of rectangular areas.

Fig. 240.—Calcar femorale.

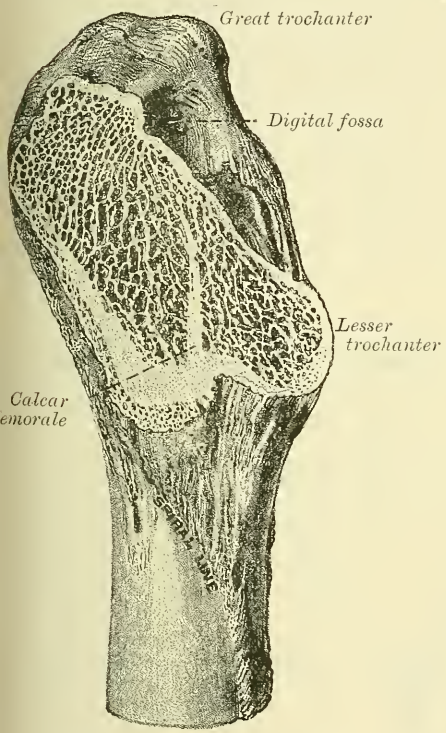

Fig. 241.—Plan of the development of the femur. By five centres.

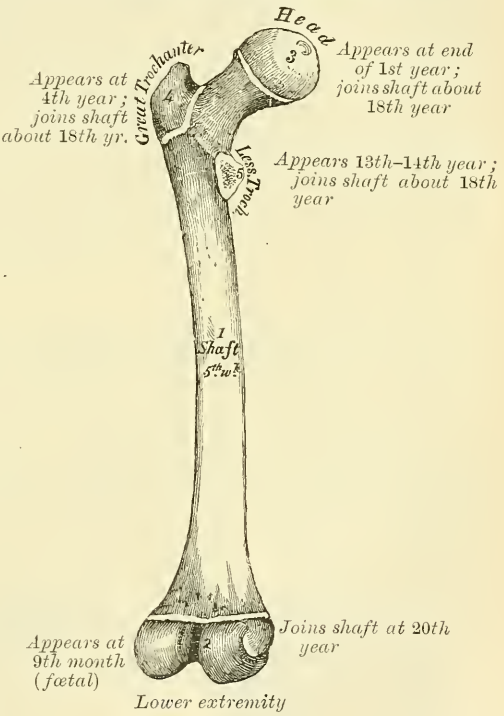


Articulations.—With three bones: the os innominatum, tibia, and patella.

Development (fig. 241).—The femur is developed by *five* centres: one for the shaft, one for each extremity, and one for each trochanter. Of all the long bones, except the clavicle, it is the first to show traces of ossification; this commences in the shaft, at about the fifth week of fœtal life, the centres of ossification in the epiphyses appearing in the following order: First, in the lower end of the bone, at the ninth month of fœtal life † (from this the condyles and tuberosities are formed); in the head at the end of the first year after birth; in the great trochanter, during the fourth year; and in the lesser trochanter, between the thirteenth and fourteenth. The order in which the epiphyses are joined to the shaft is the reverse of that of their appearance: their junction does not commence

* *Bigelow on the Hip*, p. 121.

† This is the only epiphysis in which ossification begins before birth.

until after puberty, the lesser trochanter being first joined, then the great, then the head, and, lastly, the inferior extremity (the first in which ossification commenced), which is not united until the twentieth year.

Attachment of Muscles.—To twenty-three. To the great trochanter: the Gluteus medius, Gluteus minimus, Pyriformis, Obturator internus, Obturator externus, Gemellus superior, Gemellus inferior, and Quadratus femoris. To the lesser trochanter: the Psoas magnus and the Iliacus below it. To the shaft: the Vastus externus, Gluteus maximus, short head of the Biceps, Vastus internus, Adductor magnus, Pectineus, Adductor brevis, Adductor longus, Crureus, and Subcrureus. To the condyles: the Gastrocnemius, Plantaris, and Popliteus.

Surface Form.—The femur is covered with muscles, so that in fairly muscular subjects the shaft is not to be detected through its fleshy covering, and the only parts accessible to the touch are the outer surface of the great trochanter and the lower expanded end of the bone. The external surface of the great trochanter is to be felt, especially in certain positions of the limb. Its position is generally indicated by a depression, owing to the thickness of the Gluteus medius and minimus, which project above it. When, however, the thigh is flexed, and especially if crossed over the opposite one, the trochanter produces a blunt eminence on the surface. The upper border is about on a line with the spine of the os pubis, and its exact level is indicated by a line drawn from the anterior superior spinous process of the ilium, over the outer side of the hip, to the most prominent point of the tuberosity of the ischium. This is known as Nélaton's line. The outer and inner condyles of the lower extremity are easily to be felt. The outer one is more subcutaneous than the inner one, and readily felt. The tuberosity on it is comparatively little developed, but can be more or less easily recognised. The inner condyle is more thickly covered, and this gives a general convex outline to this part, especially when the knee is flexed. The tuberosity on it is easily felt, and at the upper part of the condyle the sharp tubercle for the insertion of the tendon of the Adductor magnus can be recognised without difficulty. When the knee is flexed, and the patella situated in the interval between the condyles and the upper end of the tibia, a part of the trochlear surface of the femur can be made out above the patella.

Surgical Anatomy.—There are one or two points about the ossification of the femur bearing on practice to which allusion must be made. It has been stated above that the lower end of the femur is the only epiphysis in which ossification has commenced at the time of birth.* The presence of this ossific centre is, therefore, a proof, in newly-born children found dead, that the child has arrived at the full period of utero-gestation, and is always relied upon in medico-legal investigations. The position of the epiphysial line should be carefully noted. It is on a level with the adductor tubercle, and the epiphysis does not, therefore, form the whole of the cartilage-clad portion of the lower end of the bone. It is essential to bear this point in mind in performing excision of the knee, since growth in length of the femur takes place chiefly from the lower epiphysis, and any interference with the epiphysial cartilage in a young child would involve such ultimate shortening of the limb, from want of growth, as to render it almost useless. Separation of the lower epiphysis may take place up to the age of twenty, at which time it becomes completely joined to the shaft of the bone; but, as a matter of fact, few cases occur after the age of sixteen or seventeen. The upper epiphysis of the femur is of interest principally on account of its being the seat of origin of a large number of cases of tuberculous disease of the hip-joint. The disease commences in the majority of cases in the highly vascular and growing tissue in the neighbourhood of the epiphysis, and from here extends into the joint.

Fractures of the femur are divided, like those of the other long bones, into fractures of the upper end; of the shaft; and of the lower end. The fractures of the upper end may be classified into (1) fracture of the neck; (2) fracture at the junction of the neck with the great trochanter; (3) fracture of the great trochanter; and (4) separation of the epiphysis, either of the head or of the great trochanter. The first of these, fracture of the neck, is usually termed intracapsular fracture, but this is scarcely a correct designation, as, owing to the attachment of the capsular ligament, the fracture may be partly within and partly without the capsule when the fracture occurs at the lower part of the neck. It generally occurs in old people, principally women, and usually from a very slight degree of indirect violence. Probably the main cause of the fracture taking place in old people is in consequence of the degenerative changes which the bone has undergone. Merkel believes that it is mainly due to the absorption of the calcar femorale. These fractures are occasionally impacted. As a rule they unite by fibrous tissue, and frequently no union takes place, and the surfaces of the fracture become smooth and eburnated.

Fractures at the junction of the neck with the great trochanter are usually termed

* According to some observers the centre for the upper epiphysis of the tibia also appears before birth.

extra-capsular, but this designation is also incorrect, as the fracture is partly within the capsule, owing to its attachment in front to the anterior intertrochanteric line, which is situated below the line of fracture. These fractures are produced by direct violence to the great trochanter, as from a blow or fall laterally on the hip. From the manner in which the accident is caused, the neck of the bone is driven into the trochanter, where it may remain impacted, or the trochanter may be split up into two or more fragments, and thus no fixation takes place.

Fractures of the great trochanter may be either 'oblique fracture through the trochanter major, without implicating the neck of the bone' (Astley Cooper), or separation of the great trochanter. Most of the recorded cases of this latter injury occurred in young persons, and were probably cases of separation of the epiphysis of the great trochanter. Separation of the epiphysis of the head of the femur has been said to occur, but, as far as I know, has never been verified by post-mortem examination.

Fractures of the shaft may occur at any part, but the most usual situation is at or near the centre of the bone. They may be caused by direct or indirect violence or by muscular action. Fractures of the upper third of the shaft are almost always the result of indirect violence, whilst those of the lower third are the result, for the most part, of direct violence. In the middle third fractures occur from both forms of injury in about equal proportions. Fractures of the shaft are generally oblique, but they may be transverse, longitudinal, or spiral. The transverse fracture occurs most frequently in children. The fractures of the lower end of the femur include transverse fracture above the condyles, the most common; and this may be complicated by a vertical fracture between the condyles, constituting the T-shaped fracture. In these cases the popliteal artery is in danger of being wounded. Oblique fracture separating either the internal or external condyle, and a longitudinal incomplete fracture between the condyles, may also take place.

The femur as well as the other bones of the leg are frequently the seat of acute necrosis in young children. This is no doubt due to their greater exposure to injury, which is often the exciting cause of this disease. Tumours not unfrequently are found growing from the femur: the most common forms being sarcoma, which may grow either from the periosteum or from the medullary tissue within the interior of the bone; and exostosis, which is commonly found originating in the neighbourhood of the epiphysial cartilage of the lower end.

THE LEG

The skeleton of the Leg consists of three bones: the Patella, a large, sesamoid bone, placed in front of the knee; the Tibia; and the Fibula.

The Patella (figs. 242, 243)

The **Patella** (patella, *a small pan*) is a flat, triangular bone, situated at the anterior part of the knee-joint. It is usually regarded as a sesamoid bone, developed in the tendon of the Quadriceps extensor. It resembles these bones (1) in its being developed in a tendon; (2) in its centre of ossification presenting a knotty or tuberculated outline similar to other sesamoid bones; (3) in its structure being composed mainly of dense cancellous tissue, as in the other sesamoid bones. It serves to protect the front of the joint, and increases the leverage of the Quadriceps extensor by making it act at a greater angle. It presents an anterior and posterior surface, three borders, and an apex.

Fig. 242.—Right patella. Anterior surface.

Fig. 243.—Posterior surface.

The **anterior surface** is convex, perforated by small apertures, for the passage of nutrient vessels, and marked by numerous rough, longitudinal striæ. This surface is covered, in the recent state, by an expansion from the tendon of the Quadriceps extensor, which is continuous below with the superficial fibres of the ligamentum patella. It is separated from the integument by a bursa. The **posterior surface** presents a smooth, oval-shaped, articular surface, covered with

cartilage in the recent state, and divided into two facets by a vertical ridge, which descends from the superior border towards the inferior angle of the bone. The ridge corresponds to the groove on the trochlear surface of the femur, and the two facets to the articular surfaces of the two condyles; the outer facet, for articulation with the outer condyle, being the broader and deeper. This character serves to indicate the side to which the bone belongs. Below the articular surface is a rough, convex, non-articular depression, the lower half of which gives attachment to the ligamentum patellæ; the upper half being separated from the head of the tibia by adipose tissue.

The **superior border** is thick, and sloped from behind, downwards and forwards: it gives attachment to that portion of the Quadriceps extensor which is derived from the Rectus and Crureus muscles. The **lateral borders** are thinner, converging below. They give attachment to that portion of the Quadriceps extensor derived from the external and internal Vasti muscles.

The **apex** is pointed, and gives attachment to the ligamentum patellæ.

Structure.—It consists of a nearly uniform dense cancellous tissue, covered by a thin compact lamina. The cancelli immediately beneath the anterior surface are arranged parallel with it. In the rest of the bone they radiate from the posterior articular surface towards the other parts of the bone.

Development.—By a single centre, which makes its appearance, according to Béclard, about the third year. In two instances, I have seen this bone cartilaginous throughout, at a much later period (six years). More rarely, the bone is developed by two centres, placed side by side. Ossification is completed about the age of puberty.

Articulations.—With the two condyles of the femur.

Attachment of Muscles.—To four: the Rectus, Crureus, Vastus internus, and Vastus externus. These muscles, joined at their insertion, constitute the Quadriceps extensor cruris.

Surface Form.—The external surface of the patella can be seen and felt in front of the knee. In the extended position of the limb the internal border is a little more prominent than the outer, and if the Quadriceps extensor is relaxed, the bone can be moved from side to side and appears to be loosely fixed. If the joint is flexed, the patella recedes into the hollow between the condyles of the femur and the upper end of the tibia, and becomes firmly fixed against the femur.

Surgical Anatomy.—The main surgical interest about the patella is in connection with fractures, which are of common occurrence. They may be produced by muscular action, that is to say, by violent contraction of the Quadriceps extensor, while the limb is in a position of semi-flexion, so that the bone is snapped across the condyles; or by direct violence, such as falls on the knee. In the former class of cases the fracture is transverse; in the latter it may be oblique, longitudinal, stellate, or the bone variously comminuted. The principal interest in these cases attaches to their treatment. Owing to the wide separation of the fragments, and the difficulty there is in maintaining them in apposition, union takes place by fibrous tissue, and this may subsequently stretch, producing wide separation of the fragments and permanent lameness. Various plans, including opening the joint and suturing the fragments, have been advocated for overcoming this difficulty.

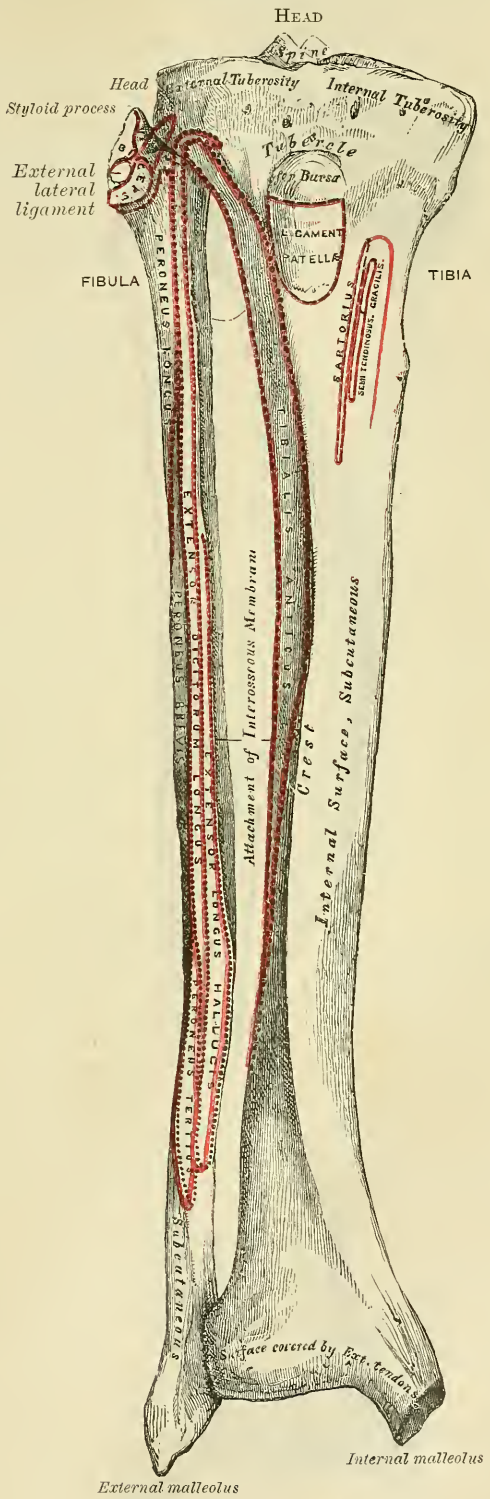
In the larger number of cases of fracture of the patella, the knee-joint is involved, the cartilage which covers its posterior surface being also torn. In some cases of fracture from direct violence, however, this need not necessarily happen, the lesion involving only the superficial part of the bone; and, as Morris has pointed out, it is an anatomical possibility, in complete fracture, if the lesion involve only the lower and non-articular part of the bone, for it to take place without injury to the synovial membrane.

The Tibia (figs. 244, 245)

The **Tibia** (tibia, *a flute* or *pipe*) is situated at the front and inner side of the leg, and, excepting the femur, is the longest and largest bone in the skeleton. It is prismoid in form, expanded above, where it enters into the knee-joint, more slightly enlarged below. In the male, its direction is vertical, and parallel with the bone of the opposite side; but in the female it has a slightly oblique direction downwards and outwards, to compensate for the oblique direction of the femur inwards. It presents for examination a shaft and two extremities.

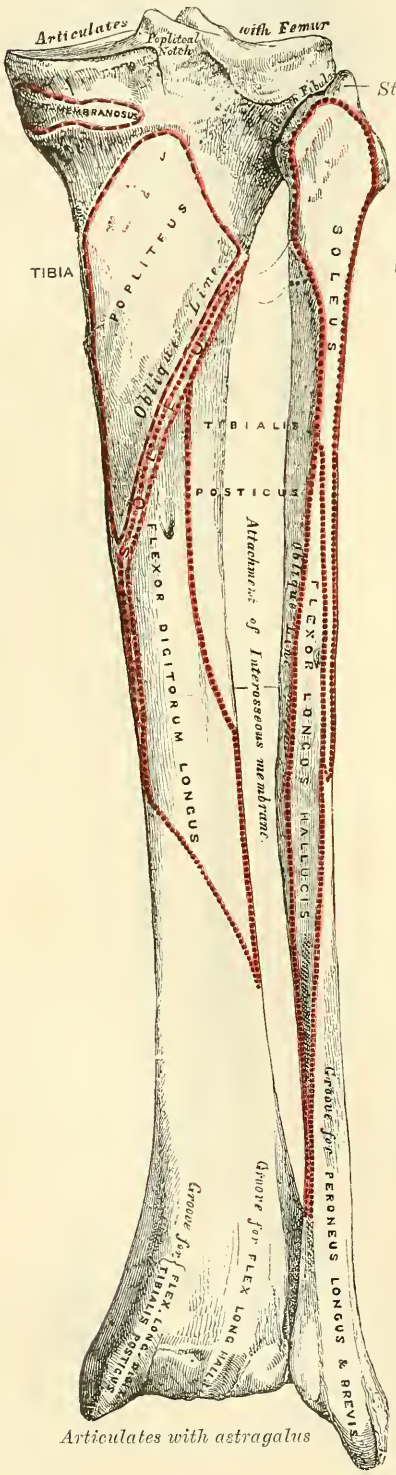
The **Upper Extremity**, or **Head**, is large, and expanded on each side into two lateral eminences, the *tuberosities*. *Superiorly*, the tuberosities present two smooth, concave surfaces, which articulate with the condyles of the femur; the internal articular surface is longer, deeper, and narrower than the external, oval from before backwards, to articulate with the internal condyle; the external one is broader, concave from side to side, but slightly convex from before backwards, and more circular, to articulate with the external condyle. Between the two articular surfaces, and nearer the posterior than the anterior aspect of the bone, is an eminence, the *spinous process* of the tibia, surmounted by a prominent tubercle on each side, which gives attachment to the extremities of the semilunar fibro-cartilages; in front and behind the spinous process is a rough depression for the attachment of the anterior and posterior crucial ligaments and the semilunar fibro-cartilages. The *anterior surfaces* of the tuberosities are continuous with one another, forming a single large surface, which is somewhat flattened: it is triangular, broad above, and perforated by large vascular foramina: narrow below where it terminates in a prominent oblong elevation of large size, the *tubercle* of the tibia; the lower half of this tubercle is rough, for the attachment of the ligamentum patellæ; the upper half presents a smooth facet supporting, in the recent state, a bursa which separates the ligament from the bone. *Posteriorly* the tuberosities are separated from each other by a shallow depression, the *popliteal notch*, which gives attachment to part of the posterior crucial ligament, and part of the posterior ligament of the knee-joint.

Fig. 244.—Bones of the right leg. Anterior surface.



The *inner tuberosity* presents posteriorly a deep transverse groove, for the insertion of one of the fasciculi of the tendon of the Semi-membranosus. Its *lateral surface* is convex, rough and prominent: it gives attachment to the internal lateral ligament. The *outer tuberosity* presents posteriorly a flat articular facet, nearly circular in form, directed downwards, backwards, and outwards, for articulation with the fibula. Its lateral surface is convex and rough, more prominent in front than the internal: it presents a prominent rough eminence, situated on a level with the upper border of the tubercle of the tibia at the junction of its anterior and outer surfaces, for the attachment of the ilio-tibial band. Just below this the Extensor longus digitorum and a slip from the Biceps are attached.

Fig. 245.—Bones of the right leg. Posterior surface.



The **Shaft** of the tibia is of a triangular prismoid form, broad above, gradually decreasing in size to its most slender part, at the commencement of its lower fourth, where fracture most frequently occurs. It then enlarges again towards its lower extremity. It presents for examination three borders and three surfaces.

The **anterior border**, the most prominent of the three, is called the *crest of the tibia*, or, in popular language, the *shin*; it commences above at the tubercle, and terminates below at the anterior margin of the inner malleolus. This border is very prominent in the upper two-thirds of its extent, smooth and rounded below. It presents a very flexuous course, being usually curved outwards above, and inwards below; it gives attachment to the deep fascia of the leg.

The **internal border** is smooth and rounded above and below, but more prominent in the centre; it commences at the back part of the inner

tuberosity, and terminates at the posterior border of the internal malleolus; its upper part gives attachment to the internal lateral ligament of the knee to the extent of about two inches, and to some fibres of the Popliteus muscle; its middle third, to some fibres of the Soleus and Flexor longus digitorum muscles.

The **external border**, or **interosseous ridge**, is thin and prominent, especially its central part, and gives attachment to the interosseous membrane; it commences above in front of the fibular articular facet, and bifurcates below, to form the boundaries of a triangular rough surface, for the attachment of the interosseous ligament connecting the tibia and fibula.

The **internal surface** is smooth, convex, and broader above than below; its upper third, directed forwards and inwards, is covered by the aponeurosis derived from the tendon of the Sartorius, and by the tendons of the Gracilis and Semitendinosus, all of which are inserted nearly as far forwards as the anterior border; in the rest of its extent it is subcutaneous.

The **external surface** is narrower than the internal; its upper two-thirds presents a shallow groove for the attachment of the Tibialis anticus muscle; its lower third is smooth, convex, curves gradually forwards to the anterior aspect of the bone, and is covered from within outwards by the tendons of the following muscles: Tibialis anticus, Extensor proprius hallucis, Extensor longus digitorum.

The **posterior surface** (fig. 245) presents, at its upper part, a prominent ridge, the *oblique line* of the tibia, which extends from the back part of the articular facet for the fibula obliquely downwards, to the internal border, at the junction of its upper and middle thirds. It marks the limit for the insertion of the Popliteus muscle, and serves for the attachment of the popliteal fascia and part of the Soleus, Flexor longus digitorum, and Tibialis posticus muscles; the triangular concave surface, above and to the inner side of this line, gives attachment to the Popliteus muscle. The middle third of the posterior surface is divided by a vertical ridge into two lateral halves: the ridge is well marked at its commencement at the oblique line, but becomes gradually indistinct below; the inner and broader half gives attachment to the Flexor longus digitorum, the outer and narrower to part of the Tibialis posticus. The remaining part of the bone presents a smooth surface covered by the Tibialis posticus, Flexor longus digitorum, and Flexor longus hallucis muscles. Immediately below the oblique line is the medullary foramen, which is directed obliquely downwards.

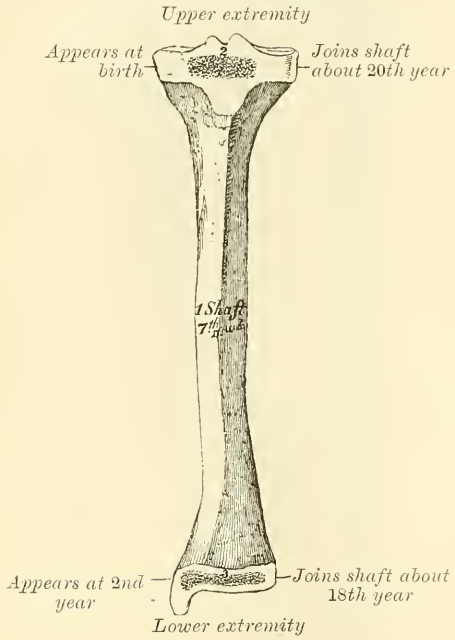
The **Lower Extremity**, much smaller than the upper, presents five surfaces; it is prolonged downwards, on its inner side into a strong process, the *internal malleolus*. The *inferior surface* of the bone is quadrilateral, and smooth for articulation with the astragalus. This surface is concave from before backwards, and broader in front than behind. It is traversed from before backwards by a slight elevation, separating two lateral depressions. It is narrow internally, where the articular surface becomes continuous with that on the inner malleolus. The *anterior surface* of the lower extremity is smooth and rounded above, and covered by the tendons of the Extensor muscles of the toes; its lower margin presents a rough transverse depression, for the attachment of the anterior ligament of the ankle-joint; the *posterior surface* presents a superficial groove directed obliquely downwards and inwards, continuous with a similar groove on the posterior extremity of the astragalus, and serving for the passage of the tendon of the Flexor longus hallucis; the *external surface* presents a triangular rough depression for the attachment of the inferior interosseous ligament connecting it with the fibula; the lower part of this depression is smooth, covered with cartilage in the recent state, and articulates with the fibula. The surface is bounded by two prominent ridges, continuous above with the interosseous ridge; they afford attachment to the anterior and posterior inferior tibio-fibular ligaments. The *internal surface* of the lower extremity is prolonged downwards to form a strong pyramidal process, flattened from without inwards—the *inner malleolus*. The *inner surface* of this process is convex and subcutaneous; its *outer surface* is smooth and slightly concave, and articulates with the astragalus; its *anterior*

border is rough, for the attachment of the anterior fibres of the Deltoid ligament; its *posterior border* presents a broad and deep groove, directed obliquely downwards and inwards, which is occasionally double; this groove transmits the tendons of the Tibialis posticus and Flexor longus digitorum muscles. The *summit* of the internal malleolus is marked by a rough depression behind, for the attachment of the internal lateral ligament of the ankle-joint.

Structure.—Like that of the other long bones. At the junction of the middle and lower third, where the bone is smallest, the wall of the shaft is thicker than in other parts, in order to compensate for the smallness of the calibre of the bone.

Development.—By *three* centres (fig. 246): one for the shaft, and one for each extremity. Ossification commences in the centre of the shaft about the seventh week, and gradually extends towards either extremity. The centre for the upper epiphysis appears during the first year; it is flattened in form, and has a thin tongue-shaped process in front, which forms the tubercle. That for the lower epiphysis appears in the second year. The lower epiphysis joins the shaft at about the eighteenth, and the upper one about the twentieth year. Two additional centres occasionally exist, one for the tongue-shaped process of the upper epiphysis, which forms the tubercle, and one for the inner malleolus.

Fig. 246.—Plan of the development of the tibia. By three centres.



Articulations.—With three bones: the femur, fibula, and astragalus.

Attachment of Muscles.—To twelve: to the inner tuberosity, the Semi-membranosus; to the outer tuberosity, the Tibialis anticus and Extensor longus digitorum and Biceps; to the shaft, its internal surface, the Sartorius, Gracilis, and Semi-tendinosus; to its external surface, the Tibialis anticus; to its posterior surface, the Popliteus, Soleus, Flexor longus digitorum, and Tibialis posticus; to the tubercle, the ligamentum patellæ, by which the Quadriceps extensor muscle is inserted into the tibia. In addition to these muscles, the Tensor vaginæ femoris is inserted indirectly into the tibia, through the ilio-tibial band, and the Peroneus longus occasionally derives a few fibres of origin from the outer tuberosity.

Surface Form.—A considerable portion of the tibia is subcutaneous and easily to be felt. At the upper extremity the tuberosities are to be recognised just below the knee. The internal one is broad and smooth, and merges into the subcutaneous surface of the shaft below. The external one is narrower and more prominent, and on it, about midway between the apex of the patella and the head of the fibula, may be felt a prominent tubercle for the insertion of the ilio-tibial band. In front of the upper end of the bone, between the tuberosities, is the tubercle of the tibia, forming an oval eminence, which is continuous below with the anterior border or crest of the bone. This border can be felt, forming the prominence of the shin, in the upper two-thirds of its extent as a sharp and flexuous ridge, curved outwards above and inwards below. In the lower third of the leg the border disappears and the bone is concealed by the tendons of the muscles on the front of the leg. Internal to the anterior border is to be felt the broad internal surface of the tibia, slightly encroached upon by the muscles in front and behind. It commences above at the wide expanded inner tuberosity and terminates below at the internal malleolus. The internal malleolus is a broad prominence situated on a higher level and somewhat further forwards than the external malleolus. It overhangs the inner border of

the arch of the foot. Its anterior border is nearly straight, its posterior border presents a sharp edge, which forms the inner margin of the groove for the tendon of the Tibialis posticus muscle.

The Fibula (figs. 244, 245)

The **Fibula** (fibula, *a clasp*) is situated at the outer side of the leg. It is the smaller of the two bones, and, in proportion to its length, the most slender of all the long bones; it is placed on the outer side of the tibia, with which it is connected above and below. Its upper extremity is small, placed towards the back of the head of the tibia, below the level of the knee-joint, and excluded from its formation; the lower extremity inclines a little forwards, so as to be on a plane anterior to that of the upper end, projects below the tibia, and forms the outer ankle. It presents for examination a shaft and two extremities.

The **Upper Extremity**, or **Head**, is of an irregular quadrate form, presenting above a flattened articular facet, directed upwards, forwards and inwards, for articulation with a corresponding facet on the external tuberosity of the tibia. On the outer side is a thick and rough prominence, continued behind into a pointed eminence, the *styloid process*, which projects upwards from the posterior part of the head. The prominence gives attachment to the tendon of the Biceps muscle, and to the long external lateral ligament of the knee, the ligament dividing the tendon into two parts. The summit of the styloid process gives attachment to the short external lateral ligament. The remaining part of the circumference of the head is rough, for the attachment of muscles and ligaments. It presents in front a tubercle for the origin of the upper and anterior part of the Peroneus longus, and the adjacent surface gives attachment to the anterior superior tibio-fibular ligament; and behind, another tubercle for the attachment of the posterior superior tibio-fibular ligament, and the upper fibres of the Soleus muscle.

The **shaft** presents four borders—the antero-external, the antero-internal, the postero-external, and the postero-internal; and four surfaces—anterior, posterior, internal, and external.

The **antero-external border** commences above in front of the head, runs vertically downwards to a little below the middle of the bone, and then curving somewhat outwards, bifurcates so as to embrace the triangular subcutaneous surface immediately above the outer surface of the external malleolus. This border gives attachment to an intermuscular septum, which separates the extensor muscles on the anterior surface of the leg from the Peroneus longus and brevis muscles.

The **antero-internal border**, or **interosseous ridge**, is situated close to the inner side of the preceding, and runs nearly parallel with it in the upper third of its extent, but diverges from it so as to include a broader space in the lower two-thirds. It commences above just beneath the head of the bone (sometimes it is quite indistinct for about an inch below the head), and terminates below at the apex of a rough triangular surface immediately above the articular facet of the external malleolus. It serves for the attachment of the interosseous membrane, which separates the extensor muscles in front from the flexor muscles behind.

The **postero-external border** is prominent; it commences above at the base of the styloid process, and terminates below in the posterior border of the outer malleolus. It is directed outwards above, backwards in the middle of its course, backwards and a little inwards below, and gives attachment to an aponeurosis which separates the Peronei muscles on the outer surface of the shaft from the flexor muscles on its posterior surface.

The **postero-internal border**, sometimes called the *oblique line*, commences above at the inner side of the head, and terminates by becoming continuous with the antero-internal border or interosseous ridge at the lower fourth of the bone. It is well marked and prominent at the upper and middle parts of the bone. It

gives attachment to an aponeurosis which separates the Tibialis posticus from the Soleus above and the Flexor longus hallucis below.

The **anterior surface** is the interval between the antero-external and antero-internal borders. It is extremely narrow and flat in the upper third of its extent; broader and grooved longitudinally in its lower third; it serves for the attachment of three muscles, the Extensor longus digitorum, Peroneus tertius, and Extensor proprius hallucis.

The **external surface** is the space between the antero-external and postero-external borders. It is much broader than the preceding, and often deeply grooved, is directed outwards in the upper two-thirds of its course, backwards in the lower third, where it is continuous with the posterior border of the external malleolus. This surface is completely occupied by the Peroneus longus and brevis muscles.

The **internal surface** is the interval included between the antero-internal and the postero-internal borders. It is directed inwards, and is grooved for the attachment of the Tibialis posticus muscle.

The **posterior surface** is the space included between the postero-external and the postero-internal borders; it is continuous below with the rough triangular surface above the articular facet of the outer malleolus; it is directed backwards above, backwards and inwards at its middle, directly inwards below. Its upper third is rough, for the attachment of the Soleus muscle; its lower part presents a triangular rough surface, connected to the tibia by a strong interosseous ligament, and between these two points the entire surface is covered by the fibres of origin of the Flexor longus hallucis muscle. At about the middle of this surface is the nutrient foramen, which is directed downwards.

The **Lower Extremity**, or **external malleolus**, is of a pyramidal form, somewhat flattened from without inwards, and is longer, and descends lower, than the internal malleolus. Its *external surface* is convex, subcutaneous, and continuous with the triangular (also subcutaneous) surface on the outer side of the shaft. The *internal surface* presents in front a smooth triangular facet, broader above than below, and convex from above downwards, which articulates with a corresponding surface on the outer side of the astragalus. Behind and beneath the articular surface is a rough depression, which gives attachment to the posterior fasciculus of the external lateral ligament of the ankle. The *anterior border* is thick and rough, and marked below by a depression for the attachment of the anterior fasciculus of the external lateral ligament. The *posterior border* is broad and marked by a shallow groove, for the passage of the tendons of the Peroneus longus and brevis muscles. The *summit* is rounded, and gives attachment to the middle fasciculus of the external lateral ligament.

Fig. 247.—Plan of the development of the fibula. By three centres.

In order to distinguish the side to which the bone belongs, hold it with the lower extremity downwards, and the broad groove for the Peronei tendons backwards, i.e. towards the holder: the triangular subcutaneous surface will then be directed to the side to which the bone belongs.

Articulations.—With two bones: the tibia and astragalus.

Development.—By *three* centres (fig. 247): one for the shaft, and one for

each extremity. Ossification commences in the shaft about the eighth week of fœtal life, a little later than in the tibia, and extends gradually towards the extremities. At birth both ends are cartilaginous. Ossification commences in the lower end in the second year, and in the upper one about the fourth year. The lower epiphysis, the first in which ossification commences, becomes united to the shaft about the twentieth year; the upper epiphysis joins about the twenty-fifth year. Ossification appearing first in the lower epiphysis is contrary to the rule which prevails with regard to the commencement of ossification in epiphyses, viz. that that epiphysis towards which the nutrient artery is directed commences to ossify last; but it follows the rule which prevails with regard to the union of epiphyses, by uniting first.

Attachment of Muscles.—To nine: to the head, the Biceps, Soleus, and Peroneus longus; to the shaft, its anterior surface, the Extensor longus digitorum, Peroneus tertius, and Extensor proprius hallucis; to the internal surface, the Tibialis posticus; to the posterior surface, the Soleus and Flexor longus hallucis; to the external surface, the Peroneus longus and brevis.

Surface Form.—The only parts of the fibula which are to be felt are the head, the lower part of the external surface of the shaft and the external malleolus. The head is to be seen and felt behind and to the outer side of the outer tuberosity of the tibia. It presents a small, prominent, triangular eminence slightly above the level of the tubercle of the tibia. The external malleolus presents a narrow elongated prominence, situated on a plane posterior to the internal malleolus and reaching to a lower level. From it may be traced the lower third or half of the external surface of the shaft of the bone in the interval between the Peroneus tertius in front and the other two Peronei tendons behind.

Surgical Anatomy.—In fractures of the bones of the leg, both bones are usually fractured, but each bone may be broken separately, the fibula more frequently than the tibia. Fracture of both bones may be caused either by direct or indirect violence. When it occurs from indirect force, the fracture in the tibia is at the junction of the middle and lower third of the bone. Many causes conduce to render this the weakest part of the bone. The fracture of the fibula is usually at rather a higher level. These fractures present great variety, both as regards their direction and condition. They may be oblique, transverse, longitudinal, or spiral. When oblique, they are usually the result of indirect violence, and the direction of the fracture is from behind, downwards, forwards, and inwards in many cases, but may be downwards and outwards, or downwards and backwards. When transverse, the fracture is often at the upper part of the bone, and is the result of direct violence. The spiral fracture usually commences as a vertical fissure, involving the ankle-joint, and is associated with fracture of the fibula higher up. It is the result of torsion, from twisting of the body whilst the foot is fixed.

Fractures of the tibia alone are almost always the result of direct violence, except where the malleolus is broken off by twists of the foot. Fractures of the fibula alone may arise from indirect or direct force, those of the lower end being usually the result of the former, and those higher up being caused by a direct blow on the part.

The tibia and fibula, like the femur, are frequently the seat of acute necrosis. Chronic abscess is more frequently met with in the cancellous tissue of the head and lower end of the tibia than in any other bone of the body. The abscess is of small size, very chronic, and probably the result of tuberculous osteitis in the highly vascular growing tissue at the end of the shaft near the epiphysial cartilage in the young subject.

The tibia is the bone which is most frequently and most extensively distorted in rickets. It gives way at the junction of the middle and lower third, its weakest part, and presents a curve forwards and outwards.

THE FOOT (figs. 248, 249)

The skeleton of the foot consists of three divisions: the Tarsus, Metatarsus, and Phalanges.

THE TARSUS

The bones of the **Tarsus** are seven in number: viz. the calcaneum or os calcis, astragalus, cuboid, navicular, internal, middle, and external cuneiform bones.

The Calcaneum (fig. 250)

The **Calcaneum**, or **Os Calcis** (calx, *the heel*), is the largest and strongest of the tarsal bones. It is irregularly cuboidal in form, having its long axis directed

FIG. 248.—Bones of the right foot. Dorsal surface.

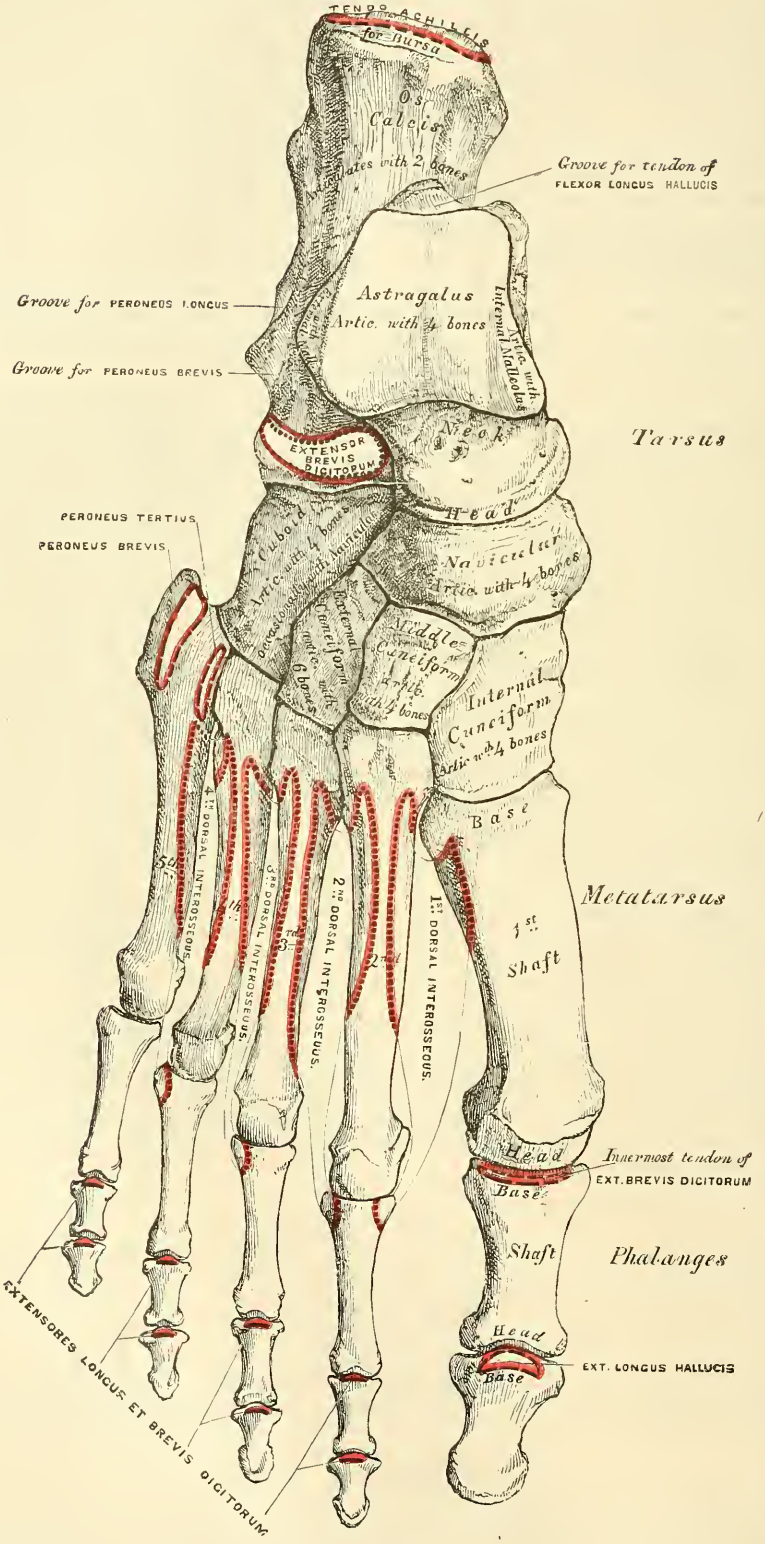


Fig. 249.—Bones of the right foot. Plantar surface.

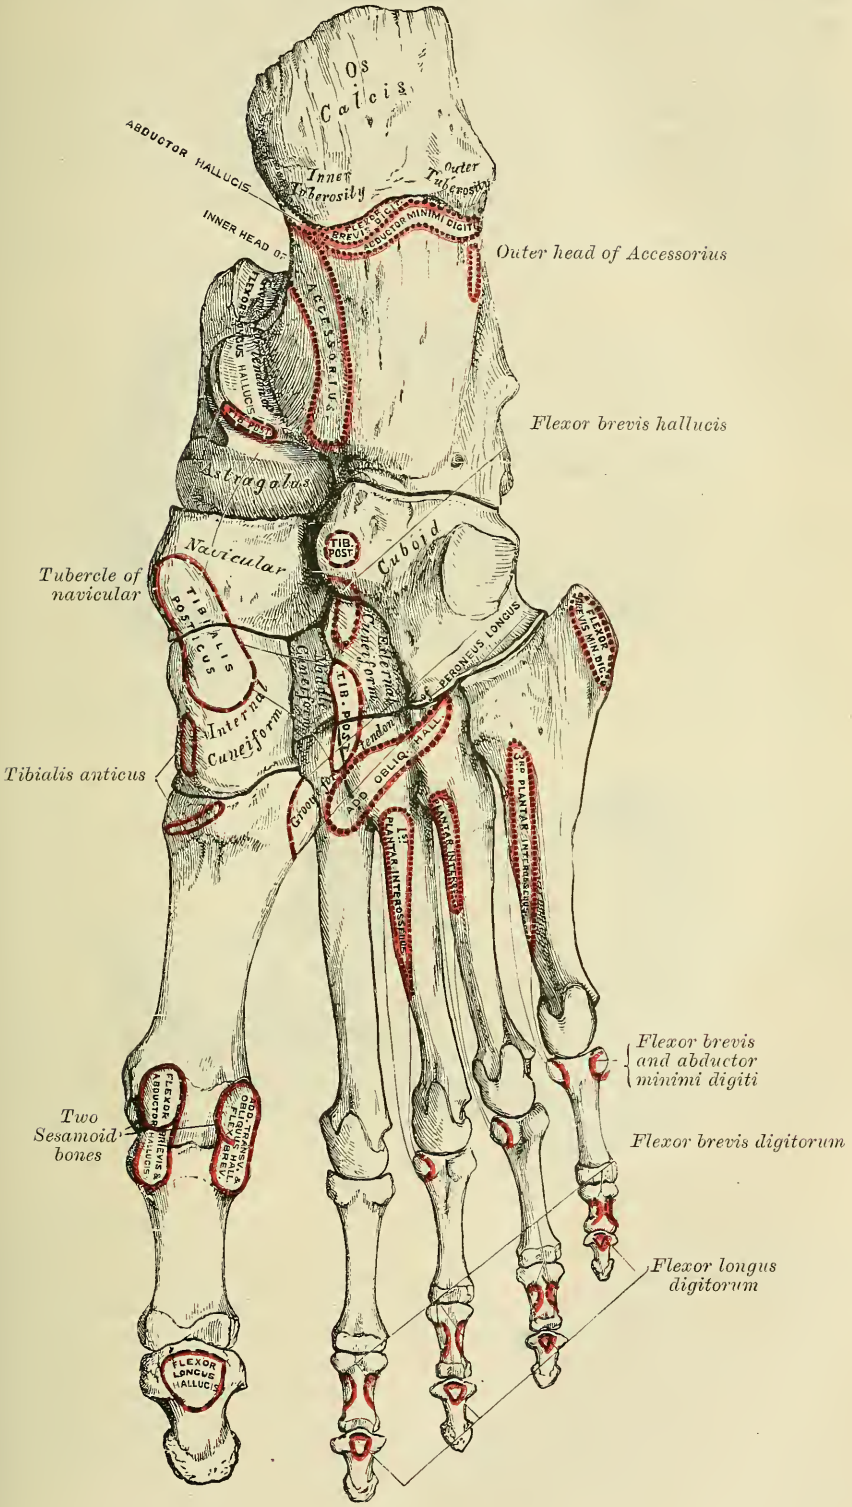
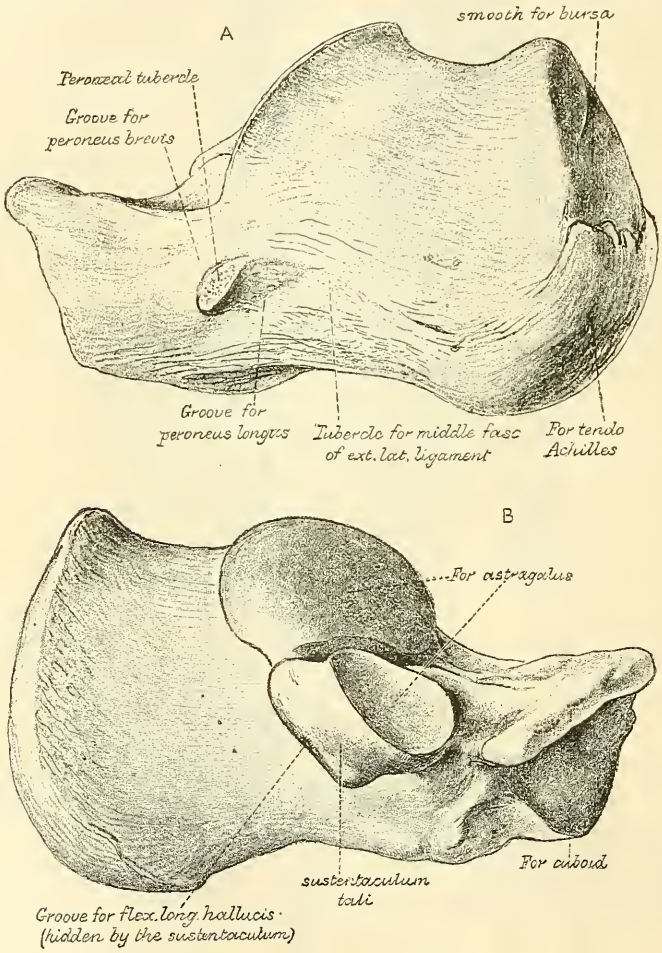


forwards and outwards. It is situated at the lower and back part of the foot, serving to transmit the weight of the body to the ground, and forming a strong lever for the muscles of the calf. It presents for examination six surfaces: superior, inferior, external, internal, anterior, and posterior.

The *superior surface* is formed behind by the upper aspect of that part of the os calcis which projects backwards to form the heel. It varies in length in different individuals; is convex from side to side, concave from before backwards, and upon it rests a mass of adipose substance placed in front of the tendo Achillis. In the middle of the superior surface are two (sometimes three) articular facets, separated by a broad shallow groove, which is directed obliquely forwards

FIG. 250.—The left os calcis. A. Postero-external view. B. Antero-internal view.



and outwards, and is rough for the attachment of the interosseous ligament connecting the astragalus and os calcis. Of the two articular surfaces, the *external* is the larger, and situated on the body of the bone: it is of an oblong form, wider behind than in front and convex from before backwards. The *internal articular surface* is supported on a projecting process of bone, called the *lesser process* of the calcaneum (*sustentaculum tali*); it is also oblong, concave longitudinally, and sometimes subdivided into two parts, which differ in size and shape. More anteriorly is seen the upper surface of the *greater process*, marked by a rough depression for the attachment of numerous ligaments, and a tubercle for the origin of the Extensor brevis digitorum muscle.

The *inferior surface* is narrow, rough, uneven, wider behind than in front,

and convex from side to side; it is bounded posteriorly by two tubercles, separated by a rough depression; the *external*, small, prominent, and rounded, gives attachment to part of the Abductor minimi digiti; the *internal*, broader and larger, for the support of the heel, gives attachment, by its prominent inner margin, to the Abductor hallucis, and in front to the Flexor brevis digitorum muscles; the depression between the tubercles gives attachment to the Abductor minimi digiti and plantar fascia. The rough surface in front of the tubercles gives attachment to the long plantar ligament, and to the outer head of the Flexor accessorius muscle; and to a prominent tubercle nearer the anterior part of this surface, as well as to a transverse groove in front of it, is attached the short plantar ligament.

The *external surface* is broad, flat, and almost subcutaneous; it presents near its centre a tubercle, for the attachment of the middle fasciculus of the external lateral ligament. At its upper and anterior part, this surface gives attachment to the external calcaneo-astragaloid ligament; and in front of the tubercle it presents a narrow surface marked by two oblique grooves, separated by an elevated ridge which varies much in size in different bones; it is named the *peroneal tubercle*, and gives attachment to a fibrous process from the external annular ligament. The *superior groove* transmits the tendon of the Peroneus brevis; the *inferior*, the tendon of the Peroneus longus.

The *internal surface* is deeply concave; it is directed obliquely downwards and forwards, and serves for the transmission of the plantar vessels and nerves into the sole of the foot; it affords attachment to part of the Flexor accessorius muscle. At its upper and fore part it presents an eminence of bone, the *lesser process* or *sustentaculum tali*, which projects horizontally inwards, and to it a slip of the tendon of the Tibialis posticus is attached. This process is concave above, and supports the anterior articular surface of the astragalus; below, it is grooved for the tendon of the Flexor longus hallucis. Its free margin is rough for the attachment of part of the internal lateral ligament of the ankle-joint.

The *anterior surface*, of a somewhat triangular form, articulates with the cuboid. It is concave from above, downwards and outwards, and convex in the opposite direction. Its inner border gives attachment to the inferior calcaneo-navicular ligament.

The *posterior surface* is rough, prominent, convex, and wider below than above. Its lower part is rough, for the attachment of the tendo Achillis and the tendon of the Plantaris muscle; its upper part is smooth, and is covered by a bursa which separates the tendons from the bone.

Articulations.—With two bones: the astragalus and cuboid.

Attachment of Muscles.—To eight: part of the Tibialis posticus, the tendo Achillis, Plantaris, Abductor hallucis, Abductor minimi digiti, Flexor brevis digitorum, Flexor accessorius, and Extensor brevis digitorum.

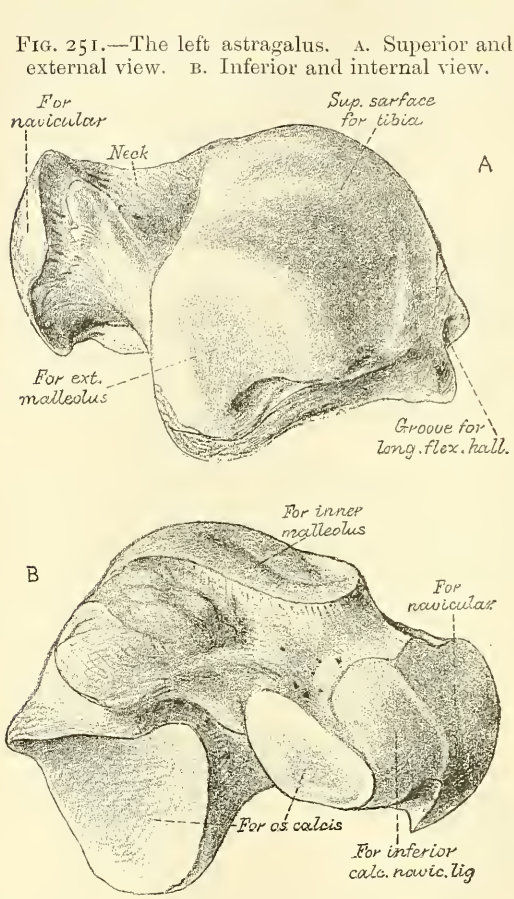
The Astragalus (fig. 251)

The **Astragalus** (ἀστράγαλος, *a die*) is the largest of the tarsal bones, next to the os calcis. It occupies the middle and upper part of the tarsus, supporting the tibia above, articulating with the malleoli on either side, resting below upon the os calcis, and joined in front to the navicular. This bone may easily be recognised by its large rounded head, by the broad articular facet on its upper convex surface, or by the two articular facets separated by a deep groove on its under concave surface. It presents six surfaces for examination.

The *superior surface* presents, behind, a broad smooth trochlear surface, for articulation with the tibia. The trochlea is broader in front than behind, convex from before backwards, slightly concave from side to side: in front of it is the upper surface of the neck of the astragalus; rough for the attachment of ligaments. The *inferior surface* presents two articular facets separated by a deep groove.

The groove runs obliquely forwards and outwards, becoming gradually broader and deeper in front: it corresponds with a similar groove upon the upper surface of the os calcis, and forms, when articulated with that bone, a canal, filled up in the recent state by the interosseous calcaneo-astragaloid ligament. Of the two articular facets, the posterior is the larger, of an oblong form, and deeply concave from side to side; the anterior is shorter and narrower, of an elongated oval form, convex longitudinally, and often subdivided into two by an elevated ridge; of these the posterior articulates with the lesser process of the os calcis; the anterior, with the upper surface of the inferior calcaneo-navicular ligament. The *internal surface* presents at its upper part a pear-shaped articular facet for the inner malleolus, continuous above with the trochlear surface; below the articular surface is a rough depression, for the attachment of the deep portion of the internal lateral ligament. The *external surface* presents a large triangular facet, concave from above downwards, for articulation with the external malleolus; it is continuous above with the trochlear surface; and in front of it is a rough depression for the attachment of the anterior fasciculus of the external lateral ligament of the ankle-joint. The *anterior surface*, convex and rounded, forms the *head* of the astragalus; it is smooth, of an oval form, and directed obliquely inwards and downwards; it articulates with the navicular. On its under and inner surface is a small facet, continuous in front with the articular surface of the head, and behind with the smaller facet for the os calcis. This rests on the inferior calcaneo-navicular ligament, being separated from it by the synovial membrane, which is prolonged from the anterior calcaneo-astragaloid joint to the astragalo-navicular joint. The head is surrounded by a constricted portion, the *neck* of the astragalus. The *posterior surface* is narrow, and traversed by a groove, which runs obliquely downwards and inwards, and transmits the tendon of the Flexor longus hallucis, external to which is a prominent tubercle, to which the posterior fasciculus of the external lateral ligament is attached. To the inner side of the groove is a second, but less marked tubercle.

Fig. 251.—The left astragalus. A. Superior and external view. B. Inferior and internal view.



To ascertain to which foot the bone belongs, hold it with the broad articular surface upwards, and the rounded head forwards; the lateral triangular articular surface for the external malleolus will then point to the side to which the bone belongs.

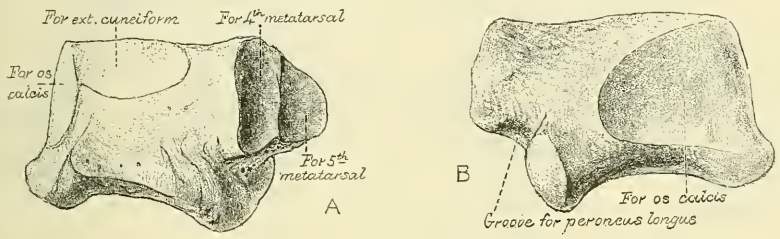
Articulations.—With four bones: tibia, fibula, os calcis, and navicular.

The Cuboid (fig. 252)

The **Cuboid** (*κύβος, a cube*; *εἶδος, like*) bone is placed on the outer side of the foot, in front of the os calcis, and behind the fourth and fifth metatarsal bones. It is of a pyramidal shape, its base being directed inwards, its apex outwards. It may be distinguished from the other tarsal bones by the existence of a deep groove on its under surface, for the tendon of the Peroneus longus muscle. It presents for examination six surfaces: three articular, and three non-articular.

The **non-articular surfaces** are the superior, inferior, and external. The *superior* or *dorsal surface*, directed upwards and outwards, is rough, for the attachment of numerous ligaments. The *inferior* or *plantar surface* presents in front a deep groove, which runs obliquely from without, forwards and inwards; it lodges the tendon of the Peroneus longus, and is bounded behind by a prominent ridge, to which is attached the long calcaneo-cuboid ligament. The ridge terminates externally in an eminence, the *tuberosity of the cuboid*, the surface of which presents a convex facet, for articulation with the sesamoid bone of the tendon contained in the groove. The surface of bone behind the groove is rough, for the attachment of the short plantar ligament, a few fibres of the

Fig. 252.—The left cuboid. A. Antero-internal view. B. Postero-external view.



Flexor brevis hallucis and a fasciculus from the tendon of the Tibialis posticus. The *external surface*, the smallest and narrowest of the three, presents a deep notch formed by the commencement of the peroneal groove.

The **articular surfaces** are the posterior, anterior, and internal. The *posterior surface* is smooth, triangular, and concavo-convex, for articulation with the anterior surface of the os calcis. The *anterior*, of smaller size, but also irregularly triangular, is divided by a vertical ridge into two facets: the inner one, quadrilateral in form, articulates with the fourth metatarsal bone; the outer one, larger and more triangular, articulates with the fifth metatarsal. The *internal surface* is broad, rough, irregularly quadrilateral, presenting at its middle and upper part a smooth oval facet, for articulation with the external cuneiform bone; and behind this (occasionally) a smaller facet, for articulation with the navicular; it is rough in the rest of its extent, for the attachment of strong interosseous ligaments.

To ascertain to which foot the bone belongs, hold it so that its under surface, marked by the peroneal groove, looks downwards, and the large concavo-convex articular surface backwards, towards the holder: the narrow non-articular surface, marked by the commencement of the peroneal groove, will point to the side to which the bone belongs.

Articulations.—With four bones: the os calcis, external cuneiform, and the fourth and fifth metatarsal bones; occasionally with the navicular.

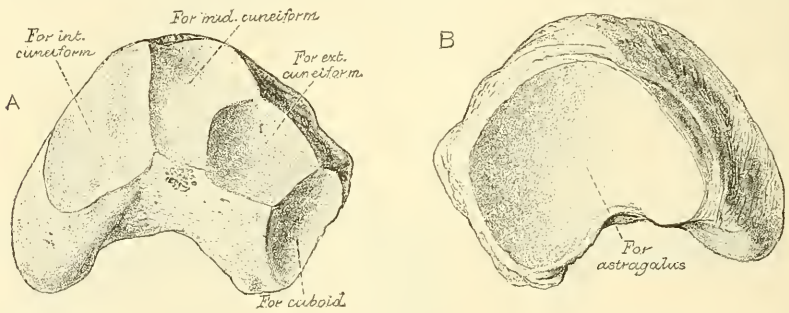
Attachment of Muscles.—Part of the Flexor brevis hallucis and a slip from the tendon of the Tibialis posticus.

The Navicular (fig. 253)

The **Navicular** or **Scaphoid bone** is situated at the inner side of the tarsus, between the astragalus behind and the three cuneiform bones in front. It may be distinguished by its form, being concave behind, convex and subdivided into three facets in front.

The *anterior surface*, of an oblong form, is convex from side to side, and subdivided by two ridges into three facets, for articulation with the three cuneiform bones. The *posterior surface* is oval, concave, broader externally than internally, and articulates with the rounded head of the astragalus. The *superior surface* is convex from side to side, and rough for the attachment of ligaments. The *inferior* is irregular, and also rough for the attachment of ligaments. The *internal surface* presents a rounded tubercular eminence, the *tuberosity* of the navicular, the lower part of which projects, and gives attachment to part of the tendon of the Tibialis posticus. The *external surface* is rough, and irregular, for the attachment of ligamentous fibres, and occasionally presents a small facet for articulation with the cuboid bone.

Fig. 253.—The left navicular. A. Antero-external view. B. Postero-internal view.



To ascertain to which foot the bone belongs, hold it with the concave articular surface backwards, and the convex dorsal surface upwards; the external surface, i.e. the surface opposite the tubercle, will point to the side to which the bone belongs.

Articulations.—With four bones: astragalus and three cuneiform; occasionally also with the cuboid.

Attachment of Muscles.—Part of the Tibialis posticus.

The Cuneiform Bones

The **Cuneiform Bones** have received their name from their wedge-like shape (cuneus, *a wedge*; forma, *likeness*). They form, with the cuboid, the anterior row of the tarsus, being placed between the navicular behind, the three innermost metatarsal bones in front, and the cuboid externally. They are called the *first*, *second*, and *third*, counting from the inner to the outer side of the foot, and, from their position, *internal*, *middle*, and *external*.

The Internal Cuneiform (fig. 254)

The **Internal Cuneiform** is the largest of the three. It is situated at the inner side of the foot, between the navicular behind and the base of the first metatarsal in front. It may be distinguished from the other two by its large size, and by its not presenting such a distinct wedge-like form. Without the others, it may be known by the large kidney-shaped anterior articulating surface, and by the prominence on the inferior or plantar surface for the attachment of the Tibialis posticus. It presents for examination six surfaces.

The *internal surface* is subcutaneous, and forms part of the inner border of the foot; it is broad, quadrilateral, and presents at its anterior inferior angle a smooth oval facet, into which the tendon of the Tibialis anticus is partially inserted; in the rest of its extent it is rough, for the attachment of ligaments. The *external surface* is concave, presenting, along its superior and posterior borders, a narrow reversed L-shaped surface for articulation with the middle cuneiform behind, and second metatarsal bone in front: in the rest of its extent it is rough for the attachment of ligaments and part of the tendon of the Peroneus longus. The *anterior surface*, kidney-shaped, much larger than the posterior, articulates with the metatarsal bone of the great toe. The *posterior surface* is triangular, concave, and articulates with the innermost and largest of the three facets on the anterior surface of the navicular. The *inferior* or *plantar surface* is rough, and presents a prominent tuberosity at its back part for the attachment of part of the tendon of the Tibialis posticus. It also gives attachment in front to part of the tendon of the Tibialis anticus. The *superior surface* is the narrow pointed end of the wedge, which is directed upwards and outwards; it is rough for the attachment of ligaments.

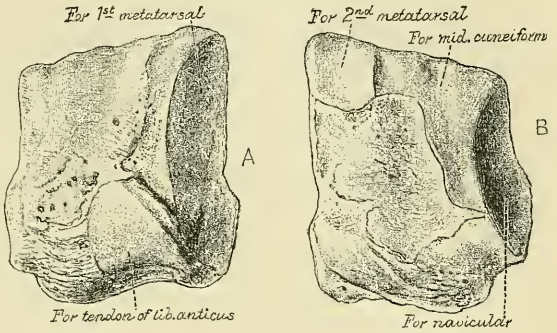


Fig. 254.—The left internal cuneiform. A. Antero-internal view. B. Postero-external view.

To ascertain to which side the bone belongs, hold it so that its superior narrow edge looks upwards, and the long, kidney-shaped, articular surface forwards; the external surface, marked by its vertical and horizontal articular facets, will point to the side to which it belongs.

Articulations.—With four bones: navicular, middle cuneiform, first and second metatarsal bones.

Attachment of Muscles.—To three: the Tibialis anticus and posticus, and Peroneus longus.

The Middle Cuneiform (fig. 255)

The **Middle Cuneiform**, the smallest of the three, is of very regular wedge-like form, the broad extremity being placed upwards, the narrow end downwards. It is situated between the other two bones of the same name, and articulates with the navicular behind, and the second metatarsal in front. It may be distinguished from the external cuneiform bone, which it much resembles in general appearance, by the articular facet, of angular form, which runs round the upper and back part of its inner surface; and if the two bones from the same foot are together, the middle cuneiform is much the smaller.

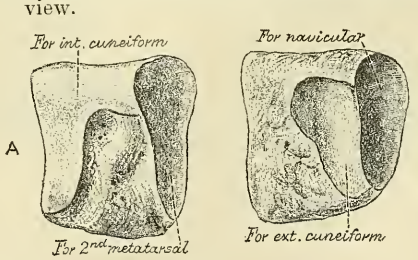

Fig. 255.—The left middle cuneiform. A. Antero-internal view. B. Postero-external view.

The *anterior surface*, triangular in form, and narrower than the posterior, articulates with the base of the second metatarsal bone. The *posterior surface*, also triangular, articulates with the navicular. The *internal surface* presents a reversed L-shaped articular facet,

running along the superior and posterior borders, for articulation with the internal cuneiform, and is rough in the rest of its extent for the attachment of ligaments. The *external surface* presents posteriorly a smooth facet for articulation with the external cuneiform bone. The *superior surface* forms the base of the wedge; it is quadrilateral, broader behind than in front, and rough for the attachment of ligaments. The *inferior surface*, pointed and tubercular, is also rough for ligamentous attachment, and for the insertion of a slip from the tendon of the Tibialis posticus.

To ascertain to which foot the bone belongs, hold its superior or dorsal surface upwards, the broadest edge being towards the holder: the smooth facet (limited to the posterior border) will then point to the side to which it belongs.

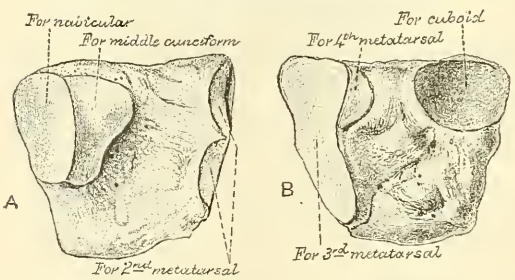
Articulations.—With four bones: navicular, internal and external cuneiform, and second metatarsal bone.

Attachment of Muscle.—A slip from the tendon of the Tibialis posticus is attached to this bone.

The External Cuneiform (fig. 256)

The **External Cuneiform**, intermediate in size between the two preceding, is of a very regular wedge-like form, the broad extremity being placed upwards, the narrow end downwards. It occupies the centre of the front row of the tarsus between the middle cuneiform internally, the cuboid externally, the navicular behind, and the third metatarsal in front. It is distinguished from the internal cuneiform bone by its more regular wedge-like shape, and by the absence of the kidney-shaped articular surface: from the middle cuneiform, by the absence of the reversed L-shaped facet, and by the two articular facets which are present on both its inner and outer surfaces. It has six surfaces for examination.

Fig. 256.—The left external cuneiform. A. Postero-internal view. B. Antero-external view.



The *anterior surface*, triangular in form, articulates with the third metatarsal bone. The *posterior surface* articulates with the most external facet of the navicular, and is rough below for the attachment of ligamentous fibres. The *internal surface* presents two articular facets, separated by a rough depression, the anterior one, sometimes divided into two, articulates with the outer side of the base of the second metatarsal bone; the posterior one skirts the posterior border, and articulates with the middle cuneiform; the rough depression between the two gives attachment to an interosseous ligament. The *external surface* also presents two articular facets, separated by a rough non-articular surface; the anterior facet, situated at the superior angle of the bone, is small, and articulates with the inner side of the base of the fourth metatarsal; the posterior and larger one articulates with the cuboid; the rough, non-articular surface serves for the attachment of an interosseous ligament. The three facets for articulation with the three metatarsal bones are continuous with one another, and covered by a prolongation of the same cartilage; the facets for articulation with the middle cuneiform and navicular are also continuous, but that for articulation with the cuboid is usually separate. The *superior* or *dorsal surface* is of an oblong square form; its posterior external angle being prolonged backwards. The *inferior* or *plantar surface* is an obtuse rounded margin, and serves for the attachment of part of the tendon of the Tibialis posticus, part of the Flexor brevis hallucis, and ligaments.

To ascertain to which side the bone belongs, hold it with the broad dorsal

surface upwards, the prolonged edge backwards; the separate articular facet for the cuboid will point to the proper side.

Articulations.—With six bones: the navicular, middle cuneiform, cuboid, and second, third, and fourth metatarsal bones.

Attachment of Muscles.—To two: part of the Tibialis posticus, and Flexor brevis hallucis.

The Metatarsal Bones

The **Metatarsal Bones** are five in number, and are numbered one to five, in accordance with their position from within outwards; they are long bones, and present for examination a shaft and two extremities.

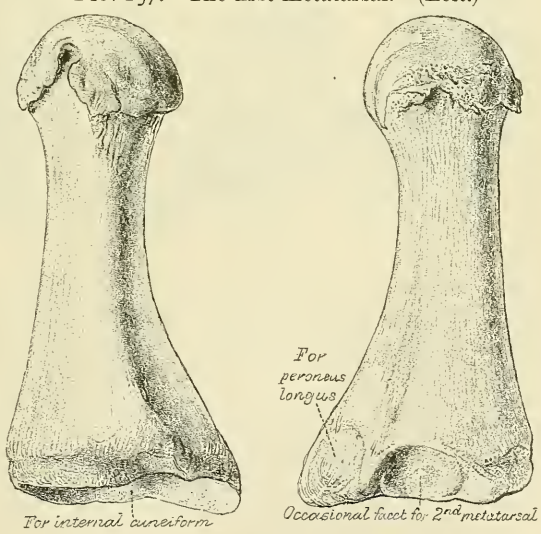
Common Characters of the Metatarsal Bones

The **Shaft** is prismoid in form, tapers gradually from the tarsal to the phalangeal extremity, and is slightly curved longitudinally, so as to be concave below, slightly convex above. The *posterior extremity*, or *base*, is wedge-shaped, articulating by its terminal surface with the tarsal bones, and by its lateral surfaces with the contiguous metatarsal bones: its dorsal and plantar surfaces being rough for the attachment of ligaments. The *anterior extremity*, or *head*, presents a terminal rounded articular surface, oblong from above downwards, and extending further backwards below than above. Its sides are flattened, and present a depression, surmounted by a tubercle, for ligamentous attachment. Its under surface is grooved in the middle line for the passage of the Flexor tendon, and marked on each side by an articular eminence continuous with the terminal articular surface.

Peculiar Characters of the Metatarsal Bones

The **First** (fig. 257) is remarkable for its great thickness, but is the shortest of all the metatarsal bones. The *shaft* is strong, and of well-marked prismoid form. The *posterior extremity* presents, as a rule, no lateral articular facets, but occasionally on the outer side there is an oval facet, by which it articulates with the second metatarsal bones. Its terminal articular surface is of large size, kidney-shaped; its circumference is grooved, for the tarso-metatarsal ligaments, and internally gives attachment to part of the tendon of the Tibialis anticus; its inferior angle presents a rough oval prominence for the insertion of the tendon of the Peroneus longus. The *head* is of large size; on its plantar surface are two grooved facets, over which glide sesamoid bones; the facets are separated by a smooth elevated ridge.

Fig. 257.—The first metatarsal. (Left.)



This bone is known by the single kidney-shaped articular surface on its base; the deeply grooved appearance of the plantar surface of its head; and its great thickness, relatively to its length. When it is placed in its natural position, the concave border of the kidney-shaped articular surface on its base points to the side to which the bone belongs.

Attachment of Muscles.—To three: part of the Tibialis anticus, the Peroneus longus, and the First dorsal interosseous.

The **Second** (fig. 258) is the longest and largest of the remaining metatarsal bones, being prolonged backwards into the recess formed between the three cuneiform bones. Its *tarsal extremity* is broad above, narrow and rough below. It presents four articular surfaces: one behind, of a triangular form, for articulation with the middle cuneiform; one at the upper part of its internal lateral surface, for articulation with the internal cuneiform; and two on its external lateral surface, an upper and lower, separated by a rough non-articular interval. Each of these articular surfaces is divided by a vertical ridge into two facets, thus making four facets; the two anterior of these articulate with the third metatarsal; the two posterior (sometimes continuous) with the external cuneiform. In addition to these articular surfaces, there is occasionally a fifth when this bone articulates with the first metatarsal bone. It is oval in shape, and is situated on the inner side of the shaft near the base.

Fig. 258.—The second metatarsal. (Left.)

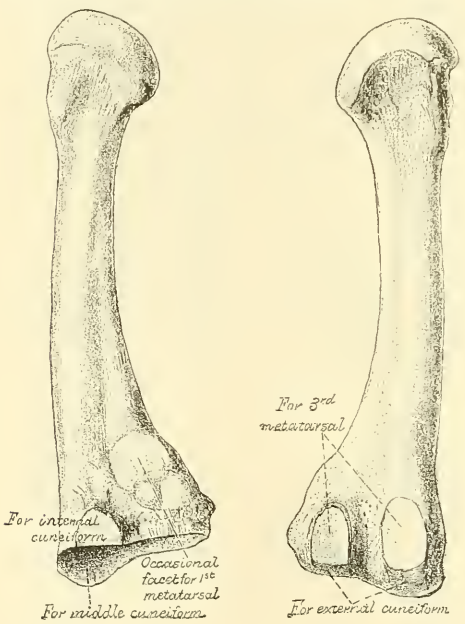


Fig. 259.—The third metatarsal. (Left.)

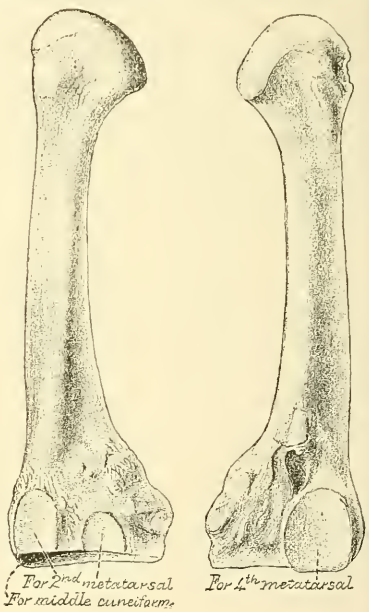

The facets on the tarsal extremity of the second metatarsal bone serve at once to distinguish it from the rest, and to indicate the foot to which it belongs; there being one facet at the upper angle of the internal surface, and two facets, each subdivided into two parts, on the external surface, pointing to the side to which the bone belongs. The fact that the two posterior subdivisions of these external facets sometimes run into one should not be forgotten.

Attachment of Muscles.—To four: the Adductor obliquus hallucis, First and Second dorsal interosseous, and a slip from the tendon of the Tibialis posticus, occasionally also a slip from the Peroneus longus.

The **Third** (fig. 259) articulates behind, by means of a triangular smooth surface, with the external cuneiform; on its inner side, by two facets, with the second metatarsal; and on its outer side, by a single facet, with the fourth metatarsal. The latter facet is of circular form, and situated at the upper angle of the base.

Thé third metatarsal is known by its having at its tarsal end two undivided facets on the inner side, and a single facet on the outer. This distinguishes it from the second metatarsal, in which the two facets, found on one side of its

tarsal end, are each subdivided into two. The single facet (when the bone is put in its natural position) is on the side to which the bone belongs.

Attachment of Muscles.—To five: Adductor obliquus hallucis, Second and Third dorsal, and First plantar interosseous, and a slip from the tendon of the Tibialis posticus.

The **Fourth** (fig. 260) is smaller in size than the preceding; its *tarsal extremity* presents a terminal quadrilateral surface for articulation with the cuboid; a smooth facet on the inner side, divided by a ridge into an anterior portion for articulation with the third metatarsal, and a posterior portion for articulation with the external cuneiform; on the outer side a single facet, for articulation with the fifth metatarsal.

The fourth metatarsal is known by its having a single facet on either side of the tarsal extremity, that on the inner side being divided into two parts. If this subdivision be not recognisable, the fact that its tarsal end is bent somewhat outwards will indicate the side to which it belongs.

Fig. 260.—The fourth metatarsal. (Left.)

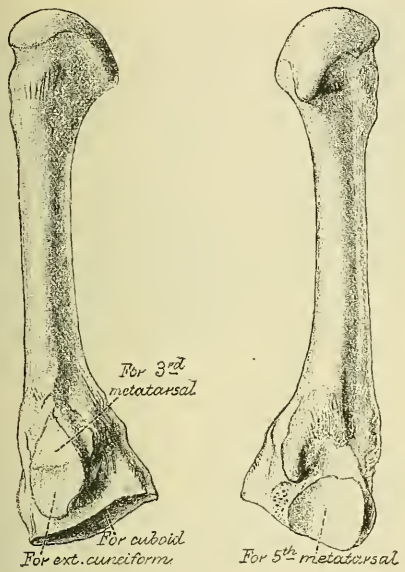

Fig. 261.—The fifth metatarsal. (Left.)

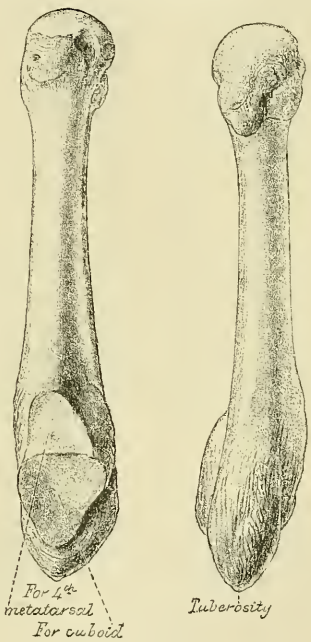


Attachment of Muscles.—To five: Adductor obliquus hallucis, Third and Fourth dorsal, and Second plantar interosseous, and a slip from the tendon of the Tibialis posticus.

The **Fifth** (fig. 261) is recognised by the tubercular eminence on the outer side of its base. It articulates behind, by a triangular surface cut obliquely from without inwards, with the cuboid; and internally, with the fourth metatarsal.

The projection on the outer side of this bone at its tarsal end at once distinguishes it from the others, and points to the side to which it belongs.

Attachment of Muscles.—To six: the Peroneus brevis, Peroneus tertius, Flexor brevis minimi digiti, Adductor transversus hallucis, Fourth dorsal, and Third plantar.

Articulations.—Each bone articulates with the tarsal bones by one extremity, and by the other with the first row of phalanges. The number of tarsal bones with which each metatarsal articulates is one for the first, three for the second, one for the third, two for the fourth, and one for the fifth.

Phalanges

The **Phalanges** of the foot, both in number and general arrangement, resemble those in the hand; there being two in the great toe, and three in each of the other toes.

The phalanges of the *first row* closely resemble those of the hand. The *shaft* is compressed from side to side, convex above, concave below. The *posterior extremity* is concave; and the *anterior extremity* presents a trochlear surface, for articulation with the second phalanges.

The phalanges of the *second row* are remarkably small and short, but rather broader than those of the first row.

The *ungual* phalanges, in form, resemble those of the fingers; but they are smaller, flattened from above downwards, presenting a broad base for articulation with the second row, and an expanded extremity for the support of the nail and end of the toe.

Articulations.—The first row, with the metatarsal bones behind and second phalanges in front; the second row, of the four outer toes, with the first and third phalanges; of the great toe, with the first phalanx; the third row, of the four outer toes, with the second phalanges.

Attachment of Muscles.—To the first phalanges. Great toe five muscles: innermost tendon of Extensor brevis digitorum, Abductor hallucis, Adductor obliquus hallucis, Flexor brevis hallucis, Adductor transversus hallucis. Second toe, three muscles: First and Second dorsal interosseous, and First lumbrical. Third toe, three muscles: Third dorsal and First plantar interosseous, and Second lumbrical. Fourth toe, three muscles: Fourth dorsal and Second plantar interosseous, and Third lumbrical. Fifth toe, four muscles: Flexor brevis minimi digiti, Abductor minimi digiti, and Third plantar interosseous, and Fourth lumbrical.—Second phalanges. Great toe: Extensor longus hallucis, Flexor longus hallucis. Other toes: Flexor brevis digitorum, one slip of the common tendon of the Extensor longus and brevis digitorum.*—Third phalanges: two slips from the common tendon of the Extensor longus and Extensor brevis digitorum, and the Flexor longus digitorum.

Development of the Foot (fig. 262)

The **Tarsal bones** are each developed by a single centre, excepting the os calcis, which has an epiphysis for its posterior extremity. The centres make their appearance in the following order: os calcis, at the sixth month of fœtal life; astragalus, about the seventh month; cuboid, at the ninth month; external cuneiform, during the first year; internal cuneiform, in the third year; middle cuneiform and navicular in the fourth year. The epiphysis for the posterior tuberosity of the os calcis appears at the tenth year, and unites with the rest of the bone soon after puberty.

The **Metatarsal bones** are each developed by *two* centres: one for the shaft, and one for the digital extremity, in the four outer metatarsal; one for the shaft, and one for the base, in the metatarsal bone of the great toe.† Ossification commences in the centre of the shaft about the ninth week, and extends towards either extremity. The centre in the proximal end of the first metatarsal bone appears about the third year; the centre in the distal end of the other bones between the fifth and eighth year; they become joined between the eighteenth and twentieth years.

The **Phalanges** are developed by *two* centres for each bone; one for the shaft,

* Except the second phalanx of the fifth toe, which receives no slip from the Extensor brevis digitorum.

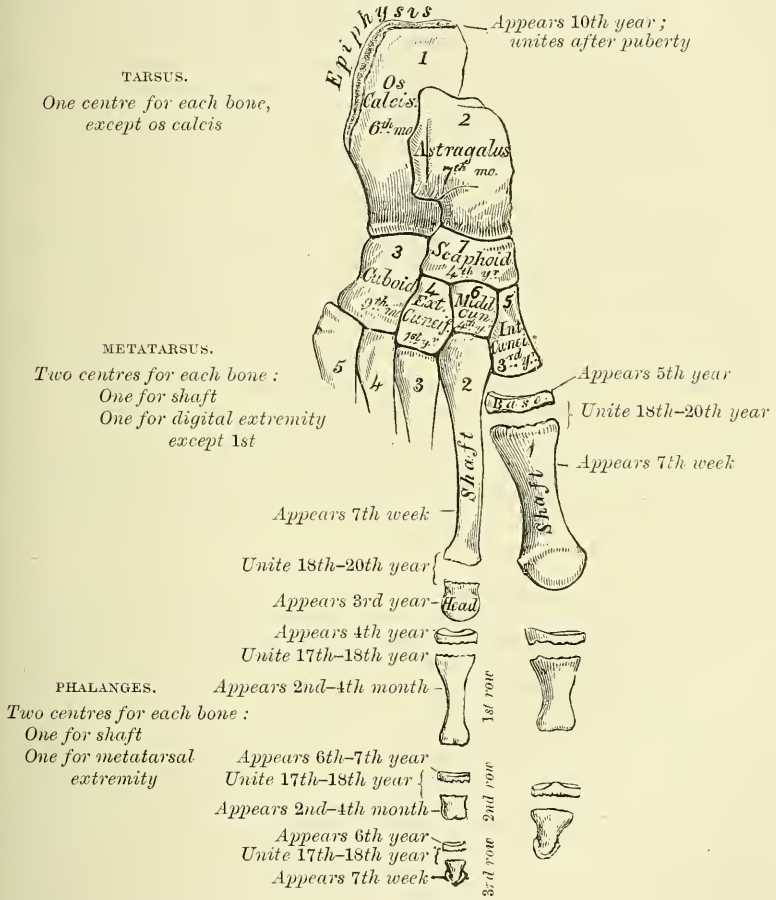
† As was noted in the first metacarpal bone, so in the first metatarsal, there is often to be observed a tendency to the formation of a second epiphysis in the distal extremity (see footnote, p. 259).

and one for the metatarsal extremity. The centre for the shaft appears about the tenth week; that for the epiphysis between the fourth and tenth year, they join the shaft about the eighteenth year.

Construction of the Foot as a Whole

The foot is constructed on the same principles as the hand, but modified to form a firm basis of support for the rest of the body when in the erect position. It is more solidly constructed, and its component parts are less movable on each other than in the hand. This is especially the case with the great toe, which has to assist in supporting the body, and is therefore constructed with greater solidity;

Fig. 262.—Plan of the development of the foot.



it lies parallel with the other toes, and has a very limited degree of mobility, whereas the thumb, which is occupied in numerous and varied movements, is constructed in such a manner as to permit of great mobility; its metacarpal bone is directed away from the others, so as to form an acute angle with the second, and it enjoys a considerable range of motion at its articulation with the carpus. The foot is placed at right angles to the leg—a position which is almost peculiar to man, and has relation to the erect position which he maintains. In order to allow of its supporting the weight of the whole body in this position, with the least expenditure of material, it is constructed in the form of an arch. This arch is not, however, made up of two equal limbs. The hinder one, which is made up of the os calcis and the posterior part of the astragalus, is about half

the length of the anterior limb, and measures about three inches. The anterior limb consists of the rest of the tarsal and the metatarsal bones, and measures about six inches. It may be said to consist of two parts, an inner segment made up of the head of the astragalus, the navicular, the three cuneiform, and the three inner metatarsal bones; and an outer segment composed of the cuboid and the two outer metatarsal bones. The summit of the arch is at the superior articular surface of the astragalus; and its two extremities, that is to say the two points on which the arch rests in standing, are the tubercles on the under surface of the os calcis posteriorly, and the heads of the metatarsal bones anteriorly. The weakest part of the arch is the joint between the astragalus and scaphoid, and here it is more liable to yield in those who are overweighted, and in those in whom the ligaments which complete and preserve the arch are relaxed. This weak point in the arch is braced on its concave surface by the inferior calcaneo-navicular ligament, which is more elastic than most other ligaments, and thus allows the arch to yield from jars or shocks applied to the anterior portion of the foot, and quickly restores it to its pristine condition. This ligament is supported on its under surface by the tendon of the Tibialis posticus muscle, which is spread out into a fan-shaped insertion, and prevents undue tension of the ligament or such an amount of stretching as would permanently elongate it.

In addition to this longitudinal arch the foot presents a transverse arch, at the antèrior part of the tarsus and hinder part of the metatarsus. This, however, can scarcely be described as a true arch, but presents more the character of a half-dome. The inner border of the central portion of the longitudinal arch is elevated from the ground, and from this point the bones arch over to the outer border, which is in contact with the ground, and, assisted by the longitudinal arch, produce a sort of rounded niche on the inner side of the foot, which gives the appearance of a transverse as well as a longitudinal arch.

The line of the foot, from the point of the heel to the toes, is not quite straight, but is directed a little outwards, so that the inner border is a little convex and the outer border concave. This disposition of the bones becomes more marked when the longitudinal arch of the foot is lost, as in the disease known under the name of 'flat-foot.'

Surface Form.—On the dorsum of the foot the individual bones are not to be distinguished, with the exception of the head of the astragalus, which forms a rounded projection in front of the ankle-joint when the foot is forcibly extended. The whole surface forms a smooth convex outline, the summit of which is the ridge formed by the head of the astragalus, the navicular, the middle cuneiform, and the second metatarsal bones; from this it gradually inclines outwards and more rapidly inwards. On the inner side of the foot, the internal tuberosity of the os calcis and the ridge separating the inner from the posterior surface of the bone may be felt most posteriorly. In front of this, and below the internal malleolus, may be felt the projection of the sustentaculum tali. Passing forwards is the well-marked tuberosity of the navicular bone, situated about an inch or an inch and a quarter in front of the internal malleolus. Further towards the front, the ridge formed by the base of the first metatarsal bone can be obscurely felt, and from this the shaft of the bone can be traced to the expanded head articulating with the base of the first phalanx of the great toe. Immediately beneath the base of this phalanx, the internal sesamoid bone is to be felt. Lastly, the expanded ends of the bones forming the last joint of the great toe are to be felt. On the outer side of the foot the most posterior bony point is the outer tuberosity of the os calcis, with the ridge separating the posterior from the outer surface of the bone. In front of this the greater part of the external surface of the os calcis is subcutaneous; on it, below and in front of the external malleolus, may be felt the peroneal ridge, when this process is present. Further forwards, the base of the fifth metatarsal bone forms a prominent and well-defined landmark, and in front of this the shaft of the bone, with its expanded head, and the base of the first phalanx, may be defined. The sole of the foot is almost entirely covered by soft parts, so that but few bony parts are to be made out, and these somewhat obscurely. The hinder part of the under surface of the os calcis and the heads of the metatarsal bones, with the exception of the first, which is concealed by the sesamoid bones, may be recognised.

Surgical Anatomy.—Considering the injuries to which the foot is subjected, it is surprising how seldom the tarsal bones are fractured. This is no doubt due to the fact that the tarsus is composed of a number of bones, articulated by a considerable extent of

surface and joined together by very strong ligaments, which serve to break the force of violence applied to this part of the body. When fracture does occur, these bones being composed for the most part of a soft cancellous structure, covered only by a thin shell of compact tissue, are often extensively comminuted, especially as most of the fractures are produced by direct violence. And having only a very scanty amount of soft parts over them, the fractures are very often compound, and amputation is frequently necessary.

When fracture occurs in the anterior group of tarsal bones, it is almost invariably the result of direct violence; but fractures of the posterior group, that is, of the calcaneum and astragalus, are most frequently produced by falls from a height on to the feet; though fracture of the os calcis may be caused by direct violence or by muscular action. The posterior part of the bone, that is, the part behind the articular surfaces, is the most frequent seat of the fracture, though some few cases of fracture of the sustentaculum tali and of vertical fracture between the two articulating facets have been recorded. The neck of the astragalus, being the weakest part of the bone, is most frequently fractured, though fractures may occur in any part and almost in any direction, either associated or not with fracture of other bones.

In cases of club foot, especially in congenital cases, the bones of the tarsus become altered in shape and size, and displaced from their proper positions. This is especially the case in congenital equino-varus, in which the astragalus, particularly about the head, becomes twisted and atrophied, and a similar condition may be present in the other bones, more especially the navicular. The tarsal bones are peculiarly liable to become the seat of tuberculous caries from comparatively trivial injuries. There are several reasons to account for this. They are composed of a delicate cancellated structure, surrounded by intricate synovial membranes. They are situated at the furthest point from the central organ of the circulation and exposed to vicissitudes of temperature; and, moreover, on their dorsal surface are thinly clad with soft parts which have but a scanty blood-supply. And finally, after slight injuries, they are not maintained in a condition of rest to the same extent as similar injuries in some other parts of the body. Caries of the calcaneum and astragalus may remain limited to the one bone for a long period, but when one of the other bones is affected, the remainder frequently become involved, in consequence of the disease spreading through the large and complicated synovial membrane which is more or less common to these bones.

Amputation of the whole or a part of the foot is frequently required either for injury or disease. The principal amputations are as follow: (1) Syme's: amputations at the ankle-joint by a heel-flap, with removal of the malleoli and sometimes a thin slice from the lower end of the tibia. (2) Roux's: amputation at the ankle-joint by a large internal flap. (3) Pirogoff's amputation: removal of the whole of the tarsal bones, except the posterior part of the os calcis, and a thin slice from the tibia and fibula including the two malleoli. The sawn surface of the os calcis is then turned up and united to the similar surface of the tibia. (4) Subastragaloid amputation: removal of the foot below the astragalus through the joint between it and the os calcis. This operation has been modified by Hancock, who leaves the posterior third of the os calcis and turns it up against the denuded surface of the astragalus. This latter operation is of doubtful utility, and is rarely performed. (5) Chopart's or medio-tarsal: removal of the anterior part of the foot with all the tarsal bones except the os calcis and astragalus; disarticulation being effected through the joints between the scaphoid and cuboid in front, and the astragalus and os calcis behind. (6) Lisfranc's: amputation of the anterior part of the foot through the tarso-metatarsal joints. This has been modified by Hey, who disarticulated through the joints of the four outer metatarsal bones with the tarsus, and sawed off the projecting internal cuneiform; and by Skey, who sawed off the base of the second metatarsal bone and disarticulated the others.

The bones of the tarsus occasionally require removal individually. This is especially the case with the astragalus and os calcis for disease limited to the one bone, or again the astragalus may require excision in cases of subastragaloid dislocation, or, as recommended by Mr. Lund, in cases of inveterate talipes. The cuboid has been removed for the same reason by Mr. Solly. But both these two latter operations have fallen very much into disuse, and have been superseded by resection of a wedge-shaped piece of bone from the outer side of the tarsus. Finally, Mickulicz and Watson have devised operations for the removal of more extensive portions of the tarsus. Mickulicz's operation consists in the removal of the os calcis and astragalus, along with the articular surfaces of the tibia and fibula, and also of the scaphoid and cuboid. The remaining portion of the tarsus is then brought into contact with the sawn surfaces of the tibia and fibula, and fixed there. The result is a position of the shortened foot resembling talipes equinus. Watson's operation is adapted to those cases where the disease is confined to the anterior tarsal bones. By two lateral incisions he saws through the bases of the metatarsal bones in front and opens up the joints between the scaphoid and astragalus, and the cuboid and os calcis, and removes the intervening bones.

The metatarsal bones and phalanges are nearly always broken by direct violence, and in the majority of cases the injury is the result of severe crushing accidents, necessitating amputation. The metatarsal bones, and especially the one of the great toe, are frequently diseased, either in tuberculous subjects or in perforating ulcer of the foot.

Sesamoid Bones

These are small rounded masses, cartilaginous in early life, osseous in the adult, which are developed in those tendons which exert a great amount of pressure upon the parts over which they glide. It is said that they are more commonly found in the male than in the female, and in persons of an active muscular habit than in those who are weak and debilitated. They are invested throughout their whole surface by the fibrous tissue of the tendon in which they are found, excepting upon that side which lies in contact with the part over which they play, where they present a free articular facet. They may be divided into two kinds: those which glide over the articular surfaces of joints, and those which play over the cartilaginous facets found on the surfaces of certain bones.

The sesamoid bones of the joints in the upper extremity are two on the palmar surface of the metacarpo-phalangeal joint in the thumb, developed in the tendons of the Flexor brevis pollicis; occasionally one or two opposite the metacarpo-phalangeal articulations of the fore and little fingers; and, still more rarely, one opposite the same joints of the third and fourth fingers. In the lower extremity, the patella, which is developed in the tendon of the Quadriceps extensor; two small sesamoid bones, found in the tendons of the Flexor brevis hallucis, opposite the metatarso-phalangeal joint of the great toe; and occasionally one in the metatarso-phalangeal joint of the second toe, the little toe, and, still more rarely, the third and fourth toes.

Those found in the tendons which glide over certain bones occupy the following situations: one sometimes found in the tendon of the Biceps cubiti, opposite the tuberosity of the radius; one in the tendon of the Peroneus longus, where it glides through the groove in the cuboid bone; one appears late in life in the tendon of the Tibialis anticus, opposite the smooth facet of the internal cuneiform bone; one is found in the tendon of the Tibialis posticus, opposite the inner side of the head of the astragalus; one in the outer head of the Gastrocnemius, behind the outer condyle of the femur; and one in the conjoined tendon of the Psoas and Iliacus, where it glides over the os pubis. Sesamoid bones are found occasionally in the tendon of the Gluteus maximus, as it passes over the great trochanter; and in the tendons which wind round the inner and outer malleoli.

THE ARTICULATIONS

THE various bones of which the Skeleton consists are connected together at different parts of their surfaces, and such a connection is designated by the name of *Joint* or *Articulation*. If the joint is *immovable*, as between the cranial and most of the facial bones, the adjacent margins of the bones are applied in almost close contact, a thin layer of fibrous membrane, the *sutural ligament*, and, at the base of the skull, in certain situations, a thin layer of cartilage being interposed. Where slight movement is required, combined with great strength, the osseous surfaces are united by tough and elastic fibro-cartilages, as in the joints of the spine, the sacro-iliac and interpubic articulations; but in the *movable* joints, the bones forming the articulation are generally expanded for greater convenience of mutual connection, covered by *cartilage*, held together by strong bands or capsules of fibrous tissue, called *ligaments*, and partially lined by a membrane, the *synovial membrane*, which secretes a fluid to lubricate the various parts of which the joint is formed: so that the structures which enter into the formation of a joint are bone, cartilage, fibro-cartilage, ligament, and synovial membrane.

Bone constitutes the fundamental element of all the joints. In the long bones, the extremities are the parts which form the articulations; they are generally somewhat enlarged, consisting of spongy cancellous tissue with a thin coating of compact substance. In the flat bones, the articulations usually take place at the edges; and in the short bones at various parts of their surface. The layer of compact bone which forms the articular surface, and to which the cartilage is attached, is called the *articular lamella*. It is of white colour, extremely dense, and varies in thickness. Its structure differs from ordinary bone-tissue in this respect, that it contains no Haversian canals, and its lacunæ are much larger than in ordinary bone, and have no canaliculi. The vessels of the cancellous tissue, as they approach the articular lamella, turn back in loops, and do not perforate it; this layer is consequently more dense and firmer than ordinary bone, and is evidently designed to form a firm and unyielding support for the articular cartilage.

The **cartilage** which covers the articular surfaces of bone, and is called *articular*, will be found described, with the other varieties of cartilage, in the section on General Anatomy (page 21).

Ligaments consist of bands of various forms, serving to connect together the articular extremities of bones, and composed mainly of bundles of *white fibrous tissue* placed parallel with, or closely interlaced with one another, and presenting a white, shining silvery aspect. A ligament is pliant and flexible, so as to allow of the most perfect freedom of movement, but strong, tough, and inextensile, so as not readily to yield under the most severely applied force; it is consequently well adapted to serve as the connecting medium between the bones. Some ligaments consist entirely of *yellow elastic tissue*, as the ligamenta subflava, which connect together the adjacent arches of the vertebræ, and the ligamentum nuchæ in the lower animals. In these cases it will be observed that the elasticity of the ligament is intended to act as a substitute for muscular power.

Synovial membrane is a thin, delicate membrane of connective tissue, with branched connective-tissue corpuscles. Its secretion is thick, viscid, and glairy, like the white of an egg; and is hence termed *synovia*. The synovial membranes found in the body admit of subdivision into three kinds—articular, bursal, and vaginal.

The *articular synovial membranes* are found in all the freely movable joints. In the fœtus this membrane is said, by Toynbee, to be continued over the surface of the cartilages; but in the adult it is wanting, excepting at their circumference, upon which it encroaches for a short distance and to which it is firmly attached: it then invests the inner surface of the capsular or other ligaments enclosing the

joint, and is reflected over the surface of any tendons passing through its cavity, as the tendon of the Popliteus in the knee, and the tendon of the Biceps in the shoulder. Hence the articular synovial membrane may be regarded as a short wide tube, attached by its open ends to the margins of the articular cartilages and covering the inner surface of the various ligaments which connect the articular surfaces, so that along with the cartilages it completely encloses the joint cavity. In some of the joints the synovial membrane is thrown into folds, which pass across the cavity. They are called *synovial ligaments*, and are especially distinct in the knee. In other joints there are flattened folds, subdivided at their margins into fringe-like processes, the vessels of which have a convoluted arrangement. These latter generally project from the synovial membrane near the margin of the cartilage, and lie flat upon its surface. They consist of connective tissue, covered with endothelium, and contain fat-cells in variable quantities, and, more rarely, isolated cartilage-cells. The larger folds often contain considerable quantities of fat. They were described, by Clopton Havers, as *mucilaginous glands*, and as the source of the synovial secretion. Under certain diseased conditions, similar processes are found covering the entire surface of the synovial membrane, forming a mass of pedunculated fibro-fatty growths, which projects into the joint. Similar structures are also found in some of the bursal and vaginal synovial membranes.

The *bursal synovial membranes* are found interposed between surfaces which move upon each other, producing friction, as in the gliding of a tendon, or of the integument over projecting bony surfaces. They admit of subdivision into two kinds, the *bursæ mucosæ* and the *bursæ synoviæ*. The *bursæ mucosæ* are large, simple, or irregular cavities in the subcutaneous areolar tissue, enclosing a clear viscid fluid. They are found in various situations, as between the integument and the front of the patella, over the olecranon, the malleoli, and other prominent parts. The *bursæ synoviæ* are found interposed between muscles or tendons as they play over projecting bony surfaces, as between the Glutei muscles and the surface of the great trochanter. They consist of a thin wall of connective tissue, partially covered by patches of cells, and contain a viscid fluid. Where one of these exists in the neighbourhood of a joint, it usually communicates with its cavity, as is generally the case with the bursa between the tendon of the Psoas and Iliacus and the capsular ligament of the hip, or the one interposed between the under surface of the Subscapularis and the neck of the scapula.

The *vaginal synovial membranes* (*synovial sheaths*) serve to facilitate the gliding of tendons in the osseo-fibrous canals through which they pass. The membrane is here arranged in the form of a sheath, one layer of which adheres to the wall of the canal, and the other is reflected upon the surface of the contained tendon; the space between the two free surfaces of the membrane being partially filled with the synovia. These sheaths are chiefly found surrounding the tendons of the flexor and extensor muscles of the fingers and toes, as they pass through the osseo-fibrous canals in the hand or foot.

Synovia is a transparent, yellowish-white, or slightly reddish fluid, viscid like the white of egg, having an alkaline reaction and slightly saline taste. It consists, according to Frerichs, in the ox, of 94·85 water, 0·56 mucus and epithelium, 0·07 fat, 3·51 albumen and extractive matter, and 0·99 salts.

The articulations are divided into three classes: *synarthrosis*, or immovable; *amphiarthrosis*, or mixed; and *diarthrosis*, or movable joints.

1. Synarthrosis: Immovable Articulations

Synarthrosis includes all those articulations in which the surfaces of the bones are in almost direct contact, fastened together by an intervening mass of connective tissue, and in which there is no appreciable motion, as the joints between the bones of the cranium and face, excepting those of the lower jaw. The varieties of synarthrosis are four in number: Sutura, Schindylesis, Gomphosis, and Synchondrosis.

Sutura (*a seam*) is that form of articulation where the contiguous margins of flat bones are united by a thin layer of fibrous tissue. It is met with only in the skull. When the articulating surfaces are connected by a series of processes and indentations interlocked together, it is termed *sutura vera*; of which there are three varieties: sutura dentata, serrata, and limbosa. The surfaces of the bones are not in direct contact, being separated by a layer of membrane, continuous externally with the pericranium, internally with the dura mater. The *sutura dentata* (dens, *a tooth*) is so called from the tooth-like form of the projecting articular processes, as in the suture between the parietal bones. In the *sutura serrata* (serra, *a saw*) the edges of the two bones forming the articulation are serrated like the teeth of a fine saw, as between the two portions of the frontal bone. In the *sutura limbosa* (limbus, *a selvage*), besides the dentated processes, there is a certain degree of bevelling of the articular surfaces, so that the bones overlap one another, as in the suture between the parietal and frontal bones. When the articulation is formed by roughened surfaces placed in apposition with one another, it is termed the *false suture* (*sutura notha*), of which there are two kinds, the *sutura squamosa* (squama, *a scale*), formed by the overlapping of two contiguous bones by broad bevelled margins, as in the squamo-parietal (squamous) suture; and the *sutura harmonia* (ἁρμονία, *a joining together*), where there is simple apposition of two contiguous rough bony surfaces, as in the articulation between the two superior maxillary bones, or of the horizontal plates of the palate bones.

Schindylesis (σχινδύλησις, *a fissure*) is that form of articulation in which a thin plate of bone is received into a cleft or fissure formed by the separation of two laminæ in another bone, as in the articulation of the rostrum of the sphenoid and perpendicular plate of the ethmoid with the vomer, or in the reception of the latter in the fissure between the superior maxillary and palate bones.

Gomphosis (γόμφος, *a nail*) is an articulation formed by the insertion of a conical process into a socket, as a nail is driven into a board; this is not illustrated by any articulation between bones, properly so called, but is seen in the articulation of the teeth with the alveoli of the maxillary bones.

Synchondrosis.—Where the connecting medium is cartilage the joint is termed a synchondrosis. This is a temporary form of joint, for the cartilage becomes converted into bone before adult life. Such a joint is found between the epiphyses and shafts of long bones.

2. Amphiarthrosis. Mixed Articulations

In this form of articulation, the contiguous osseous surfaces are either connected together by broad flattened discs of fibro-cartilage, of a more or less complex structure, which adhere to the end of each bone, as in the articulation between the bodies of the vertebræ, and the sacro-iliac and pubic symphyses. This is termed **Symphysis.** Or, secondly, the bony surfaces are united by an interosseous ligament, as in the inferior tibio-fibular articulation. To this the term **Syndosmosis** is applied.

3. Diarthrosis. Movable Articulations

This form of articulation includes the greater number of the joints in the body, mobility being their distinguishing character. They are formed by the approximation of two contiguous bony surfaces, covered with cartilage, connected by ligaments, and lined by synovial membrane. The varieties of joints in this class have been determined by the kind of motion permitted in each. There are two varieties in which the movement is uniaxial, that is to say, all movements take place around one axis. In one form, the Ginglymus, this axis is practically speaking transverse; in the other, the trochoid or pivot-joint, it is longitudinal. There are two varieties where the movement is biaxial, or around two horizontal axes at right angles to each other, or at any intervening axis between the two. These are the condyloid and saddle-joint. There is one form of joint where the

movement is polyaxial, the enarthrosis or ball-and-socket joint. And finally there are the Arthrodia or Gliding joints.

Ginglymus or Hinge-joint (*γίγγλυμος, a hinge*).—In this form of joint the articular surfaces are moulded to each other in such a manner as to permit motion only in one plane, forwards and backwards; the extent of motion at the same time being considerable. The direction which the distal bone takes in this motion is never in the same plane as that of the axis of the proximal bone, but there is always a certain amount of alteration from the straight line during flexion. The articular surfaces are connected together by strong lateral ligaments, which form their chief bond of union. The most perfect forms of ginglymus are the interphalangeal joints and the joint between the humerus and ulna; the knee and ankle are less perfect, as they allow a slight degree of rotation or lateral movement in certain positions of the limb.

Trochoides (*pivot-joint*).—Where the movement is limited to rotation, the joint is formed by a pivot-like process turning within a ring, or the ring on the pivot, the ring being formed partly of bone, partly of ligament. In the superior radio-ulnar articulation, the ring is formed partly by the lesser sigmoid cavity of the ulna; in the rest of its extent, by the orbicular ligament; here, the head of the radius rotates within the ring. In the articulation of the odontoid process of the axis with the atlas, the ring is formed in front by the anterior arch of the atlas; behind, by the transverse ligament; here the ring rotates round the odontoid process.

Condyloid Articulations.—In this form of joint, an ovoid articular head, or condyle, is received into an elliptical cavity in such a manner as to permit of flexion and extension, adduction and abduction and circumduction, but no axial rotation. The articular surfaces are connected together by anterior, posterior, and lateral ligaments. An example of this form of joint is found in the wrist.

Articulations by Reciprocal Reception (*saddle-joint*).—In this variety the articular surfaces are concavo-convex; that is to say, they are inversely convex in one direction and concave in the other. The movements are the same as in the preceding form; that is to say, there is flexion, extension, adduction, abduction, and circumduction, but no axial rotation. The articular surfaces are connected by a capsular ligament. The best example of this form of joint is the carpo-metacarpal joint of the thumb.

Enarthrosis is that form of joint in which the distal bone is capable of motion around an indefinite number of axes, which have one common centre. It is formed by the reception of a globular head into a deep cup-like cavity (hence the name 'ball-and-socket'), the parts being kept in apposition by a capsular ligament strengthened by accessory ligamentous bands. Examples of this form of articulation are found in the hip and shoulder.

Arthrodia is that form of joint which admits of a gliding movement; it is formed by the approximation of plane surfaces, or one slightly concave, the other slightly convex; the amount of motion between them being limited by the ligaments, or osseous processes, surrounding the articulation; as in the articular processes of the vertebræ, the carpal joints, except that of the os magnum with the scaphoid and semilunar bones, and the tarsal joints with the exception of the joint between the astragalus and the navicular.

On the next page, in a tabular form, are the names, distinctive characters, and examples of the different kinds of articulations.

The Kinds of Movement admitted in Joints

The movements admissible in joints may be divided into four kinds: gliding, angular movement, circumduction, and rotation. These movements are often, however, more or less combined in the various joints, so as to produce an infinite variety, and it is seldom that we find only one kind of motion in any particular joint.

Synarthrosis, or Immovable Joint. Surfaces separated by fibrous membrane, without any intervening synovial cavity, and immovably connected with each other.

As in joints of cranium and face (except lower jaw).

Sutura. Articulation by processes and indentations interlocked together.

Sutura vera (true) articulate by indented borders.

Dentata, having tooth-like processes.

As in interparietal suture.

Serrata, having serrated edges like the teeth of a saw.

As in interfrontal suture.

Limbosa, having bevelled margins, and dentated processes.

As in fronto-parietal suture.

Sutura notha (false) articulate by rough surfaces.

Squamosa, formed by thin bevelled margins, overlapping each other.

As in squamo-parietal suture.

Harmonia, formed by the apposition of contiguous rough surfaces.

As in intermaxillary suture.

Schindylesis.—Articulation formed by the reception of a thin plate of one bone into a fissure of another.

As in articulation of rostrum of sphenoid with vomer.

Gomphosis.—Articulation formed by the insertion of a conical process into a socket.

The teeth.

Amphiarthrosis, Mixed Articulation.

Symphysis.—Surfaces connected by fibro-cartilage, not separated by synovial membrane, and having limited motion. As in joints between bodies of vertebræ.

Syndosmosis.—Surfaces united by an interosseous ligament. As in the inferior tibio-fibular articulation.

Diarthrosis, Movable Joint.

Ginglymus.—Hinge-joint; motion limited to two directions, forwards and backwards. Articular surfaces fitted together so as to permit of movement in one plane. As in the inter-phalangeal joints and the joint between the humerus and the ulna.

Trochoides or Pivot-joint.—Articulation by a pivot process turning within a ring, or ring around a pivot. As in superior radio-ulnar articulation, and atlanto-axial joint.

Condyloid.—Ovoid head received into elliptical cavity. Movements in every direction except axial rotation. As the wrist-joint.

Reciprocal Reception (*Saddle-joint*).—Articular surfaces inversely convex in one direction and concave in the other. Movement in every direction except axial rotation. As in the carpo-metacarpal joint of the thumb.

Enarthrosis.—Ball-and-socket joint; capable of motion in all directions. Articulations by a globular head received into a cup-like cavity. As in hip- and shoulder-joints.

Arthrodia.—Gliding-joint; articulations by plane surfaces, which glide upon each other. As in carpal and tarsal articulations.

Gliding movement is the most simple kind of motion that can take place in a joint, one surface gliding or moving over another without any angular or rotatory movement. It is common to all movable joints; but in some, as in most of the articulations of the carpus and tarsus, it is the only motion permitted. This movement is not confined to plane surfaces, but may exist between any two contiguous surfaces, of whatever form, limited by the ligaments which enclose the articulation.

Angular movement occurs only between the long bones, and by it the angle between the two bones is increased or diminished. It may take place in four directions: forwards and backwards, constituting flexion and extension, or inwards and outwards, from the mesial line of the body (or in the fingers and toes from the middle line of the hand or foot), constituting adduction and abduction. The strictly ginglymoid or hinge-joints admit of flexion and extension only. Abduction and adduction, combined with flexion and extension, are met with in the more movable joints; as in the hip, shoulder, and metacarpal joint of the thumb, and partially in the wrist.

Circumduction is that limited degree of motion which takes place between the head of a bone and its articular cavity, whilst the extremity and sides of the limb are made to circumscribe a conical space, the base of which corresponds with the inferior extremity of the limb, the apex with the articular cavity; this kind of motion is best seen in the shoulder- and hip-joints.

Rotation is the movement of a bone upon an axis, which is the axis of the pivot on which the bone turns, as in the articulation between the atlas and axis, where the odontoid process serves as a pivot around which the atlas turns; or else is the axis of a pivot-like process which turns within a ring, as in the rotation of the radius upon the humerus.

Ligamentous Action of Muscles.—The movements of the different joints of a limb are combined by means of the long muscles which pass over more than one joint, and which, when relaxed and stretched to their greatest extent, act to a certain extent as elastic ligaments in restraining certain movements of one joint, except when combined with corresponding movements of the other—these latter movements being usually in the opposite direction. Thus the shortness of the hamstring muscles prevents complete flexion of the hip, unless the knee-joint is also flexed, so as to bring their attachments nearer together. The uses of this arrangement are threefold. 1. It co-ordinates the kinds of movement which are the most habitual and necessary, and enables them to be performed with the least expenditure of power. 'Thus in the usual gesture of the arms, whether in grasping or rejecting, the shoulder and the elbow are flexed simultaneously, and simultaneously extended,' in consequence of the passage of the Biceps and Triceps cubiti over both joints. 2. It enables the short muscles which pass over only one joint to act upon more than one. 'Thus, if the Rectus femoris remain tonically of such length that, when stretched over the extended hip, it compels extension of the knee, then the Gluteus maximus becomes, not only an extensor of the hip, but an extensor of the knee as well.' 3. It provides the joints with ligaments which, while they are of very great power in resisting movements to an extent incompatible with the mechanism of the joint, at the same time spontaneously yield when necessary. 'Taxed beyond its strength a ligament will be ruptured, whereas a contracted muscle is easily relaxed; also, if neighbouring joints be united by ligaments, the amount of flexion or extension of each must remain in constant proportion to that of the other; while, if the union be by muscles, the separation of the points of attachment of those muscles may vary considerably in different varieties of movement, the muscles adapting themselves tonically to the length required.' The quotations are from a very interesting paper by Dr. Cleland in the 'Journal of Anatomy and Physiology,' No. 1, 1866, p. 85; by whom I believe this important fact in the mechanism of joints was first clearly pointed out, though it has been independently observed afterwards by other anatomists. Dr. W. W. Keen points out how important it is 'that the

surgeon should remember this ligamentous action of muscles in making passive motion—for instance, at the wrist after Colles' fracture. If the fingers be extended, the wrist can be flexed to a right angle. If, however, they be first flexed as in "making a fist," flexion at the wrist is quickly limited to from forty to fifty degrees in different persons, and is very painful beyond that point. Hence passive motion here should be made with the fingers extended. In the leg, when flexing the hip, the knee should be flexed.' Dr. Keen further points out that 'a beautiful illustration of this is seen in the perching of birds, whose toes are forced to clasp the perch by just such a passive ligamentous action so soon as they stoop. Hence they can go to sleep and not fall off the perch.'

The articulations may be arranged into those of the trunk, those of the upper extremity, and those of the lower extremity.

ARTICULATIONS OF THE TRUNK

These may be divided into the following groups, viz.:—

I. Of the vertebral column.
II. Of the atlas with the axis.
III. Of the atlas with the occipital bone.
IV. Of the axis with the occipital bone.
V. Of the lower jaw.
VI. Of the ribs with the vertebræ.
VII. Of the cartilages of the ribs with the sternum, and with each other.
VIII. Of the sternum.
IX. Of the vertebral column with the pelvis.
X. Of the pelvis.

I. Articulations of the Vertebral Column

The different segments of the spine are connected together by ligaments, which admit of the same arrangement as the vertebræ. They may be divided into five sets. 1. Those connecting the *bodies* of the vertebræ. 2. Those connecting the *laminæ*. 3. Those connecting the *articular processes*. 4. Those connecting the *spinous processes*. 5. Those connecting the *transverse processes*.

The articulations of the *bodies* of the vertebræ with each other form a series of amphiarthrodial joints; those between the *articular processes* form a series of arthrodial joints.

1. The Ligaments of the Bodies

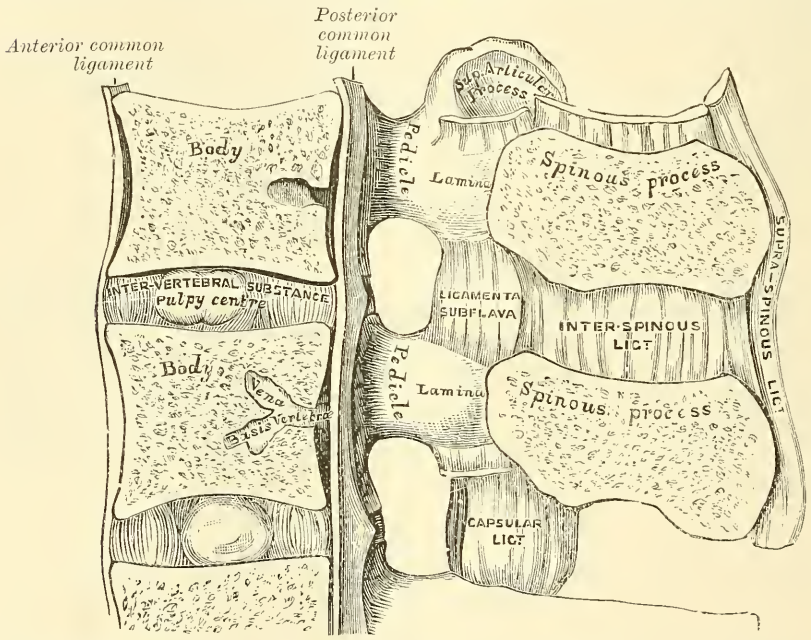
Anterior Common Ligament. Posterior Common Ligament.
Intervertebral Substance.

The **Anterior Common Ligament** (figs. 263, 264, 271, 275) is a broad and strong band of ligamentous fibres, which extends along the front surface of the bodies of the vertebræ, from the axis to the sacrum. It is broader below than above, thicker in the dorsal than in the cervical or lumbar regions, and somewhat thicker opposite the front of the body of each vertebra than opposite the intervertebral substance. It is attached, above, to the body of the axis by a pointed process, where it is continuous with the anterior atlanto-axial ligament, and is connected with the tendon of insertion of the Longus colli muscle, and extends down as far as the upper bone of the sacrum. It consists of dense longitudinal fibres, which are intimately adherent to the intervertebral substance, and the prominent margins of the vertebræ; but less closely to the middle of the bodies. In the latter situation the fibres are exceedingly thick, and serve to fill up the concavities on their front surface, and to make the anterior surface of the spine more even. This ligament is composed of several layers of fibres, which vary in length, but are closely interlaced with each other. The most superficial or longest fibres extend between four or five vertebræ. A second subjacent set extend between two or three vertebræ; whilst a third set, the

shortest and deepest, extend from one vertebra to the next. At the sides of the bodies the ligament consists of a few short fibres, which pass from one vertebra to the next, separated from the median portion by large oval apertures, for the passage of vessels.

The **Posterior Common Ligament** (figs. 263, 267) is situated within the spinal canal, and extends along the posterior surface of the bodies of the vertebræ, from the body of the axis above, where it is continuous with the occipito-axial ligament, to the sacrum below. It is broader above than below, and thicker in the dorsal than in the cervical or lumbar regions. In the situation of the intervertebral substance and contiguous margins of the vertebræ, where the ligament is more intimately adherent, it is broad, and presents a series of dentations with intervening concave margins; but it is narrow and thick over the centre of the bodies, from which it is separated by the *venæ basis vertebræ*. This ligament is composed of smooth, shining, longitudinal fibres, denser and more compact than those of the anterior ligament, and composed of a superficial layer occupying

Fig. 263.—Vertical section of two vertebræ and their ligaments, from the lumbar region.



the interval between three or four vertebræ, and of a deeper layer which extends between one vertebra and the next adjacent to it. It is separated from the dura mater of the spinal cord by some loose connective tissue which is very liable to serous infiltration.

The **Intervertebral Substance** (figs. 263, 272) is a lenticular disc of composite structure interposed between the adjacent surfaces of the bodies of the vertebræ, from the axis to the sacrum, and forming the chief bond of connection between these bones. The discs vary in shape, size, and thickness, in different parts of the spine. In *shape* they accurately correspond with the surfaces of the bodies between which they are placed, being oval in the cervical and lumbar regions, and circular in the dorsal. Their *size* is greatest in the lumbar region. In *thickness* they vary not only in the different regions of the spine, but in different parts of the same disc: thus, they are much thicker in front than behind in the cervical and lumbar regions, while they are uniformly thick in the dorsal region. The intervertebral discs form about one-fourth of the spinal column, exclusive of the first two vertebræ; they are not equally distributed, however, between

the various bones; the dorsal portion of the spine having, in proportion to its length, a much smaller quantity than the cervical and lumbar regions, which necessarily gives to the latter parts greater pliancy and freedom of movement. The intervertebral discs are adherent, by their surfaces, to a thin layer of hyaline cartilage which covers the upper and under surfaces of the bodies of the vertebræ, and in which in early life the epiphysial plate develops; and by their circumference are closely connected in front to the anterior, and behind to the posterior common ligament; whilst in the dorsal region they are connected laterally, by means of the interarticular ligament, to the heads of those ribs which articulate with two vertebræ: they, consequently, form part of the articular cavities in which the heads of these bones are received.

Structure of the Intervertebral Substance.—The intervertebral substance is composed, at its circumference, of laminæ of fibrous tissue and fibro-cartilage; and, at its centre, of a soft, pulpy, highly elastic substance, of a yellowish colour, which rises up considerably above the surrounding level when the disc is divided horizontally. This pulpy substance, which is especially well developed in the lumbar region, is the remains of the chorda dorsalis, and, according to Luschka, contains a small synovial cavity in its centre. The laminæ are arranged concentrically one within the other, the outermost consisting of ordinary fibrous tissue, but the others and more numerous consisting of white fibro-cartilage. These plates are not quite vertical in their direction, those near the circumference being curved outwards and closely approximated; whilst those nearest the centre curve in the opposite direction, and are somewhat more widely separated. The fibres of which each plate is composed are directed, for the most part, obliquely from above downwards; the fibres of adjacent plates passing in opposite directions and varying in every layer: so that the fibres of one layer are directed across those of another, like the limbs of the letter X. This laminar arrangement belongs to about the outer half of each disc. The pulpy substance presents no concentric arrangement, and consists of a fine fibrous matrix, containing angular cells, united to form a reticular structure.

2. Ligaments connecting the Laminæ

Ligamenta Subflava.

The **Ligamenta Subflava** (fig. 263) are interposed between the laminæ of the vertebræ, from the axis to the sacrum. They are most distinct when seen from the interior of the spinal canal: when viewed from the outer surface they appear short, being overlapped by the laminæ. Each ligament consists of two lateral portions, which commence on each side at the root of either articular process, and pass backwards to the point where the laminæ converge to form the spinous process, where their margins are in contact and to a certain extent united; slight intervals being left for the passage of small vessels. These ligaments consist of yellow elastic tissue, the fibres of which, almost perpendicular in direction, are attached to the anterior surface of the lamina above, some distance from its inferior margin, and to the posterior surface, as well as to the margin of the lamina below. In the cervical region they are thin in texture, but very broad and long; they become thicker in the dorsal region; and in the lumbar acquire very considerable thickness. Their highly elastic property serves to preserve the upright posture, and to assist the spine in resuming it, after it has been flexed. These ligaments do not exist between the occiput and atlas, or between the atlas and axis.

3. Ligaments connecting the Articular Processes

Capsular.

The **Capsular Ligaments** (fig. 265) are thin and loose ligamentous sacs, attached to the contiguous margins of the articulating processes of each vertebra, through

the greater part of their circumference, and completed internally by the ligamenta subflava. They are longer and looser in the cervical than in the dorsal or lumbar regions. The capsular ligaments are lined on their inner surface by synovial membrane.

4. Ligaments connecting the Spinous Processes

Supraspinous. Interspinous.

The **Supraspinous Ligament** (fig. 263) is a strong fibrous cord, which connects together the apices of the spinous processes from the seventh cervical to the spinous processes of the sacrum. It is thicker and broader in the lumbar than in the dorsal region, and intimately blended, in both situations, with the neighbouring aponeurosis. The most superficial fibres of this ligament connect three or four vertebræ; those deeper-seated pass between two or three vertebræ; whilst the deepest connect the contiguous extremities of neighbouring vertebræ. It is continued upwards to the external occipital protuberance, as the ligamentum nuchæ, which, in the human subject, is thin, and forms merely an intermuscular septum.

The **Interspinous Ligaments** (fig. 263), thin and membranous, are interposed between the spinous processes. These ligaments extend from the root to the summit of each spinous process, and are connected with the ligamenta subflava in front and the supraspinous ligament behind. They are narrow and elongated in the dorsal region; broader, quadrilateral in form, and thicker in the lumbar region; and only slightly developed in the neck.

5. Ligaments connecting the Transverse Processes

Intertransverse.

The **Intertransverse Ligaments** consist of bundles of fibres, interposed between the transverse processes. In the cervical region they consist of a few irregular, scattered fibres; in the dorsal, they are rounded cords intimately connected with the deep muscles of the back; in the lumbar region they are thin and membranous.

Actions.—The movements permitted in the spinal column are, Flexion, Extension, Lateral Movement, Circumduction, and Rotation.

In *Flexion*, or movement of the spine forwards, the anterior common ligament is relaxed, and the intervertebral substances are compressed in front; while the posterior common ligament, the ligamenta subflava, and the inter- and supraspinous ligaments are stretched, as well as the posterior fibres of the intervertebral discs. The interspaces between the laminæ are widened, and the inferior articular processes of the vertebræ above glide upwards, upon the articular processes of the vertebræ below. Flexion is the most extensive of all the movements of the spine.

In *Extension*, or movement of the spine backwards, an exactly opposite disposition of the parts takes place. This movement is not extensive, being limited by the anterior common ligament, and by the approximation of the spinous processes.

Flexion and extension are most free in the lower part of the lumbar region between the third and fourth and fourth and fifth lumbar vertebræ; above the third they are much diminished, and reach their minimum in the middle and upper part of the back. They increase again in the neck, the capability of motion backwards from the upright position being in this region greater than that of the motion forwards, whereas in the lumbar region the reverse is the case.

In *Lateral Movement*, the sides of the intervertebral discs are compressed, the extent of motion being limited by the resistance offered by the surrounding ligaments, and by the approximation of the transverse processes. This movement may take place in any part of the spine, but is most free in the neck and loins.

Circumduction is very limited, and is produced merely by a succession of the preceding movements.

Rotation is produced by the twisting of the intervertebral substances; this, although only slight between any two vertebræ, produces a great extent of movement, when it takes place in the whole length of the spine, the front of the upper part of the column being turned to one or the other side. This movement takes place only to a slight extent in the neck, but is freer in the upper part of the dorsal region, and is altogether absent in the lumbar region.

It is thus seen that the *cervical region* enjoys the greatest extent of each variety of movement, flexion and extension especially being very free. In the *dorsal region*, the three movements of flexion, extension, and circumduction are only permitted to a slight extent; while rotation is very free in the upper part and ceases below. In the lumbar region there is free flexion, extension, and lateral movement, but no rotation.

As Sir George Humphry has pointed out, the movements permitted are mainly due to the shape and position of the articulating processes. In the loins the inferior articulating processes are turned outwards and embraced by the superior; this renders rotation in this region of the spine impossible, while there is nothing to prevent a sliding upwards and downwards of the surfaces on each other so as to allow of flexion and extension. In the dorsal region, on the other hand, the articulating processes, by their direction and mutual adaptation, especially at the upper part of the series, permit of rotation, but prevent extension and flexion; while in the cervical region the greater obliquity and lateral slant of the articular processes allow not only flexion and extension, but also rotation.

The principal muscles which produce *flexion* are the Sterno-mastoid, Rectus capitus anticus major, and Longus colli; the Scaleni; the abdominal muscles and the Psoas magnus. *Extension* is produced by the fourth layer of the muscles of the back, assisted in the neck by the Splenius, Semispinalis dorsi et colli, and the Multifidus spinæ. *Lateral* motion is produced by the fourth layer of the muscles of the back, by the Splenius and the Scaleni, the muscles of one side only acting; and *rotation* by the action of the following muscles of one side only, viz. the Sterno-mastoid, the Rectus capitus anticus major, the Scaleni, the Multifidus spinæ, the Complexus, and the abdominal muscles.

II. Articulation of the Atlas with the Axis

The articulation of the Atlas with the Axis is of a complicated nature, comprising no fewer than four distinct joints. There is a pivot articulation between the odontoid process of the axis and the ring formed between the anterior arch of the atlas and the transverse ligament (see fig. 266). Here there are two joints: one in front between the posterior surface of the anterior arch of the atlas and the front of the odontoid process (the *atlo-odontoid joint of Cruveilhier*); the other between the anterior surface of the transverse ligament and the back of the process (the *syndesmo-odontoid joint*). Between the articulating processes of the two bones there is a double arthrodia or gliding joint. The ligaments which connect these bones are the

Two Anterior Atlanto-axial.	Transverse.
Posterior Atlanto-axial.	Two Capsular.

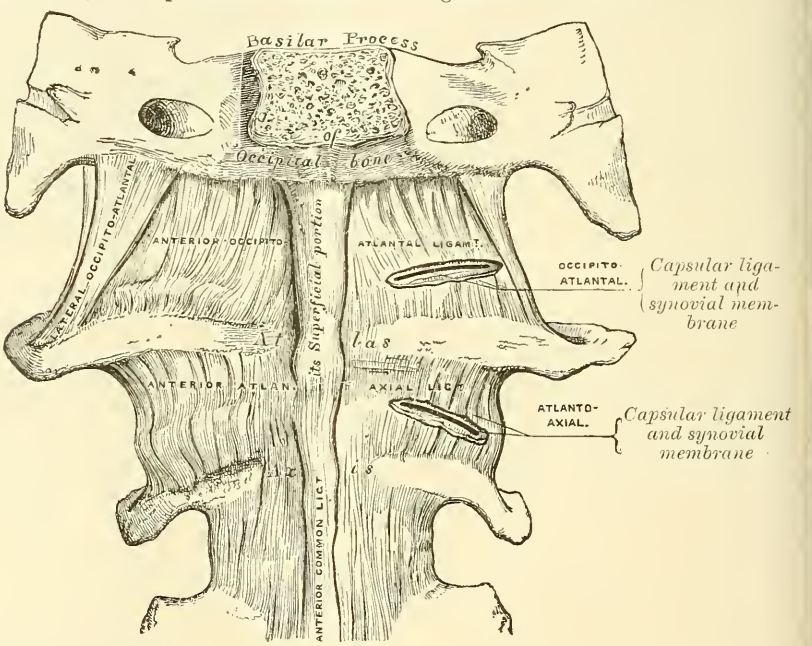
Of the **Two Anterior Atlanto-axial Ligaments** (fig. 264), the more superficial is a rounded cord, situated in the middle line; it is attached, above, to the tubercle on the anterior arch of the atlas; below, to the base of the odontoid process and to the front of the body of the axis. The deeper ligament is a membranous layer, attached, above, to the lower border of the anterior arch of the atlas; below, to the base of the odontoid process, and front of the

body of the axis. These ligaments are in relation, in front, with the Recti antici majores.

The **Posterior Atlanto-axial Ligament** (fig. 265) is a broad and thin membranous layer, attached, above, to the lower border of the posterior arch of the atlas; below, to the upper edge of the laminæ of the axis. This ligament supplies the place of the ligamenta subflava, and is in relation, behind, with the Inferior oblique muscles.

The **Transverse Ligament** * (figs. 266, 267) is a thick and strong ligamentous band, which arches across the ring of the atlas, and serves to retain the odontoid process in firm connection with its anterior arch. This ligament is flattened from before backwards, broader and thicker in the middle than at either extremity, and firmly attached on each side to a small tubercle on the inner surface of the lateral mass of the atlas. As it crosses the odontoid process, a small fasciculus is derived from its upper and lower borders; the former passing upwards, to be

Fig. 264.—Occipito-atloid and atlo-axoid ligaments. Front view.



inserted into the basilar process of the occipital bone; the latter, downwards, to be attached to the posterior surface of the body of the axis; hence, the whole ligament has received the name of *cruciform*. The transverse ligament divides the ring of the atlas into two unequal parts: of these, the posterior and larger serves for the transmission of the cord and its membranes and the spinal accessory nerves; the anterior and smaller contains the odontoid process. Since the space between the anterior arch of the atlas and the transverse ligament is smaller at the lower part than the upper (because the transverse ligament embraces firmly the narrow neck of the odontoid process), this process is retained in firm connection with the atlas after all the other ligaments have been divided.

The **Capsular Ligaments** are two thin and loose capsules, connecting the articular processes of the atlas and axis, the fibres being strongest on the posterior and inner part of the articulation.

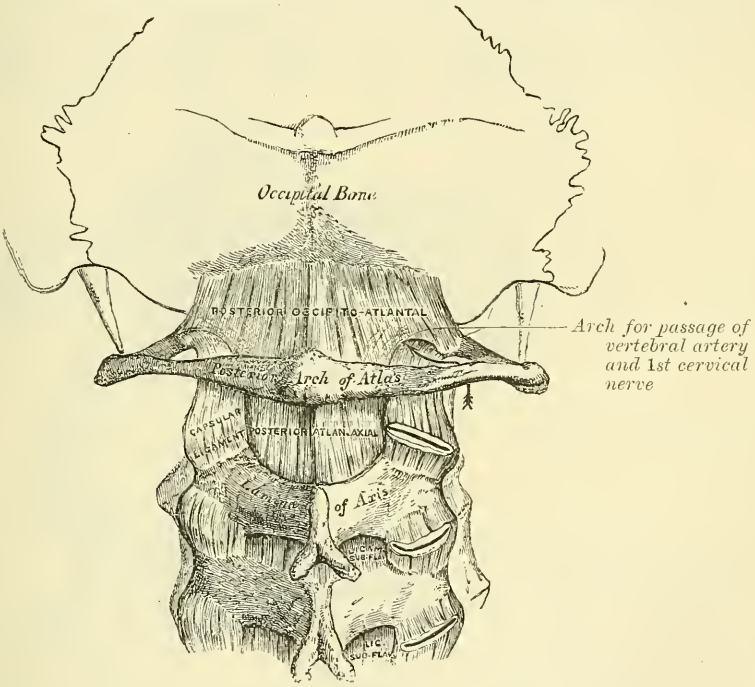
* It has been found necessary to describe the transverse ligament with those of the atlas and axis; but the student must remember that it is really a portion of the mechanism by which the movements of the head on the spine are regulated; so that the connections between the atlas and axis ought always to be studied together with those between the latter bones and the skull.

There are *four* **Synovial Membranes** in this articulation: one lining the inner surface of each of the capsular ligaments; one between the anterior surface of the odontoid process and the anterior arch of the atlas, the *atlo-odontoid joint*; and one between the posterior surface of the odontoid process and the transverse ligament, the *syndesmo-odontoid joint*. The latter often communicates with those between the condyles of the occipital bone and the articular surfaces of the atlas.

Actions.—This joint allows the rotation of the atlas (and, with it, of the cranium) upon the axis, the extent of rotation being limited by the odontoid ligaments.

The principal muscles by which this action is produced are the Sterno-mastoid and Complexus of one side, acting with the Rectus capitis anticus major, Splenius, Trachelo-mastoid, Rectus capitus posticus major, and Inferior oblique of the other side.

Fig. 265.—Occipito-atloid and atlo-axoid ligaments. Posterior view.



Articulations of the Spine with the Cranium

The ligaments connecting the spine with the cranium may be divided into two sets, those connecting the occipital bone with the atlas, and those connecting the occipital bone with the axis.

III. Articulation of the Atlas with the Occipital Bone

This articulation is a double condyloid joint. Its ligaments are, the

Two Anterior Occipito-atlantal.	Two Lateral Occipito-atlantal.
Posterior Occipito-atlantal.	Two Capsular.

Of the **Two Anterior Occipito-atlantal Ligaments** (fig. 264) the superficial is a strong, narrow, rounded cord, attached, above, to the basilar process of the occiput; below, to the tubercle on the anterior arch of the atlas: the deeper ligament is a broad and thin membranous layer which passes between the anterior margin of the foramen magnum above, and the whole length of

the upper border of the anterior arch of the atlas below. This ligament is in relation, in front, with the Recti antici minores; behind, with the odontoid ligaments.

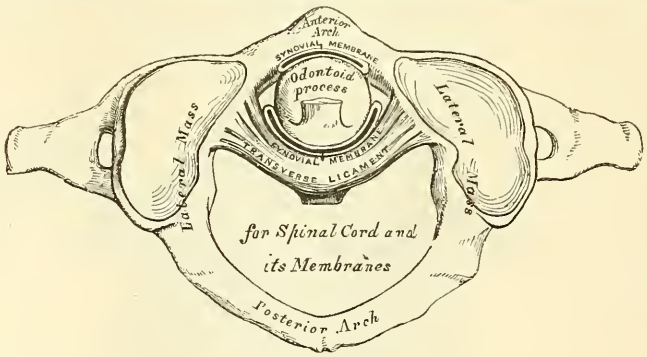
The **Posterior Occipito-atlantal Ligament** (fig. 265) is a very broad but thin membranous lamina, intimately blended with the dura mater. It is connected, above, to the posterior margin of the foramen magnum; below, to the upper border of the posterior arch of the atlas. This ligament is incomplete at each side, and forms, with the superior intervertebral notch, an opening for the passage of the vertebral artery and suboccipital nerve. It is in relation, behind, with the Recti postici minores and Obliqui superiores; in front, with the dura mater of the spinal canal, to which it is intimately adherent.

The **Lateral Ligaments** are strong fibrous bands, directed obliquely upwards and inwards, attached above to the jugular process of the occipital bone; below, to the base of the transverse process of the atlas.

The **Capsular Ligaments** surround the condyles of the occipital bone, and connect them with the articular processes of the atlas; they consist of thin and loose capsules, which enclose the synovial membrane of the articulation.

Synovial Membranes.—There are two synovial membranes in this articulation: one lining the inner surface of each of the capsular ligaments. These

Fig. 266.—Articulation between odontoid process and atlas.



occasionally communicate with that between the posterior surface of the odontoid process and the transverse ligament.

Actions.—The movements permitted in this joint are flexion and extension, which give rise to the ordinary forward and backward nodding of the head, besides slight lateral motion to one or the other side. When either of these actions is carried beyond a slight extent, the whole of the cervical portion of the spine assists in its production. Flexion is mainly produced by the action of the Rectus capitis anticus major et minor and the Sterno-mastoid muscles; extension by the Rectus capitis posticus major et minor, the Superior oblique, the Complexus, Splenius, and upper fibres of the Trapezius. The Recti laterales are concerned in the lateral movement, assisted by the Trapezius, Splenius, Complexus, Sterno-mastoid and the Recti laterales of the same side, all acting together. According to Cruveilhier, there is a slight motion of rotation in this joint.

IV. Articulation of the Axis with the Occipital Bone

Occipito-axial. Three Odontoid

To expose these ligaments, the spinal canal should be laid open by removing the posterior arch of the atlas, the laminæ and spinous process of the axis, and the portion of the occipital bone behind the foramen magnum, as seen in fig. 267.

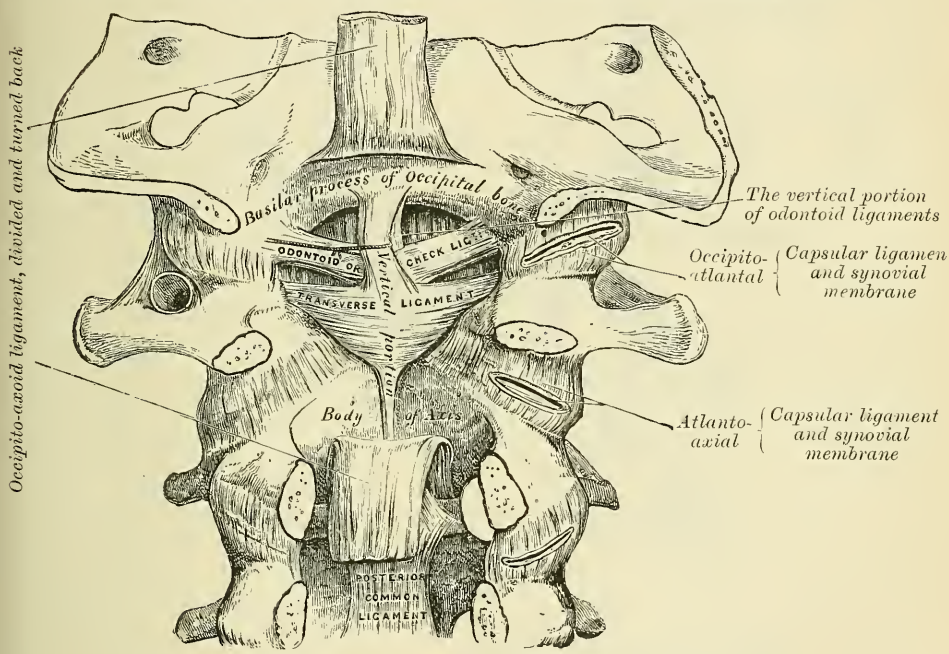
The **Occipito-axial Ligament** (*apparatus ligamentosus colli*) is situated within the spinal canal. It is a broad and strong ligamentous band which covers the

odontoid process and its ligaments, and appears to be a prolongation upwards of the posterior common ligament of the spine. It is attached, below, to the posterior surface of the body of the axis, and, becoming expanded as it ascends, is inserted into the basilar groove of the occipital bone, in front of the foramen magnum, where it becomes blended with the dura mater of the skull.

Relations.—By its anterior surface with the transverse ligament, by its posterior surface with the dura mater.

The **Odontoid** or **Check Ligaments** (*alar ligaments*) are strong, rounded, fibrous cords, which arise one on either side of the upper part of the odontoid process, and, passing obliquely upwards and outwards, are inserted into the rough depressions on the inner side of the condyles of the occipital bone. In the triangular interval left between these ligaments another strong fibrous cord (*ligamentum suspensorium* or *middle odontoid ligament*) may be seen, which

FIG. 267.—Occipito-axoid and atlo-axoid ligaments. Posterior view, obtained by removing the arches of the vertebræ and the posterior part of the skull.



passes almost perpendicularly from the apex of the odontoid process to the anterior margin of the foramen magnum, being intimately blended with the deep portion of the anterior occipito-atloid ligament, and upper fasciculus of the transverse ligament of the atlas.

Actions.— The odontoid ligaments serve to limit the extent to which rotation of the cranium may be carried; hence they have received the name of *check ligaments*.

In addition to these ligaments which connect the atlas and axis to the skull, the ligamentum nuchæ must be regarded as one of the ligaments by which the spine is connected with the cranium. It is described on a subsequent page.

Surgical Anatomy.—The ligaments which unite the component parts of the vertebræ together are so strong, and these bones are so interlocked by the arrangement of their articulating processes, that dislocation is very uncommon, and, indeed, unless accompanied by fracture, rarely occurs, except in the upper part of the neck. Dislocation of the occiput from the atlas has only been recorded in one or two cases; but dislocation of the atlas from the axis, with rupture of the transverse ligament, is much more common: it is the

mode in which death is produced in many cases of execution by hanging. In the lower part of the neck—that is, below the third cervical vertebra—dislocation unattended by fracture occasionally takes place.

V. Articulation of the Lower Jaw (Temporo-maxillary)

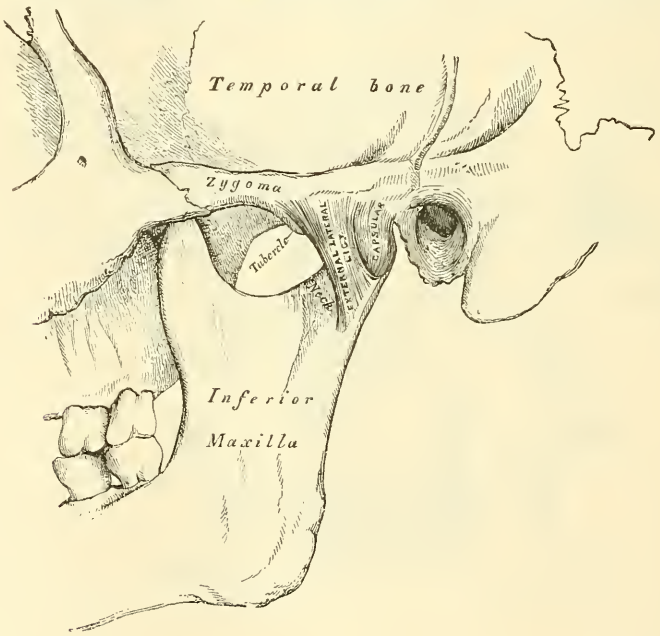
This is a ginglymo-arthrodial joint; the parts entering into its formation on each side are, above, the anterior part of the glenoid cavity of the temporal bone and the eminentia articularis; and, below, the condyle of the lower jaw. The ligaments are the following:—

External Lateral.	Stylo-maxillary.
Internal Lateral.	Capsular.

Interarticular Fibro-cartilage.

The **External Lateral Ligament** (fig. 268) is a short, thin, and narrow fasciculus attached, above, to the outer surface of the zygoma and to the tubercle on

Fig. 268.—Temporo-maxillary articulation. External view.

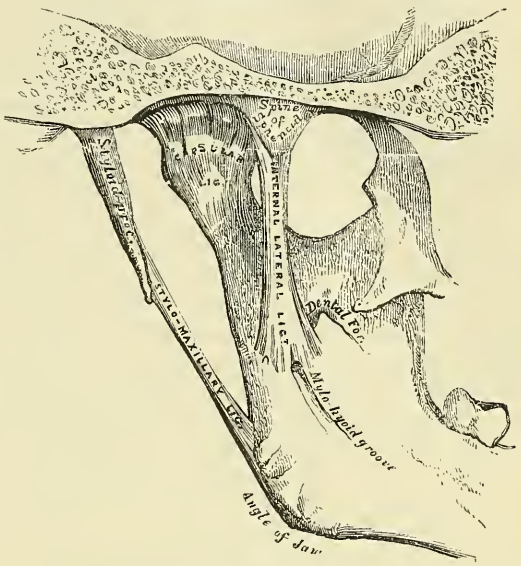


its lower border; below, to the outer surface and posterior border of the neck of the lower jaw. It is broader above than below; its fibres are placed parallel with one another, and directed obliquely downwards and backwards. Externally, it is covered by the parotid gland, and by the integument. Internally, it is in relation with the capsular ligament of which it is an accessory band, and not separable from it.

The **Internal Lateral Ligament** (fig. 269) is a flat thin band which is attached above to the spinous process of the sphenoid bone, and, becoming broader as it descends, is inserted into the lingula and margin of the dental foramen. Its outer surface is in relation, above, with the External pterygoid muscle; lower down, it is separated from the neck of the condyle by the internal maxillary artery; and still more inferiorly, the inferior dental vessels and nerve separate it from the ramus of the jaw. The inner surface is in relation with the Internal pterygoid. It is really the fibrous covering of a part of Meckel's cartilage (see p. 93).

The **Stylo-maxillary Ligament** is a specialised band of the cervical fascia, which extends from near the apex of the styloid process of the temporal bone to the angle and posterior border of the ramus of the lower jaw, between the Masseter and Internal pterygoid muscles. This ligament separates the parotid from the submaxillary gland, and has attached to its inner side part of the fibres of origin of the Stylo-glossus muscle. Although usually classed among the ligaments of the jaw, it can only be considered as an accessory to the articulation.

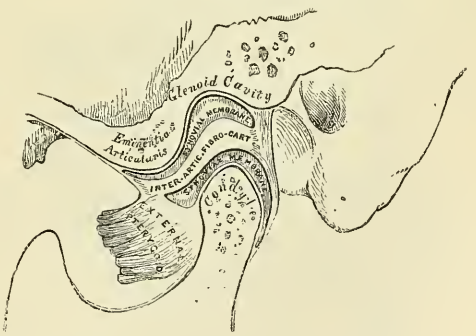
Fig. 269.—Temporo-maxillary articulation. Internal view.



The **Capsular Ligament** forms a thin and loose ligamentous capsule, attached above to the circumference of the glenoid cavity and the articular surface immediately in front; below, to the neck of the condyle of the lower jaw. It consists of a few thin scattered fibres, and can hardly be considered as a distinct ligament; it is thickest at the back part of the articulation.*

The **Interarticular Fibro-cartilage** (fig. 270) is a thin plate of an oval form, placed horizontally between the condyle of the jaw and the glenoid cavity. Its upper surface is concavo-convex from before backwards, and a little convex transversely, to accommodate itself to the form of the glenoid cavity. Its under surface, where it is in contact with the condyle, is concave. Its circumference is connected to the capsular ligament; and in front to the tendon of the External pterygoid muscle. It is thicker at its circumference, especially behind, than at its centre. The fibres of which it is composed have a concentric arrangement, more apparent at the circumference than at the centre. Its surfaces are smooth. It divides the joint into two cavities, each of which is furnished with a separate synovial membrane.

Fig. 270.—Vertical section of temporo-maxillary articulation.



The **Synovial Membranes**, two in number, are placed one above, and the other below, the fibro-cartilage. The upper one, the larger and looser of the two, is continued from the margin of the cartilage covering the glenoid cavity and eminentia articularis on to the upper surface of the fibro-cartilage. The lower one passes from the under surface of the fibro-cartilage to the neck of the condyle of the jaw, being prolonged downwards a little further behind than in front.

* Sir G. Humphry describes the internal portion of the capsular ligament separately, as the short internal lateral ligament; and it certainly seems as deserving of a separate description as the external lateral ligament is.

The interarticular cartilage is sometimes perforated in its centre, the two synovial sacs then communicate with each other.

The *nerves* of this joint are derived from the auriculo-temporal and masseteric branches of the inferior maxillary. The *arteries* are derived from the temporal branch of the external carotid.

Actions.—The movements permitted in this articulation are very extensive. Thus, the jaw may be depressed or elevated, or it may be carried forwards or backwards. It must be borne in mind that there are two distinct joints in this articulation—that is to say, one between the condyle of the jaw and the interarticular fibro-cartilage, and another between the fibro-cartilage and the glenoid fossa; when the jaw is depressed, as in opening the mouth, the movements which take place in these two joints are not the same. In the lower compartment, that between the condyle and the fibro-cartilage, the movement is of a ginglymoid or hinge-like character, the condyle rotating on a transverse axis on the fibro-cartilage; whilst in the upper compartment the movement is of a gliding character, the fibro-cartilage, together with the condyle, gliding forwards on to the eminentia articularis. These two movements take place simultaneously, the condyle and fibro-cartilage move forwards on the eminence, and at the same time the condyle revolves on the fibro-cartilage. In the opposite movement of shutting the mouth the reverse action takes place; the fibro-cartilage glides back, carrying the condyle with it, and this at the same time revolves back to its former position. When the jaw is carried horizontally forwards, as in protruding the lower incisors in front of the upper, the movement takes place principally in the upper compartment of the joint, the fibro-cartilage, carrying with it the condyle, glides forwards on the glenoid fossa. This is because this movement is mainly effected by the External pterygoid muscles, which are inserted into both condyle and interarticular fibro-cartilage. The grinding or chewing movement is produced by the alternate movement of one condyle, with its fibro-cartilage, forwards and backwards, while the other condyle moves simultaneously in the opposite direction; at the same time the condyle undergoes a vertical rotation on its own axis on the fibro-cartilage in the lower compartment. One condyle advances and rotates, the other condyle recedes and rotates, in alternate succession.

The lower jaw is *depressed* by its own weight, assisted by the Platysma, the Digastric, the Mylo-hyoid, and the Genio-hyoid. It is *elevated* by the anterior part of the Temporal, Masseter, and Internal pterygoid. It is drawn *forwards* by the simultaneous action of the External pterygoid, and the superficial fibres of the Masseter; and it is drawn *backwards* by the deep fibres of the Masseter and the posterior fibres of the Temporal muscle. The grinding movement is caused by the alternate action of the two External pterygoids.

Surface Form.—The temporo-maxillary articulation is quite superficial, situated below the base of the zygoma, in front of the tragus and external auditory meatus, and behind the posterior border of the upper part of the Masseter muscle. Its exact position can be at once ascertained by feeling for the condyle of the jaw, the working of which can be distinctly felt in the movements of the lower jaw in opening and shutting the mouth. When the mouth is opened wide, the condyle advances out of the glenoid fossa on to the eminentia articularis and a depression is felt in the situation of the joint.

Surgical Anatomy.—The lower jaw is dislocated only in one direction—viz. forwards. The accident is caused by violence or muscular action. When the mouth is open, the condyle is situated on the eminentia articularis, and any sudden violence, or even a sudden muscular spasm as during a convulsive yawn, may displace the condyle forwards into the zygomatic fossa. The displacement may be unilateral or bilateral, according as one or both of the condyles are displaced. The latter of the two is the more common.

Sir Astley Cooper described a condition which he termed 'subluxation.' It occurs principally in delicate women, and is believed by some to be due to relaxation of the ligaments, permitting too free movement of the bone, and possibly some displacement of the fibro-cartilage. Others have believed that it is due to gouty or rheumatic changes in the joint. In close relation to the condyle of the jaw is the external auditory meatus and the tympanum; any force, therefore, applied to the bone is liable to be attended with damage to these parts, or inflammation in the joint may extend to the ear, or on the other hand

inflammation of the middle ear may involve the articulation and cause its destruction, thus leading to ankylosis of the joint. In children, arthritis of this joint may also follow the exanthemata, and in adults occurs as the result of some constitutional conditions, as rheumatism or gout. The temporo-maxillary joint is also frequently the seat of osteo-arthritis, leading to great suffering during efforts of mastication. A peculiar affection sometimes attacks the neck and condyle of the lower jaw, consisting in hypertrophy and elongation of these parts and consequent protrusion of the chin to the opposite side.

VI. Articulations of the Ribs with the Vertebræ

The articulations of the ribs with the vertebral column may be divided into two sets: 1. Those which connect the heads of the ribs with the bodies of the vertebræ (*costo-central*). 2. Those which connect the necks and tubercles of the ribs with the transverse processes (*costo-transverse*).

1. Articulations between the Heads of the Ribs and the Bodies of the Vertebræ (fig. 271)

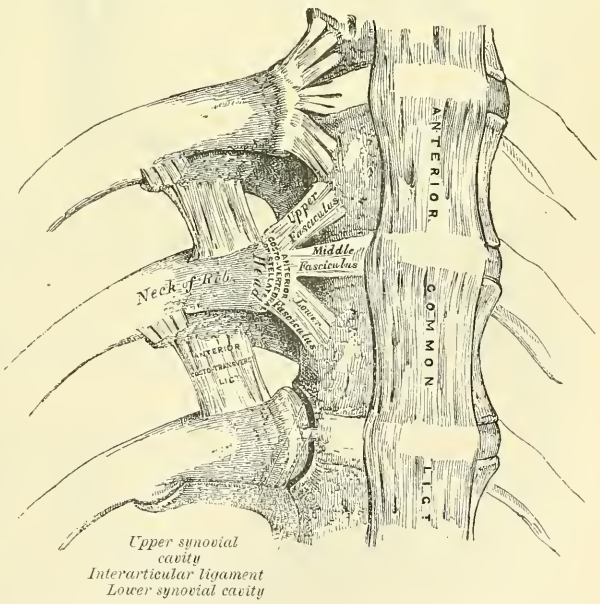
These constitute a series of arthrodial joints, formed by the articulation of the heads of the ribs with the cavities on the contiguous margins of the bodies of the dorsal vertebræ and the intervertebral substance between them, except in the case of the first, tenth, eleventh, and twelfth ribs, where the cavity is formed by a single vertebra. The bones are connected by the following ligaments:—

Anterior Costo-vertebral or Stellate.

Capsular. Interarticular.

The **Anterior Costo-vertebral** or **Stellate Ligament** connects the anterior part of the head of each rib with the sides of the bodies of two vertebræ, and the intervertebral disc between them. It consists of flat bundles of ligamentous fibres, which are attached to the anterior part of the head of the rib, just beyond the articular surface. The superior fibres pass upwards to be connected with the body of the vertebra above; the inferior ones descend to the body of the vertebra below; and the middle ones, the smallest and least distinct, pass horizontally inwards, to be attached to the intervertebral substance.

Fig. 271.—Costo-vertebral and costo-transverse articulations. Anterior view.



Relations.—In front, with the thoracic ganglia of the sympathetic, the pleura, and, on the right side, with the vena azygos major; behind, with the interarticular ligament and synovial membranes.

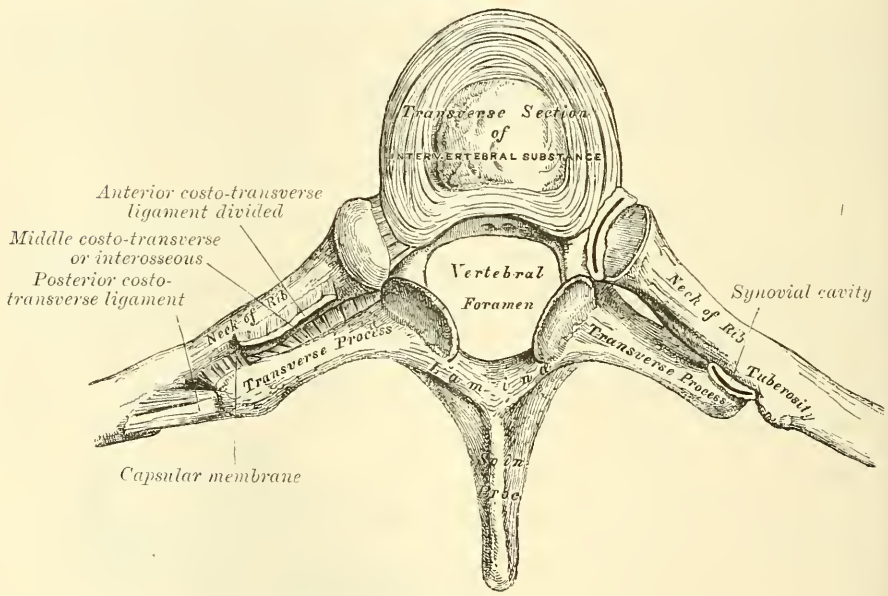
In the first rib, which articulates with a single vertebra, this ligament does not present a distinct division into three fasciculi; its fibres, however, radiate, and are attached to the body of the last cervical vertebra, as well as to the body

of the vertebra with which the rib articulates. In the tenth, eleventh, and twelfth ribs, which also articulate with a single vertebra, the division does not exist; but the fibres of the ligament in each case radiate and are connected with the vertebra above, as well as that with which the ribs articulate.

The **Capsular Ligament** is a thin and loose ligamentous bag, which surrounds the joint between the head of the rib and the articular cavity formed by the intervertebral disc and the adjacent vertebræ. It is very thin, firmly connected with the anterior ligament, and most distinct at the upper and lower parts of the articulation. Behind, some of its fibres pass through the intervertebral foramen to the back of the intervertebral disc. This is the analogue of the ligamentum conjugale of some mammals, which unites the heads of opposite ribs across the back of the intervertebral disc.

The **Interarticular Ligament** is situated in the interior of the joint. It consists of a short band of fibres, flattened from above downwards, attached by one extremity to the sharp crest which separates the two articular facets on the head

Fig. 272.—Costo-transverse articulation. Seen from above.



of the rib, and by the other to the intervertebral disc. It divides the joint into two cavities, which have no communication with each other. In the first, tenth, eleventh, and twelfth ribs, the interarticular ligament does not exist; consequently, there is but one synovial membrane.

The Synovial Membrane.—There are two synovial membranes in each of the articulations in which there is an interarticular ligament, one on each side of this structure.

2. Articulations of the Necks and Tubercles of the Ribs with the Transverse Processes (fig. 272)

The articular portion of the tubercle of the rib and adjacent transverse process form an arthrodial joint.

In the *eleventh* and *twelfth ribs* this articulation is wanting.

The ligaments connecting these parts are the—

Anterior Costo-transverse.
Middle Costo-transverse (Interosseous).
Posterior Costo-transverse.
Capsular.

The **Anterior Costo-transverse Ligament** (*superior* or *long*) consists of two sets of fibres: the one (anterior) is attached below to the sharp crest on the upper border of the neck of each rib, and passes obliquely upwards and outwards, to the lower border of the transverse process immediately above; the other (posterior) is attached below to the neck of the rib, and passes upwards and inwards to the base of the transverse process and outer border of the lower articular process of the vertebra above. This ligament is in relation, in front, with the intercostal vessels and nerves; behind, with the Longissimus dorsi. Its *internal border* is thickened and free, and bounds an aperture through which pass the posterior branches of the intercostal vessels and nerves. Its *external border* is continuous with a thin aponeurosis, which covers the External intercostal muscle.

The *first rib* has no anterior costo-transverse ligament.

The **Middle Costo-transverse** or **Interosseous Ligament** consists of short but strong fibres, which pass between the rough surface on the posterior part of the neck of each rib and the anterior surface of the adjacent transverse process. In order fully to expose this ligament a horizontal section should be made across the transverse process and corresponding part of the rib; or the rib may be forcibly separated from the transverse process, and its fibres put on the stretch.

In the *eleventh* and *twelfth ribs* this ligament is quite rudimentary or wanting.

The **Posterior Costo-transverse Ligament** is a short but thick and strong fasciculus, which passes obliquely from the summit of the transverse process to the rough non-articular portion of the tubercle of the rib. This ligament is shorter and more oblique in the upper than in the lower ribs. Those corresponding to the superior ribs ascend, while those of the inferior ribs descend slightly.

In the *eleventh* and *twelfth ribs* this ligament is wanting.

The **Capsular Ligament** is a thin, membranous sac attached to the circumference of the articular surfaces, and enclosing a small synovial membrane.

In the *eleventh* and *twelfth ribs* this ligament is absent.

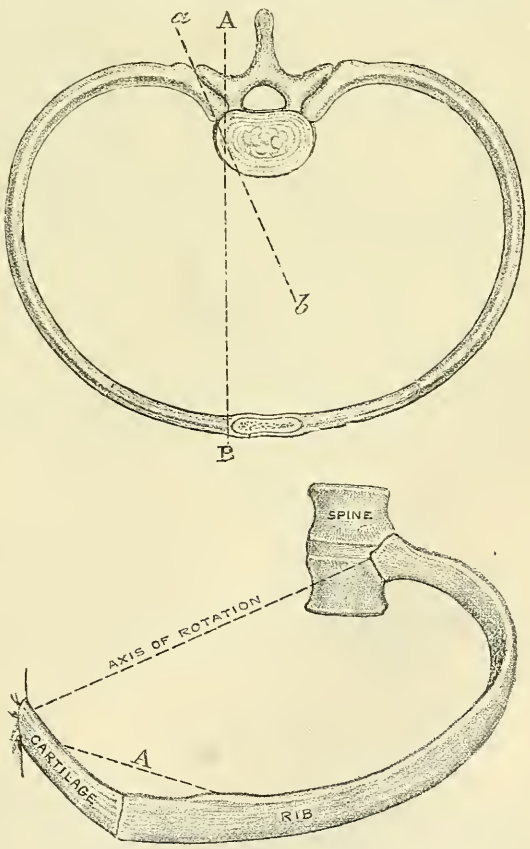


Fig. 273.—Diagrams showing the axis of rotation of the ribs in the movements of respiration. The one axis of rotation corresponds with a line drawn through the two articulations which the rib forms with the spine (*a*, *b*), and the other with a line drawn from the head of the rib to the sternum (A, B). (From Kirke's 'Handbook of Physiology.')

Actions.—The heads of the ribs are so closely connected to the bodies of the vertebræ by the stellate and interarticular ligaments, and the necks and tubercles of the ribs to the transverse processes, that only a slight gliding movement of

the articular surfaces on each other can take place in these articulations. The result of this gliding movement is an elevation of the front and middle portion of the rib, the hinder part being prevented from performing any upward movement by its close connection with the spine. In this gliding movement there are two axes of rotation—that is to say, the rib rotates on an axis corresponding with a line drawn through the two articulations, Costo-central and Costo-transverse, which the rib forms with the spine; and secondly, it rotates on an axis corresponding with a line drawn from the head of the rib to the sternum. By the first movement—that of rotation of the rib on an axis corresponding with a line drawn through the two articulations which this bone forms with the spine—an elevation of the anterior part of the rib takes place, and a consequent enlargement of the antero-posterior diameter of the chest. None of the ribs lie in a truly horizontal plane: they are all directed more or less obliquely, so that their anterior extremities lie on a lower level than their posterior, and this obliquity increases from the first to the seventh, and then again decreases. If we examine any one rib—say, that in which there is the greatest obliquity—we shall see that it is obvious that as its sternal extremity is carried upwards, it must also be thrown forwards; so that the rib may be regarded as a radius, moving on the vertebral joint as a centre, and causing the sternal attachment to describe an arc of a circle in the vertical plane of the body. Since all the ribs are oblique and connected in front to the sternum by the elastic costal cartilages, they must have a tendency to thrust the sternum forwards, and so increase the antero-posterior diameter of the chest. By the second movement—that of the rotation of the rib on an axis corresponding with a line drawn from the head of the rib to the sternum—an elevation of the middle portion of the rib takes place, and consequently an increase in the transverse diameter of the chest. For the ribs not only slant downwards and forwards from their vertebral attachment, but they are also oblique in relation to their transverse plane—that is to say, their middle is on a lower level than either their vertebral or sternal extremities. It results from this that when the ribs are raised, the centre portion is thrust outwards, somewhat after the fashion in which the handle of a bucket is thrust away from the side when raised to a horizontal position, and the lateral diameter of the chest is increased (see fig. 273). The mobility of the different ribs varies very much. The first rib is more fixed than the others, on account of the weight of the upper extremity and the strain of the ribs beneath; but on the freshly dissected thorax it moves as freely as the others. From the same causes the movement of the second rib is also not very extensive. In the other ribs, this mobility increases successively down to the last two, which are very movable. The ribs are generally more movable in the female than in the male.

VII. Articulation of the Cartilages of the Ribs with the Sternum, etc. (fig. 274)

The articulations of the cartilages of the true ribs with the sternum are arthrodial joints, with the exception of the first, in which the cartilage is almost always directly united with the sternum, and which must, therefore, be regarded as a synarthrodial articulation. The ligaments connecting them are—

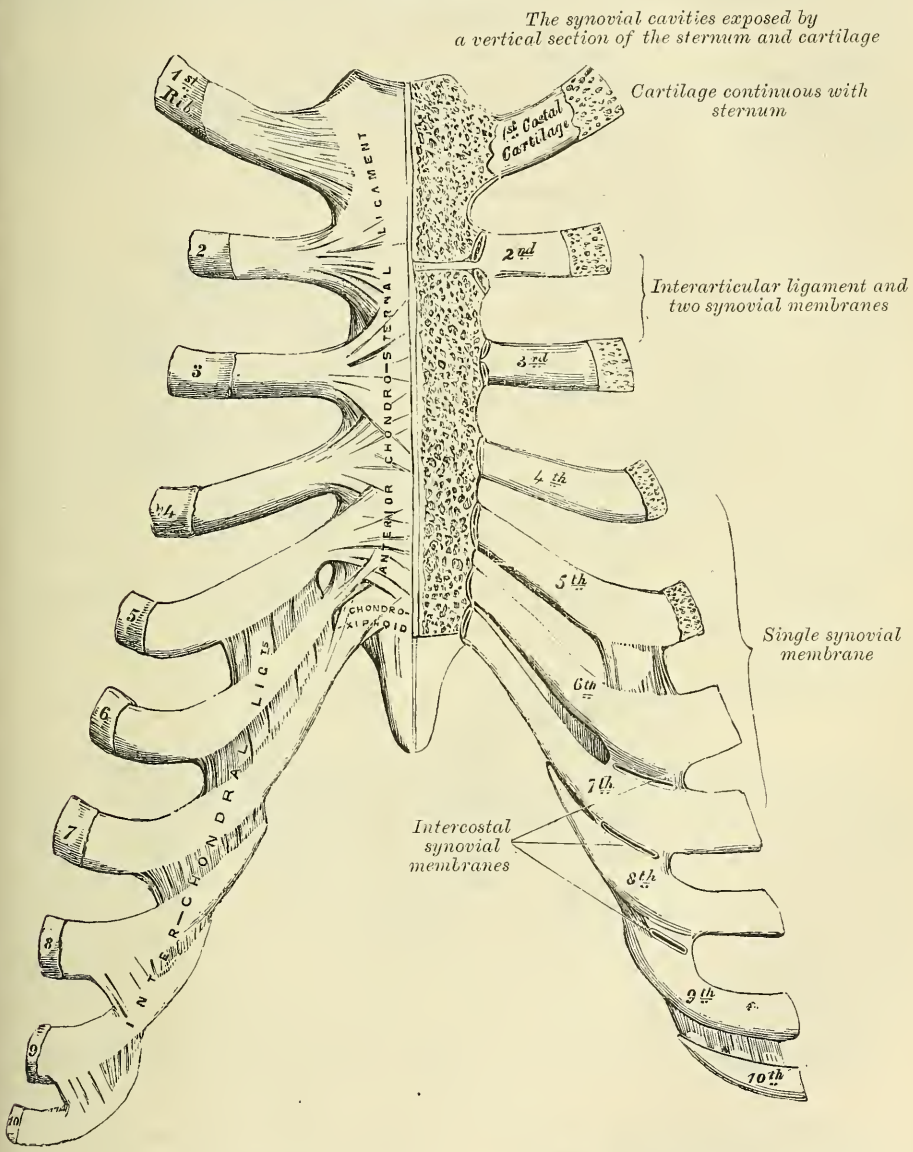
Anterior Chondro-sternal.	Interarticular Chondro-sternal.
Posterior Chondro-sternal.	Anterior Chondro-xiphoid.
Capsular.	Posterior Chondro-xiphoid.

The **Anterior Chondro-sternal Ligament** is a broad and thin membranous band that radiates from the front of the inner extremity of the cartilages of the true ribs to the anterior surface of the sternum. It is composed of fasciculi which pass in different directions. The *superior fasciculi* ascend obliquely, the *inferior* pass obliquely downwards, and the *middle fasciculi* horizontally. The superficial fibres of this ligament are the longest; they intermingle with the fibres of the

ligaments above and below them, with those of the opposite side, and with the tendinous fibres of origin of the Pectoralis major, forming a thick fibrous membrane, which covers the surface of the sternum. This is more distinct at the lower than at the upper part.

The **Posterior Chondro-sternal Ligament**, less thick and distinct than the anterior, is composed of fibres which radiate from the posterior surface of the

Fig. 274.—Chondro-sternal, chondro-xiphoid, and interchondral articulations. Anterior view.



sternal end of the cartilages of the true ribs to the posterior surface of the sternum, becoming blended with the periosteum.

The **Capsular Ligament** surrounds the joints formed between the cartilages of the true ribs and the sternum. It is very thin, intimately blended with the anterior and posterior ligaments, and strengthened at the upper and lower part of the articulation by a few fibres, which pass from the cartilage to the side of the sternum. These ligaments protect the synovial membranes.

The **Interarticular Chondro-sternal Ligaments.**—These are only found between the second and third costal cartilages and the sternum. The cartilage of the *second rib* is connected with the sternum by means of an interarticular ligament, attached by one extremity to the cartilage of the second rib, and by the other extremity to the cartilage which unites the first and second pieces of the sternum. This articulation is provided with two synovial membranes. The cartilage of the *third rib* is connected with the sternum by means of an interarticular ligament which is attached by one extremity to the cartilage of the third rib, and by the other extremity to the point of junction of the second and third pieces of the sternum. This articulation is provided with two synovial membranes.

The Anterior Chondro-xiphoid.—This is a band of ligamentous fibres, which connects the anterior surface of the seventh costal cartilage, and occasionally also that of the sixth, to the anterior surface of the ensiform appendix. It varies in length and breadth in different subjects.

The **Posterior Chondro-xiphoid** is a similar band of fibres on the internal or posterior surface, though less thick and distinct.

Synovial Membranes.—There is no synovial membrane between the first costal cartilage and the sternum, as this cartilage is directly continuous with the sternum. There are two synovial membranes both in the articulation of the second and third costal cartilages to the sternum. There is generally one synovial membrane in each of the joints between the fourth, fifth, sixth, and seventh costal cartilages to the sternum ; but it is sometimes absent in the sixth and seventh chondro-sternal joints. Thus there are *eight* synovial cavities on each side in the articulations between the costal cartilages of the true ribs and the sternum. After middle life the articular surfaces lose their polish, become roughened, and the synovial membranes appear to be wanting. In old age, the articulations do not exist, the cartilages of most of the ribs becoming continuous with the sternum.

Actions.—The movements which are permitted in the chondro-sternal articulations are limited to elevation and depression, and these only to a slight extent.

Articulations of the Cartilages of the Ribs with each other (Interchondral) (fig. 274)

The contiguous borders of the sixth, seventh, and eighth, and sometimes the ninth and tenth, costal cartilages articulate with each other by small, smooth, oblong-shaped facets. Each articulation is enclosed in a thin *capsular ligament* lined by *synovial membrane*, and strengthened externally and internally by ligamentous fibres (interchrondral ligaments), which pass from one cartilage to the other. Sometimes the fifth costal cartilage, more rarely that of the ninth, articulates, by its lower border, with the adjoining cartilage by a small oval facet; more frequently they are connected together by a few ligamentous fibres. Occasionally, the articular surfaces above mentioned are wanting.

Articulations of the Ribs with their Cartilages (Costo-chondral) (fig. 274)

The outer extremity of each costal cartilage is received into a depression in the sternal end of the ribs, and the two are held together by the periosteum.

VIII. Articulations of the Sternum

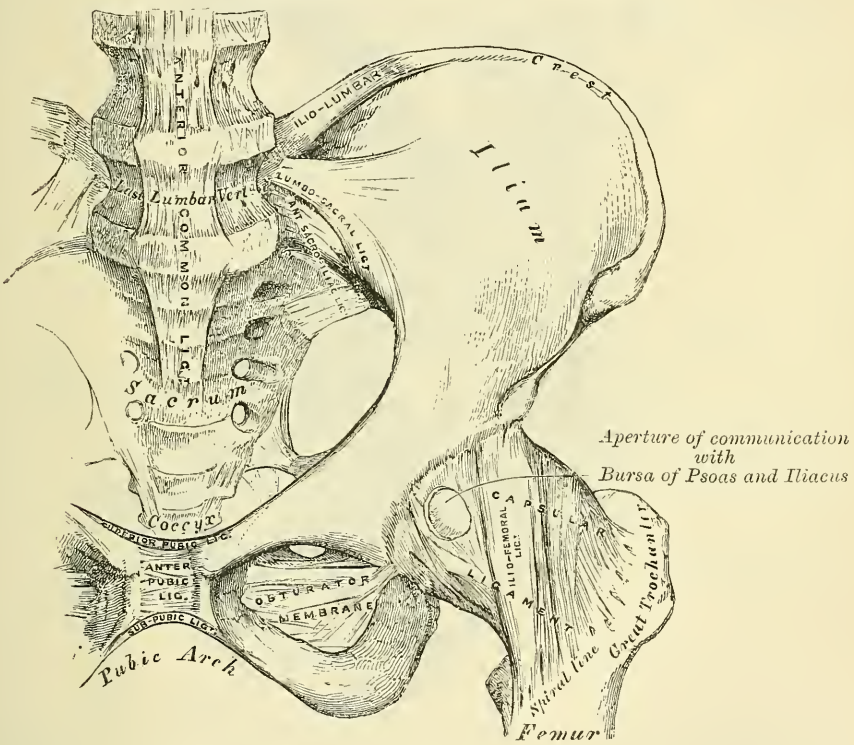
The first piece of the sternum is united to the second either by an amphiarthrodial joint—a single piece of true fibro-cartilage uniting the segments—or by a diarthrodial joint, in which each bone is clothed with a distinct lamina of cartilage, adherent on one side, free and lined with synovial membrane on the

other. In the latter case, the cartilage covering the gladiolus is continued without interruption on to the cartilages of the second ribs. Mr. Rivington has found the diarthrodial form of joint in about one-third of the specimens examined by him, Mr. Maisonneuve more frequently. It appears to be rare in childhood, and is formed, in Mr. Rivington's opinion, from the amphiarthrodial form, by absorption. The diarthrodial joint seems to have no tendency to ossify at any age, while the amphiarthrodial is more liable to do so, and has been found ossified as early as thirty-four years of age. The two segments are further connected by an

Anterior Intersternal Ligament.
Posterior Intersternal Ligament.

The **Anterior Intersternal Ligament** consists of a layer of fibres, having a longitudinal direction; it blends with the fibres of the anterior chondro-sternal

Fig. 275.—Articulations of pelvis and hip. Anterior view.



ligaments on both sides, and with the tendinous fibres of origin of the Pectoralis major. This ligament is rough, irregular, and much thicker below than above.

The **Posterior Intersternal Ligament** is disposed in a somewhat similar manner on the posterior surface of the articulation.

IX. Articulation of the Vertebral Column with the Pelvis

The ligaments connecting the last lumbar vertebra with the sacrum are similar to those which connect the segments of the spine with each other—viz.: 1. The continuation downwards of the anterior and posterior common ligaments. 2. The intervertebral substance connecting the flattened oval surfaces of the two bones and forming an amphiarthrodial joint. 3. Ligamenta subflava, connecting the arch of the last lumbar vertebra with the posterior border of the

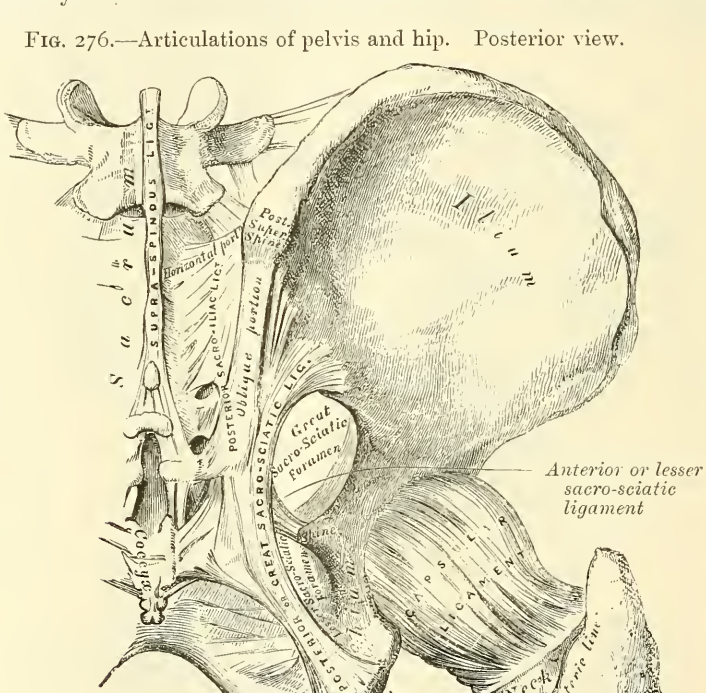
sacral canal. 4. Capsular ligaments connecting the articulating processes and forming a double arthrodia. 5. Inter- and supra-spinous ligaments.

The two proper ligaments connecting the pelvis with the spine are the lumbo-sacral and ilio-lumbar.

The **Lumbo-sacral Ligament** (fig. 275) is a short, thick, triangular fasciculus, which is connected above to the lower and front part of the transverse process of the last lumbar vertebra, passes obliquely outwards, and is attached below to the lateral surface of the base of the sacrum, becoming blended with the anterior sacro-iliac ligament. This ligament is in relation, in front, with the Psoas muscle.

The **Ilio-lumbar Ligament** (fig. 275) passes horizontally outwards from the apex of the transverse process of the last lumbar vertebra to the crest of the ilium immediately in front of the sacro-iliac articulation. It is of a triangular

Fig. 276.—Articulations of pelvis and hip. Posterior view.



form, thick and narrow internally, broad and thinner externally. It is in relation, in front, with the Psoas muscle; behind, with the muscles occupying the vertebral groove; above, with the Quadratus lumborum.

X. Articulations of the Pelvis

The ligaments connecting the bones of the pelvis with each other may be divided into four groups: 1. Those connecting the sacrum and ilium. 2. Those passing between the sacrum and ischium. 3. Those connecting the sacrum and coccyx. 4. Those between the two pubic bones.

1. Articulations of the Sacrum and Ilium

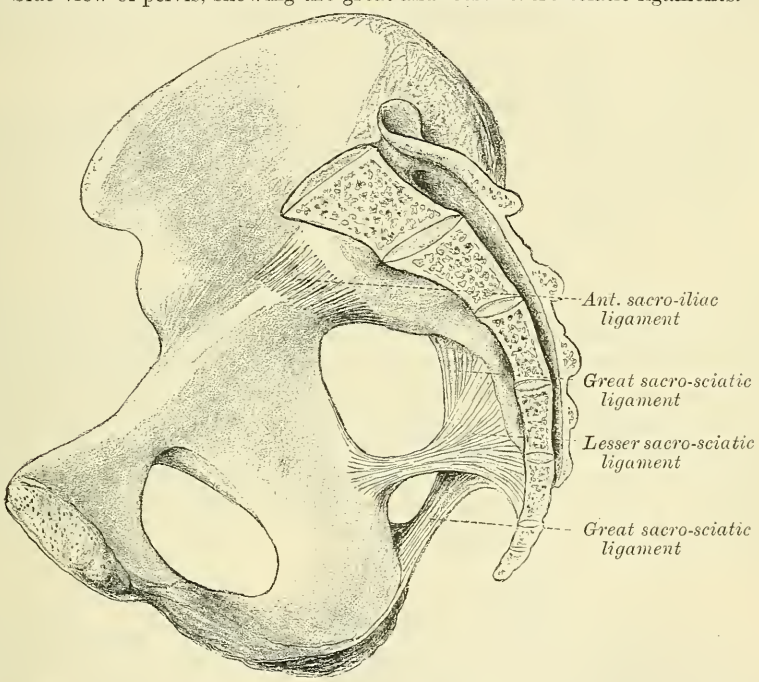
The sacro-iliac articulation is an amphiarthrodial joint, formed between the lateral surfaces of the sacrum and ilium. The anterior or auricular portion of

each articular surface is covered with a thin plate of cartilage, thicker on the sacrum than on the ilium. These are usually connected together by fine transverse fibres, so as to convert the whole into one mass; but occasionally the surfaces of the cartilages are rough and irregular, and separated from one another by a soft, yellow, pulpy substance. The ligaments connecting these surfaces are the anterior and posterior sacro-iliac.

The **Anterior Sacro-iliac Ligament** (fig. 277) consists of numerous thin ligamentous bands, which connect the anterior surfaces of the sacrum and ilium.

The **Posterior Sacro-iliac** (fig. 276) is a strong interosseous ligament, situated in a deep depression between the sacrum and ilium behind, and forming the chief bond of connection between those bones. It consists of numerous strong fasciculi, which pass between the bones in various directions. Three of these are of large size; the *two superior*, nearly horizontal in direction, arise from the first and second transverse tubercles on the posterior surface of the sacrum, and are inserted into the rough, uneven surface at the posterior part of the inner

Fig. 277.—Side view of pelvis, showing the great and lesser sacro-sciatic ligaments.



surface of the ilium. The third fasciculus, oblique in direction, is attached by one extremity to the third transverse tubercle on the posterior surface of the sacrum, and by the other to the posterior superior spine of the ilium; it is sometimes called the *oblique sacro-iliac ligament*.

The position of the sacro-iliac joint is indicated by the posterior superior spine of the ilium. This process is immediately behind the centre of the articulation.

2. Ligaments passing between the Sacrum and Ischium (fig. 277)

The Great Sacro-sciatic (Posterior).
The Lesser Sacro-sciatic (Anterior).

The **Great** or **Posterior Sacro-sciatic Ligament** is situated at the lower and back part of the pelvis. It is thin, flat, and triangular in form; narrower in the middle than at the extremities; attached by its broad base to the posterior inferior spine of the ilium, to the fourth and fifth transverse tubercles of the sacrum, and

to the lower part of the lateral margin of that bone and the coccyx. Passing obliquely downwards, outwards, and forwards, it becomes narrow and thick; and at its insertion into the inner margin of the tuberosity of the ischium, it increases in breadth, and is prolonged forwards along the inner margin of the ramus, forming what is known as the *falciform ligament*. The free concave edge of this prolongation has attached to it the obturator fascia, with which it forms a kind of groove, protecting the internal pudic vessels and nerve. One of its surfaces is turned towards the perinæum, the other towards the Obturator internus muscle.

The *posterior surface* of this ligament gives origin, by its whole extent, to fibres of the Gluteus maximus. Its *anterior surface* is united to the lesser sacro-sciatic ligament. Its *external border* forms, above, the posterior boundary of the great sacro-sciatic foramen, and, below, the lower boundary of the lesser sacro-sciatic foramen. Its *lower border* forms part of the boundary of the perinæum. It is pierced by the coccygeal branch of the sciatic artery and coccygeal nerve.

The **Lesser** or **Anterior Sacro-sciatic Ligament**, much shorter and smaller than the preceding, is thin, triangular in form, attached by its apex to the spine of the ischium, and internally, by its broad base, to the lateral margin of the sacrum and coccyx, anterior to the attachment of the great sacro-sciatic ligament with which its fibres are intermingled.

It is in relation, *anteriorly*, with the Coccygeus muscle; *posteriorly*, it is covered by the great sacro-sciatic ligament, and crossed by the internal pudic vessels and nerve. Its *superior border* forms the lower boundary of the great sacro-sciatic foramen; its *inferior border*, part of the lesser sacro-sciatic foramen.

These two ligaments convert the sacro-sciatic notches into foramina. The *superior* or *great* sacro-sciatic foramen is bounded, in front and above, by the posterior border of the os innominatum; behind, by the great sacro-sciatic ligament; and below, by the lesser sacro-sciatic ligament. It is partially filled up, in the recent state, by the Pyriformis muscle which passes through it. Above this muscle, the gluteal vessels and superior gluteal nerve emerge from the pelvis; and below it, the sciatic vessels and nerves, the internal pudic vessels and nerve, and muscular branches from the sacral plexus. The *inferior* or *lesser* sacro-sciatic foramen is bounded, in front, by the tuber ischii; above, by the spine and lesser sacro-sciatic ligament; behind, by the greater sacro-sciatic ligament. It transmits the tendon of the Obturator internus muscle, its nerve, and the internal pudic vessels and nerve.

3. Articulation of the Sacrum and Coccyx

This articulation is an amphiarthrodial joint, formed between the oval surface at the apex of the sacrum, and the base of the coccyx. It is analogous to the joints between the bodies of the vertebræ, and is connected by similar ligaments. They are the

Anterior Sacro-coccygeal.	Lateral Sacro-coccygeal.
Posterior Sacro-coccygeal.	Interposed Fibro-cartilage.

The **Anterior Sacro-coccygeal Ligament** consists of a few irregular fibres, which descend from the anterior surface of the sacrum to the front of the coccyx, becoming blended with the periosteum.

The **Posterior Sacro-coccygeal Ligament** is a flat band of ligamentous fibres, of a pearly tint, which arises from the margin of the lower orifice of the sacral canal, and descends to be inserted into the posterior surface of the coccyx. This ligament completes the lower and back part of the sacral canal. Its superficial fibres are much longer than the more deeply seated. This ligament is in relation, behind, with the Gluteus maximus.

The **Lateral Sacro-coccygeal Ligaments** are ligamentous bands which pass

from the cornua of the last sacral vertebra to the cornua of the first piece of the coccyx.

A **Fibro-cartilage** is interposed between the contiguous surfaces of the sacrum and coccyx; it differs from that interposed between the bodies of the vertebræ in being thinner, and its central part firmer in texture. It is somewhat thicker in front and behind than at the sides. Occasionally, a synovial membrane is found when the coccyx is freely movable, which is more especially the case during pregnancy.

The different segments of the coccyx are connected together by an extension downwards of the anterior and posterior sacro-coccygeal ligaments, a thin annular disc of fibro-cartilage being interposed between each of the bones. In the adult male, all the pieces become ossified; but in the female, this does not commonly occur until a later period of life. The separate segments of the coccyx are first united, and at a more advanced age the joint between the sacrum and coccyx is obliterated.

Actions.—The movements which take place between the sacrum and coccyx, and between the different pieces of the latter bone, are slightly forwards and backwards; they are very limited. Their extent increases during pregnancy.

4. Articulation of the Ossa Pubis (fig. 278)

The articulation between the pubic bones is an amphiarthrodial joint, formed by the junction of the two oval articular surfaces of the ossa pubis. The articular surface has been described on a former page under the name of *symphysis*, and the same name is given to the joint. The ligaments of this articulation are the

Anterior Pubic.	Posterior Pubic.
Superior Pubic.	Subpubic.

Interpubic Disc.

The **Anterior Pubic Ligament** consists of several superimposed layers, which pass across the front of the articulation. The superficial fibres pass obliquely from one bone to the other, decussating and forming an interlacement with the fibres of the aponeurosis of the External oblique and the tendon of the Rectus muscles. The deep fibres pass transversely across the symphysis, and are blended with the fibro-cartilage.

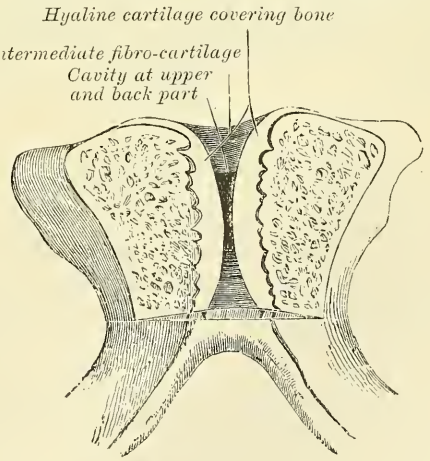


Fig. 278.—Vertical section of the symphysis pubis. Made near its posterior surface.

The **Posterior Pubic Ligament** consists of a few thin, scattered fibres, which unite the two pubic bones posteriorly.

The **Superior Pubic Ligament** is a band of fibres, which connects together the two pubic bones superiorly.

The **Subpubic Ligament** is a thick, triangular arch of ligamentous fibres, connecting together the two pubic bones below, and forming the upper boundary of the pubic arch. Above, it is blended with the interarticular fibro-cartilage; laterally, it is united with the descending rami of the ossa pubis. Its fibres are closely connected, and have an arched direction.

The **Interpubic Disc** consists of a disc of cartilage and fibro-cartilage connecting the surfaces of the pubic bones in front. Each pubic symphysis is

covered by a thin layer of hyaline cartilage, which is firmly connected to the bone by a series of nipple-like processes which accurately fit within corresponding depressions on the osseous surfaces. These opposed cartilaginous surfaces are connected together by an intermediate stratum of fibrous tissue and fibro-cartilage which varies in thickness in different subjects. It often contains a cavity in its centre, probably formed by the softening and absorption of the fibro-cartilage, since it rarely appears before the tenth year of life, and is not lined by synovial membrane. It is larger in the female than in the male, but it is very questionable whether it enlarges, as was formerly supposed, during pregnancy. It is most frequently limited to the upper and back part of the joint; but it occasionally reaches to the front, and may extend the entire length of the cartilage. This cavity may be easily demonstrated by making a vertical section of the symphysis pubis near its posterior surface.

The **Obturator Ligament** is more properly regarded as analogous to the muscular fasciæ, with which it will be described.

ARTICULATIONS OF THE UPPER EXTREMITY

The articulations of the Upper Extremity may be arranged in the following groups:—I. Sterno-clavicular articulation. II. Acromio-clavicular articulation. III. Ligaments of the Scapula. IV. Shoulder-joint. V. Elbow-joint. VI. Radio-ulnar articulations. VII. Wrist-joint. VIII. Articulations of the Carpal Bones. IX. Carpo-metacarpal articulations. X. Metacarpo-phalangeal articulations. XI. Articulations of the Phalanges.

I. Sterno-clavicular Articulation (fig. 279)

The **Sterno-clavicular** is regarded by most anatomists as an arthrodial joint; but Cruveilhier considers it to be an articulation by reciprocal reception. Probably the former opinion is the correct one; the varied movements, which the joint enjoys, being due to the interposition of an interarticular fibro-cartilage between the joint surfaces. The parts entering into its formation are the sternal end of the clavicle, the upper and lateral part of the first piece of the sternum, and the cartilage of the first rib. The articular surface of the clavicle is much larger than that of the sternum, and invested with a layer of cartilage,* which is considerably thicker than that on the latter bone. The ligaments of this joint are the

Capsular.	Interclavicular.
Anterior Sterno-clavicular.	Costo-clavicular (rhomboid).
Posterior Sterno-clavicular.	Interarticular Fibro-cartilage.

The **Capsular Ligament** completely surrounds the articulation, consisting of fibres of varying degrees of thickness and strength. Those in front and behind are of considerable thickness, and form the anterior and posterior sterno-clavicular ligaments, but those above and below, especially in the latter situation, are thin and scanty, and partake more of the character of connective tissue than true fibrous tissue.

The **Anterior Sterno-clavicular Ligament**, the anterior part of the capsular ligament, is a broad band of fibres, which covers the anterior surface of the articulation, being attached, above, to the upper and front part of the inner extremity of the clavicle; and, passing obliquely downwards and inwards, is attached, below, to the upper and front part of the first piece of the sternum. This ligament is covered, in front, by the sternal portion of the Sterno-cleido-mastoid and the integument; behind, it is in relation with the interarticular fibro-cartilage and the two synovial membranes.

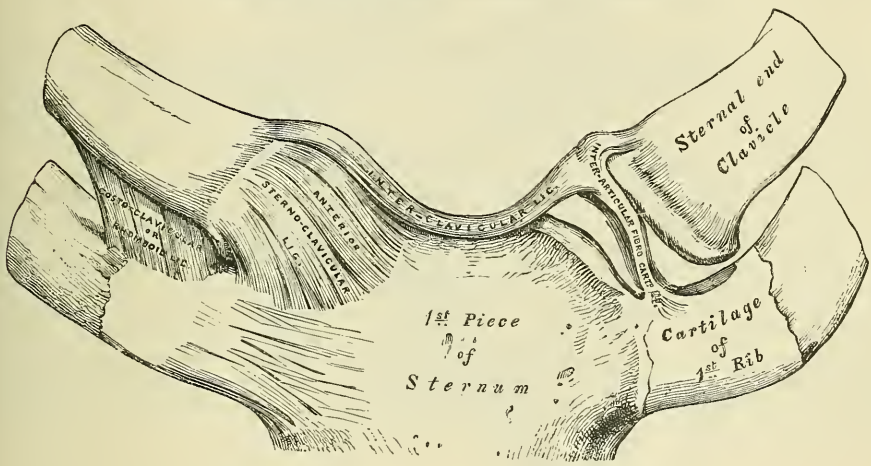
* According to Bruch, the sternal end of the clavicle is covered by a tissue, which is rather fibrous than cartilaginous in structure.

The **Posterior Sterno-clavicular Ligament**, the posterior part of the capsular ligament, is a similar band of fibres, which covers the posterior surface of the articulation, being attached, above, to the upper and back part of the inner extremity of the clavicle; and, passing obliquely downwards and inwards, is attached, below, to the upper and back part of the first piece of the sternum. It is in relation, in front, with the interarticular fibro-cartilage and synovial membranes; behind, with the Sterno-hyoid and Sterno-thyroid muscles.

The **Interclavicular Ligament** is a flattened band, which varies considerably in form and size in different individuals; it passes in a curved direction from the upper part of the inner extremity of one clavicle to the other, and is closely attached to the upper margin of the sternum. It is in relation, in front, with the integument; behind, with the Sterno-thyroid muscles.

The **Costo-clavicular Ligament (rhomboid)** is short, flat, and strong: it is of a rhomboid form, attached, below, to the upper and inner part of the cartilage of the first rib, it ascends obliquely backwards and outwards, and is attached, above, to the rhomboid depression on the under surface of the clavicle. It is in relation, in front, with the tendon of origin of the Subclavius; behind, with the subclavian vein.

Fig. 279.—Sterno-clavicular articulation. Anterior view.



The **Interarticular Fibro-cartilage** is a flat and nearly circular disc, interposed between the articulating surfaces of the sternum and clavicle. It is attached, above, to the upper and posterior border of the articular surface of the clavicle; below, to the cartilage of the first rib, at its junction with the sternum; and by its circumference to the anterior and posterior sterno-clavicular and interclavicular ligaments. It is thicker at the circumference, especially its upper and back part, than at its centre, or below. It divides the joint into two cavities, each of which is furnished with a separate synovial membrane.

Of the two **Synovial Membranes** found in this articulation, one is reflected from the sternal end of the clavicle, over the adjacent surface of the fibro-cartilage, and cartilage of the first rib; the other is placed between the articular surface of the sternum and adjacent surface of the fibro-cartilage; the latter is the larger of the two.

Actions.—This articulation is the centre of the movements of the shoulder, and admits of a limited amount of motion in nearly every direction—upwards, downwards, backwards, forwards, as well as circumduction. When these movements take place in the joint, the clavicle in its motion carries the scapula with it, this bone gliding on the outer surface of the chest. This joint therefore forms

the centre from which all movements of the supporting arch of the shoulder originate, and is the only point of articulation of this part of the skeleton with the trunk. 'The movements attendant on elevation and depression of the shoulder take place between the clavicle and the interarticular fibro-cartilage, the bone rotating upon the ligament on an axis drawn from before backwards through its own articular facet. When the shoulder is moved forwards and backwards, the clavicle, with the interarticular fibro-cartilage, rolls to and fro on the articular surface of the sternum, revolving, with a sliding movement, round an axis drawn nearly vertically through the sternum. In the circumduction of the shoulder, which is compounded of these two movements, the clavicle revolves upon the interarticular fibro-cartilage, and the latter, with the clavicle, rolls upon the sternum.'* Elevation of the clavicle is principally limited by the costo-clavicular ligament; depression, by the interclavicular. The muscles which *raise* the clavicle, as in shrugging the shoulders, are the upper fibres of the Trapezius, the Levator anguli scapulæ, the clavicular head of the Sterno-mastoid, assisted to a certain extent by the two Rhomboids, which pull the inferior angle of the Scapula backwards and upwards and so raise the clavicle. The *depression* of the clavicle is principally effected by gravity, assisted by the Subclavius, Pectoralis minor, and lower fibres of the Trapezius. It is drawn *backwards* by the Rhomboids and the middle and lower fibres of the Trapezius, and *forwards* by the Serratus magnus and Pectoralis minor.

Surface Form.—The position of the sterno-clavicular joint may be easily ascertained by feeling the enlarged sternal end of the collar-bone just external to the long, cord-like, sternal origin of the Sterno-mastoid muscle. If this muscle is relaxed by bending the head forwards, a depression just internal to the end of the clavicle, and between it and the sternum, can be felt, indicating the exact position of the joint, which is subcutaneous. When the arm hangs by the side, the cavity of the joint is V-shaped. If the arm is raised, the bones become more closely approximated, and the cavity becomes a mere slit.

Surgical Anatomy.—The strength of this joint mainly depends upon its ligaments, and it is owing to this, and to the fact that the force of the blow is generally transmitted along the long axis of the clavicle, that dislocation rarely occurs, and that the bone is generally broken rather than displaced. When dislocation does occur, the course which the displaced bone takes depends more upon the direction in which the violence is applied than upon the anatomical construction of the joint; it may be either forwards, backwards, or upwards. The chief point worthy of note, as regards the construction of the joint, in regard to dislocations, is the fact that, owing to the shape of the articular surfaces being so little adapted to each other, and that the strength of the joint mainly depends upon the ligaments, the displacement when reduced is very liable to recur, and hence it is extremely difficult to keep the end of the bone in its proper place.

II. Acromio-clavicular Articulation (fig. 280)

The **Acromio-clavicular** is an arthrodial joint, formed between the outer extremity of the clavicle and the inner margin of the acromion process of the scapula. Its ligaments are the

Superior Acromio-clavicular.		Trapezoid
Inferior Acromio-clavicular.	Coraco-clavicular	and
Interarticular Fibro-cartilage.		Conoid.

The **Superior Acromio-clavicular Ligament** is a broad band, of a quadrilateral form, which covers the superior part of the articulation, extending between the upper part of the outer end of the clavicle and the adjoining part of the upper surface of the acromion. It is composed of parallel fibres, which interlace with the aponeurosis of the Trapezius and Deltoid muscles; below, it is in contact with the interarticular fibro-cartilage (when it exists) and the synovial membranes.

The **Inferior Acromio-clavicular Ligament**, somewhat thinner than the preceding, covers the under part of the articulation, and is attached to the adjoining

* Humphry. *On the Human Skeleton*, p. 402.

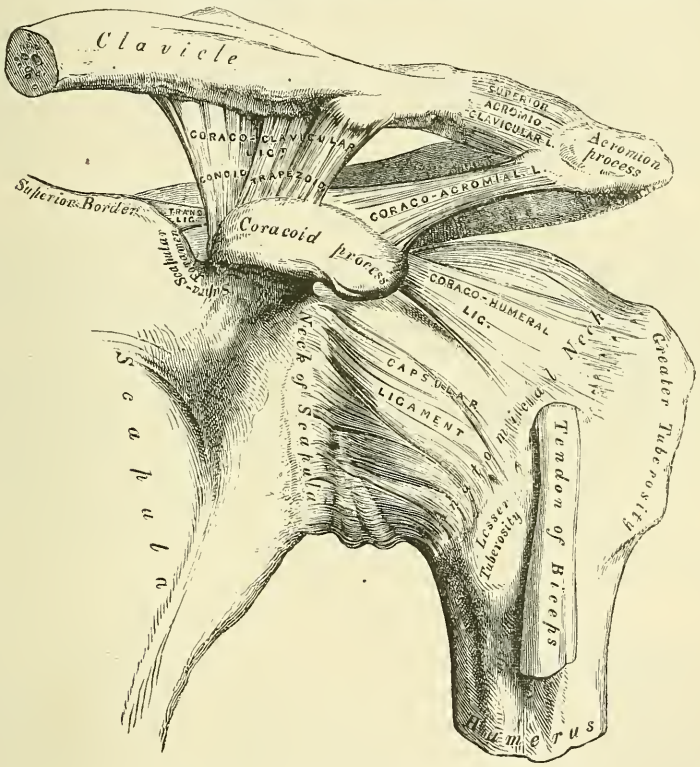
surfaces of the two bones. It is in relation, above, with the synovial membranes, and in rare cases with the interarticular fibro-cartilage; below, with the tendon of the Supraspinatus. These two ligaments are continuous with each other in front and behind, and form a complete capsule round the joint.

The **Interarticular Fibro-cartilage** is frequently absent in this articulation. When it exists, it generally only partially separates the articular surfaces, and occupies the upper part of the articulation. More rarely, it completely separates the joint into two cavities.

The Synovial Membrane.—There is usually only one synovial membrane in this articulation, but when a complete interarticular fibro-cartilage exists, there are two synovial membranes.

The **Coraco-clavicular Ligament** serves to connect the clavicle with the coracoid process of the scapula. It does not properly belong to this articulation,

Fig. 280.—The left shoulder-joint, scapulo-clavicular articulation, and proper ligaments of scapula.



but as it forms a most efficient means in retaining the clavicle in contact with the acromial process, it is usually described with it. It consists of two fasciculi, called the *trapezoid* and *conoid ligaments*.

The *Trapezoid Ligament*, the anterior and external fasciculus, is broad, thin, and quadrilateral: it is placed obliquely between the coracoid process and the clavicle. It is attached, below, to the upper surface of the coracoid process; above, to the oblique line on the under surface of the clavicle. Its anterior border is free; its posterior border is joined with the conoid ligament: the two forming, by their junction, a projecting angle.

The *Conoid Ligament*, the posterior and internal fasciculus, is a dense band of fibres, conical in form, the base being turned upwards, the summit downwards. It is attached by its apex to a rough impression at the base of the coracoid process, internal to the preceding; above, by its expanded base, to the conoid tubercle on

the under surface of the clavicle, and to a line proceeding internally from it for half an inch. These ligaments are in relation, in front, with the Subclavius and Deltoid; behind, with the Trapezius. They serve to limit rotation of the scapula; the Trapezoid limiting rotation forwards, and the Conoid backwards.

Actions.—The movements of this articulation are of two kinds. 1. A gliding motion of the articular end of the clavicle on the acromion. 2. Rotation of the scapula forwards and backwards upon the clavicle, the extent of this rotation being limited by the two portions of the coraco-clavicular ligament.

The acromio-clavicular joint has important functions in the movements of the upper extremity. It has been well pointed out by Sir George Humphry, that if there had been no joint between the clavicle and scapula, the circular movement of the scapula on the ribs (as in throwing the shoulders backwards or forwards) would have been attended with a greater alteration in the direction of the shoulder than is consistent with the free use of the arm in such positions, and it would have been impossible to give a blow straight forwards with the full force of the arm, that is to say, with the combined force of the scapula, arm, and fore-arm. 'This joint,' as he happily says, 'is so adjusted as to enable either bone to turn in a hinge-like manner upon a vertical axis drawn through the other, and it permits the surfaces of the scapula, like the baskets in a roundabout swing, to look the same way in every position, or nearly so.' Again, when the whole arch formed by the clavicle and scapula rises and falls (in elevation or depression of the shoulders), the joint between these two bones enables the scapula still to maintain its lower part in contact with the ribs.

Surface Form.—The position of the acromio-clavicular joint can generally be ascertained by the slightly enlarged extremity of the outer end of the clavicle, which causes it to project above the level of the acromion process of the scapula. Sometimes this enlargement is so considerable as to form a rounded eminence, which is easily to be felt. The joint lies in the plane of a vertical line passing up the middle of the front of the arm.

Surgical Anatomy.—Owing to the slanting shape of the articular surfaces of this joint, dislocation generally occurs downwards, that is to say, the acromion process of the scapula is dislocated under the outer end of the clavicle; but dislocation in the opposite direction has been described. The displacement is often incomplete, on account of the strong coraco-clavicular ligaments, which remain untorn. The same difficulty exists, as in the sterno-clavicular dislocation, in maintaining the ends of the bone in position after reduction.

III. Proper Ligaments of the Scapula (fig. 280)

The proper ligaments of the scapula are, the

Coraco-acromial. Transverse.

The **Coraco-acromial Ligament** is a broad, thin, flat band, of a triangular shape, extended transversely above the upper part of the shoulder-joint, between the coracoid and acromial processes. It is attached, by its apex, to the summit of the acromion just in front of the articular surface for the clavicle; and by its broad base to the whole length of the outer border of the coracoid process. Its posterior fibres are directed obliquely backwards and inwards, its anterior fibres transversely inwards. This ligament completes the vault formed by the coracoid and acromion processes for the protection of the head of the humerus. It is in relation, above, with the clavicle and under surface of the Deltoid; below, with the tendon of the Supraspinatus muscle, a bursa being interposed. Its anterior border is continuous with a dense cellular lamina that passes beneath the Deltoid upon the tendons of the Supra- and Infraspinatus muscles. This ligament is sometimes described as consisting of two marginal bands and a thinner intervening portion, the two bands being attached respectively to the apex and base of the coracoid process, and joining together at their attachment into the acromion process. When the Pectoralis minor is inserted, as sometimes is the case, into the capsule of the shoulder-joint instead of into the coracoid process, it passes between these two bands, and the intervening portion is then deficient.

The **Transverse** or **Coracoid** (*suprascapular*) **Ligament** converts the suprascapular notch into a foramen. It is a thin and flat fasciculus, narrower at the middle than at the extremities, attached by one end to the base of the coracoid process, and by the other to the inner extremity of the scapular notch. The suprascapular nerve passes through the foramen ; the suprascapular vessels pass over the ligament.

Movements of Scapula.—The scapula is capable of being moved upwards and downwards, forwards and backwards, or, by a combination of these movements, circumducted on the wall of the chest. The muscles which *raise* the scapula are the upper fibres of the Trapezius, the Levator anguli scapulæ, and the two Rhomboids; those which *depress* it are the lower fibres of the Trapezius, the Pectoralis minor and, through the clavicle, the Subclavius. The scapula is drawn *backwards* by the Rhomboids and the middle and lower fibres of the Trapezius, and *forwards* by the Serratus magnus and Pectoralis minor, assisted, when the arm is fixed, by the Pectoralis major. The mobility of the scapula is very considerable, and greatly assists the movements of the arm at the shoulder-joint. Thus, in raising the arm from the side, the Deltoid and Supraspinatus can only lift it to a right angle with the trunk, the further elevation of the limb being effected by the Trapezius moving the scapula on the wall of the chest. This mobility is of special importance in ankylosis of the shoulder-joint, the movements of this bone compensating to a very great extent for the immobility of the joint.

IV. Shoulder-Joint (fig. 280)

The **Shoulder** is an enarthrodial or ball-and-socket joint. The bones entering into its formation are the large globular head of the humerus, which is received into the shallow glenoid cavity of the scapula, an arrangement which permits of very considerable movement, whilst the joint itself is protected against displacement by the tendons which surround it and by atmospheric pressure. The ligaments do not maintain the joint surfaces in apposition, because when they alone remain the humerus can be separated to a considerable extent from the glenoid cavity; their use therefore is to limit the amount of movement. Above, the joint is protected by an arched vault, formed by the under surface of the coracoid and acromion processes, and the coraco-acromial ligament. The articular surfaces are covered by a layer of cartilage: that on the head of the humerus is thicker at the centre than at the circumference, the reverse being the case in the glenoid cavity. The ligaments of the shoulder are, the

Capsular.	Coraco-humeral.
Glenoid.*	Transverse-humeral.

The **Capsular Ligament** completely encircles the articulation, being attached, above, to the circumference of the glenoid cavity beyond the glenoid ligament; below, to the anatomical neck of the humerus, approaching nearer to the articular cartilage above than in the rest of its extent. It is thicker above and below than elsewhere, and is remarkably loose and lax, and much larger and longer than is necessary to keep the bones in contact, allowing them to be separated from each other more than an inch, an evident provision for that extreme freedom of movement which is peculiar to this articulation. Its external surface is strengthened, above, by the Supraspinatus; below, by the long head of the Triceps; externally, by the tendons of the Infraspinatus and Teres minor; and internally, by the tendon of the Subscapularis. The capsular ligament usually presents three openings: one anteriorly, below the coracoid process, establishes a communication between the synovial membrane of the joint and a bursa

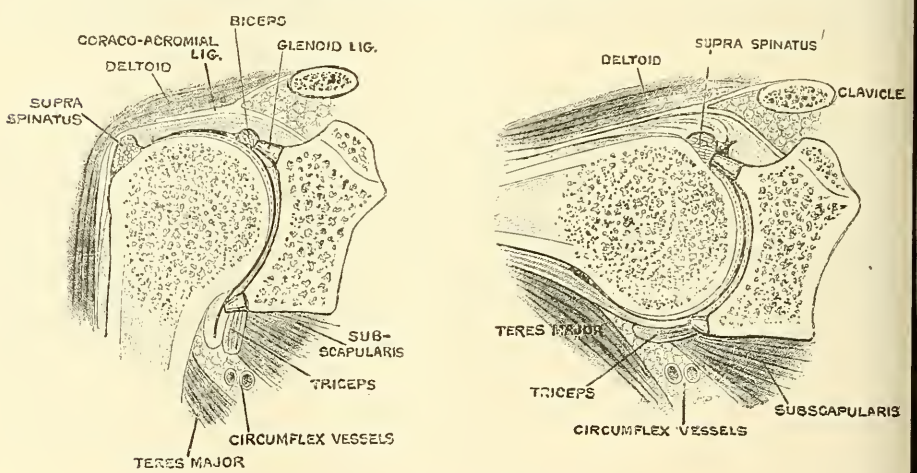
* The long tendon of origin of the Biceps muscle also acts as one of the ligaments of this joint. See the observations on p. 310, on the function of the muscles passing over more than one joint.

beneath the tendon of that muscle. The second, which is not constant, is at the outer part, where a communication sometimes exists between the joint and a bursal sac belonging to the Infraspinatus muscle. The third is seen in the lower border of the ligament, between the two tuberosities, for the passage of the long tendon of the Biceps muscle.

The **Coraco-humeral** or **Accessory Ligament** is a broad band which strengthens the upper part of the capsular ligament. It arises from the outer border of the coracoid process, and passes obliquely downwards and outwards to the front of the great tuberosity of the humerus, being blended with the tendon of the Supraspinatus muscle. This ligament is intimately united to the capsular in the greater part of its extent.

The Transverse Humeral Ligament.—This is a broad band of fibrous tissue passing from the lesser to the greater tuberosity of the humerus, and always limited to that portion of the bone which lies above the epiphysial line. It converts the bicipital groove into an osseo-aponeurotic canal, and is the analogue of the strong process of bone which connects the summits of the two tuberosities in the musk ox.

Fig. 281.—Vertical sections through the shoulder-joint, the arm being vertical and horizontal. (After Henle.)



Supplemental Bands of the Capsular Ligament.—In addition to the coraco-humeral or accessory ligament, the capsular ligament is strengthened by supplemental bands in the interior of the joint. One of these bands is situated on the inner side of the joint, and passes from the inner edge of the glenoid cavity to the lower part of the lesser tuberosity of the humerus. This is sometimes known as *Flood's ligament*, and is supposed to correspond with the ligamentum teres of the hip-joint. A second of these bands is situated at the lower part of the joint, and passes from the under edge of the glenoid cavity to the under part of the neck of the humerus, and is known as *Schlemm's ligament*. A third, called the *gleno-humeral ligament*, is situated at the upper part of the joint, and projects into its interior, so that it can only be seen when the capsule is opened. It is attached above to the apex of the glenoid cavity close to the root of the zygoma, and passing downwards along the inner edge of the tendon of the Biceps is attached below to the lesser tuberosity of the humerus, where it forms the inner boundary of the upper part of the bicipital groove. It is a thin, ribbon-like band, occasionally quite free from the capsule.

The **Glenoid Ligament** is a fibro-cartilaginous rim attached round the margin of the glenoid cavity. It is triangular on section, the thickest portion being fixed to the circumference of the cavity, the free edge being thin and sharp. It is

continuous above with the long tendon of the Biceps muscle, which bifurcates at the upper part of the cavity into two fasciculi, and becomes continuous with the fibrous tissue of the glenoid ligament. This ligament deepens the cavity for articulation, and protects the edges of the bone. It is lined by the synovial membrane.

The **Synovial Membrane** is reflected from the margin of the glenoid cavity over the fibro-cartilaginous rim surrounding it; it is then reflected over the internal surface of the capsular ligament, covers the lower part and sides of the neck of the humerus, and is continued a short distance over the cartilage covering the head of the bone. The long tendon of the Biceps muscle which passes through the capsular ligament is enclosed in a tubular sheath of synovial membrane, which is reflected upon it at the point where it perforates the capsule, and is continued around it as far as the summit of the glenoid cavity. The tendon of the Biceps is thus enabled to traverse the articulation, but it is not contained in the interior of the synovial cavity. The synovial membrane communicates with a large bursal sac beneath the tendon of the Subscapularis, by an opening at the inner side of the capsular ligament; it also occasionally communicates with another bursal sac, beneath the tendon of the Infraspinatus, through an orifice at its outer part. A third bursal sac, which does not communicate with the joint, is placed between the under surface of the Deltoid and the outer surface of the capsule.

The *Muscles* in relation with the joint are, above, the Supraspinatus; below, the long head of the Triceps; internally, the Subscapularis; externally, the Infraspinatus and Teres minor; within, the long tendon of the Biceps. The Deltoid is placed most externally, and covers the articulation on its outer side, as well as in front and behind.

The *Arteries* supplying the joint are articular branches of the anterior and posterior circumflex, and suprascapular.

The *Nerves* are derived from the circumflex and suprascapular.

Actions.—The shoulder-joint is capable of movement in every direction, forwards, backwards, abduction, adduction, circumduction, and rotation. The humerus is drawn *forwards* by the Pectoralis major, anterior fibres of the Deltoid, Coraco-brachialis, and by the Biceps, when the forearm is flexed; *backwards* by the Latissimus dorsi, Teres major, posterior fibres of the Deltoid, and by the Triceps when the forearm is extended; it is *abducted* (elevated) by the Deltoid and Supraspinatus; it is *adducted* (depressed) by the Subscapularis, Pectoralis major, Latissimus dorsi, and Teres major; it is *rotated outwards* by the Infraspinatus and Teres minor; and it is *rotated inwards* by the Subscapularis, Latissimus dorsi, Teres major, and Pectoralis major.

The most striking peculiarities in this joint are: 1. The large size of the head of the humerus in comparison with the depth of the glenoid cavity, even when supplemented by the glenoid ligament. 2. The looseness of the capsule of the joint. 3. The intimate connection of the capsule with the muscles attached to the head of the humerus. 4. The peculiar relation of the Biceps tendon to the joint.

It is in consequence of the relative size of the two articular surfaces that the joint enjoys such free movement in every possible direction. When these movements of the arm are arrested in the shoulder-joint by the contact of the bony surfaces, and by the tension of the corresponding fibres of the capsule, together with that of the muscles acting as accessory ligaments, they can be carried considerably further by the movements of the scapula, involving, of course, motion at the acromio- and sterno-clavicular joints. These joints are therefore to be regarded as accessory structures to the shoulder-joint.* The extent of these movements of the scapula is very considerable, especially in extreme elevation of the arm, which movement is best accomplished when the arm is thrown

* See p. 338.

somewhat forwards, since the articular surface of the humerus is broader in the middle than at either end, especially the lower, so that the range of elevation directly forwards is less, and that directly backwards still more restricted. The great width of the central portion of the humeral head also allows of very free horizontal movement when the arm is raised to a right angle, in which movement the arch formed by the acromion, the coracoid process, and the coraco-acromial ligament, constitutes a sort of supplemental articular cavity for the head of the bone.

The looseness of the capsule is so great that the arm will fall about an inch from the scapula when the muscles are dissected from the capsular ligament, and an opening made in it to remove the atmospheric pressure. The movements of the joint, therefore, are not regulated by the capsule so much as by the surrounding muscles and by the pressure of the atmosphere, an arrangement which 'renders the movements of the joint much more easy than they would otherwise have been, and permits a swinging, pendulum-like vibration of the limb when the muscles are at rest' (Humphry). The fact, also, that in all ordinary positions of the joint the capsule is not put on the stretch, enables the arm to move freely in all directions. Extreme movements are checked by the tension of appropriate portions of the capsule, as well as by the interlocking of the bones. Thus it is said that 'abduction is checked by the contact of the great tuberosity with the upper edge of the glenoid cavity, adduction by the tension of the coraco-humeral ligament' (Beaunis et Bouchard).

The intimate union of the tendons of the four short muscles with the capsule converts these muscles into elastic and spontaneously acting ligaments of the joint, and it is regarded as being also intended to prevent the folds into which all portions of the capsule would alternately fall in the varying positions of the joint from being driven between the bones by the pressure of the atmosphere.

The peculiar relations of the Biceps tendon to the shoulder-joint appear to subserve various purposes. In the first place, by its connection with both the shoulder and elbow the muscle harmonises the action of the two joints, and acts as an elastic ligament in all positions, in the manner previously adverted to.* Next, it strengthens the upper part of the articular cavity, and prevents the head of the humerus from being pressed up against the acromion process, when the Deltoid contracts, instead of forming the centre of motion in the glenoid cavity. By its passage along the bicipital groove it assists in rendering the head of the humerus steady in the various movements of the arm. When the arm is raised from the side it assists the Supra- and Infraspinatus in rotating the head of the humerus in the glenoid cavity. It also holds the head of the bone firmly in contact with the glenoid cavity, and prevents its slipping over its lower edge, or being displaced by the action of the Latissimus dorsi and Pectoralis major, as in climbing and many other movements.

Surface Form.—The direction and position of the shoulder-joint may be indicated by a line drawn from the middle of the coraco-acromial ligament, in a curved direction, with its convexity inwards, to the innermost part of that portion of the head of the humerus which can be felt in the axilla when the arm is forcibly abducted from the side. When the arm hangs by the side, not more than one-third of the head of the bone is in contact with the glenoid cavity, and three-quarters of its circumference is in front of a vertical line drawn from the anterior border of the acromion process.

Surgical Anatomy.—Owing to the construction of the shoulder-joint and the freedom of movement which it enjoys, as well as in consequence of its exposed situation, it is more frequently dislocated than any other joint in the body. Dislocation occurs when the arm is abducted, and when, therefore, the head of the humerus presses against the lower and front part of the capsule, which is the thinnest and least supported part of the ligament. The rent in the capsule almost invariably takes place in this situation, and through it the head of the bone escapes, so that the dislocation in most instances is primarily subglenoid. The head of the bone does not usually remain in this situation, but generally assumes some other position, which varies according to the direction and amount of force producing the dislocation and the relative strength of the muscles in front and behind the joint.

* See p. 310.

In consequence of the muscles at the back being stronger than those in front, and especially on account of the long head of the Triceps preventing the bone passing backwards, dislocation forwards is much more common than backwards. The most frequent position which the head of the humerus ultimately assumes is on the front of the neck of the scapula, beneath the coracoid process, and hence named subcoracoid. Occasionally, in consequence probably of a greater amount of force being brought to bear on the limb, the head is driven farther inwards, and rests on the upper part of the front of the chest, beneath the clavicle (subclavicular). Sometimes it remains in the position in which it was primarily displaced, resting on the axillary border of the scapula (subglenoid), and rarely it passes backwards and remains in the infraspinatus fossa, beneath the spine (subspinous).

The shoulder-joint is sometimes the seat of all those inflammatory affections, both acute and chronic, which attack joints, though perhaps less frequently than some other joints of equal size and importance. Acute synovitis may result from injury, rheumatism, or pyæmia, or may follow secondarily on the so-called acute epiphysitis of infants. It is attended with effusion into the joint, and when this occurs the capsule is evenly distended, and the contour of the joint rounded. Special projections may occur at the site of the openings in the capsular ligament. Thus a swelling may appear just in front of the joint, internal to the lesser tuberosity, from effusion into the bursa beneath the Subscapularis muscle; or, again, a swelling which is sometimes bilobed may be seen in the interval between the Deltoid and Pectoralis major muscles, from effusion into the diverticulum, which runs down the bicipital groove with the tendon of the Biceps. The effusion into the synovial membrane can be best ascertained by examination from the axilla, where a soft, elastic, fluctuating swelling can usually be felt.

Tuberculous arthritis not unfrequently attacks the shoulder-joint, and may lead to total destruction of the articulation, when ankylosis may result, or long protracted suppuration may necessitate excision. This joint is also one of those which is most liable to be the seat of osteo-arthritis, and may also be affected in gout and rheumatism; or in locomotor ataxy, when it becomes the seat of Charcot's disease.

Excision of the shoulder-joint may be required in cases of arthritis (especially the tuberculous form) which have gone on to destruction of the articulation; in compound dislocations and fractures, particularly those arising from gunshot injuries, in which there has been extensive injury to the head of the bone; in some cases of old unreduced dislocation, where there is much pain; and possibly in some few cases of growth connected with the upper end of the bone. The operation is best performed by making an incision from the middle of the coraco-acromial ligament down the arm for about three inches: this will expose the bicipital groove and the tendon of the biceps, which may be either divided or hooked out of the way, according as to whether it is implicated in the disease or not. The capsule is then freely opened, and the muscles attached to the greater and lesser tuberosities of the humerus divided. The head of the bone can then be thrust out of the wound and sawn off; or divided with a narrow saw *in situ* and subsequently removed. The section should be made, if possible, just below the articular surface, so as to leave the bone as long as possible. The glenoid cavity must then be examined, and gouged if carious.

V. Elbow-Joint

The **Elbow** is a *ginglymus* or hinge-joint. The bones entering into its formation are the trochlear surface of the humerus, which is received into the greater sigmoid cavity of the ulna, and admits of the movements peculiar to this joint, viz. flexion and extension; whilst the lesser, or radial, head of the humerus articulates with the cup-shaped depression on the head of the radius; the circumference of the head of the radius articulates with the lesser sigmoid cavity of the ulna, allowing of the movement of rotation of the radius on the ulna, the chief action of the superior radio-ulnar articulation. The articular surfaces are covered with a thin layer of cartilage, and connected together by a capsular ligament of unequal thickness, being especially thickened on its two sides and, to a less extent, in front and behind. These thickened portions are usually described as distinct ligaments under the following names:—

Anterior.	Internal Lateral.
Posterior.	External Lateral.

The orbicular ligament of the upper radio-ulnar articulation must also be reckoned among the ligaments of the elbow.

The **Anterior Ligament** (fig. 282) is a broad and thin fibrous layer, which covers the anterior surface of the joint. It is attached to the front of the internal

condyle and to the front of the humerus immediately above the coronoid fossa; below, to the anterior surface of the coronoid process of the ulna and orbicular ligament, being continuous on each side with the lateral ligaments. Its superficial fibres pass obliquely from the inner condyle of the humerus outwards to the orbicular ligament. The middle fibres, vertical in direction, pass from the upper part of the coronoid depression and become partly blended with the preceding, but mainly inserted into the anterior surface of the coronoid process. The deep or transverse set intersects these at right angles. This ligament is in relation, in front, with the Brachialis anticus, except at its outermost part; behind, with the synovial membrane.

The **Posterior Ligament** (fig. 283) is a thin and loose membranous fold, attached, above, to the lower end of the humerus, on a level with the upper part

Fig. 282.—Left elbow-joint, showing anterior and internal ligaments.

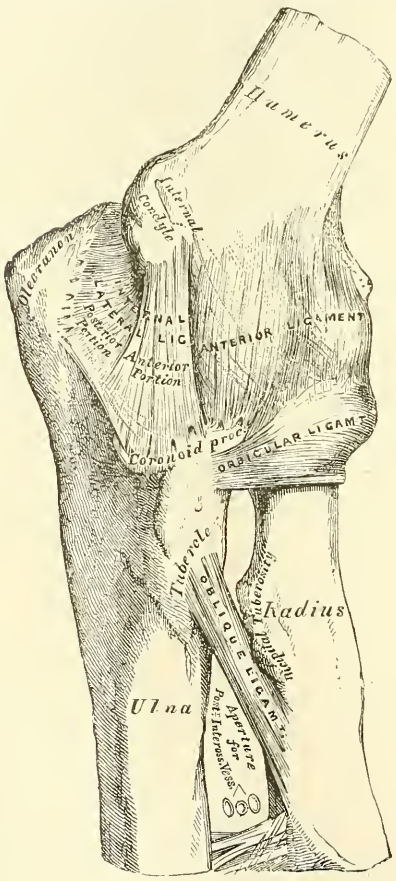


Fig. 283.—Left elbow-joint, showing posterior and external ligaments.

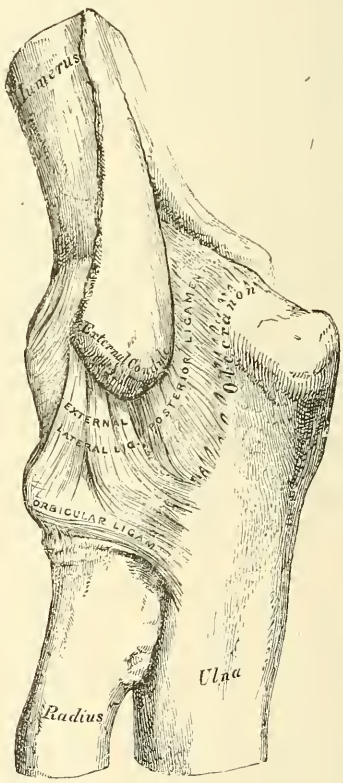


of the olecranon fossa; below, to the groove on the upper and outer surfaces of the olecranon. The superficial or transverse fibres pass between the adjacent margins of the olecranon fossa. The deeper portion consists of vertical fibres, some of which, thin and weak, pass from the upper part of the olecranon fossa to the margin of the olecranon; others, thicker and stronger, pass from the back of the capitellum of the humerus to the posterior border of the lesser sigmoid cavity of the ulna. This ligament is in relation, behind, with the tendon of the Triceps and the Anconeus; in front, with the synovial membrane.

The **Internal Lateral Ligament** (fig. 282) is a thick triangular band consisting of two portions, an anterior and posterior, united by a thinner intermediate portion. The *anterior portion*, directed obliquely forwards, is attached, above,

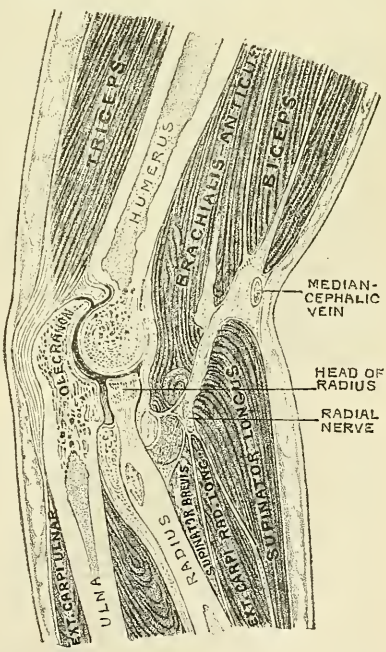
by its apex, to the lowest front part of the internal condyle of the humerus; and, below, by its broad base, to the inner margin of the coronoid process. The *posterior portion*, also of triangular form, is attached, above, by its apex, to the lower and back part of the internal condyle; below, to the inner margin of the olecranon. Between these two bands a few intermediate fibres descend from the internal condyle to blend with a transverse band of ligamentous tissue which bridges across the notch between the olecranon and coronoid processes. This ligament is in relation, internally, with the Triceps and Flexor carpi ulnaris muscles, and the ulnar nerve, and gives origin to part of the Flexor sublimis digitorum.

The **External Lateral Ligament** (fig. 283) is a short and narrow fibrous band, less distinct than the internal, attached, above, to a depression below the external condyle of the humerus; below, to the orbicular ligament, some of its most posterior fibres passing over that ligament, to be inserted into the outer margin of the ulna. This ligament is intimately blended with the tendon of origin of the Supinator brevis muscle.

The **Synovial Membrane** is very extensive. It covers the margin of the articular surface of the humerus, and lines the coronoid and olecranon fossæ on that bone: from these points, it is reflected over the anterior, posterior, and lateral ligaments; and forms a pouch between the lesser sigmoid cavity, the internal surface of the orbicular ligament, and the circumference of the head of the radius. Projecting into the cavity is a crescentic fold of synovial membrane, between the radius and ulna, suggesting the division of the joint into two; one the humero-radial, the other the humero-ulnar.

Between the capsular ligament and the synovial membrane are three masses of fat: one, the largest, above the olecranon fossa, which is pressed into the fossa by the Triceps during flexion; a second, over the coronoid fossa; and a third over the radial fossa. These are pressed into their respective fossæ during extension.

Fig. 284.—Sagittal section of the right elbow-joint, taken somewhat obliquely and seen from the radial aspect. (After Braune.)



The *Muscles* in relation with the joint are, in front, the Brachialis anticus; behind, the Triceps and Anconeus; externally, the Supinator brevis, and the common tendon of origin of the Extensor muscles; internally, the common tendon of origin of the Flexor muscles, and the Flexor carpi ulnaris, with the ulnar nerve (fig. 284).

The *Arteries* supplying the joint are derived from the communicating branches between the superior profunda, inferior profunda, and anastomotica magna arteries, branches of the brachial, with the anterior, posterior, and interosseous recurrent branches of the ulna, and the recurrent branch of the radial. These vessels form a complete chain of inosculation around the joint.

The *Nerves* are derived from the ulnar, as it passes between the internal condyle and the olecranon; a filament from the musculo-cutaneous (Rüdinger), and two from the median (Macalister).

Actions.—The elbow-joint comprises three different portions: viz. the joint between the ulna and humerus, that between the head of the radius and the humerus, and the superior radio-ulnar articulation, described below. All these articular surfaces are invested by a

common synovial membrane, and the movements of the whole joint should be studied together. The combination of the movements of flexion and extension of the forearm with those of pronation and supination of the hand, which is ensured by the two being performed at the same joint, is essential to the accuracy of the various minute movements of the hand.

The portion of the joint between the ulna and humerus is a simple hinge-joint, and allows of movements of flexion and extension only. Owing to the obliquity of the trochlear surface of the humerus, this movement does not take place in a straight line; so that when the forearm is extended and supinated, the axis of the arm and forearm is not in the same line, but the one portion of the limb forms an angle with the other, and the hand, with the forearm, is directed outwards. During flexion, on the other hand, the forearm and the hand tend to approach the middle line of the body, and thus enable the hand to be easily carried to the face. The shape of the articular surface of the humerus, with its prominences and depressions accurately adapted to the opposing surfaces of the olecranon, prevents any lateral movement. *Flexion* is produced by the action of the Biceps and Brachialis anticus, assisted by the muscles arising from the internal condyle of the humerus and the Supinator longus; *extension*, by the Triceps and Anconeus, assisted by the extensors of the wrist and by the Extensor communis digitorum and Extensor minimi digiti.

The joint between the head of the radius and the capitellum or radial head of the humerus is an arthrodial joint. The bony surfaces would of themselves constitute an enarthrosis and allow of movement in all directions, were it not for the orbicular ligament by which the head of the radius is bound down firmly to the sigmoid cavity of the ulna, and which prevents any separation of the two bones laterally. It is to the same ligament that the head of the radius owes its security from dislocation, which would otherwise constantly occur, as a consequence of the shallowness of the cup-like surface on the head of the radius. In fact, but for this ligament, the tendon of the Biceps would be liable to pull the head of the radius out of the joint.* In complete extension, the head of the radius glides so far back on the outer condyle that its edge is plainly felt at the back of the articulation. Flexion and extension of the elbow-joint are limited by the tension of the structures on the front and back of the joint; the limitation of flexion being also aided by the soft structures of the arm and forearm coming in contact.

In combination with any position of flexion or extension, the head of the radius can be rotated in the upper radio-ulnar joint, carrying the hand with it. The hand is articulated to the lower surface of the radius only, and the concave or sigmoid surface on the lower end of the radius travels round the lower end of the ulna. The latter bone is excluded from the wrist-joint (as will be seen in the sequel) by the interarticular fibro-cartilage. Thus, rotation of the head of the radius round an axis which passes through the centre of the radial head of the humerus imparts circular movement to the hand through a very considerable arc.

Surface Form.—If the forearm be slightly flexed on the arm, a curved crease or fold with its convexity downwards may be seen running across the front of the elbow, extending from one condyle to the other. The centre of this fold is some slight distance above the line of the joint. The position of the radio-humeral portion of the joint can be at once ascertained by feeling for a slight groove or depression between the head of the radius and the capitellum of the humerus at the back of the articulation.

Surgical Anatomy.—From the great breadth of the joint, and the manner in which the articular surfaces are interlocked, and also on account of the strong lateral ligaments and the support which the joint derives from the mass of muscles attached to each condyle of the humerus, lateral displacement of the bones is very uncommon. Whereas antero-posterior dislocation, on account of the shortness of the antero-posterior diameter, the weakness of the anterior and posterior ligaments, and the want of support of muscles, much more frequently takes place. Dislocation backwards takes place when the forearm

* Humphry, *op. cit.* p. 419.

is in a position of extension, and forwards when in a position of flexion. For, in the former position, that of extension, the coronoid process is not interlocked into the coronoid fossa, and loses its grip to a certain extent, whereas the olecranon process is in the olecranon fossa, and entirely prevents displacement forwards. On the other hand, during flexion, the coronoid process is in the coronoid fossa, and prevents dislocation backwards, while the olecranon loses its grip and is not so efficient, as during extension, in preventing a forward displacement. When lateral dislocation does take place it is generally incomplete.

Dislocation of the elbow-joint is of common occurrence in children, far more common than dislocation of any other articulation, for, as a rule, fracture of a bone more frequently takes place, under the application of any severe violence, in young persons than dislocation. In lesions of this joint there is often very great difficulty in ascertaining the exact nature of the injury.

The elbow-joint is occasionally the seat of acute synovitis. The synovial membrane then becomes distended with fluid, the bulging showing itself principally around the olecranon process, that is to say, on its inner and outer sides and above, in consequence of the laxness of the posterior ligament. Occasionally a well-marked triangular projection may be seen on the outer side of the olecranon, from bulging of the synovial membrane beneath the Anconeus muscle. Again, there is often some swelling just above the head of the radius, in the line of the radio-humeral joint. There is generally not much swelling at the front of the joint, though sometimes deep-seated fulness beneath the Brachialis anticus may be noted. When suppuration occurs the abscess usually points at one or other border of the Triceps muscle; occasionally the pus discharges itself in front, near the insertion of the Brachialis anticus muscle. Chronic synovitis, usually of tuberculous origin, is of common occurrence in the elbow-joint: under these circumstances the forearm tends to assume the position of semi-flexion, which is that of greatest ease and relaxation of ligaments. It should be borne in mind, that should ankylosis occur in this or the extended position, the limb will not be nearly so useful as if ankylosed in a position of rather less than a right angle. Loose cartilages are sometimes met with in the elbow-joint, not so commonly, however, as in the knee; nor do they, as a rule, give rise to such urgent symptoms as in this articulation, and rarely require operative interference. The elbow-joint is also sometimes affected with osteo-arthritis, but this affection is less common in this articulation than in some other of the larger joints.

Excision of the elbow is principally required for three conditions—viz. tuberculous arthritis, injury and its results, and faulty ankylosis—but may be necessary for some other rarer conditions, such as disorganising arthritis after pyæmia, unreduced dislocations, and osteo-arthritis. The results of the operation are, as a rule, more favourable than those of excision of any other joint, and it is one, therefore, that the surgeon should never hesitate to perform, especially in the first three of the conditions mentioned above. The operation is best performed by a single vertical incision down the back of the joint, a transverse incision, over the outer condyle, being added if the parts are much thickened and fixed. A straight incision is made about four inches long, the mid-point of which is on a level with and a little to the inner side of the tip of the olecranon. This incision is made down to the bone, through the substance of the Triceps muscle. The operator with the point of his knife, and guarding the soft parts with his thumb-nail, separates them from the bone. In doing this there are two structures which he should carefully avoid: the ulnar nerve, which lies parallel to his incision, but a little internal, as it courses down between the internal condyle and the olecranon process, and the prolongation of the Triceps into the deep fascia of the forearm over the Anconeus muscle. Having cleared the bones and divided the lateral and posterior ligaments, the forearm is strongly flexed and the ends of the bone turned out and sawn off. The section of the humerus should be through the base of the condyles, that of the ulna and radius should be just below the level of the lesser sigmoid cavity of the ulna and the neck of the radius. In this operation the object is to obtain such union as shall allow free motion of the bones of the forearm; and, therefore, passive motion must be commenced early—that is to say, about the tenth day.

VI. Radio-ulnar Articulations

The articulation of the radius with the ulna is effected by ligaments, which connect together both extremities as well as the shafts of these bones. They may, consequently, be subdivided into three sets:—1. The superior radio-ulnar, which is a portion of the elbow-joint; 2. the middle radio-ulnar; and, 3. the inferior radio-ulnar articulations.

1. Superior Radio-ulnar Articulation

This articulation is a trochoid or pivot-joint. The bones entering into its formation are the inner side of the circumference of the head of the radius

rotating within the lesser sigmoid cavity of the ulna. Its only ligament is the *annular* or *orbicular*.

The **Orbicular Ligament** (fig. 283) is a strong, flat band of ligamentous fibres, which surrounds the head of the radius, and retains it in firm connection with the lesser sigmoid cavity of the ulna. It forms about four-fifths of an osseo-fibrous ring, attached by each end to the extremities of the lesser sigmoid cavity, and is smaller at the lower part of its circumference than above, by which means the head of the radius is more securely held in its position. Its *outer surface* is strengthened by the external lateral ligament of the elbow, and affords origin to part of the Supinator brevis muscle. Its *inner surface* is smooth, and lined by synovial membrane. The synovial membrane is continuous with that which lines the elbow-joint.

Actions.—The movement which takes place in this articulation is limited to rotation of the head of the radius within the orbicular ligament, and upon the lesser sigmoid cavity of the ulna; rotation forwards being called *pronation*; rotation backwards, *supination*. Supination is performed by the Biceps and Supinator brevis, assisted to a slight extent by the Extensor muscles of the thumb and, in certain positions, by the Supinator longus. Pronation is performed by the Pronator radii teres and the Pronator quadratus, assisted, in some positions, by the Supinator longus.

Surface Form.—The position of the superior radio-ulnar joint is marked on the surface of the body by the little dimple on the back of the forearm which indicates the position of the head of the radius.

Surgical Anatomy.—Dislocation of the head of the radius alone is not an uncommon accident, and occurs most frequently in young persons from falls on the hand when the forearm is extended and supinated, the head of the bone being displaced forward. It is attended by rupture of the orbicular ligament.

2. Middle Radio-ulnar Articulation

The interval between the shafts of the radius and ulna is occupied by two ligaments.

Oblique. Interosseous.

The **Oblique** or **Round Ligament** (fig. 282) is a small, flattened fibrous band, which extends obliquely downwards and outwards, from the tubercle of the ulna at the base of the coronoid process to the radius a little below the bicipital tuberosity. Its fibres run in the opposite direction to those of the interosseous ligament; and it appears to be placed as a substitute for it in the upper part of the interosseous interval. This ligament is sometimes wanting.

The **Interosseous Membrane** is a broad and thin plane of fibrous tissue descending obliquely downwards and inwards, from the interosseous ridge on the radius to that on the ulna. It is deficient above, commencing about an inch beneath the tubercle of the radius; is broader in the middle than at either extremity; and presents an oval aperture just above its lower margin for the passage of the anterior interosseous vessels to the back of the forearm. This ligament serves to connect the bones, and to increase the extent of surface for the attachment of the deep muscles. Between its upper border and the oblique ligament an interval exists, through which the posterior interosseous vessels pass. Two or three fibrous bands are occasionally found on the posterior surface of this membrane, which descend obliquely from the ulna towards the radius, and which have consequently a direction contrary to that of the other fibres. It is in relation, *in front*, by its upper three-fourths, with the Flexor longus pollicis on the outer side, and with the Flexor profundus digitorum on the inner, lying upon the interval between which are the anterior interosseous vessels and nerve; by its lower fourth with the Pronator quadratus; *behind*, with the Supinator brevis, Extensor ossis metacarpi pollicis, Extensor brevis pollicis,

Extensor longus pollicis, Extensor indicis; and, near the wrist, with the anterior interosseous artery and posterior interosseous nerve.

3. Inferior Radio-ulnar Articulation

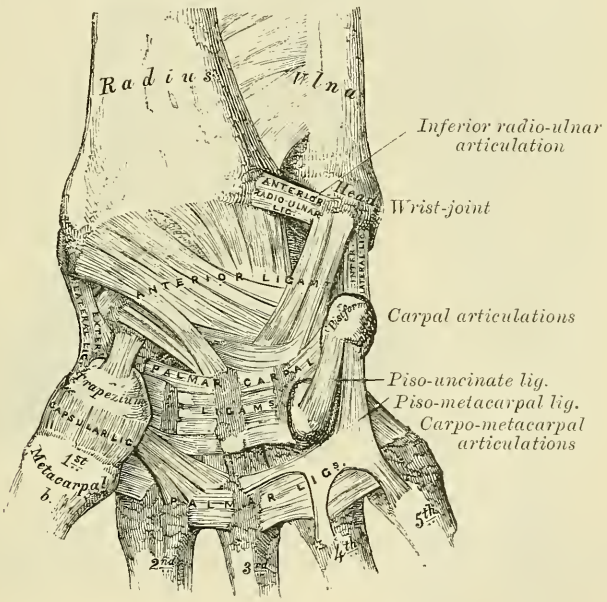
This is a pivot-joint, formed by the head of the ulna received into the sigmoid cavity at the inner side of the lower end of the radius. The articular surfaces are covered by a thin layer of cartilage, and connected together by the following ligaments :—

Anterior Radio-ulnar. Posterior Radio-ulnar.
Interarticular Fibro-cartilage.

The **Anterior Radio-ulnar Ligament** (fig. 285) is a narrow band of fibres extending from the anterior margin of the sigmoid cavity of the radius to the anterior surface of the head of the ulna.

The **Posterior Radio-ulnar Ligament** (fig. 286) extends between similar points on the posterior surface of the articulation.

Fig. 285.—Ligaments of wrist and hand. Anterior view.



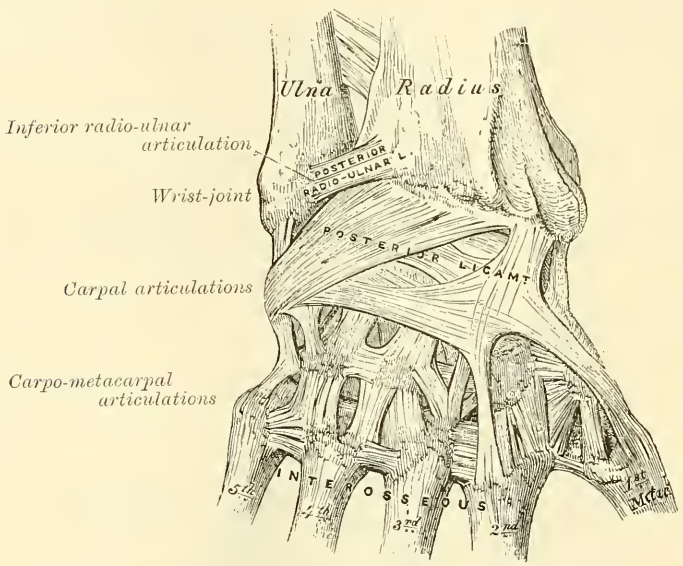
The **Interarticular Fibro-cartilage** (fig. 288) is triangular in shape, and is placed transversely beneath the head of the ulna, binding the lower end of this bone and the radius firmly together. Its circumference is thicker than its centre, which is thin and occasionally perforated. It is attached by its apex to a depression which separates the styloid process of the ulna from the head of that bone; and by its base, which is thin, to the prominent edge of the radius, which separates the sigmoid cavity from the carpal articulating surface. Its margins are united to the ligaments of the wrist-joint. Its *upper surface*, smooth and concave, articulates with the head of the ulna, forming an arthrodial joint; its *under surface*, also concave and smooth, forms part of the wrist-joint and articulates with the cuneiform bone. Both surfaces are lined by a synovial membrane: the upper surface, by one peculiar to the radio-ulnar articulation; the under surface, by the synovial membrane of the wrist.

The **Synovial Membrane** (fig. 288) of this articulation has been called, from its extreme looseness, the *membrana sacciformis*; it extends horizontally inwards

between the head of the ulna and the interarticular fibro-cartilage, and upwards between the radius and the ulna, forming here a very loose *cul-de-sac*. The quantity of synovia which it contains is usually considerable.

Actions.—The movement in the inferior radio-ulnar articulation is just the reverse of that between the two bones above. It consists of a movement of rotation of the lower end of the radius round an axis which corresponds to the centre of the head of the ulna. When the radius rotates forwards, *pronation* of the forearm and hand is the result; and when backwards, *supination*. It will thus be seen that in pronation and supination of the forearm and hand the radius describes a segment of a cone, the axis of which extends from the centre of the head of the radius to the middle of the head of the ulna. In this movement, however, the ulna is not quite stationary, but rotates a little in the opposite direction. So that it also describes the segment of a cone, though of smaller size than that described by the radius. The movement which causes this altera-

Fig. 286.—Ligaments of wrist and hand. Posterior view.



tion in the position of the head of the ulna takes place principally at the shoulder-joint by a rotation of the humerus, but possibly also to a slight extent at the elbow-joint.*

Surface Form.—The position of the inferior radio-ulnar joint may be ascertained by feeling for a slight groove at the back of the wrist, between the prominent head of the ulna and the lower end of the radius, when the forearm is in a state of almost complete pronation.

VII. Radio-carpal or Wrist-joint

The **Wrist** is a condyloid articulation. The parts entering into its formation are the lower end of the radius and under surface of the interarticular fibro-cartilage, which form together the receiving cavity; and the scaphoid, semilunar, and cuneiform bones, which form the condyle. The articular surface of the radius and the under surface of the interarticular fibro-cartilage, the receiving cavity, form together a transversely elliptical concave surface. The articular surfaces of the scaphoid, semilunar, and cuneiform bones form together a smooth, convex surface, the *condyle*, which is received into the concavity above mentioned. All the bony surfaces of the articulation are covered with cartilage,

* See *Journ. of Anat. and Phys.*, vol. xix. parts ii., iii., and iv.

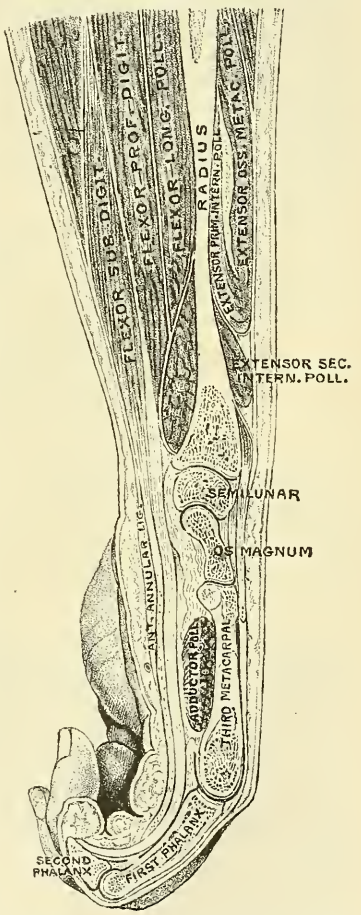
and connected together by a capsule, which is divided into the following ligaments:—

External Lateral.	Anterior.
Internal Lateral.	Posterior.

The **External Lateral Ligament** (*radio-carpal*) (fig. 285) extends from the summit of the styloid process of the radius to the outer side of the scaphoid, some of its fibres being prolonged to the trapezium and annular ligament.

The **Internal Lateral Ligament** (*ulno-carpal*) is a rounded cord, attached, above, to the extremity of the styloid process of the ulna; and dividing below into two fasciculi, which are attached, one to the inner side of the cuneiform bone, the other to the pisiform bone and annular ligament.

Fig. 287.—Longitudinal section of the right forearm, hand, and third finger, viewed from the ulnar aspect. (After Braune.)



The **Anterior Ligament** is a broad membranous band, attached, above, to the anterior margin of the lower end of the radius, its styloid process and the ulna; its fibres pass downwards and inwards to be inserted into the palmar surface of the scaphoid, semilunar, and cuneiform bones, some of the fibres being continued to the os magnum. In addition to this broad membrane, there is a distinct rounded fasciculus, superficial to the rest, which passes from the base of the styloid process of the ulna to the semilunar and cuneiform bones. This ligament is perforated by numerous apertures for the passage of vessels, and is in relation, in front, with the tendons of the Flexor profundus digitorum and Flexor longus pollicis; behind, with the synovial membrane of the wrist-joint.

The **Posterior Ligament** (fig. 286), less thick and strong than the anterior, is attached, above, to the posterior border of the lower end of the radius; its fibres pass obliquely downwards and inwards, to be attached to the dorsal surface of the scaphoid, semilunar, and cuneiform bones, being continuous with those of the dorsal carpal ligaments. This ligament is in relation, behind, with the extensor tendons of the fingers; in front, with the synovial membrane of the wrist.

The **Synovial Membrane** (fig. 288) lines the inner surface of the ligaments above described, extending from the lower end of the radius and interarticular fibro-cartilage above to the articular surfaces of the carpal bones below. It is loose and lax, and presents numerous folds, especially behind.

Relations.—The wrist-joint is covered in front by the flexor, and behind by the extensor tendons; it is also in relation with the radial and ulnar arteries.

The *Arteries* supplying the joint are the anterior and posterior carpal branches of the radial and ulnar, the anterior and posterior interosseous, and some ascending branches from the deep palmar arch.

The *Nerves* are derived from the ulnar and posterior interosseous.

Actions.—The movements permitted in this joint are flexion, extension,

abduction, adduction, and circumduction. Its actions will be further studied with those of the carpus, with which they are combined.

Surface Form.—The line of the radio-carpal joint is on a level with the apex of the styloid process of the ulna.

Surgical Anatomy.—The wrist-joint is rarely dislocated, its strength depending mainly upon the numerous strong tendons which surround the articulation. Its security is further provided for by the number of small bones of which the carpus is made up, and which are united by very strong ligaments. The slight movement which takes place between the several bones serves to break the jars that result from falls or blows on the hand. Dislocation backwards, which is the more common, simulates to a considerable extent Colles' fracture of the radius, and is liable to be mistaken for it. The diagnosis can be easily made out by observing the relative position of the styloid processes of the radius and the ulna. In the natural condition the styloid process of the radius is on a lower level, i.e. nearer the ground, when the arm hangs by the side, than that of the ulna, and the same would be the case in dislocation. In Colles' fracture, on the other hand, the styloid process of the radius is on the same, or even a higher level than that of the ulna.

The wrist-joint is occasionally the seat of acute synovitis, the result of traumatism, or arising in the rheumatic or pyæmic state. When the synovial sac is distended with fluid, the swelling is greatest on the dorsal aspect of the wrist, showing a general fulness, with some bulging between the tendons. The inflammation is prone to extend to the intercarpal joints and to attack also the sheaths of the tendons in the neighbourhood. Chronic inflammation of the wrist is generally tuberculous, and often leads to similar disease in the synovial sheaths of adjacent tendons and of the intercarpal joints. The disease, therefore, when progressive, often leads to necrosis of the carpal bones, and the result is often unsatisfactory.

VIII. Articulations of the Carpus

These articulations may be subdivided into three sets—

1. The Articulations of the First Row of Carpal Bones.
2. The Articulations of the Second Row of Carpal Bones.
3. The Articulations of the Two Rows with each other.

1. Articulations of the First Row of Carpal Bones

These are arthrodial joints. The ligaments connecting the scaphoid, semilunar, and cuneiform bones are—

Dorsal. Palmar.
Two Interosseous.

The **Dorsal Ligaments** are placed transversely behind the bones of the first row; they connect the scaphoid and semilunar, and the semilunar and cuneiform.

The **Palmar Ligaments** connect the scaphoid and semilunar, and the semilunar and cuneiform bones; they are less strong than the dorsal, and placed very deeply under the anterior ligament of the wrist.

The **Interosseous Ligaments** (fig. 288) are two narrow bundles of fibrous tissue, connecting the semilunar bone, on one side with the scaphoid, and on the other with the cuneiform. They are on a level with the superior surfaces of these bones, and close the upper part of the spaces between them. Their upper surfaces are smooth, and form with the bones the convex articular surfaces of the wrist-joint.

The ligaments connecting the pisiform bone are—

Capsular. Two palmar ligaments.

The **Capsular Ligament** is a thin membrane which connects the pisiform bone to the cuneiform. It is lined with a separate synovial membrane.

The **two Palmar Ligaments** are two strong fibrous bands which connect the pisiform to the unciform, the *piso-uncinate*, and to the base of the fifth metacarpal bone, the *piso-metacarpal ligament* (fig. 285).

2. Articulations of the Second Row of Carpal Bones

These are also arthrodial joints. The articular surfaces are covered with cartilage, and connected by the following ligaments :—

Dorsal. Palmar.
Three Interosseous.

The **Dorsal Ligaments** extend transversely from one bone to another on the dorsal surface, connecting the trapezium with the trapezoid, the trapezoid with the os magnum, and the os magnum with the unciform.

The **Palmar Ligaments** have a similar arrangement on the palmar surface.

The **three Interosseous Ligaments**, much thicker than those of the first row, are placed one between the os magnum and the unciform, a second between the os magnum and the trapezoid, and a third between the trapezium and trapezoid. The first of these is much the strongest, and the third is sometimes wanting. Sometimes a slender interosseous band connects the os magnum and the scaphoid.

3. Articulations of the Two Rows of Carpal Bones with each other

The joint between the scaphoid, semilunar, and cuneiform, and the second row of the carpus, or the *mid-carpal joint*, is made up of three distinct portions ; in the centre the head of the os magnum and the superior surface of the unciform articulate with the deep cup-shaped cavity formed by the scaphoid and semilunar bones, and constitute a sort of ball-and-socket joint. On the outer side the trapezium and trapezoid articulate with the scaphoid, and on the inner side the unciform articulates with the cuneiform, forming gliding joints.

The ligaments are :—

Anterior or Palmar. External Lateral.
Posterior or Dorsal. Internal Lateral.

The **Anterior** or **Palmar Ligament** consists of short fibres, which pass, for the most part, from the palmar surface of the bones of the first row to the front of the os magnum.

The **Posterior** or **Dorsal Ligament** consists of short, irregular bundles of fibres passing between the bones of the first and second row on the dorsal surface of the carpus.

The **Lateral Ligaments** are very short : they are placed, one on the radial, the other on the ulnar side of the carpus ; the former, the stronger and more distinct, connecting the scaphoid and trapezium bones, the latter the cuneiform and unciform ; they are continuous with the lateral ligaments of the wrist-joint.

The **Synovial Membrane of the Carpus** is very extensive ; it passes from the under surface of the scaphoid, semilunar, and cuneiform bones to the upper surface of the bones of the second row, sending upwards two prolongations—between the scaphoid and semilunar, and the semilunar and cuneiform—sending downwards three prolongations between the four bones of the second row, which are further continued onwards into the carpo-metacarpal joints of the four inner metacarpal bones, and also for a short distance between the metacarpal bones. There is a separate synovial membrane between the pisiform and cuneiform bones.

Actions.—The articulation of the hand and wrist, considered as a whole, is divided into three parts : (1) the radius and the interarticular fibro-cartilage ; (2) the meniscus, formed by the scaphoid, semilunar, and cuneiform—the pisiform bone having no essential part in the movement of the hand ; (3) the hand proper, the metacarpal bones with the four carpal bones on which they are supported, viz. the trapezium, trapezoid, os magnum, and unciform. These three elements form two joints : (1) the superior (wrist-joint proper), between the

meniscus and bones of the forearm; (2) the inferior, between the hand and meniscus (transverse or mid-carpal joint).

(1) The articulation between the forearm and carpus is a true condyloid articulation, and therefore all movements but rotation are permitted. Flexion and extension are the most free, and of these a greater amount of extension than flexion is permitted on account of the articulating surfaces extending further on the dorsal than on the palmar aspect of the carpal bones. In this movement the carpal bones rotate on a transverse axis drawn between the tips of the styloid processes of the radius and ulna. A certain amount of adduction (or ulnar flexion) and abduction (or radial flexion) is also permitted. Of these the former is considerably greater in extent than the latter. In this movement the carpus revolves upon an antero-posterior axis drawn through the centre of the wrist. Finally, circumduction is permitted by the consecutive movements of adduction, extension, abduction, and flexion, with intermediate movements between them. There is no rotation, but this is provided for by the supination and pronation of the radius on the ulna. The movement of *flexion* is performed by the Flexor carpi radialis, the Flexor carpi ulnaris, and the Palmaris longus; *extension* by the Extensor carpi radialis longior et brevior and the Extensor carpi ulnaris; *adduction* (ulnar flexion) by the Flexor carpi ulnaris and the Extensor carpi ulnaris; and *abduction* (radial flexion) by the Extensors of the thumb, and the Extensor carpi radialis longior et brevior and the Flexor carpi radialis.

(2) The chief movements permitted in the transverse or mid-carpal joint are flexion and extension and a slight amount of rotation. In flexion and extension, which is the movement most freely enjoyed, the trapezium and trapezoid on the radial side and the unciform on the ulnar side glide forwards and backwards on the scaphoid and cuneiform respectively, while the head of the os magnum and the superior surface of the unciform rotate in the cup-shaped cavity of the scaphoid and semilunar. Flexion at this joint is freer than extension. A very trifling amount of rotation is also permitted, the head of the os magnum rotating round a vertical axis drawn through its own centre, while at the same time a slight gliding movement takes place in the lateral portions of the joint.

IX. Carpo-metacarpal Articulations

1. Articulation of the Metacarpal Bone of the Thumb with the Trapezium

This is a joint of reciprocal reception, and enjoys a great freedom of movement, on account of the configuration of its articular surfaces, which are saddle-shaped, so that, on section, each bone appears to be received into a cavity in the other, according to the direction in which they are cut. Its ligaments are a capsular ligament and a synovial membrane.

The **Capsular Ligament** is a thick but loose capsule, which passes from the circumference of the upper extremity of the metacarpal bone to the rough edge bounding the articular surface of the trapezium; it is thickest externally and behind, and lined by a separate *synovial membrane*.

Movements.—In the articulation of the metacarpal bone of the thumb with the trapezium, the movements permitted are flexion, extension, adduction, abduction, and circumduction. When the joint is flexed, the metacarpal bone is brought in front of the palm, and the thumb is gradually turned to the fingers. It is by this peculiar movement that the tip of the thumb is opposed to the other digits; for, by slightly flexing the fingers, the palmar surface of the thumb can be brought in contact with their palmar surfaces one after another.

2. Articulations of the Metacarpal Bones of the Four Inner Fingers with the Carpus

The joints formed between the carpus and four inner metacarpal bones are arthrodial joints. The ligaments are

Dorsal. Palmar.
Interosseous.

The **Dorsal Ligaments**, the strongest and most distinct, connect the carpal and metacarpal bones on their dorsal surface. The second metacarpal bone receives two fasciculi, one from the trapezium, the other from the trapezoid; the third metacarpal receives two, one from the trapezoid, and one from the os magnum; the fourth two, one from the os magnum, and one from the unciform; the fifth receives a single fasciculus from the unciform bone, which is continuous with a similar ligament on the palmar surface, forming an incomplete capsule.

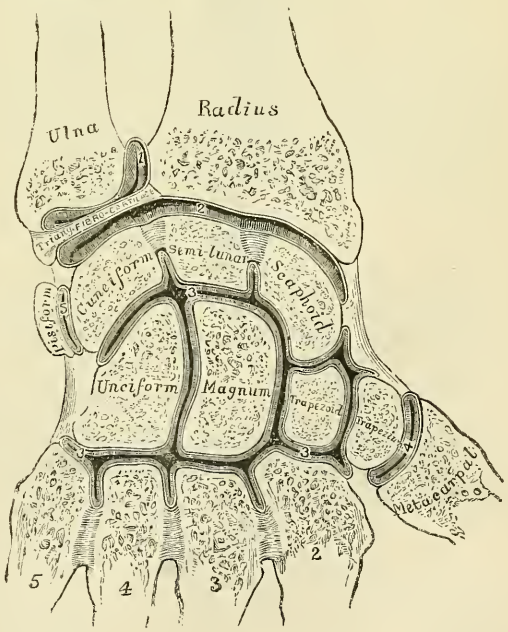
The **Palmar Ligaments** have a somewhat similar arrangement on the palmar surface, with the exception of the third metacarpal, which has three ligaments, an external one from the trapezium, situated above the sheath of the tendon of the Flexor carpi radialis; a middle one from the os magnum; and an internal one from the unciform.

The **Interosseous Ligaments** consist of short, thick fibres, which are limited to one part of the carpo-metacarpal articulation; they connect the contiguous inferior angles of the os magnum and unciform with the adjacent surfaces of the third and fourth metacarpal bones.

The **Synovial Membrane** is a continuation of that between the two rows of carpal bones. Occasionally, the articulation of the unciform with the fourth and fifth metacarpal bones has a separate synovial membrane.

The synovial membranes of the wrist and carpus (fig. 288) are thus seen to be five in number. The *first*, the *membrana sacciformis*, passes from the lower end of the ulna to the sigmoid cavity of the radius, and lines the upper surface of the interarticular fibro-cartilage. The *second* passes from the lower end of the radius and interarticular fibro-cartilage above, to the bones of the first row below. The *third*, the most extensive, passes between the contiguous margins of the two rows of carpal bones and between the bones of the second row to the carpal extremities of the four inner metacarpal bones. The *fourth*, from the margin of the trapezium to the metacarpal bone of the thumb. The *fifth*, between the adjacent margins of the cuneiform and pisiform bones.

Fig. 288.—Vertical section through the articulations at the wrist, showing the five synovial membranes.



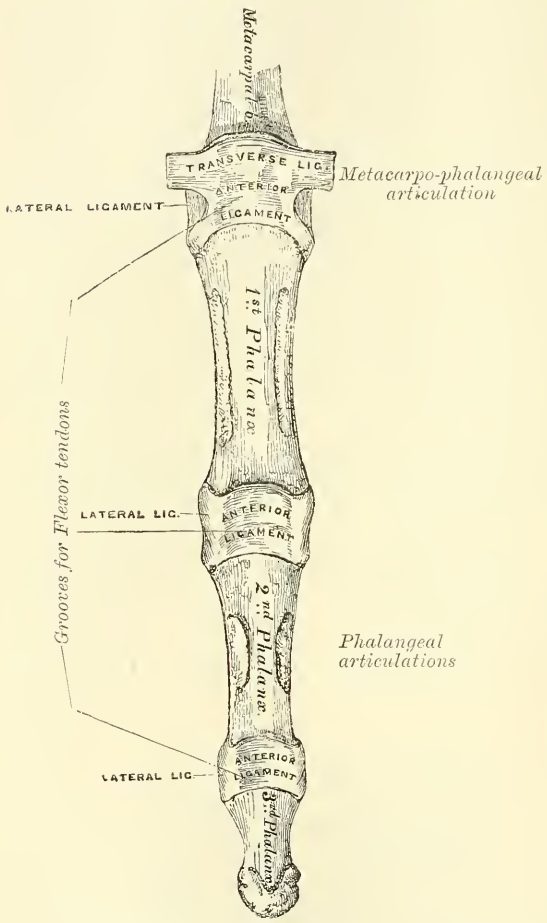
Actions.—The movement permitted in the carpo-metacarpal articulations of the four inner fingers is limited to a slight gliding of the articular surfaces upon each other, the extent of which varies in the different joints. Thus the articulation

of the metacarpal bone of the little finger is most movable, then that of the ring-finger. The metacarpal bones of the index and middle fingers are almost immovable.

3. Articulations of the Metacarpal Bones with each other

The carpal extremities of the four inner metacarpal bones articulate with one another at each side by small surfaces covered with cartilage, and connected together by dorsal, palmar, and interosseous ligaments.

Fig. 289.—Articulations of the phalanges.



The **Dorsal** and **Palmar Ligaments** pass transversely from one bone to another on the dorsal and palmar surfaces. The *Interosseous Ligaments* pass between their contiguous surfaces, just beneath their lateral articular facets.

The **Synovial Membrane** between the lateral facets is a reflection from that between the two rows of carpal bones.

The **Transverse Metacarpal Ligament** (fig. 289) is a narrow fibrous band, which passes transversely across the anterior surfaces of the digital extremities of the four inner metacarpal bones, connecting them together. It is blended anteriorly with the anterior (glenoid) ligament of the metacarpo-phalangeal articulations. To its posterior border is connected the fascia which covers the Interossei muscles. Its superficial surface is concave where the flexor tendons pass over it. Beneath it the tendons of the Interossei muscles pass to their insertion.

X. Metacarpo-phalangeal Articulations (fig. 289)

These articulations are of the condyloid kind, formed by the reception of the rounded head of the metacarpal bone into a superficial cavity in the extremity of the first phalanx. The ligaments are:

Anterior. Two lateral.

The **Anterior Ligaments** (*Glenoid Ligaments* of Cruveilhier) are thick, dense, fibrous structures, placed on the palmar surface of the joints in the intervals between the lateral ligaments, to which they are connected; they are loosely united to the metacarpal bone, but very firmly to the base of the first phalanges. Their palmar surface is intimately blended with the transverse metacarpal ligament, and presents a groove for the passage of the flexor tendons, the sheath surrounding which is connected to each side of the groove. By their deep

surface, they form part of the articular surface for the head of the metacarpal bone, and are lined by a synovial membrane.

The **Lateral Ligaments** are strong, rounded cords, placed one on each side of the joint, each being attached by one extremity to the posterior tubercle on the side of the head of the metacarpal bone, and by the other to the contiguous extremity of the phalanx.

Actions.—The movements which occur in these joints are flexion, extension, adduction, abduction, and circumduction; the lateral movements are very limited.

Surface Form.—The prominences of the knuckles do not correspond to the position of the joints either of the metacarpo-phalangeal or interphalangeal articulations. These prominences are invariably formed by the distal ends of the proximal bone of each joint, and the line indicating the position of the joint must be sought considerably in front of the middle of the knuckle. The usual rule for finding these joints is to flex the distal phalanx on the proximal one to a right angle; the position of the joint is then indicated by an imaginary line drawn along the middle of the lateral aspect of the proximal phalanx.

XI. Articulations of the Phalanges

These are ginglymus joints. The ligaments are:—

Anterior. Two Lateral.

The arrangement of these ligaments is similar to those in the metacarpo-phalangeal articulations; the extensor tendon supplies the place of a posterior ligament.

Actions.—The only movements permitted in the phalangeal joints are flexion and extension; these movements are more extensive between the first and second phalanges than between the second and third. The movement of flexion is very considerable, but extension is limited by the anterior and lateral ligaments.

ARTICULATIONS OF THE LOWER EXTREMITY

The articulations of the Lower Extremity comprise the following groups:—I. The hip-joint. II. The knee-joint. III. The articulations between the tibia and fibula. IV. The ankle-joint. V. The articulations of the tarsus. VI. The tarso-metatarsal articulations. VII. Articulations of the metatarsal bones with each other. VIII. The metatarso-phalangeal articulations. IX. The articulations of the phalanges.

I. Hip-Joint (fig. 290)

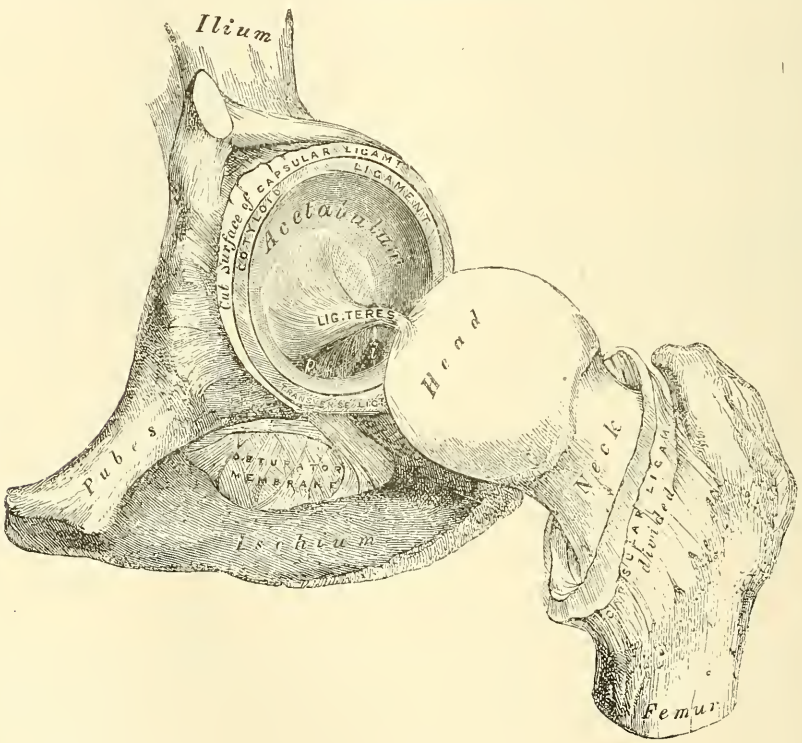
This articulation is an enarthrodial, or ball-and-socket joint, formed by the reception of the head of the femur into the cup-shaped cavity of the acetabulum. The articulating surfaces are covered with cartilage, that on the head of the femur being thicker at the centre than at the circumference, and covering the entire surface with the exception of a depression just below its centre for the ligamentum teres; that covering the acetabulum is much thinner at the centre than at the circumference. It forms an incomplete cartilaginous ring, of a horseshoe shape, deficient below and in front, and having in its centre a circular depression, which is occupied in the recent state by a mass of fat, covered by synovial membrane. The ligaments of the joint are the

Capsular. Teres.
Ilio-femoral. Cotyloid.
Transverse.

The **Capsular Ligament** is a strong, dense, ligamentous capsule, embracing the margin of the acetabulum above, and surrounding the neck of the femur below. Its *upper circumference* is attached to the acetabulum, two or three lines external to the cotyloid ligament, above and behind; but in front, it is attached

to the outer margin of the ligament, and opposite to the notch where the margin of the cavity is deficient, it is connected to the transverse ligament, and by a few fibres to the edge of the obturator foramen. Its *lower circumference* surrounds the neck of the femur, being attached, in front, to the spiral or anterior intertrochanteric line; above, to the base of the neck; behind, to the neck of the bone, about half an inch above the posterior intertrochanteric line. From this insertion the fibres are reflected upwards over the neck of the femur, forming a sort of tubular sheath (the *cervical reflection*), which blends with the periosteum, and can be traced as far as the articular cartilage. On the surface of the neck of the femur some of these reflected fibres are raised into longitudinal folds, termed *retinacula*. It is much thicker at the upper and fore part of the joint, where the greatest amount of resistance is required, than below and internally, where it is thin, loose, and longer than in any other part. It consists of two sets of fibres, circular and longitudinal. The circular fibres are most abundant

Fig. 290.—Left hip-joint laid open.



at the lower and back part of the capsule, while the longitudinal fibres are greatest in amount at the upper and front part of the capsule, where they form distinct bands, or accessory ligaments, of which the most important is the *ilio-femoral*. The other accessory bands are known as the *pubo-femoral*, passing from the ilio-pectineal eminence to the front of the capsule; *ilio-trochanteric*, from the anterior inferior spine of the ilium to the front of the great trochanter; and *ischio-capsular*, passing from the ischium, just below the acetabulum, to blend with the circular fibres at the lower part of the joint. The external surface (fig. 275, page 329) is rough, covered by numerous muscles, and separated in front from the Psoas and Iliacus by a synovial bursa, which not unfrequently communicates, by a circular aperture, with the cavity of the joint. It differs from the capsular ligament of the shoulder in being much less loose and lax, and in not being perforated for the passage of a tendon.

The **Ilio-femoral Ligament** (figs. 275 and 291) is an accessory band of fibres

extending obliquely across the front of the joint; it is intimately connected with the capsular ligament, and serves to strengthen it in this situation. It is attached, above, to the lower part of the anterior inferior spine of the ilium; and, diverging below, forms two bands, of which one passes downwards to be inserted into the lower part of the anterior intertrochanteric line; the other passes downwards and outwards to be inserted into the upper part of the same line and adjacent part of the neck of the femur. Between the two bands is a thinner part of the capsule. Sometimes there is no division, but the ligament spreads out into a flat triangular band, which is attached below into the whole length of the anterior intertrochanteric line. This ligament is frequently called the Y-shaped ligament of Bigelow.

The **Ligamentum Teres** is a triangular band implanted by its apex into the depression a little behind and below the centre of the head of the femur, and by

Fig. 291.—Hip-joint, showing the ilio-femoral ligament. (After Bigelow.)

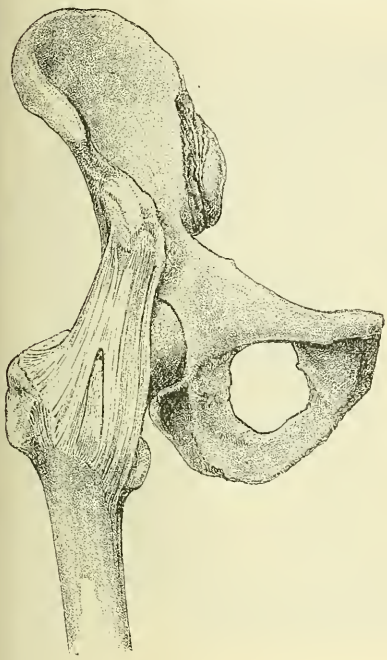


Fig. 292.—Vertical section through hip-joint. (Henle.)

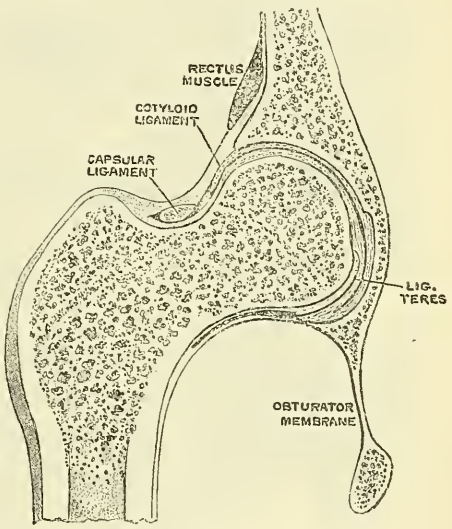


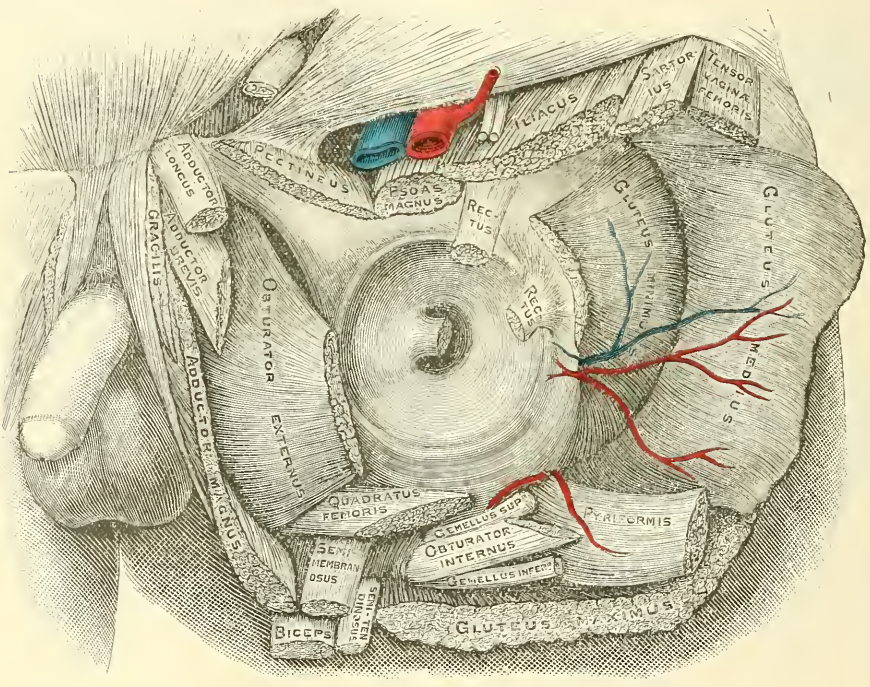
its broad base into the margins of the cotyloid notch, becoming blended with the transverse ligament. It is formed of connective tissue, surrounded by a tubular sheath of synovial membrane. Sometimes only the synovial fold exists, or the ligament may be altogether absent. The ligament is made tense when the hip is semiflexed, and the limb then adducted and rotated outwards; it is, on the other hand, relaxed when the limb is abducted. It has, however, but little influence as a ligament, though it may to a certain extent limit movement, and would appear to be merely a modification of the folds which in other joints fringe the margins of reflection of synovial membranes (see page 306).

The **Cotyloid Ligament** is a fibro-cartilaginous rim attached to the margin of the acetabulum, the cavity of which it deepens; at the same time it protects the edges of the bone, and fills up the inequalities on its surface. It bridges over the notch as the *transverse ligament*, and thus forms a complete circle, which closely surrounds the head of the femur, and assists in holding it in its place, acting as a sort of valve. It is prismoid in form, its base being attached to the margin of the acetabulum, and its opposite edge being free and sharp; whilst its two

surfaces are invested by synovial membrane, the external one being in contact with the capsular ligament, the internal one being inclined inwards so as to narrow the acetabulum, and embrace the cartilaginous surface of the head of the femur. It is much thicker above and behind than below and in front, and consists of close compact fibres, which arise from different points of the circumference of the acetabulum, and interlace with each other at very acute angles.

The **Transverse Ligament** is in reality a portion of the cotyloid ligament, though differing from it in having no nests of cartilage cells amongst its fibres. It consists of strong, flattened fibres, which cross the notch at the lower part of the acetabulum, and convert it into a foramen. Thus an interval is left beneath the ligament for the passage of nutrient vessels to the joint.

Fig. 293.—Relation of muscles to the capsule of the hip-joint. From a drawing by Mr. F. A. Barton.



The **Synovial Membrane** is very extensive. Commencing at the margin of the cartilaginous surface of the head of the femur, it covers all that portion of the neck which is contained within the joint; from the neck it is reflected on the internal surface of the capsular ligament, covers both surfaces of the cotyloid ligament and the mass of fat contained in the depression at the bottom of the acetabulum, and is prolonged in the form of a tubular sheath around the ligamentum teres, as far as the head of the femur. It sometimes communicates by a hole in the capsular ligament between the two limbs of the Y-shaped ligament with a bursa situated on the under surface of the Ilio-psoas muscle.

The muscles in relation with the joint are, in front, the Psoas and Iliacus, separated from the capsular ligament by a synovial bursa; above, the reflected head of the Rectus and Gluteus minimus, the latter being closely adherent to the capsule; internally the Obturator externus and Pectineus; behind, the Pyriformis, Gemellus superior, Obturator internus, Gemellus inferior, Obturator externus, and Quadratus femoris (fig. 293).

The arteries supplying the joint are derived from the obturator, sciatic, internal circumflex, and gluteal.

The nerves are articular branches from the sacral plexus, great sciatic, obturator, accessory obturator, and a filament from the branch of the anterior crural supplying the Rectus.

Actions.—The movements of the hip, like those of all enarthrodial joints, are very extensive; they are, flexion, extension, adduction, abduction, circumduction, and rotation.

The hip-joint presents a very striking contrast to the other great enarthrodial joint—the shoulder—in the much more complete mechanical arrangements for its security and for the limitation of its movements. In the shoulder, as we have seen, the head of the humerus is not adapted at all in shape to the glenoid cavity, and is hardly restrained in any of its ordinary movements by the capsular ligament. In the hip-joint, on the contrary, the head of the femur is closely fitted to the acetabulum for a distance extending over nearly half a sphere, and at the margin of the bony cup it is still more closely embraced by the ligamentous ring of the cotyloid ligament, so that the head of the femur is held in its place by that ligament even when the fibres of the capsule have been quite divided (Humphry). The anterior portion of the capsule, described as the ilio-femoral or accessory ligament, is the strongest of all the ligaments in the body, and is put on the stretch by any attempt to extend the femur beyond a straight line with the trunk. That is to say, this ligament is the chief agent in maintaining the erect position without muscular fatigue; for a vertical line passing through the centre of gravity of the trunk falls behind the centres of rotation in the hip-joints, and therefore the pelvis tends to fall backwards, but is prevented by the tension of the ilio-femoral and capsular ligaments. The security of the joint may be also provided for by the two bones being directly united through the ligamentum teres; but it is doubtful whether this so-called ligament can have much influence upon the mechanism of the joint. Flexion of the hip-joint is arrested by the soft parts of the thigh and abdomen being brought into contact when the leg is flexed on the thigh; but, when the leg is extended, by the action of the hamstring muscles;* extension by the tension of the ilio-femoral ligament and front of the capsule; adduction by the thighs coming into contact; adduction with flexion by the outer band of the ilio-femoral ligament, the ilio-trochanteric ligament, the outer part of the capsular ligament; abduction by the inner band of the ilio-femoral ligament and the pubo-femoral band; rotation outwards by the outer band of the ilio-femoral ligament; and rotation inwards by the ischio-capsular ligament and the hinder part of the capsule. The muscles which *flex* the femur on the pelvis are, the Psoas, Iliacus, Rectus, Sartorius, Pectineus, Adductor longus and brevis, and the anterior fibres of the Gluteus medius and minimus. *Extension* is mainly performed by the Gluteus maximus, assisted by the hamstring muscles. The thigh is *adducted* by the Adductor magnus, longus and brevis, the Pectineus, and Gracilis, and *abducted* by the Gluteus maximus, medius, and minimus. The muscles which *rotate* the thigh *inwards* are the anterior fibres of the Gluteus medius, the Gluteus minimus, and the Tensor vaginæ femoris; while those which rotate it *outwards* are the posterior fibres of the Gluteus medius, the Pyriformis, Obturator externus and internus, Gemellus superior and inferior, Quadratus femoris, Psoas, Iliacus, Gluteus maximus, the three Adductors, the Pectineus, and the Sartorius.

Surface Form.—A line drawn from the anterior superior spinous process of the ilium to the most prominent part of the tuberosity of the ischium (Nélaton's line) runs through the centre of the acetabulum, and would, therefore, indicate the level of the hip-joint; or, in other words, the upper border of the great trochanter, which lies on Nélaton's line, is on a level with the centre of the hip-joint.

Surgical Anatomy.—In dislocation of the hip, 'the head of the thigh-bone may rest at any point around its socket' (Bryant); but whatever position the head ultimately assumes,

* The hip-joint cannot be completely flexed, in most persons, without at the same time flexing the knee, on account of the shortness of the hamstring muscles.—Cleland, *Journ. of Anat. and Phys.* No. I. Old Series, p. 87.

the primary displacement is generally downwards and inwards, the capsule giving way at its weakest—that is, its lower and inner—part. The situation that the head of the bone subsequently assumes is determined by the degree of flexion or extension, and of outward or inward rotation of the thigh at the moment of luxation, influenced, no doubt, by the ilio-femoral ligament, which is not easily ruptured. When, for instance, the head is forced backwards, this ligament forms a fixed axis, round which the head of the bone rotates, and is thus driven on to the dorsum of the ilium. The ilio-femoral ligament also influences the position of the thigh in the various dislocations: in the dislocations backwards it is tense, and produces inversion of the limb; in the dislocation on to the pubes, it is relaxed, and therefore allows the external rotators to evert the thigh; while in the thyroid dislocation it is tense, and produces flexion. The muscles inserted into the upper part of the femur, with the exception of the Obturator internus, have very little direct influence in determining the position of the bone. But Bigelow has endeavoured to show that the Obturator internus is the principal agent in determining whether, in the backward dislocations, the head of the bone shall be ultimately lodged on the dorsum of the ilium, or in or near the sciatic notch. In both dislocations the head passes, in the first instance, in the same direction; but, as Bigelow asserts, in the displacement on to the dorsum, the head of the bone travels up behind the acetabulum, between the muscle and the pelvis; while in the dislocation into the sciatic notch the head passes behind the muscle, and is therefore prevented from reaching the dorsum, in consequence of the tendon of the muscle arching over the neck of the bone, and so remains in the neighbourhood of the sciatic notch. Bigelow, therefore, distinguishes these two forms of dislocation by describing them as dislocations backwards, 'above and below,' the Obturator internus.

The ilio-femoral ligament is rarely torn in dislocations of the hip, and this fact is taken advantage of by the surgeon in reducing these dislocations by manipulation. It is made to act as a fulcrum to a lever, of which the long arm is the shaft of the femur, and the short arm the neck of the bone.

The hip-joint is rarely the seat of acute synovitis from injury, on account of its deep position and its thick covering of soft parts. Acute inflammation may, and does, frequently occur as the result of constitutional conditions, as rheumatism, pyæmia, &c. When, in these cases, effusion takes place, and the joint becomes distended with fluid, the swelling is not very easy to detect on account of the thickness of the capsule and the depth of the articulation. It is principally to be found on the front of the joint, just internal to the ilio-femoral ligament; or behind, at the lower and back part. In these two places the capsule is thinner than elsewhere. Disease of the hip-joint is much more frequently of a chronic character, and is usually of a tuberculous origin. It begins either in the bones or in the synovial membrane. More frequently in the former, and probably, in most cases, at the growing, highly vascular tissue in the neighbourhood of the epiphysial cartilage. In this respect it differs very materially from tuberculous arthritis of the knee, where the disease usually commences in the synovial membrane. The reasons for this are two-fold: first, this part being the centre of rapid growth, its nutrition is unstable and apt to pass into inflammatory action; and, secondly, great strain is thrown upon it, from the frequency of falls and blows upon the hip, which causes crushing of the epiphysial cartilage or the cancellous tissue in its neighbourhood, with the results likely to follow such an injury. In addition to these, the depth of the joint protects it from the causes of synovitis.

In chronic hip-disease the affected limb assumes an altered position, the cause of which it is important to understand. In the early stage of a typical case, the limb is flexed, abducted, and rotated outwards. In this position all the ligaments of the joint are relaxed: the front of the capsule by flexion; the outer band of the ilio-femoral ligament by abduction; and the inner band of this ligament and the back of the capsule by rotation outwards. It is, therefore, the position of greatest ease. The condition is not quite obvious at first, upon examining a patient. If the patient is laid in the supine position, the affected limb will be found to be extended and parallel with the other. But it will be found that the pelvis is tilted downwards on the diseased side and the limb apparently longer than its fellow, and that the lumbar spine is arched forwards (lordosis). If now the thigh is abducted and flexed, the tilting downwards and the arching forwards of the pelvis disappear. The condition is thus explained. A limb which is flexed and abducted is obviously useless for progression, and, in order to overcome the difficulty, the patient depresses the affected side of his pelvis in order to produce parallelism of his limbs, and at the same time rotates his pelvis on its transverse horizontal axis, so as to direct the limb downwards, instead of forwards. In the later stages of the disease the limb becomes flexed and adducted and inverted. This position probably depends upon muscular action, at all events as regards the adduction. The Adductor muscles are supplied by the obturator nerve, which also largely supplies the joint. These muscles are therefore thrown into reflex action by the irritation of the peripheral terminations of this nerve in the inflamed articulation.

Osteo-arthritis is not uncommon in the hip-joint, and is said to be more common in the male than in the female, in whom the knee-joint is more frequently affected. It is a disease of middle age or more advanced period of life.

Congenital dislocation is more commonly met with in the hip-joint than in any other articulation. The displacement usually takes place on to the dorsum ilii. It gives rise to extreme lordosis, and a waddling gait is noticed as soon as the child commences to walk.

Excision of the hip may be required for disease or for injury, especially gunshot. It may be performed either by an anterior incision or a posterior one. The former entails less interference with important structures, especially muscles, than the posterior one, but permits of less efficient drainage. In these days, however, when the surgeon aims at securing healing of his wound without suppuration, this second desideratum is not of so much importance. In the operation in front, the surgeon makes an incision three to four inches in length, starting immediately below and external to the anterior superior spinous process of the ilium, downwards and inwards between the Sartorius and Tensor vaginæ femoris, to the neck of the bone, dividing the capsule at its upper part. A narrow bladed saw now divides the neck of the femur, and the head of the bone is extracted with sequestrum forceps. All diseased tissue is carefully removed with a sharp spoon or scissors, and the cavity thoroughly flushed out with a hot antiseptic fluid.

The posterior method consists in making an incision three or four inches long, commencing midway between the top of the great trochanter and the anterior superior spine, and ending over the shaft, just below the trochanter. The muscles are detached from the great trochanter, and the capsule opened freely. The head and neck are freed from the soft parts and the bone sawn through just below the top of the trochanter with a narrow saw. The head of the bone is then levered out of the acetabulum. In both operations, if the acetabulum is eroded, it must be freely gouged.

II. Knee-Joint

The knee-joint was formerly described as a ginglymus or hinge-joint, but is really of a much more complicated character. It must be regarded as consisting of three articulations in one: one between each condyle of the femur and the corresponding tuberosity of the tibia, which are condyloid joints, and one between the patella and the femur, which is partly arthrodial, but not completely so, since the articular surfaces are not mutually adapted to each other, so that the movement is not a simple gliding one. This view of the construction of the knee-joint receives confirmation from the study of the articulation in some of the lower mammals, where three synovial membranes are sometimes found, corresponding to these three subdivisions, either entirely distinct or only connected together by small communications. This view is further rendered probable by the existence of the two crucial ligaments within the joint, which must be regarded as the external and internal lateral ligaments of the inner and outer joints respectively. The existence of the ligamentum mucosum would further indicate a tendency to separation of the synovial cavity into two minor sacs, one corresponding to each joint.

The bones entering into the formation of the knee-joint are the condyles of the femur above, the head of the tibia below, and the patella in front. The bones are connected together by ligaments, some of which are placed on the exterior of the joint, while others occupy its interior.

External Ligaments	*Interior Ligaments*
Anterior, or Ligamentum Patellæ.	Anterior, or External Crucial.
Posterior, or Ligamentum Posticum Winslowii.	Posterior, or Internal Crucial.
Internal Lateral.	Two Semilunar Fibro-Cartilages.
Two External Lateral.	Transverse.
Capsular.	Coronary.
	Ligamentum mucosum.
	Ligamenta alaria.

The **Anterior Ligament** or **Ligamentum Patellæ** (fig. 294) is the central portion of the common tendon of the Extensor muscles of the thigh which is continued from the patella to the tubercle of the tibia, supplying the place of an anterior ligament. It is a strong, flat, ligamentous band, about three inches in length, attached, above, to the apex of the patella and the rough depression on its posterior surface; below, to the lower part of the tubercle of the tibia; its superficial fibres being continuous over the front of the patella with those of the tendon of the Quadriceps extensor. The lateral portions of the tendon of the Extensor muscles pass down on either side of the patella, attached to the borders

of this bone and its ligament, to be inserted into the upper extremity of the tibia on each side of the tubercle; externally, these portions merge into the capsular ligament. They are termed *lateral patellar ligaments*. The posterior surface of the ligamentum patellæ can usually be easily separated from the front of the capsular ligament.

The **Posterior Ligament** (**Ligamentum Posticum Winslowii**) (fig. 295) is a broad, flat, fibrous band, formed of fasciculi separated from one another by apertures for the passage of vessels and nerves. It is attached above to the upper margin of the intercondyloid notch of the femur, and below to the posterior margin of the head of the tibia. Superficial to the main part of the ligament is a strong fasciculus derived from the tendon of the Semi-membranosus, and passing from the back part of the inner tuberosity of the tibia obliquely upwards and

Fig. 294.—Right knee-joint. Anterior view.

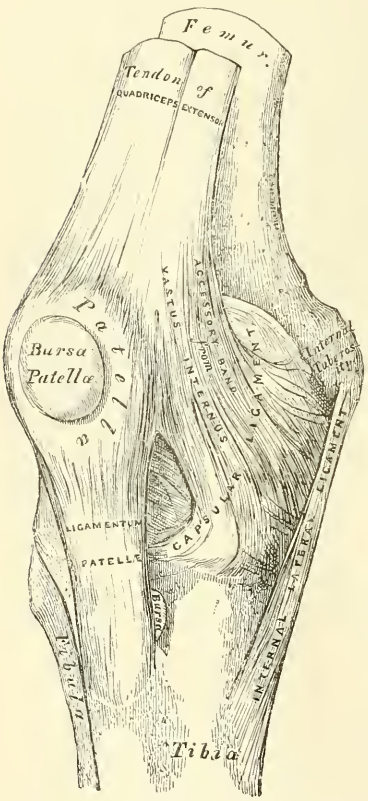


Fig. 295.—Right knee-joint. Posterior view.

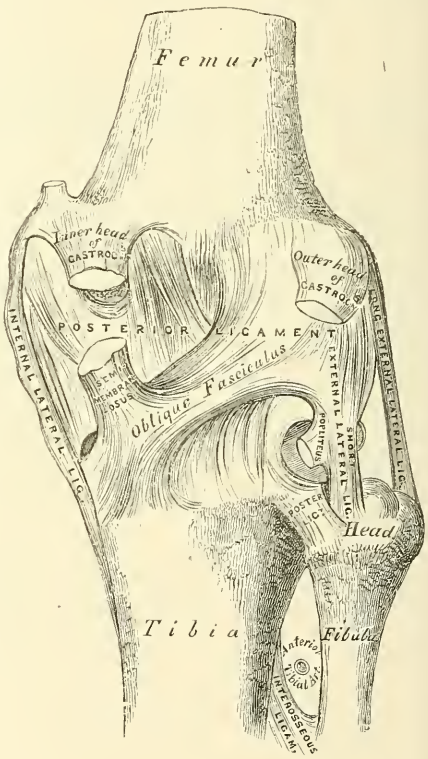


outwards to the back part of the outer condyle of the femur. The posterior ligament forms part of the floor of the popliteal space, and the popliteal artery rests upon it.

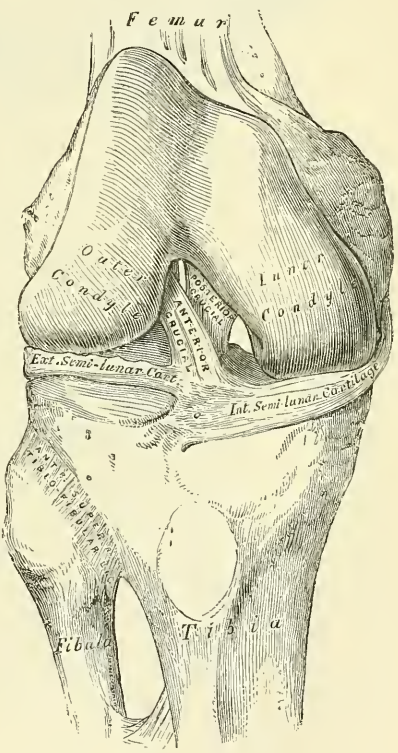
The **Internal Lateral Ligament** is a broad, flat, membranous band, thicker behind than in front, and situated nearer to the back than the front of the joint. It is attached, above, to the inner tuberosity of the femur; below, to the inner tuberosity and inner surface of the shaft of the tibia, to the extent of about two inches. It is crossed, at its lower part, by the tendons of the Sartorius, Gracilis, and Semi-tendinosus muscles, a synovial bursa being interposed. Its *deep surface* covers the anterior portion of the tendon of the Semi-membranosus, with which it is connected by a few fibres, the synovial membrane of the joint, and the inferior internal articular vessels and nerve; it is intimately adherent to the internal semilunar fibro-cartilage.

The **Long External Lateral Ligament** is a strong, rounded, fibrous cord, situated nearer to the back than the front of the joint. It is attached, above, to the back part of the outer tuberosity of the femur; below, to the outer part of the head of the fibula. Its *outer surface* is covered by the tendon of the Biceps, which divides at its insertion into two parts, separated by the ligament. The ligament has passing beneath it the tendon of the Popliteus muscle, and the inferior external articular vessels and nerve.

The **Short External Lateral Ligament** is an accessory bundle of fibres placed behind and parallel with the preceding, attached, above, to the lower and back part of the outer tuberosity of the femur; below, to the summit of the styloid process of the fibula. This ligament is intimately connected with the capsular ligament, and has, passing beneath it, the tendon of the Popliteus muscle, and the inferior external articular vessels and nerve.

The **Capsular Ligament** consists of an exceedingly thin, but strong, fibrous membrane, which fills in the intervals left between the stronger bands above described, and is inseparably connected with them. In front it blends with and forms part of the lateral patellar ligaments, and fills in the interval between the anterior and lateral ligaments of the joint, with which latter structures it is closely connected. Behind, it is strong, and formed chiefly of vertical fibres, which arise above from the condyles and intercondyloid notch of the femur, and is connected below with the back part of the head of the tibia, being closely united with the origins of the Gastrocnemius, Plantaris, and Popliteus muscles. It passes in front of, but is inseparably connected with, the posterior ligament.

Fig. 296.—Right knee-joint. Showing internal ligaments.



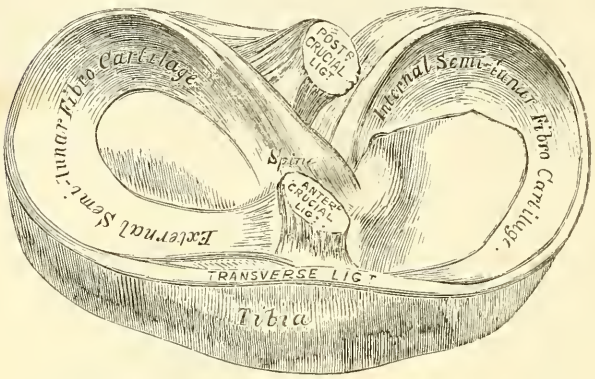
The **Crucial** are two interosseous ligaments of considerable strength, situated in the interior of the joint, nearer its posterior than its anterior part. They are called *crucial* because they cross each other somewhat like the lines of the letter X; and have received the names *anterior* and *posterior*, from the position of their attachment to the tibia.

The **Anterior** or **External Crucial Ligament** (fig. 296) is attached to the depression in front of the spine of the tibia, being blended with the anterior extremity of the external semilunar fibro-cartilage, and passing obliquely upwards, backwards, and outwards, is inserted into the inner and back part of the outer condyle of the femur. Its direction is upwards, backwards, and outwards.

The **Posterior**, or **Internal Crucial Ligament**, is stronger, but shorter and less oblique in its direction, than the anterior. It is attached to the back part of the depression behind the spine of the tibia, to the popliteal notch, and to the posterior extremity of the external semilunar fibro-cartilage; and passes upwards, forwards, and inwards, to be inserted into the outer and fore part of the inner condyle of the femur. As it crosses the anterior crucial ligament, a fasciculus is given off from it, which blends with the posterior part of that ligament. It is in relation, in front, with the anterior crucial ligament; behind, with the capsular ligament.

The **Semilunar Fibro-cartilages** (fig. 297) are two crescentic lamellæ, which serve to deepen the surface of the head of the tibia, for articulation with the condyles of the femur. The circumference of each cartilage is thick, convex, and attached to the inside of the capsule of the knee; the inner border is thin, concave, and free. Their upper surfaces are concave, and in relation with the condyles of the femur; their lower surfaces are flat, and rest upon the head of the tibia. Each cartilage covers nearly the outer two-thirds of the corresponding articular surface of the tibia, leaving the inner third uncovered; both surfaces are smooth, and invested by synovial membrane.

Fig. 297.—Head of tibia, with semilunar cartilages, etc. Seen from above. Right side.



The **Internal Semilunar Fibro-cartilage** is nearly semicircular in form, a little elongated from before backwards, and broader behind than in front; its anterior extremity, thin and pointed, is attached to a depression on the anterior margin of the head of the tibia, in front of the anterior crucial ligament; its posterior extremity is attached to the depression behind the spine, between the attachments of the external semilunar fibro-cartilage and the posterior crucial ligaments.

The **External Semilunar Fibro-cartilage** forms nearly an entire circle, covering a larger portion of the articular surface than the internal one. It is grooved on its outer side for the tendon of the Popliteus muscle. Its extremities, at their insertion, are interposed between the two extremities of the internal semilunar fibro-cartilage; the anterior extremity being attached in front of the spine of the tibia to the outer side of, and behind, the anterior crucial ligament, with which it blends; the posterior extremity being attached behind the spine of the tibia, in front of the posterior extremity of the internal semilunar fibro-cartilage. Just before its insertion posteriorly it gives off a strong fasciculus, which passes obliquely upwards and outwards, to be inserted into the inner condyle of the femur, close to the attachment of the posterior crucial ligament. Occasionally a small fasciculus is given off, which passes forwards to be inserted into the back part of the anterior crucial ligament. The external semilunar fibro-cartilage gives off from its anterior convex margin a fasciculus, which forms the transverse ligament.

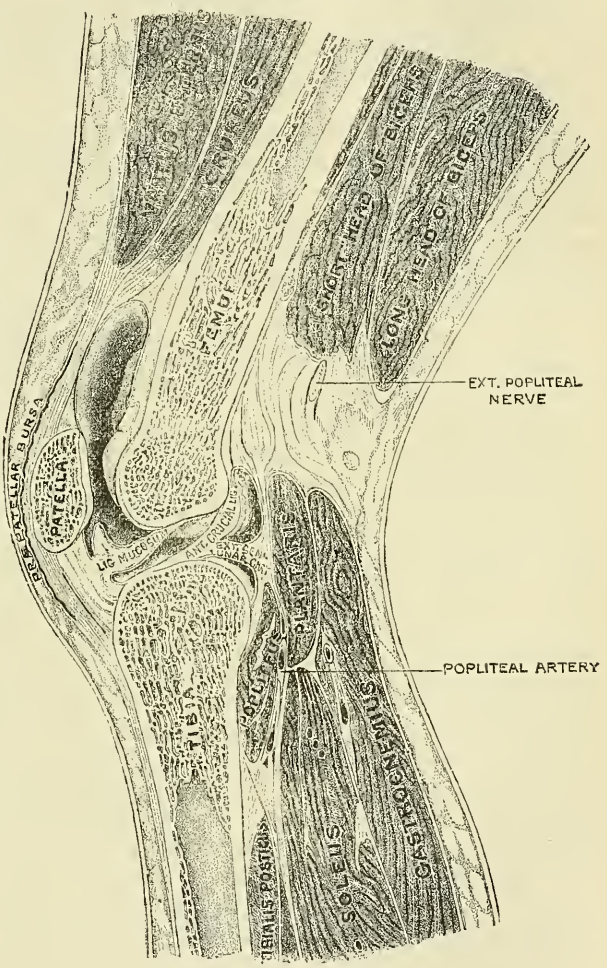
The **Transverse Ligament** is a band of fibres which passes transversely from the anterior convex margin of the external semilunar fibro-cartilage to the anterior convex margin of the internal semilunar fibro-cartilage; its thickness varies considerably in different subjects, and it is sometimes absent altogether.

The **Coronary Ligaments** are merely portions of the capsular ligament, which connect the circumference of each of the semilunar fibro-cartilages with the margin of the head of the tibia.

The **Synovial Membrane** of the knee-joint is the largest and most extensive in the body. Commencing at the upper border of the patella, it forms a short *cul-de-sac* beneath the Quadriceps extensor tendon of the thigh, on the lower part of the front of the shaft of the femur: this communicates with a synovial bursa interposed between the tendon and the front of the femur, by an orifice of variable size. On each side of the patella, the synovial membrane extends beneath the

aponeurosis of the Vasti muscles, and more especially beneath that of the Vastus internus. Below the patella it is separated from the anterior ligament by the anterior part of the capsule and a considerable quantity of adipose tissue. In this situation it sends off a triangular prolongation, containing a few ligamentous fibres, which extends from the anterior part of the joint below the patella, to the front of the intercondyloid notch. This fold has been termed the **ligamentum mucosum**. It also sends off two fringe-like folds, called the **ligamenta alaria**, which extend from the sides of the ligamentum mucosum, upwards and laterally between the patella and femur. On either side of the joint, it passes downwards from the femur, lining the capsule to its point of attachment to the semilunar cartilages; it may then be traced over the upper surfaces of these cartilages to their free borders, and thence along their under surfaces to the tibia. At the back part of the external one it forms a *cul-de-sac* between the groove on its surface and the tendon of the Popliteus; it surrounds the crucial ligaments, and lines the inner surface of the ligaments which enclose the joints. The pouch of synovial membrane between the Extensor tendon and front of the femur is supported, during the movements of the knee, by a small muscle, the Subcrureus, which is inserted into the upper part of the capsular ligament.

Fig. 298.—Longitudinal section through the middle of the right knee-joint. (After Braune.)



The folds of synovial membrane and the fatty processes contained in them act, as it seems, mainly as padding to fill up interspaces and obviate concussions. Sometimes the bursa beneath the Quadriceps extensor is completely shut off from the rest of the synovial cavity, thus forming a closed sac between the Quadriceps and the lower part of the front of the femur; or it may communicate with the synovial cavity by a minute aperture.

The bursæ about the knee-joint are the following:—

In front there are three bursæ: one is interposed between the patella and the skin; another of small size between the upper part of the tuberosity of the tibia and the ligamentum patellæ; and a third between the lower part of the tuberosity of the tibia and the skin. On the outer side there are four bursæ: (1) one beneath the outer head of the Gastrocnemius (which sometimes communicates with the joint); (2) one above the external lateral ligament between it and the tendon of

the Biceps; (3) one beneath the external lateral ligament between it and the tendon of the Popliteus (this is sometimes only an expansion from the next bursa); (4) one beneath the tendon of the Popliteus between it and the condyle of the femur, which is almost always an extension from the synovial membrane. On the inner side there are five bursæ: (1) one beneath the inner head of the Gastrocnemius, which sends a prolongation between the tendons of the Gastrocnemius and Semi-membranosus. This bursa often communicates with the joint; (2) one above the internal lateral ligament between it and the tendons of the Sartorius, Gracilis, and Semi-tendinosus; (3) one beneath the internal lateral ligament between it and the tendon of the Semi-membranosus (this is sometimes only an expansion from the next bursa); (4) one beneath the tendon of the Semi-membranosus, between it and the head of the tibia; (5) sometimes there is a bursa between the tendons of the Semi-membranosus and of the Semi-tendinosus.

Structures around the Joint.—In front and at the sides, the Quadriceps extensor; on the outer side, the tendons of the Biceps and the Popliteus and the external popliteal nerve; on the inner side, the Sartorius, Gracilis, Semi-tendinosus and Semi-membranosus; behind, an expansion from the tendon of the Semi-membranosus, the popliteal vessels, and the internal popliteal nerve, Popliteus, Plantaris, and inner and outer heads of the Gastrocnemius, some lymphatic glands, and fat.

The *Arteries* supplying the joint are derived from the anastomotica magna branch of the femoral, articular branches of the popliteal, anterior and posterior recurrent branches of the anterior tibial, and descending branch from the external circumflex of the Profunda.

The *Nerves* are derived from the obturator, anterior crural, and external and internal popliteal.

Actions.—The knee-joint permits of movements of flexion and extension, and, in certain positions, of slight rotation inwards and outwards. The movement of flexion and extension does not, however, take place in a simple hinge-like manner, as in other joints, but is a complicated movement, consisting of a certain amount of gliding and rotation; so that the same part of one articular surface is not always applied to the same part of the other articular surface, and the axis of motion is not a fixed one. If the joint is examined while in a condition of extreme flexion, the posterior part of the articular surfaces of the tibia will be found to be in contact with the posterior rounded extremities of the condyles of the femur; and if a simple hinge-like movement were to take place, the axis, round which the revolving movement of the tibia occurs, would be in the back part of the condyle. If the leg is now brought forwards into a position of semi-flexion, the upper surface of the tibia will be seen to glide over the condyles of the femur, so that the middle part of the articular facets are in contact, and the axis of rotation must therefore have shifted forwards to nearer the centre of the condyles. If the leg is now brought into the extended position, a still further gliding takes place, and a further shifting forwards of the axis of rotation. This is not, however, a simple movement, but is accompanied by a certain amount of rotation outwards round a vertical axis drawn through the centre of the head of the tibia. This rotation is due to the greater length of the internal condyle and to the fact that the anterior portion of its articular surface is inclined obliquely outwards. In consequence of this, it will be seen that towards the close of the movement of extension, that is to say, just before complete extension is effected, the tibia glides obliquely upwards and outwards over this oblique surface on the inner condyle, and the leg is therefore necessarily rotated outwards. In flexion of the joint the converse of these movements takes place: the tibia glides backwards round the end of the femur, and at the commencement of the movement the tibia is directed downwards and inwards along the oblique curve of the inner condyle, thus causing an inward rotation to the leg.

During flexion and extension, the patella moves on the lower end of the

femur, but this movement is not a simple gliding one; for if the articular surface of this bone is examined, it will be found to present on each side of the central vertical ridge two less marked transverse ridges, which divide the surface, except a small portion along the inner border, which is cut off by a slight vertical ridge, into six facets (see fig. 299), and therefore does not present a uniform curved surface, as would be the case if a simple gliding movement took place. These six facets—three on each side of the median vertical ridge—correspond to and denote the parts of the bone respectively in contact with the condyles of the femur during flexion, semi-flexion, and extension. In flexion, only the upper facets on the patella are in contact with the condyles of the femur; the lower two-thirds of the bone rests upon the mass of fat which occupies the space between the femur and tibia. In the semi-flexed position of the joint, the middle facets on the patella rest upon the most prominent portion of the condyles, and thus afford greater leverage to the Quadriceps by increasing its distance from the centre of motion. In complete extension the patella is drawn up so that only the lower facets are in contact with the articular surfaces of the condyles. The narrow strip along the inner border is an exception to this, and would appear to be in contact with the internal condyle throughout its whole extent, in every position of the joint. As in the elbow, so it is in the knee—the axis of rotation in flexion and extension is not precisely at right angles to the axis of the bone, but during flexion there is a certain amount of alteration of plane; so that, whereas in flexion the femur and tibia are in the same plane, in extension the one bone forms an angle of about ten degrees with the other. There is, however, this difference between the two extremities—that in the upper, during extension, the humeri are parallel, and the bones of the forearm diverge; in the lower, the femora converge below, and the tibiæ are parallel.

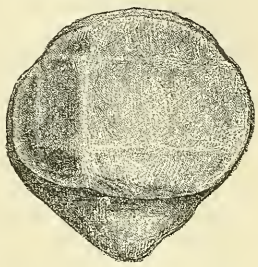


Fig. 299.—View of the posterior surface of the patella. Showing diagrammatically the areas of contact with the femur in different positions of the knee.

In addition to the slight rotation during flexion and extension, the tibia enjoys an independent rotation on the condyles of the femur, in certain positions of the joint. This movement takes place between the interarticular fibro-cartilages and the tibia, whereas the movement of flexion and extension takes place between the interarticular fibro-cartilages and the femur. So that the knee may be said to consist of two joints, separated by the fibro-cartilages: an upper (menisco-femoral), in which flexion and extension take place; and a lower (menisco-tibial), allowing of a certain amount of rotation. This latter movement can only take place in the semiflexed position of the limb, when all the ligaments are relaxed.

During *flexion* the ligamentum patellæ is put upon the stretch, as is also the posterior crucial ligament in extreme flexion. The other ligaments are all relaxed by flexion of the joint, though the relaxation of the anterior crucial ligament is very trifling. Flexion is only checked during life by the contact of the leg with the thigh. In *extension* the ligamentum patellæ becomes relaxed, and, in extreme extension, completely so, so as to allow free lateral movement to the patella, which then rests on the front of the lower end of the femur. The other ligaments, with the exception of the posterior crucial, which is partly relaxed, are all on the stretch. When the limb has been brought into a straight line, extension is checked mainly by the tension of all the ligaments except the posterior crucial and ligamentum patellæ. The movements of *rotation*, of which the knee is capable, are permitted in the semi-flexed condition by the partial relaxation of both crucial ligaments, as well as the lateral ligaments. Rotation inwards appears to be limited by the tension of the anterior crucial ligament, and by the interlocking of the two ligaments; but rotation outwards does not appear to be checked by either crucial ligament, since they uncross during the

execution of this movement, but by the lateral ligaments, especially the internal. The main function of the crucial ligaments is to act as a direct bond of union between the tibia and femur, preventing the former bone from being carried too far backwards or forwards. Thus the anterior crucial ligament prevents the tibia being carried too far forwards by the extensor tendons, and the posterior crucial checks too great movement backwards by the flexors. They also assist the lateral ligaments in resisting any lateral bending of the joint. The interarticular cartilages are intended, as it seems, to adapt the surface of the tibia to the shape of the femur to a certain extent, so as to fill up the intervals which would otherwise be left in the varying positions of the joint, and to interrupt the jars which would be so frequently transmitted up the limb in jumping or falls on the feet; also to permit of the two varieties of motion, flexion and extension, and rotation, as explained above. The patella is a great defence to the knee-joint from any injury inflicted in front, and it distributes upon a large and tolerably even surface, during kneeling, the pressure which would otherwise fall upon the prominent ridges of the condyles; it also affords leverage to the Quadriceps extensor muscle to act upon the tibia, and Mr. Ward has pointed out * how this leverage varies in the various positions of the joint, so that the action of the muscle produces velocity at the expense of force in the commencement of extension, and, on the contrary, at the close of extension tends to diminish velocity, and therefore the shock to the ligaments at the moment tension of these structures takes place.

Extension of the leg on the thigh is performed by the Quadriceps extensor. *Flexion* by the hamstring muscles, assisted by the Gracilis and Sartorius, and, indirectly, by the Gastrocnemius, Popliteus, and Plantaris. *Rotation outwards* by the Biceps, and *rotation inwards* by the Popliteus, Semitendinosus, and, to a slight extent, the Semimembranosus, the Sartorius, and the Gracilis.

Surface Form.—The interval between the two bones entering into the formation of the knee-joint can always easily be felt. If the limb is extended, it is situated on a slightly higher level than the apex of the patella; but if the limb is slightly flexed, a knife carried horizontally backwards immediately below the apex of the patella would pass directly into the joint. When the knee-joint is distended with fluid, the outline of the synovial membrane at the front of the knee may be fairly well mapped out.

Surgical Anatomy.—From a consideration of the construction of the knee-joint, it would at first sight appear to be one of the least secure of any of the joints in the body. It is formed between the two longest bones, and therefore the amount of leverage which can be brought to bear upon it is very considerable; the articular surfaces are but ill-adapted to each other, and the range and variety of motion which it enjoys is great. All these circumstances tend to render the articulation very insecure; but, nevertheless, on account of the very powerful ligaments which bind the bones together, the joint is one of the strongest in the body, and dislocation from traumatism is of very rare occurrence. When, on the other hand, the ligaments have been softened or destroyed by disease, partial displacement is very liable to occur, and is frequently brought about by the mere action of the muscles displacing the articular surfaces from each other. The tibia may be dislocated in any direction from the femur—forwards, backwards, inwards, or outwards; or a combination of two of these dislocations may occur—that is, the tibia may be dislocated forwards and laterally, or backwards and laterally; and any of these dislocations may be complete or incomplete. As a rule, however, the antero-posterior dislocations are complete, the lateral ones incomplete.

One or other of the semilunar cartilages may become displaced and nipped between the femur and tibia. The accident is produced by a twist of the leg when the knee is flexed, and is accompanied by a sudden pain and fixation of the knee in a flexed position. The cartilage may be displaced either inwards or outwards: that is to say, either inwards towards the tibial spine, so that the cartilage becomes lodged in the intercondyloid notch; or outwards, so that the cartilage projects beyond the margin of the two articulating bones. Acute synovitis, the result of traumatism or exposure to cold, is very common in the knee, on account of its superficial position. When distended with fluid, the swelling shows itself above and at the sides of the patella, reaching about an inch or more above the trochlear surface of the femur, and extending a little higher under the Vastus internus than the Vastus externus. Occasionally the swelling may extend two inches or more. At the sides of the patella the swelling extends lower at the inner side than it does on the outer side. The lower level of the synovial membrane is just above the level of the upper part of the

* *Human Osteology*, p. 405.

head of the fibula. In the middle line it covers the upper third of the ligamentum patellæ, being separated from it, however, by the capsule and a little fat. Chronic synovitis principally shows itself in the form of pulpy degeneration of the synovial membrane, leading to tuberculous arthritis. The reasons why tuberculous disease of the knee usually commences in the synovial membrane appear to be the complex and extensive nature of this sac; the extensive vascular supply to it; and the fact that injuries are generally diffused and applied to the front of the joint rather than to the ends of the bones. Syphilitic disease not unfrequently attacks the knee-joint. In the hereditary form of the disease it is usually symmetrical, attacking both joints, which become filled with synovial effusion, and is very intractable and difficult of cure. In the tertiary form of the disease, gummatous infiltration of the synovial membrane may take place. The knee is one of the joints most commonly affected with osteo-arthritis, and is said to be more frequently the seat of this disease in women than in men. The occurrence of the so-called loose cartilage is almost confined to the knee, though they are occasionally met with in the elbow, and, rarely, in some other joints. Many of them occur in cases of osteo-arthritis, in which calcareous or cartilaginous material is formed in one of the synovial fringes and constitutes the foreign body, and may or may not become detached, in the former case only meriting the usual term, 'loose' cartilage. In other cases they have their origin in the exudation of inflammatory lymph, and possibly, in some rare instances, a portion of the articular cartilage or one of the semilunar cartilages becomes detached and constitutes the foreign body.

Genu valgum, or knock knee, is a common deformity of childhood, in which, owing to changes in and about the joint, the angle between the outer border of the tibia and femur is diminished, so that as the patient stands the two internal condyles of the femora are in contact, but the two internal malleoli of the tibiæ are more or less widely separated from each other. When, however, the knees are flexed to a right angle, the two legs are practically parallel with each other. At the commencement of the disease there is a yielding of the internal lateral ligament and other fibrous structures on the inner side of the joint; as a result of this there is a constant undue pressure of the outer tuberosity of the tibia against the outer condyle of the femur. This extra pressure causes arrest of growth and, possibly, wasting of the outer condyle, and a consequent tendency for the tibia to become separated from the internal condyle. To prevent this the internal condyle becomes depressed; probably, as was first pointed out by Mikulicz, by an increased growth of the lower end of the diaphysis on its inner side, so that the line of the epiphysis becomes oblique instead of transverse to the axis of the bone, with a direction downwards and inwards.

Excision of the knee-joint is most frequently required for tuberculous disease of this articulation, but is also practised in cases of disorganisation of the knee after rheumatic fever, pyæmia, &c., in osteo-arthritis, and in ankylosis. It is also occasionally called for in cases of injury, gunshot or otherwise. The operation is best performed either by a horseshoe incision, starting from one condyle, descending as low as the tubercle of the tibia, where it crosses the leg, and is then carried upward to the other condyle; or by a transverse incision across the patella. In this latter incision the patella is either removed or sawn across, and the halves subsequently sutured together. The bones having been cleared, and in those cases where the operation is performed for tuberculous disease, all pulpy tissue having been carefully removed, the section of the femur is first made. This should never include, in children, more than, at the most, two-thirds of the articular surface, otherwise the epiphysial cartilage will be included, with disastrous results as regards the growth of the limb. Afterwards a thin slice should be removed from the upper end of the tibia, not more than half an inch. If any diseased tissue still appears to be left in the bones, it should be removed with the gouge, rather than that a further section of the bones should be made.

III. Articulations between the Tibia and Fibula

The articulations between the tibia and fibula are effected by ligaments which connect both extremities, as well as the shafts of the bones. They may, consequently, be subdivided into three sets:—1. The Superior Tibio-fibular articulation. 2. The Middle Tibio-fibular ligament or interosseous membrane. 3. The Inferior Tibio-fibular articulation.

1. Superior Tibio-fibular Articulation

This articulation is an arthrodial joint. The contiguous surfaces of the bones present two flat, oval facets covered with cartilage, and connected together by the following ligaments:—

Capsular.

Anterior Superior Tibio-fibular. Posterior Superior Tibio-fibular.

The **Capsular Ligament** consists of a membranous bag, which surrounds the articulation, being attached round the margins of the articular facets on the tibia and fibula, and is much thicker in front than behind.

The **Anterior Superior Ligament** (fig. 296) consists of two or three broad and flat bands, which pass obliquely upwards and inwards from the front of the head of the fibula to the front of the outer tuberosity of the tibia.

The **Posterior Superior Ligament** (fig. 295) is a single thick and broad band, which passes upwards and inwards from the back part of the head of the fibula to the back part of the outer tuberosity of the tibia. It is covered by the tendon of the Popliteus muscle.

A **Synovial Membrane** lines this articulation, which at its upper and back part is occasionally continuous with that of the knee-joint.

2. Middle Tibio-fibular Ligament or Interosseous Membrane

An interosseous membrane extends between the contiguous margins of the tibia and fibula, and separates the muscles on the front from those on the back of the leg. It consists of a thin, aponeurotic lamina composed of oblique fibres, which for the most part pass downwards and outwards between the interosseous ridges on the two bones; some few fibres, however, pass in the opposite direction, downwards and inwards. It is broader above than below. Its upper margin does not quite reach the superior tibio-fibular joint, but presents a free concave border, above which is a large, oval aperture for the passage of the anterior tibial vessels forwards to the anterior aspect of the leg. At its lower part is an opening for the passage of the anterior peroneal vessels. It is continuous below with the inferior interosseous ligament; and is perforated in numerous parts for the passage of small vessels. It is in relation, in front, with the Tibialis anticus, Extensor longus digitorum, Extensor proprius hallucis, Peroneus tertius, and the anterior tibial vessels and nerve; behind, with the Tibialis posticus and Flexor longus hallucis.

3. Inferior Tibio-fibular Articulation

This articulation is formed by the rough, convex surface of the inner side of the lower end of the fibula, connected with a concave rough surface on the outer side of the tibia. Below, to the extent of about two lines, these surfaces are smooth, and covered with cartilage, which is continuous with that of the ankle-joint. The ligaments of this joint are:—

Anterior Inferior Tibio-fibular.	Transverse.
Posterior Inferior Tibio-fibular.	Inferior Interosseous.

The **Anterior Inferior Ligament** (fig. 301) is a flat, triangular band of fibres, broader below than above, which extends obliquely downwards and outwards between the adjacent margins of the tibia and fibula, on the front aspect of the articulation. It is in relation, in front, with the Peroneus tertius, the aponeurosis of the leg, and the integument; behind, with the inferior interosseous ligament; and lies in contact with the cartilage covering the astragalus.

The **Posterior Inferior Ligament**, smaller than the preceding, is disposed in a similar manner on the posterio surface of the articulation.

The **Transverse Ligament** is a long, narrow band, continuous with the preceding, passing transversely across the back of the joint, from the external malleolus to the posterior border of the articular surface of the tibia, almost as far as its malleolar process. This ligament projects below the margin of the bones, and forms part of the articulating surface for the astragalus.

The **Inferior Interosseous Ligament** consists of numerous short, strong, fibrous bands, which pass between the contiguous rough surfaces of the tibia and fibula, and constitute the chief bond of union between the bones. This ligament is continuous, above, with the interosseous membrane.

The **Synovial Membrane** lining the articular surface is derived from that of the ankle-joint.

Actions.—The movement permitted in these articulations is limited to a very slight gliding of the articular surfaces one upon another.

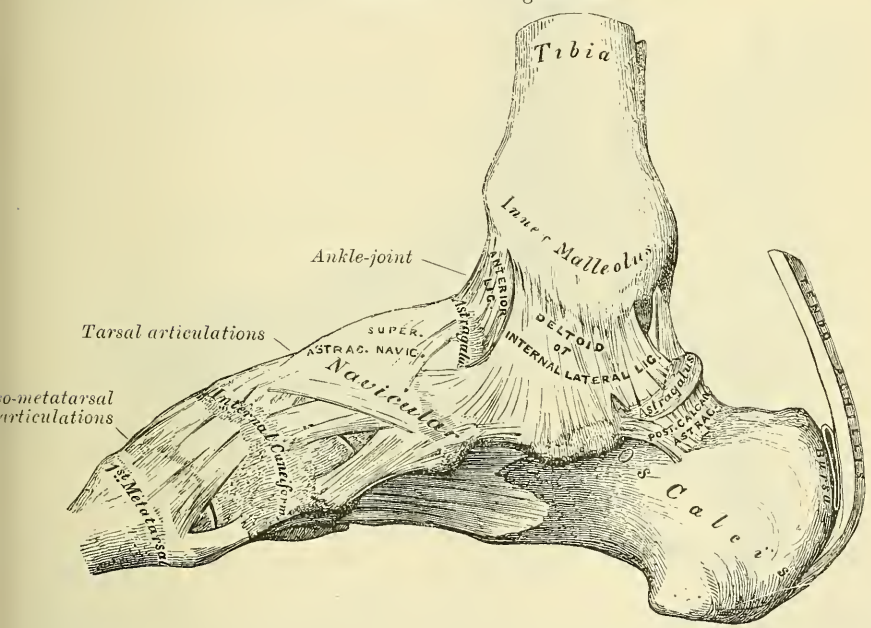
IV. Ankle-Joint

The **Ankle** is a ginglymus, or hinge-joint. The bones entering into its formation are the lower extremity of the tibia and its malleolus, and the external malleolus of the fibula, which form a mortise to receive the upper convex surface of the astragalus and its two lateral facets. The bony surfaces are covered with cartilage, and connected by a capsule, which in places forms thickened bands constituting the following ligaments :—

Anterior.	Internal Lateral.
Posterior.	External Lateral.

The **Anterior Tibio-tarsal Ligament** (fig. 300) is a broad, thin, membranous layer, attached, above, to the margin of the articular surface of the tibia ; below,

Fig. 300.—Ankle-joint : tarsal and tarso-metatarsal articulations. Internal view. Right side.



to the margin of the astragalus, in front of its articular surface. It is in relation, in front, with the Extensor tendons of the toes, with the tendons of the Tibialis anticus and Peroneus tertius, and the anterior tibial vessels and nerve ; behind, it lies in contact with the synovial membrane.

The **Posterior Tibio-tarsal Ligament** is very thin, and consists principally of transverse fibres. It is attached, above, to the margin of the articular surface of the tibia, blending with the transverse tibio-fibular ligament ; below, to the astragalus, behind its superior articular facet. Externally, where a somewhat thickened band of transverse fibres is attached to the hollow on the inner surface of the external malleolus, it is thicker than internally.

The **Internal Lateral** or **Deltoid Ligament** is a strong, flat, triangular band, attached, above, to the apex and anterior and posterior borders of the inner malleolus. The most anterior fibres pass forwards to be inserted into the navicular bone and the inferior calcaneo-navicular ligament ; the middle descend almost

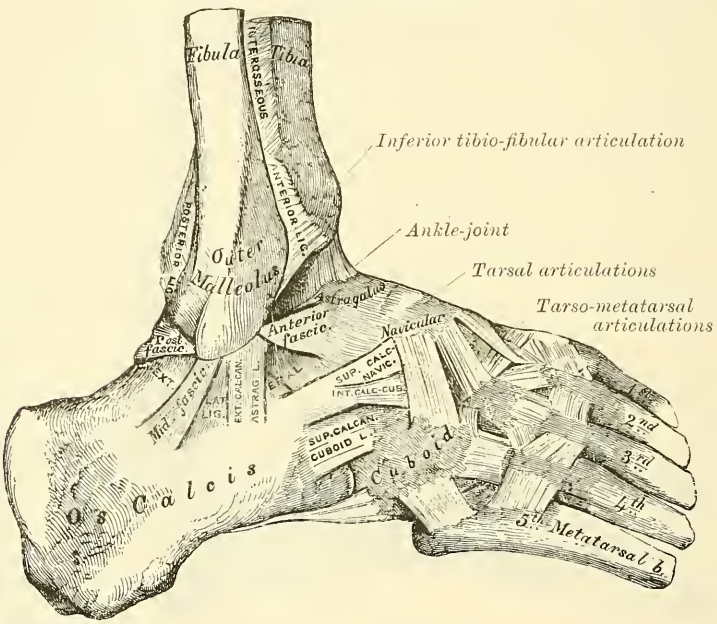
perpendicularly to be inserted into the sustentaculum tali of the os calcis; and the posterior fibres pass backwards and outwards to be attached to the inner side of the astragalus. This ligament is covered by the tendons of the Tibialis posticus and Flexor longus digitorum muscles.

The **External Lateral Ligament** (fig. 301) consists of three distinctly specialised fasciculi of the capsule, taking different directions, and separated by distinct intervals, for which reason it is described by some anatomists as three distinct ligaments.*

The *anterior fasciculus* (anterior astragalo-fibular), the shortest of the three, passes from the anterior margin of the summit of the external malleolus, downwards and forwards, to the astragalus, in front of its external articular facet.

The *posterior fasciculus* (posterior astragalo-fibular), the most deeply seated, passes from the depression at the inner and back part of the external malleolus to a prominent tubercle on the posterior surface of the astragalus. Its fibres are almost horizontal in direction.

Fig. 301.—Ankle-joint: tarsal and tarso-metatarsal articulations. External view. Right side.



The *middle fasciculus* (calcaneo-fibular), the longest of the three, is a narrow, rounded cord, passing from the apex of the external malleolus downwards and slightly backwards to a tubercle on the outer surface of the os calcis. It is covered by the tendons of the Peroneus longus and brevis.

The **Synovial Membrane** invests the inner surface of the ligaments, and sends a duplicature upwards between the lower extremities of the tibia and fibula for a short distance.

Relations.—The tendons, vessels, and nerves in connection with the joint are, in front, from within outwards, the Tibialis anticus, Extensor proprius hallucis, anterior tibial vessels, anterior tibial nerve, Extensor longus digitorum, and Peroneus tertius; behind, from within outwards, the Tibialis posticus, Flexor longus digitorum, posterior tibial vessels, posterior tibial nerve, Flexor longus hallucis; and, in the groove behind the external malleolus, the tendons of the Peroneus longus and brevis.

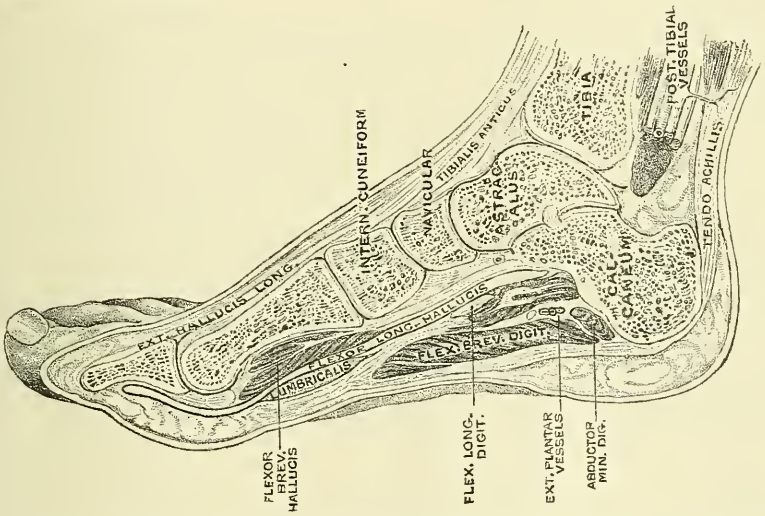
* Humphry *On the Skeleton*, p. 559.

The *Arteries* supplying the joint are derived from the malleolar branches of the anterior tibial and the peroneal.

The *Nerves* are derived from the anterior and posterior tibial.

Actions.—The movements of the joint are those of flexion and extension. The malleoli tightly embrace the astragalus in all positions of the joint, so that any slight degree of lateral movement which may exist is simply due to stretching of the inferior tibio-fibular ligaments, and slight bending of the shaft of the fibula. Of the ligaments, the internal, or deltoid, is of very great power—so much so, that it usually resists a force which fractures the process of bone to which it is attached. Its middle portion, together with the middle fasciculus of the external lateral ligament, binds the bones of the leg firmly to the foot, and resists displacement in every direction. Its anterior and posterior fibres limit extension and flexion of the foot respectively, and the anterior fibres also limit abduction. The posterior portion of the external lateral ligament assists the middle portion in resisting the displacement of the foot backwards, and deepens the cavity for the reception of the astragalus. The anterior fasciculus is a security against the displacement of the foot forwards, and limits extension of the

Fig. 302.—Section of the right foot near its inner border, dividing the tibia, astragalus navicular, internal cuneiform, and first metatarsal bone, and the first phalanx of the great toe. (After Braune.)



joint. The movements of abduction and adduction of the foot, together with the minute changes in form by which it is applied to the ground or takes hold of an object in climbing, &c., are mainly effected in the tarsal joints; the one which enjoys the greatest amount of motion being that between the astragalus and os calcis behind, and the navicular and cuboid in front. This is often called the *transverse* or *medio-tarsal joint*, and it can, with the subordinate joints of the tarsus, replace the ankle-joint in a great measure when the latter has become ankylosed.

Extension of the tarsal bones upon the tibia and fibula is produced by the Gastrocnemius, Soleus, Plantaris, Tibialis posticus, Peroneus longus and brevis, Flexor longus digitorum, and Flexor longus hallucis. *Flexion*, by the Tibialis anticus, Peroneus tertius, Extensor longus digitorum, and Extensor proprius hallucis.* *Adduction*, in the extended position, is produced by the Tibialis anticus and posticus; and *abduction* by the Peronei.

* The student must bear in mind that the Extensor longus digitorum and Extensor proprius hallucis are *extensors* of the toes, but *flexors* of the ankle; and that the Flexor longus digitorum and Flexor longus hallucis are *flexors* of the toes, but *extensors* of the ankle.

Surface Form.—The line of the ankle-joint may be indicated by a transverse line drawn across the front of the lower part of the leg, about half an inch above the level of the tip of the internal malleolus.

Surgical Anatomy.—Displacement of the trochlear surface of the astragalus from the tibio-fibular mortise is not of common occurrence, as the ankle-joint is a very strong and powerful articulation, and great force is required to produce it. Nevertheless, dislocation does occasionally occur, both in an antero-posterior and a lateral direction. In the latter, which is the most common, fracture is a necessary accompaniment of the injury. The dislocation in these cases is somewhat peculiar, and is not a displacement in a horizontally lateral direction, such as usually occurs in lateral dislocations of ginglymoid joints, but the astragalus undergoes a partial rotation round an antero-posterior axis drawn through its own centre, so that the superior surface, instead of being directed upwards, is inclined more or less inwards or outwards according to the variety of the displacement.

The ankle-joint is more frequently sprained than any joint in the body, and this may lead to acute synovitis. In these cases, when the synovial sac is distended with fluid, the bulging appears principally in the front of the joint, beneath the anterior tendons, and on either side, between the Tibialis anticus and the internal lateral ligament on the inner side, and between the Peroneus tertius and the external lateral ligament on the outer side. In addition to this, bulging frequently occurs posteriorly, and a fluctuating swelling may be detected on either side of the tendo Achillis.

Chronic synovitis may result from frequent sprains, and when once this joint has been sprained it is more liable to a recurrence of the injury than it was before; or it may be tuberculous in its origin, the disease usually commencing in the astragalus and extending to the joint, though it may commence as a tuberculous synovitis the result probably of some slight strain in a tuberculous subject.

Excision of the ankle-joint is not often performed, for two reasons. In the first place, disease of the articulation for which this operation is indicated is frequently associated with disease of the tarsal bones, which prevents its performance; and, secondly, the foot after excision is frequently of very little use; far less, in fact, than after a Symes's amputation, which is often, therefore, a preferable operation in these cases. Excision may, however, be attempted in cases of tuberculous arthritis, in a young and otherwise healthy subject, where the disease is limited to the bones forming the joint. It may also be required after injury, where the vessels and nerves have not been damaged and the patient is young and free from visceral disease. The excision is best performed by two lateral incisions. One commencing two and a half inches above the external malleolus, carried down the posterior border of the fibula, round the end of the bone, and then forwards and downwards as far as the calcaneo-cuboid joint, midway between the tip of the external malleolus and the tuberosity on the fifth metatarsal bone. Through this incision the fibula is cleared, the external lateral ligament is divided, and the bone sawn through at the upper end of the incision and removed. A similar curved incision is now made on the inner side of the foot, commencing two and a half inches above the lower end of the tibia, carried down the posterior border of the bone, round the internal malleolus and forwards and downwards to the tuberosity of the navicular bone. Through this incision the tibia is cleared in front and behind, the internal lateral, the anterior and posterior ligaments divided, and the end of the tibia protruded through the wound by displacing the foot outwards, and sawn off sufficiently high to secure a healthy section of bone. The articular surface of the astragalus is now to be sawn off or the whole bone removed. In cases where the operation is performed for tuberculous arthritis, the latter course is probably preferable, as the injury done by the saw is frequently the starting point of fresh caries; and after removal of the whole bone the shortening is not appreciably increased, and the result as regards union appears to be as good as when two sawn surfaces of bone are brought into apposition.

V. Articulations of the Tarsus

1. Articulations of the Os Calcis and Astragalus

The articulations between the os calcis and astragalus are two in number—anterior and posterior. They are arthrodial joints. The bones are connected together by four ligaments:—

External Calcaneo-astragaloid.	Posterior Calcaneo-astragaloid.
Internal Calcaneo-astragaloid.	Interosseous.

The **External Calcaneo-astragaloid Ligament** (fig. 301) is a short, strong fasciculus, passing from the outer surface of the astragalus, immediately beneath its external malleolar facet, to the outer surface of the os calcis. It is placed in front of the middle fasciculus of the external lateral ligament of the ankle-joint, with the fibres of which it is parallel.

The **Internal Calcaneo-astragaloid Ligament** is a band of fibres connecting the

internal tubercle of the back of the astragalus with the back of the sustentaculum tali. Its fibres blend with those of the inferior calcaneo-navicular ligament.

The **Posterior Calcaneo-astragaloid Ligament** (fig. 300) connects the posterior external tubercle of the astragalus with the upper and inner part of the os calcis; it is a short, narrow band, the fibres of which radiate from their narrow attachment to the astragalus.

The **Interosseous Ligament** forms the chief bond of union between the bones. It consists of numerous vertical and oblique fibres, attached by one extremity to the groove between the articulating facets on the under surface of the astragalus; by the other, to a corresponding depression on the upper surface of the os calcis. It is very thick and strong, being at least an inch in breadth from side to side, and serves to unite the os calcis and astragalus solidly together.

The **Synovial Membranes** (fig. 304) are two in number; one for the posterior calcaneo-astragaloid articulation; a second for the anterior calcaneo-astragaloid joint. The latter synovial membrane is continued forwards between the contiguous surfaces of the astragalus and navicular bones.

Actions.—The movements permitted between the astragalus and os calcis are limited to a gliding of the one bone on the other in a direction from before backwards, and from side to side.

2. Articulations of the Os Calcis with the Cuboid

The ligaments connecting the os calcis with the cuboid are four in number:—

Dorsal.	Superior Calcaneo-cuboid.
	Internal Calcaneo-cuboid (Interosseous).
Plantar.	Long Calcaneo-cuboid.
	Short Calcaneo-cuboid.

The **Superior Calcaneo-cuboid Ligament** (fig. 301) is a thin and narrow fasciculus, which passes between the contiguous surfaces of the os calcis and cuboid, on the dorsal surface of the joint.

The **Internal Calcaneo-cuboid (Interosseous) Ligament** (fig. 301) is a short, but thick and strong, band of fibres, arising from the os calcis, in the deep hollow which intervenes between it and the astragalus, and closely blended, at its origin, with the superior calcaneo-navicular ligament. It is inserted into the inner side of the cuboid bone. This ligament forms one of the chief bonds of union between the first and second rows of the tarsus.

The **Long Calcaneo-cuboid (Long Plantar) Ligament** (fig. 303), the more superficial of the two plantar ligaments, is the longest of all the ligaments of the tarsus: it is attached to the under surface of the os calcis, from near the tuberosities, as far forwards as the anterior tubercle; its fibres pass forwards to be attached to the ridge on the under surface of the cuboid bone, the more superficial fibres being continued onwards to the bases of the second, third, and fourth metatarsal bones. This ligament crosses the groove on the under surface of the cuboid bone, converting it into a canal for the passage of the tendon of the Peroneus longus.

The **Short Calcaneo-cuboid (Short Plantar) Ligament** lies nearer to the bones than the preceding, from which it is separated by a little areolar tissue. It is exceedingly broad, about an inch in length, and extends from the tubercle, and the depression in front of it, on the fore part of the under surface of the os calcis, to the inferior surface of the cuboid bone behind the peroneal groove.

Synovial Membrane.—The synovial membrane in this joint is distinct. It lines the inner surface of the ligaments.

Actions.—The movements permitted between the os calcis and cuboid are limited to a slight gliding upon each other.

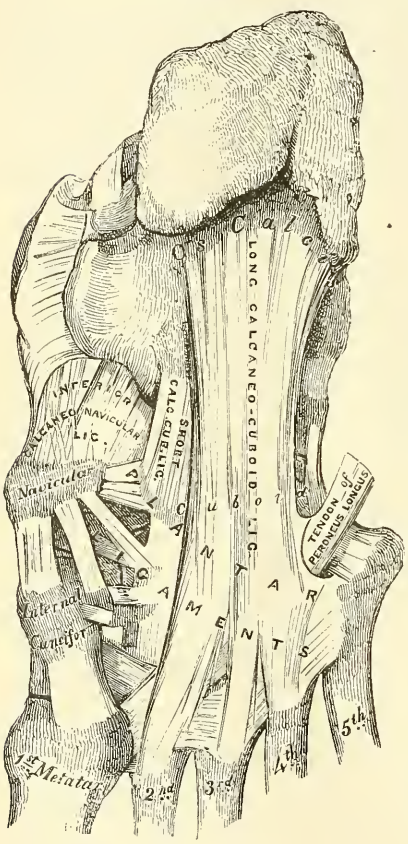
3. The Ligaments connecting the Os Calcis and Navicular

Though these two bones do not directly articulate, they are connected by two ligaments:—

Superior or External Calcaneo-navicular.
Inferior or Internal Calcaneo-navicular.

The **Superior** or **External Calcaneo-navicular** (fig. 301) arises, as already mentioned, with the internal calcaneo-cuboid in the deep hollow between the astragalus and os calcis; it passes forwards from the inner side of the anterior extremity of the os calcis to the outer side of the navicular bone. These two ligaments resemble the letter Y, being blended together behind, but separated in front.

Fig. 303.—Ligaments of plantar surface of the foot.



The **Inferior** or **Internal Calcaneo-navicular** (fig. 303) is by far the larger and stronger of the two ligaments between these bones; it is a broad and thick band of fibres, which passes forwards and inwards from the anterior margin of the sustentaculum tali of the os calcis to the under surface of the navicular bone. This ligament not only serves to connect the os calcis and navicular, but supports the head of the astragalus, forming part of the articular cavity in which it is received. The *upper surface* presents a fibro-cartilaginous facet, lined by the synovial membrane continued from the anterior calcaneo-astragaloid articulation, upon which the head of the astragalus rests. Its *under surface* is in contact with the tendon of the Tibialis posticus muscle;* its inner border is blended with the fore part of the Deltoid ligament, thus completing the socket for the head of the astragalus.

Surgical Anatomy.—The inferior calcaneo-navicular ligament, by supporting the head of the astragalus, is principally concerned in maintaining the arch of the foot, and, when it yields, the head of the astragalus is pressed downwards, inwards, and forwards by the weight of the body, and the foot becomes flattened, expanded, and turned outwards, constituting the disease known as *flat-foot*. This ligament contains a considerable amount of elastic fibre, so as to give elasticity to the arch and spring to the foot; hence it is sometimes called the 'spring' ligament. It is supported, on its under surface, by the tendon of the Tibialis posticus, which spreads out at its insertion into a number of fasciculi, which are attached to most of the tarsal and metatarsal bones; this prevents undue stretching of the ligament, and is a protection against the occurrence of flat-foot.

4. Articulation of the Astragalus with the Navicular Bone

The articulation between the astragalus and navicular is an arthrodial joint: the rounded head of the astragalus being received into the concavity formed by the posterior surface of the navicular, the anterior articulating surface of the

* Mr. Hancock describes an extension of this ligament upwards on the inner side of the foot, which completes the socket of the joint in that direction. *Lancet*, 1866, vol. i. p. 618.

calcaneum, and the upper surface of the inferior calcaneo-navicular ligament, which fills up the triangular interval between those bones. The only ligament of this joint is the **superior astragalo-navicular**. It is a broad band, which passes obliquely forwards from the neck of the astragalus to the superior surface of the navicular bone. It is thin, and weak in texture, and covered by the Extensor tendons. The inferior calcaneo-navicular supplies the place of an inferior ligament.

The **Synovial Membrane** which lines the joint is continued forwards from the anterior calcaneo-astragaloid articulation.

Actions.—This articulation permits of considerable mobility; but its feebleness is such as to allow occasionally of dislocation of the other bones of the tarsus from the astragalus.

The *transverse tarsal* or *medio-tarsal joint* is formed by the articulation of the os calcis with the cuboid, and by the articulation of the astragalus with the navicular. The movement which takes place in this joint is more extensive than that in the other tarsal joints, and consists of a sort of rotation by means of which the sole of the foot may be slightly flexed and extended or carried inwards and outwards.

5. The Articulation of the Navicular with the Cuneiform Bones

The navicular is connected to the three cuneiform bones by

Dorsal and Plantar ligaments.

The **Dorsal Ligaments** are small, longitudinal bands of fibrous tissue, arranged as three bundles, one to each of the cuneiform bones. That bundle of fibres which connects the navicular with the internal cuneiform is continued round the inner side of the articulation to be continuous with the plantar ligament which connects these two bones.

The **Plantar Ligaments** have a similar arrangement to those on the dorsum. They are strengthened by processes given off from the tendon of the Tibialis posticus.

Actions.—The movements permitted between the navicular and cuneiform bones are limited to a slight gliding upon each other.

The **Synovial Membrane** of these joints is part of the great tarsal synovial membrane.

6. The Articulation of the Navicular with the Cuboid

The navicular bone is connected with the cuboid by

Dorsal, Plantar, and Interosseous ligaments.

The **Dorsal Ligament** consists of a band of fibrous tissue which passes obliquely forwards and outwards from the navicular to the cuboid bone.

The **Plantar Ligament** consists of a band of fibrous tissue which passes nearly transversely between these two bones.

The **Interosseous Ligament** consists of strong transverse fibres which pass between the rough non-articular portions of the lateral surfaces of these two bones.

Actions.—The movements permitted between the navicular and cuboid bones are limited to a slight gliding upon each other.

The **Synovial Membrane** of this joint is part of the great tarsal synovial membrane.

7. The Articulation of the Cuneiform Bones with each other

These bones are connected together by

Dorsal, Plantar, and Interosseous ligaments.

The **Dorsal Ligaments** consist of two bands of fibrous tissue which pass trans-

versely: one connecting the internal with the middle cuneiform, and the other connecting the middle with the external cuneiform.

The **Plantar Ligaments** have a similar arrangement to those on the dorsum. They are strengthened by the processes given off from the tendon of the Tibialis posticus.

The **Interosseous Ligaments** consist of strong transverse fibres which pass between the rough non-articular portions of the lateral surfaces of the adjacent cuneiform bones.

The **Synovial Membrane** of these joints is part of the great tarsal synovial membrane.

Actions.—The movements permitted between the cuneiform bones are limited to a slight gliding upon each other.

8. The Articulation of the External Cuneiform Bone with the Cuboid

These bones are connected together by

Dorsal, Plantar, and Interosseous ligaments.

The **Dorsal Ligament** consists of a band of fibrous tissue which passes transversely between these two bones.

The **Plantar Ligament** has a similar arrangement. It is strengthened by a process given off from the tendon of the Tibialis posticus.

The **Interosseous Ligament** consists of strong transverse fibres which pass between the rough non-articular portions of the lateral surfaces of the adjacent sides of these two bones.

The **Synovial Membrane** of this joint is part of the great tarsal synovial membrane.

Actions.—The movements permitted between the external cuneiform and cuboid are limited to a slight gliding upon each other.

Nerve-supply.—All the joints of the tarsus are supplied by the anterior tibial nerve.

Surgical Anatomy.—In spite of the great strength of the ligaments which connect the tarsal bones together, dislocation at some of the tarsal joints does occasionally occur; though, on account of the spongy character of the bones, they are more frequently broken than dislocated, as the result of violence. When dislocation does occur, it is most commonly in connection with the astragalus; for not only may this bone be dislocated from the tibia and fibula at the ankle-joint, but the other bones may be dislocated from it, the trochlear surface of the bone remaining *in situ* in the tibio-fibular mortise. This constitutes what is known as the *sub-astragaloid* dislocation. Or, again, the astragalus may be dislocated from all its connections—from the tibia and fibula above, the os calcis below, and the navicular in front—and may even undergo a rotation, either on a vertical or horizontal axis. In the former case the long axis of the bone becoming directed across the joint, so that the head faces the articular surface on one or other malleolus; or, in the latter, the lateral surfaces becoming directed upwards and downwards, so that the trochlear surface faces to one or the other side. Finally, dislocation may occur at the medio-tarsal joint, the anterior tarsal bones being luxated from the astragalus and calcaneum. The other tarsal bones are also, occasionally, though rarely, dislocated from their connections.

VI. Tarso-metatarsal Articulations

These are arthrodial joints. The bones entering into their formation are four tarsal bones, viz. the internal, middle and external cuneiform, and the cuboid, which articulate with the metatarsal bones of the five toes. The metatarsal bone of the great toe articulates with the internal cuneiform; that of the second is deeply wedged in between the internal and external cuneiform, resting against the middle cuneiform, and being the most strongly articulated of all the metatarsal bones; the third metatarsal articulates with the extremity of the external cuneiform; the fourth, with the cuboid and external cuneiform; and the fifth, with the cuboid. The articular surfaces are covered with cartilage, lined by synovial membrane, and connected together by the following ligaments:—

Dorsal. Plantar. Interosseous.

The **Dorsal Ligaments** consist of strong, flat, fibrous bands, which connect the tarsal with the metatarsal bones. The first metatarsal is connected to the internal cuneiform by a single broad, thin, fibrous band; the second has three dorsal ligaments, one from each cuneiform bone; the third has one from the external cuneiform; the fourth has two, one from the external cuneiform and one from the cuboid; and the fifth, one from the cuboid.

The **Plantar Ligaments** consist of longitudinal and oblique fibrous bands connecting the tarsal and metatarsal bones, but disposed with less regularity than on the dorsal surface. Those for the first and second metatarsal are the most strongly marked; the second and third metatarsal receive strong fibrous bands, which pass obliquely across from the internal cuneiform; the plantar ligaments of the fourth and fifth metatarsal consist of a few scanty fibres derived from the cuboid.

The **Interosseous Ligaments** are three in number: internal, middle, and external. The *internal* one passes from the outer extremity of the internal cuneiform to the adjacent angle of the second metatarsal. The *middle* one, less strong than the preceding, connects the external cuneiform with the adjacent angle of the second metatarsal. The *external* interosseous ligament connects the outer angle of the external cuneiform with the adjacent side of the third metatarsal.

The **Synovial Membrane** between the internal cuneiform bone and the first metatarsal bone is a distinct sac. The synovial membrane between the middle and external cuneiform behind, and the second and third metatarsal bones in front, is part of the great tarsal synovial membrane. Two prolongations are sent forwards from it, one between the adjacent sides of the second and third metatarsal bones, and one between the third and fourth metatarsal bones. The synovial membrane between the cuboid and the fourth and fifth metatarsal bones is a distinct sac. From it a prolongation is sent forwards between the fourth and fifth metatarsal bones.

Actions.—The movements permitted between the tarsal and metatarsal bones are limited to a slight gliding upon each other.

VII. Articulations of the Metatarsal Bones with each other

The base of the first metatarsal bone is not connected with the second metatarsal bone by any ligaments; in this respect it resembles the thumb.

The bases of the four outer metatarsal bones are connected by dorsal, plantar, and interosseous ligaments.

The **Dorsal Ligaments** consist of bands of fibrous tissue which pass transversely between the adjacent metatarsal bones.

The **Plantar Ligaments** have a similar arrangement to those on the dorsum.

The **Interosseous Ligaments** consist of strong transverse fibres which pass between the rough non-articular portions of the lateral surfaces.

The **Synovial Membrane** between the second and third, and the third and fourth metatarsal bones is part of the great tarsal synovial membrane.

The synovial membrane between the fourth and fifth metatarsal bones is a prolongation of the synovial membrane of the cubo-metatarsal joint.

Actions.—The movement permitted in the tarsal ends of the metatarsal bones is limited to a slight gliding of the articular surfaces upon one another.

The Synovial Membranes in the Tarsal and Metatarsal Joints

The **Synovial Membranes** (fig. 304) found in the articulations of the tarsus and metatarsus are six in number: one for the posterior calcaneo-astragaloid articulation; a second for the anterior calcaneo-astragaloid and astragalo-navicular articulations; a third for the calcaneo-cuboid articulation; and a fourth for the articulations of the navicular with the three cuneiform, the three cuneiform with each other, the external cuneiform with the cuboid, and the middle and external

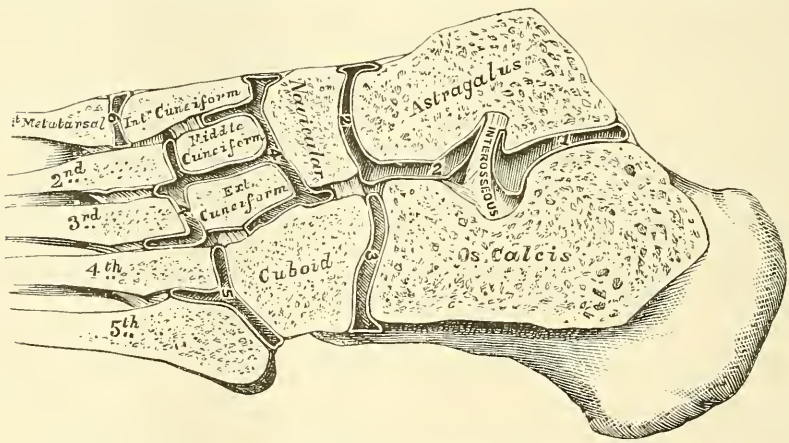
cuneiform with the bases of the second and third metatarsal bones, and the lateral surfaces of the second, third, and fourth metatarsal bones with each other; a fifth for the internal cuneiform with the metatarsal bone of the great toe; and a sixth for the articulation of the cuboid with the fourth and fifth metatarsal bones. A small synovial membrane is sometimes found between the contiguous surfaces of the navicular and cuboid bones.

Nerve-supply.—The nerves supplying the tarso-metatarsal joints are derived from the anterior tibial.

The *digital extremities* of all the metatarsal bones are connected together by the *transverse metatarsal ligament.*

The **Transverse Metatarsal Ligament** is a narrow fibrous band which passes transversely across the anterior extremities of all the metatarsal bones, connecting them together. It is blended anteriorly with the plantar (glenoid) ligament of the metatarso-phalangeal articulations. To its posterior border is connected the fascia covering the Interossei muscles. Its superficial surface is concave where the flexor tendons pass over it. Beneath it the tendons of the Interossei

Fig. 304.—Oblique section of the articulations of the tarsus and metatarsus. Showing the six synovial membranes.



muscles pass to their insertion. It differs from the transverse metacarpal ligament in that it connects the metatarsal bone of the great toe with the rest of the metatarsal bones.

VIII. Metatarso-phalangeal Articulations

The metatarso-phalangeal articulations are of the condyloid kind, formed by the reception of the rounded head of the metatarsal bone into a superficial cavity in the extremity of the first phalanx.

The ligaments are

Plantar. Two Lateral.

The **Plantar Ligaments** (Glenoid ligaments of Cruveilhier) are thick, dense, fibrous structures. Each is placed on the plantar surface of the joint in the interval between the lateral ligaments, to which they are connected; they are loosely united to the metatarsal bone, but very firmly to the base of the first phalanges. Their plantar surface is intimately blended with the transverse metatarsal ligament, and presents a groove for the passage of the flexor tendons, the sheath surrounding which is connected to each side of the groove. By their deep surface, they form part of the articular surface for the head of the metatarsal bone, and are lined by a synovial membrane.

The **Lateral Ligaments** are strong, rounded cords, placed one on each side of

the joint, each being attached, by one extremity, to the posterior tubercle on the side of the head of the metatarsal bone; and, by the other, to the contiguous extremity of the phalanx.

The **Posterior Ligament** is supplied by the extensor tendon placed over the back of the joint.

Actions.—The movements permitted in the metatarso-phalangeal articulations are flexion, extension, abduction, and adduction.

IX. Articulations of the Phalanges

The articulations of the phalanges are ginglymus joints.

The ligaments are:—

Plantar. Two lateral.

The arrangement of these ligaments is similar to those in the metatarso-phalangeal articulations; the extensor tendon supplies the place of a posterior ligament.

Actions.—The only movements permitted in the phalangeal joints are flexion and extension; these movements are more extensive between the first and second phalanges than between the second and third. The movement of flexion is very considerable, but extension is limited by the anterior and lateral ligaments.

Surface Form.—The principal joints which it is necessary to distinguish, with regard to the surgery of the foot, are the medio-tarsal and the tarso-metatarsal joints. The joint between the astragalus and the navicular is best found by means of the tubercle of the navicular bone, for the line of the joint is immediately behind this process. If the foot is grasped and forcibly extended, a rounded prominence, the head of the astragalus, will appear on the inner side of the dorsum in front of the ankle-joint, and if a knife is carried downwards, just in front of this prominence and behind the line of the navicular tubercle, it will enter the astragalo-navicular joint. The calcaneo-cuboid joint is situated midway between the external malleolus and the prominent end of the fifth metatarsal bone. The plane of the joint is in the same line as that of the astragalo-navicular. The position of the joint between the fifth metatarsal bone and the cuboid is easily found by the projection of the fifth metatarsal bone, which is the guide to it. The direction of the line of the joint is very oblique, so that, if continued onwards, it would pass through the head of the first metatarsal bone. The joint between the fourth metatarsal bone and the cuboid and external cuneiform is the direct continuation inwards of the previous joint, but its plane is less oblique; it would be represented by a line drawn from the outer side of the articulation to the middle of the first metatarsal bone. The plane of the joint between the third metatarsal bone and the external cuneiform is almost transverse. It would be represented by a line drawn from the outer side of the joint to the base of the first metatarsal bone. The tarso-metatarsal articulation of the great toe corresponds to a groove which can be felt by making firm pressure on the inner side of the foot one inch in front of the tubercle on the navicular bone; and the joint between the second metatarsal bone and the middle cuneiform is to be found on the dorsum of the foot, half an inch behind the level of the tarso-metatarsal joint of the great toe. The line of the joints between the metatarsal bones and the first phalanges is about an inch behind the webs of the corresponding toes.

THE MUSCLES AND FASCIÆ*

THE Muscles are connected with the bones, cartilages, ligaments, and skin, either directly or through the intervention of fibrous structures, called tendons or aponeuroses. Where a muscle is attached to bone or cartilage, the fibres terminate in blunt extremities upon the periosteum or perichondrium, and do not come into direct relation with the osseous or cartilaginous tissue. Where muscles are connected with the skin, they either lie as a flattened layer beneath it, or are connected with its areolar tissue by larger or smaller bundles of fibres, as in the muscles of the face.

The muscles vary extremely in their form. In the limbs, they are of considerable length, especially the more superficial ones, the deep ones being generally broad; they surround the bones, and form an important protection to the various joints. In the trunk, they are broad, flattened, and expanded, forming the parietes of the cavities which they enclose; hence the reason of the terms, *long, broad, short*, etc., used in the description of a muscle.

There is a considerable variation in the arrangement of the fibres of certain muscles with reference to the tendons to which they are attached. In some, the fibres are parallel and run directly from their origin to their insertion; these are quadrilateral muscles, such as the Thyro-hyoid. A modification of these is found in the fusiform muscles, in which the fibres are not quite parallel, but slightly curved, so that the muscle tapers at each end; in their action, however, they resemble the quadrilateral muscles. Secondly, in other muscles the fibres are convergent; arising by a broad origin, they converge to a narrow or pointed insertion. This arrangement of fibres is found in the triangular muscles—e.g. the Temporal. In some muscles, which otherwise would belong to the quadrilateral or triangular type, the origin and insertion are not in the same plane, but the plane of the line of origin intersects that of their insertion: such is the case in the Pectineus muscle. Thirdly, in some muscles the fibres are oblique and converge, like the plumes of a pen, to one side of a tendon, which runs the entire length of the muscle. Such a muscle is rhomboidal or penniform, as the Peronei. A modification of these rhomboidal muscles is found in those cases where oblique fibres converge to both sides of a central tendon which runs down the middle of the muscle; these are called bipenniform, and an example is afforded in the Rectus femoris. Finally, we have muscles in which the fibres are arranged in curved bundles in one or more planes, as in the Sphincter muscles. The arrangement of the muscular fibres is of considerable importance in respect to their relative strength and range of movement. Those muscles where the fibres are long and few in number have great range, but diminished strength; where, on

* The Muscles and Fasciæ are described conjointly, in order that the student may consider the arrangement of the latter in his dissection of the former. It is rare for the student of anatomy in this country to have the opportunity of dissecting the fasciæ separately; and it is for this reason, as well as from the close connection that exists between the muscles and their investing sheaths, that they are considered together. Some general observations are first made on the anatomy of the muscles and fasciæ, the special description being given in connection with the different regions.

the other hand, the fibres are short and more numerous, there is great power, but lessened range.

Muscles differ much in size: the Gastrocnemius forms the chief bulk of the back of the leg, and the fibres of the Sartorius are nearly two feet in length, whilst the Stapedius, a small muscle of the internal ear, weighs about a grain, and its fibres are not more than two lines in length.

The names applied to the various muscles have been derived: 1, from their situation, as the Tibialis, Radialis, Ulnaris, Peroneus; 2, from their direction, as the Rectus abdominis, Obliqui capitis, Transversalis; 3, from their uses, as Flexors, Extensors, Abductors, etc.; 4, from their shape, as the Deltoid, Trapezius, Rhomboideus; 5, from the number of their divisions, as the Biceps, the Triceps; 6, from their points of attachment, as the Sterno-cleido-mastoid, Sterno-hyoid, Sterno-thyroid.

In the description of a muscle, the term *origin* is meant to imply its more fixed or central attachment; and the term *insertion* the movable point to which the force of the muscle is directed; but the origin is absolutely fixed in only a very small number of muscles, such as those of the face, which are attached by one extremity to the bone, and by the other to the movable integument; in the greater number, the muscle can be made to act from either extremity.

In the dissection of the muscles, the student should pay especial attention to the exact *origin*, *insertion*, and *actions* of each, and its more important *relations* with surrounding parts. An accurate knowledge of the points of attachment of the muscles is of great importance in the determination of their action. By a knowledge of the action of the muscles, the surgeon is able to explain the causes of displacement in various forms of fracture, and the causes which produce distortion in various deformities, and, consequently, to adopt appropriate treatment in each case. The relations, also, of some of the muscles, especially those in immediate apposition with the larger blood-vessels, and the surface-markings they produce, should be especially remembered, as they form useful guides in the application of a ligature to those vessels.

Tendons are white, glistening, fibrous cords, varying in length and thickness, sometimes round, sometimes flattened, of considerable strength, and devoid of elasticity. They consist almost entirely of white fibrous tissue, the fibrils of which have an undulating course parallel with each other, and are firmly united together. They are very sparingly supplied with blood-vessels, the smaller tendons presenting in their interior not a trace of them. Nerves also are absent in the smaller tendons; but the larger ones, as the tendo Achillis, receive nerves which accompany the nutrient vessels. The tendons consist principally of a substance which yields gelatin.

Aponeuroses are flattened or ribbon-shaped tendons, of a pearly-white colour, iridescent, glistening, and similar in structure to the tendons. They are destitute of nerves, and the thicker ones only sparingly supplied with blood-vessels.

The tendons and aponeuroses are connected, on the one hand, with the muscles; and, on the other hand, with the movable structures, as the bones, cartilages, ligaments, and fibrous membranes (for instance, the sclerotic). Where the muscular fibres are in a direct line with those of the tendon or aponeurosis, the two are directly continuous, the muscular fibre being distinguishable from that of the tendon only by its striation. But where the muscular fibre joins the tendon or aponeurosis at an oblique angle, the former terminates, according to Kölliker, in rounded extremities, which are received into corresponding depressions on the surface of the latter, the connective tissue between the fibres being continuous with that of the tendon. The latter mode of attachment occurs in all the penniform and bipenniform muscles, and in those muscles the tendons of which commence in a membranous form, as the Gastrocnemius and Soleus.

The fasciæ (fascia, *a bandage*) are fibro-areolar or aponeurotic laminæ, of variable thickness and strength, found in all regions of the body, investing the

softer and more delicate organs. The fasciæ have been subdivided, from the situation in which they are found, into two groups, superficial and deep.

The *superficial fascia* is found immediately beneath the integument over almost the entire surface of the body. It connects the skin with the deep or aponeurotic fascia, and consists of fibro-areolar tissue, containing in its meshes pellicles of fat in varying quantity. In the eyelids and scrotum, where adipose tissue is rarely deposited, this tissue is very liable to serous infiltration. The superficial fascia varies in thickness in different parts of the body: in the groin it is so thick as to be capable of being subdivided in several laminæ. Beneath the fatty layer of the superficial fascia, which is immediately subcutaneous, there is generally another layer of the same structure, comparatively devoid of adipose tissue, in which the trunks of the subcutaneous vessels and nerves are found, as the superficial epigastric vessels in the abdominal region, the radial and ulnar veins in the forearm, the saphenous veins in the leg and thigh, and the superficial lymphatic glands; certain cutaneous muscles also are situated in the superficial fascia, as the Platysma myoides in the neck, and the Orbicularis palpebrarum around the eyelids. This fascia is most distinct at the lower part of the abdomen, the scrotum, perinæum, and extremities; is very thin in those regions where muscular fibres are inserted into the integument, as on the side of the neck, the face, and around the margin of the anus. It is very dense in the scalp, in the palms of the hands, and soles of the feet, forming a fibro-fatty layer, which binds the integument firmly to the subjacent structure.

The superficial fascia connects the skin to the subjacent parts, facilitates the movement of the skin, serves as a soft nidus for the passage of vessels and nerves to the integument, and retains the warmth of the body, since the fat contained in its areolæ is a bad conductor of heat.

The *deep fascia* is a dense inelastic unyielding fibrous membrane, forming sheaths for the muscles, and affording them broad surfaces for attachment. It consists of shining tendinous fibres, placed parallel with one another, and connected together by other fibres disposed in a rectilinear manner. It is usually exposed on the removal of the superficial fascia, forming a strong investment, which not only binds down collectively the muscles in each region, but gives a separate sheath to each, as well as to the vessels and nerves. The fasciæ are thick in unprotected situations, as on the outer side of a limb, and thinner on the inner side. The deep fasciæ assist the muscles in their action, by the degree of tension and pressure they make upon their surface: and, in certain situations, this is increased and regulated by muscular action, as, for instance, by the Tensor vaginæ femoris and Gluteus maximus in the thigh, by the Biceps in the upper and lower extremities, and Palmaris longus in the hand. In the limbs, the fasciæ not only invest the entire limb, but give off septa which separate the various muscles, and are attached beneath to the periosteum: these prolongations of fasciæ are usually spoken of as intermuscular septa.

The Muscles and Fasciæ may be arranged, according to the general division of the body, into those of the cranium, face, and neck; those of the trunk; those of the upper extremity; and those of the lower extremity.

MUSCLES AND FASCIÆ OF THE CRANIUM AND FACE

The muscles of the Cranium and Face consist of ten groups, arranged according to the region in which they are situated.

I. Cranial Region.
II. Auricular Region.
III. Palpebral Region.
IV. Orbital Region.
V. Nasal Region.
VI. Superior Maxillary Region.
VII. Inferior Maxillary Region.
VIII. Intermaxillary Region.
IX. Temporo-maxillary Region.
X. Pterygo-maxillary Region.

The muscles contained in each of these groups are the following:—

I. Cranial Region
Occipito-frontalis.

II. Auricular Region.
Attollens aurem.
Attrahens aurem.
Retrahens aurem.

III. Palpebral Region.
Orbicularis palpebrarum.
Corrugator supercilii.
Tensor tarsi.

IV. Orbital Region.
Levator palpebræ.
Rectus superior.
Rectus inferior.
Rectus internus.
Rectus externus.
Obliquus superior.
Obliquus inferior.

V. Nasal Region.
Pyramidalis nasi.
Levator labii superioris alæque nasi.
Dilatator naris posterior.
Dilatator naris anterior.
Compressor nasi.
Compressor narium minor.
Depressor alæ nasi.

VI. Superior Maxillary Region.
Levator labii superioris.
Levator anguli oris.
Zygomaticus major.
Zygomaticus minor.

VII. Inferior Maxillary Region.
Levator labii inferioris.
Depressor labii inferioris.
Depressor anguli oris.

VIII. Intermaxillary Region.
Buccinator.
Risorius.
Orbicularis oris.

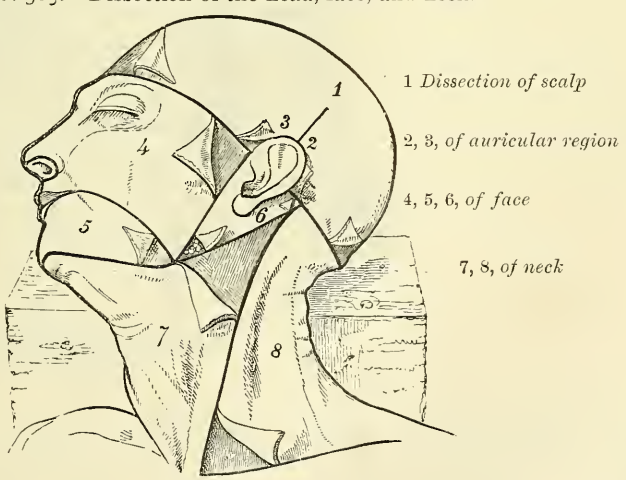
IX. Temporo-maxillary Region.
Masseter.
Temporal.

X. Pterygo-maxillary Region.
Pterygoideus externus.
Pterygoideus internus.

I. Cranial Region—Occipito-frontalis

Dissection (fig. 305).—The head being shaved, and a block placed beneath the back of the neck, make a vertical incision through the skin from before backwards, commencing at the root of the nose in front, and terminating behind at the occipital protuberance;

Fig. 305.—Dissection of the head, face, and neck.

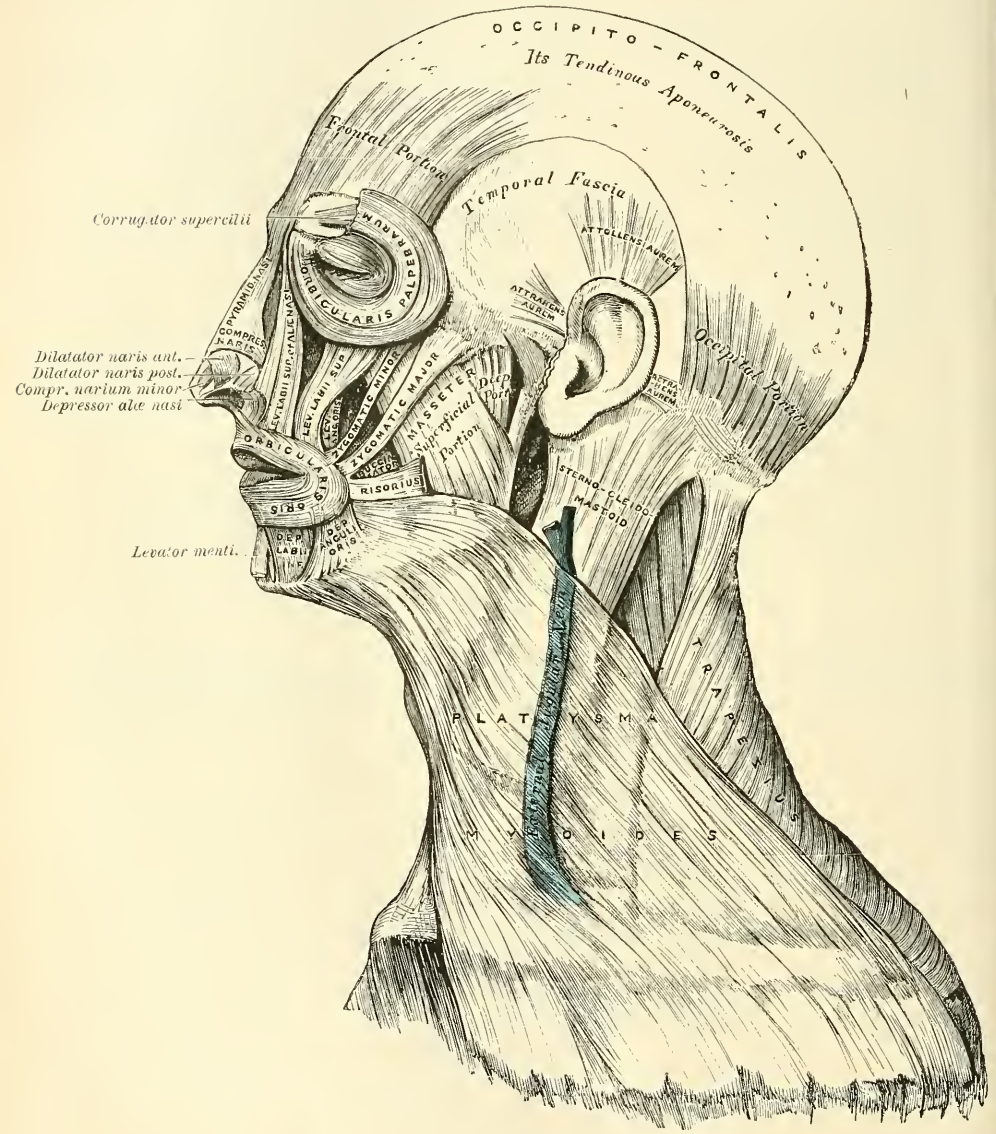


make a second incision in a horizontal direction along the forehead and round the side of the head, from the anterior to the posterior extremity of the preceding. Raise the skin in front, from the subjacent muscle, from below upwards; this must be done with great care, in order to avoid cutting through the vessels and nerves which lie immediately beneath the skin.

The Skin of the Scalp.—This is thicker than in any other part of the body. It is intimately adherent to the superficial fascia. The hair-follicles are very closely set together, and extend throughout the whole thickness of the skin. It also contains a number of sebaceous glands.

The **superficial fascia** in the cranial region is a firm, dense, fibro-fatty layer, intimately adherent to the integument, and to the Occipito-frontalis and its

Fig. 306.—Muscles of the head, face, and neck.



tendinous aponeurosis; it is continuous, behind, with the superficial fascia at the back part of the neck; and, laterally, is continued over the temporal fascia. It contains between its layers the superficial vessels and nerves and much granular fat.

The **Occipito-frontalis** (fig. 306) is a broad musculo-fibrous layer, which covers the whole of one side of the vertex of the skull, from the occiput to the eyebrow. It consists of two muscular slips, separated by an intervening tendinous

aponeurosis. The *occipital portion* (sometimes called the *occipitalis* muscle) is thin, quadrilateral in form, and about an inch and a half in length; it arises from the outer two-thirds of the superior curved line of the occipital bone, and from the mastoid portion of the temporal. Its fibres of origin are tendinous, but they soon become muscular, and ascend in a parallel direction to terminate in the tendinous aponeurosis. The *frontal portion* (sometimes called the *frontalis* muscle) is thin, of a quadrilateral form, and intimately adherent to the superficial fascia. It is broader, its fibres are longer, and their structure paler than the occipital portion. Its internal fibres are continuous with those of the Pyramidalis nasi. Its middle fibres become blended with the Corrugator supercilii and Orbicularis palpebrarum; and the outer fibres are also blended with the latter muscle over the external angular process. According to Theile the innermost fibres are attached to the nasal bones, the outer to the external angular process of the frontal bone. From these attachments, the fibres are directed upwards and join the aponeurosis below the coronal suture. The inner margins of the frontal portions of the two muscles are joined together for some distance above the root of the nose; but between the occipital portions there is a considerable, though variable, interval, which is occupied by the aponeurosis.

The **aponeurosis** covers the upper part of the vertex of the skull, being continuous across the middle line with the aponeurosis of the opposite muscle. Behind, it is attached, in the interval between the occipital origins, to the occipital protuberance and superior curved lines above the attachment of the Trapezius; in front, it forms a short and narrow prolongation between the frontal portions; and on each side it has connected with it the Attollens and Attrahens aurem muscles; in this situation it loses its aponeurotic character, and is continued over the temporal fascia to the zygoma as a layer of laminated areolar tissue. This aponeurosis is closely connected to the integument by the firm, dense, fibro-fatty layer, which forms the superficial fascia: it is connected with the pericranium by loose cellular tissue, which allows of a considerable degree of movement of the integument.

Nerves.—The frontal portion of the Occipito-frontalis is supplied by the facial nerve; its occipital portion by the posterior auricular branch of the facial, and sometimes by the occipitalis minor.

Actions.—The frontal portion of the muscle raises the eyebrows and the skin over the root of the nose, and at the same time draws the scalp forwards, throwing the integument of the forehead into transverse wrinkles. The posterior portion draws the scalp backwards. By bringing alternately into action the frontal and occipital portions the entire scalp may be moved forwards and backwards. In the ordinary action of the muscles, the eyebrows are elevated, and at the same time the aponeurosis is fixed by the posterior portion, thus giving to the face the expression of surprise: if the action is more exaggerated, the eyebrows are still further raised, and the skin of the forehead thrown into transverse wrinkles, as in the expression of fright or horror.

II. Auricular Region (fig. 306)

Attrahens aurem. Attollens aurem.
Retrahens aurem.

These three small muscles are placed immediately beneath the skin around the external ear. In man, in whom the external ear is almost immovable, they are rudimentary. They are the analogues of large and important muscles in some of the mammalia.

Dissection.—This requires considerable care, and should be performed in the following manner:—To expose the Attollens aurem, draw the pinna or broad part of the ear downwards, when a tense band will be felt beneath the skin, passing from the side of the head to the upper part of the concha; by dividing the skin over this band, in a direction from below upwards, and then reflecting it on each side, the muscle is exposed. To bring into

view the Attrahens aurem, draw the helix backwards by means of a hook, when the muscle will be made tense, and may be exposed in a similar manner to the preceding. To expose the Retrahens aurem, draw the pinna forwards, when the muscle, being made tense, may be felt beneath the skin, at its insertion into the back part of the concha, and may be exposed in the same manner as the other muscles.

The **Attrahens aurem** (*Auricularis anterior*), the smallest of the three, is thin, fan-shaped, and its fibres pale and indistinct; they arise from the lateral edge of the aponeurosis of the Occipito-frontalis, and converge to be inserted into a projection on the front of the helix.

Relations.—*Superficially*, with the skin; *deeply*, with the areolar tissue derived from the aponeurosis of the Occipito-frontalis, beneath which are the temporal artery and vein and the temporal fascia.

The **Attollens aurem** (*Auricularis superior*), the largest of the three, is thin and fan-shaped: its fibres arise from the aponeurosis of the Occipito-frontalis, and converge to be inserted by a thin, flattened tendon into the upper part of the cranial surface of the pinna.

Relations.—*Superficially*, with the integument; *deeply*, with the areolar tissue derived from the aponeurosis of the Occipito-frontalis, beneath which is the temporal fascia.

The **Retrahens aurem** (*Auricularis posterior*) consists of two or three fleshy fasciculi, which arise from the mastoid portion of the temporal bone by short aponeurotic fibres. They are inserted into the lower part of the cranial surface of the concha.

Relations.—*Superficially*, with the integument; *deeply*, with the mastoid portion of the temporal bone.

Nerves.—The Attrahens and Attollens aurem are supplied by the temporal branch of the facial; the Retrahens aurem is supplied by the posterior auricular branch of the same nerve.

Actions.—In man, these muscles possess very little action: the Attrahens aurem draws the ear forwards and upwards; the Attollens aurem slightly raises it; and the Retrahens aurem draws it backwards.

III. Palpebral Region (fig. 306)

Orbicularis palpebrarum.	Levator palpebræ.
Corrugator supercilii.	Tensor tarsi.

Dissection (fig. 305).—In order to expose the muscles of the face, continue the longitudinal incision, made in the dissection of the Occipito-frontalis, down the median line of the face to the tip of the nose, and from this point onwards to the upper lip; and carry another incision along the margin of the lip to the angle of the mouth, and transversely across the face to the angle of the jaw. Then make an incision in front of the external ear, from the angle of the jaw upwards, to join the transverse incision made in exposing the Occipito-frontalis. These incisions include a square-shaped flap, which should be removed in the direction marked in the figure, with care, as the muscles at some points are intimately adherent to the integument.

The **Orbicularis palpebrarum** is a sphincter muscle, which surrounds the circumference of the orbit and eyelids. It arises from the internal angular process of the frontal bone, from the nasal process of the superior maxillary in front of the lachrymal groove for the nasal duct, and from the anterior surface and borders of a short tendon, the *tendo oculi*, or *internal tarsal ligament*, placed at the inner angle of the orbit. From this origin, the fibres are directed outwards, forming a broad, thin, and flat layer, which covers the eyelids, surrounds the circumference of the orbit, and spreads out over the temple, and downwards on the cheek. The palpebral portion (ciliaris) of the Orbicularis is thin and pale; it arises from the bifurcation of the tendo palpebrarum, and forms a series of concentric curves, which are inserted on the outer side of the eyelids into the external tarsal ligament. The orbital portion (orbicularis latus) is thicker and

of a reddish colour: its fibres are well developed, and form complete ellipses. The upper fibres of this portion blend with the Occipito-frontalis and Corrugator supercilii.

Relations.—By its *superficial surface*, with the integument. By its *deep surface*, above, with the Occipito-frontalis and Corrugator supercilii, with which it is intimately blended, and with the supra-orbital vessels and nerve; below, it covers the lachrymal sac, and the origin of the Levator labii superioris alæque nasi, the Levator labii superioris, and the Zygomaticus minor muscles. *Internally*, it is occasionally blended with the Pyramidalis nasi. *Externally*, it lies on the temporal fascia. On the eyelids, it is separated from the conjunctiva by the Levator palpebræ, the tarsal ligaments, the tarsal plates, and the Meibomian glands.

The *tendo oculi* (internal tarsal ligament) is a short tendon, about two lines in length and one in breadth, attached to the nasal process of the superior maxillary bone in front of the lachrymal groove for the nasal duct. Crossing the lachrymal sac, it divides into two parts, each division being attached to the inner extremity of the corresponding tarsal plate. As the tendon crosses the lachrymal sac, a strong aponeurotic lamina is given off from the posterior surface, which expands over the sac, and is attached to the ridge on the lachrymal bone. This is the reflected aponeurosis of the tendo oculi.

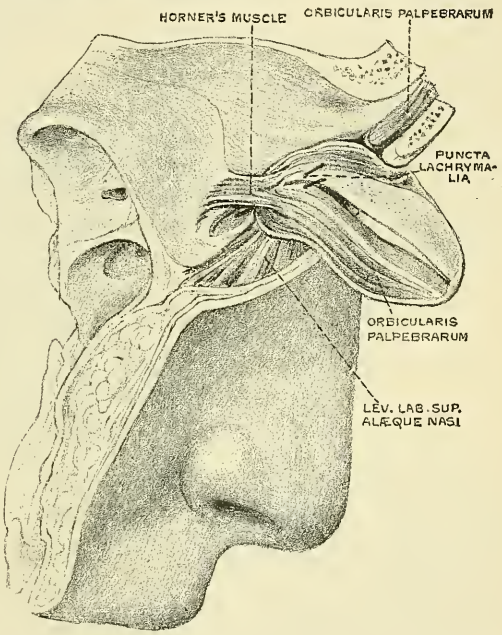


Fig. 307.—Horner's muscle. (From a preparation in the Museum of the Royal College of Surgeons of England.)

The *external tarsal ligament* is a much weaker structure than the tendo oculi, and does not divide. It is attached to the margin of the frontal process of the malar bone, and passes inwards to the outer commissure of the eyelids; it connects together the outer extremities of the two tarsal cartilages.

Use of Tendo oculi.—Besides giving attachment to part of the Orbicularis palpebrarum, and to the tarsal plates, it serves to suck the tears into the lachrymal sac, by its attachment to the sac. Thus, each time the eyelids are closed, the tendo oculi becomes tightened, through the action of the Orbicularis, and draws the wall of the lachrymal sac outwards and forwards, so that a vacuum is made in the sac, and the tears are sucked along the lachrymal canals into it.

The **Corrugator supercilii** is a small, narrow, pyramidal muscle, placed at the inner extremity of the eyebrow, beneath the Occipito-frontalis and Orbicularis palpebrarum muscles. It arises from the inner extremity of the superciliary ridge; whence its fibres pass upwards and outwards, and, passing between the palpebral and orbital portions of the Orbicularis palpebrarum, are inserted into the deep surface of the skin, opposite the middle of the orbital arch.

Relations.—By its *anterior surface*, with the Occipito-frontalis and Orbicularis palpebrarum muscles. By its *posterior surface*, with the frontal bone and supratrochlear nerve.

The **Levator palpebræ** will be described with the muscles of the orbital region.

The **Tensor tarsi** (Horner's muscle) (fig. 307) is a small thin muscle, about three lines in breadth and six in length, situated at the inner side of the orbit, behind the tendo oculi. It arises from the crest and adjacent part of the orbital surface of the lachrymal bone, and, passing across the lachrymal sac, divides into two slips, which cover the lachrymal canals, and are inserted into the tarsal plates internal to the puncta lachrymalia. Its fibres appear to be continuous with those of the palpebral portion of the Orbicularis palpebrarum; it is occasionally very indistinct.

Nerves.—The Orbicularis palpebrarum, Corrugator supercilii, and Tensor tarsi are supplied by the facial nerve.

Actions.—The Orbicularis palpebrarum is the sphincter muscle of the eyelids. The palpebral portion acts involuntarily, closing the lids gently, as in sleep or in blinking; the orbicular portion is subject to the will. When the entire muscle is brought into action, the skin of the forehead, temple, and cheek is drawn inwards towards the inner angle of the orbit, and the eyelids are firmly closed as in photophobia. When the skin of the forehead, temple, and cheek is thus drawn inwards by the action of the muscle it is thrown into folds, especially radiating from the outer angle of the eyelids, which give rise in old age to the so-called 'crow's feet.' The Levator palpebræ is the direct antagonist of this muscle; it raises the upper eyelid and exposes the globe. The Corrugator supercilii draws the eyebrow downwards and inwards, producing the vertical wrinkles of the forehead. It is the 'frowning' muscle, and may be regarded as the principal agent in the expression of suffering. The Tensor tarsi draws the eyelids and the extremities of the lachrymal canals inwards and compresses them against the surface of the globe of the eye; thus placing them in the most favourable situation for receiving the tears. It serves, also, to compress the lachrymal sac.

IV. Orbital Region (fig. 308)

Levator palpebræ superioris.
Rectus superior.
Rectus inferior.
Rectus internus.
Rectus externus.
Obliquus oculi superior.
Obliquus oculi inferior.

Dissection.—To open the cavity of the orbit, remove the skull-cap and brain; then saw through the frontal bone at the inner extremity of the supra-orbital ridge, and externally at its junction with the malar. Break in pieces the thin roof of the orbit by a few slight blows of the hammer, and take it away; drive forward the superciliary portion of the frontal bone by a smart stroke, but do not remove it, as that would destroy the pulley of the Obliquus superior. When the fragments are cleared away, the periosteum of the orbit will be exposed; this being removed, together with the fat which fills the cavity of the orbit, the several muscles of this region can be examined. The dissection will be facilitated by distending the globe of the eye. In order to effect this, puncture the optic nerve near the eyeball with a curved needle, and push the needle onwards into the globe; insert the point of a blow pipe through this aperture, and force a little air into the cavity of the eyeball; then apply a ligature round the nerve so as to prevent the air escaping. The globe being now drawn forwards, the muscles will be put upon the stretch.

The **Levator palpebræ superioris** is thin, flat, and triangular in shape. It arises from the under surface of the lesser wing of the sphenoid, above and in front of the optic foramen, from which it is separated by the origin of the Superior rectus. At its origin, it is narrow and tendinous, but soon becomes broad and fleshy, and finally terminates in a broad aponeurosis, which is inserted into the upper margin of the superior tarsal plate. From this aponeurosis a thin expansion is continued onwards, passing between the fibres of the Orbicularis to be inserted into the skin of the lid, and some deeper fibres blend with an expansion from the sheath of the Superior rectus muscle, and are with it prolonged into the conjunctiva.

Relations.—By its *upper surface*, with the frontal nerve, the supra-orbital artery, and the periosteum of the orbit; and, in the lid, with the inner surface

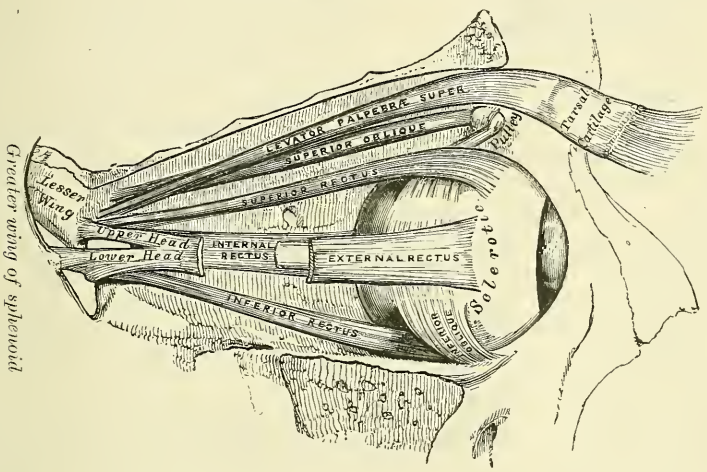
of the tarsal ligament. By its *under surface*, with the Superior rectus; and, in the lid, with the conjunctiva. A small branch of the third nerve enters its under surface.

The **Superior rectus**, the thinnest and narrowest of the four Recti, arises from the upper margin of the optic foramen beneath the Levator palpebræ, and from the fibrous sheath of the optic nerve; and is inserted, by a tendinous expansion, into the sclerotic coat, about three or four lines from the margin of the cornea.

Relations.—By its *upper surface*, with the Levator palpebræ. By its *under surface*, with the optic nerve, the ophthalmic artery, the nasal nerve, and the branch of the third nerve which supplies it; and, in front, with the tendon of the Superior oblique, and the globe of the eye.

The **Inferior** and **Internal Recti** arise by a common tendon (the *ligament of Zinn*),* which is attached round the circumference of the optic foramen, except at its upper and outer part. The **External rectus** has two heads: the upper one arises from the outer margin of the optic foramen immediately beneath the Superior rectus; the lower head, partly from the ligament of Zinn, and partly from a small pointed process of bone on the lower margin of the sphenoidal

Fig. 308.—Muscles of the right orbit.



fissure. Each muscle passes forward in the position implied by its name, to be inserted by a tendinous expansion (the *tunica albuginea*) into the sclerotic coat, about three or four lines from the margin of the cornea. Between the two heads of the External rectus is a narrow interval, through which passes the third, the nasal branch of the ophthalmic division of the fifth and the sixth nerves, and the ophthalmic vein. Although nearly all of these muscles present a common origin and are inserted in a similar manner into the sclerotic coat, there are certain differences to be observed in them, as regards their length and breadth. The Internal rectus is the broadest; the External is the longest; and the Superior is the thinnest and narrowest.

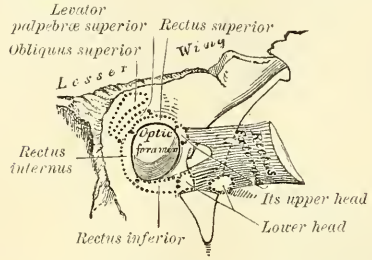
The **Superior oblique** is a fusiform muscle, placed at the upper and inner side of the orbit, internal to the Levator palpebræ. It arises about a line above the inner margin of the optic foramen, and, passing forwards to the inner angle of the orbit, terminates in a rounded tendon, which plays in a ring or pulley,

* The ligament of Zinn ought, perhaps more appropriately, to be termed the *aponeurosis* or *tendon of Zinn*. Mr. C. B. Lockwood has described a somewhat similar structure on the under surface of the Superior rectus muscle, which is attached to the lesser wing of the sphenoid forming the upper and outer margin of the optic foramen. This *superior tendon* gives origin to the Superior rectus, the superior head of the External rectus, and the upper part of the Internal rectus.—*Journal of Anatomy and Physiology*, vol. xx. part i. p. 1.

formed by cartilaginous tissue attached to a depression beneath the internal angular process of the frontal bone, the contiguous surfaces of the tendon and ring being lined by a delicate synovial membrane, and enclosed in a thin fibrous investment. The tendon is reflected backwards, outwards, and downwards beneath the Superior rectus to the outer part of the globe of the eye, and is inserted into the sclerotic coat, midway between the cornea and entrance of the optic nerve, the insertion of the muscle lying between the Superior and External recti.

Relations.—By its *upper surface,* with the periosteum covering the roof of the orbit, and the fourth nerve. The tendon, where it lies on the globe of the eye, is covered by the Superior rectus. By its *under surface,* with the nasal nerve, and the upper border of the Internal rectus.

Fig. 309.—The relative position and attachment of the muscles of the left eyeball.



The **Inferior oblique** is a thin, narrow muscle, placed near the anterior margin of the orbit. It arises from a depression on the orbital plate of the superior maxillary bone, external to the lachrymal groove for the nasal duct. Passing outwards, backwards, and upwards beneath the Inferior rectus, and then between the eyeball and the External rectus, it is inserted into the outer part of the sclerotic coat between the Superior and External recti, near to, but somewhat behind, the tendon of insertion of the Superior oblique.

Relations.—By its *ocular surface,* with the globe of the eye, and with the Inferior rectus. By its *orbital surface,* with the periosteum covering the floor of the orbit, and with the External rectus. Its borders look forwards and backwards; the posterior one receives a branch of the third nerve.

Nerves.—The Levator palpebræ, Inferior oblique, and all the Recti excepting the External, are supplied by the third nerve; the Superior oblique, by the fourth; the External rectus, by the sixth.

Actions.—The Levator palpebræ raises the upper eyelid, and is the direct antagonist of the Orbicularis palpebrarum. The four Recti muscles are attached in such a manner to the globe of the eye that, acting singly, they will turn it either upwards, downwards, inwards, or outwards, as expressed by their names. The movement produced by the Superior or Inferior rectus is not quite a simple one, for inasmuch as they pass obliquely outwards and forwards to the eyeball, the elevation or depression of the cornea must be accompanied by a certain deviation inwards, with a slight amount of rotation, which, however, is corrected by the Oblique muscles; the Inferior oblique correcting the deviation inwards of the Superior rectus, and the Superior oblique that of the Inferior rectus. The contraction of the External and Internal recti, on the other hand, produces a purely horizontal movement. If any two contiguous recti of one eye act together they carry the globe of the eye in the diagonal of these directions, viz. upwards and inwards, upwards and outwards, downwards and inwards, or downwards and outwards. The movement of circumduction, as in looking round a room, is performed by the alternate action of the four Recti. The oblique muscles rotate the eyeball on its *antero-posterior axis,* this kind of movement being required for the correct viewing of an object when the head is moved laterally, as from shoulder to shoulder, in order that the picture may fall in all respects on the same part of the retina of each eye.*

* 'On the Oblique Muscles of the Eye in Man and Vertebrate Animals,' by John Struthers, M.D., in *Anatomical and Physiological Observations.* For a fuller account of the various co-ordinated actions of the muscles of a single eye and of both eyes than our space allows, the reader may be referred to Dr. M. Foster's *Text-book of Physiology.*

Fasciæ of the Orbit.—The connective tissue of the orbit is in various places condensed into thin membranous layers, which may be conveniently described as (1) those lining the cavity; (2) those ensheathing the muscles; and (3) that covering the eyeball.

(1) The *orbital fascia*. This forms the periosteum of the orbit. It is loosely connected to the bones, from which it can be readily separated. Behind, it is connected with the dura mater by processes which pass through the optic foramen and sphenoidal fissure, and with the sheath of the optic nerve. In front, it is connected with the periosteum at the margin of the orbit, and sends off a process which assists in forming the palpebral fascia. From the internal surface of this fascia numerous processes are sent off, which encloses the fat lobules: two of these require special mention—one assisting in enclosing the lachrymal gland, the other being connected with the pulley of the Superior oblique muscle, and holding it in position.

(2) The *muscular fascia* connects together the muscles of the orbit, and splitting at their borders forms a sheath to them. Posteriorly, it is thin, and is connected to the orbital fascia. Anteriorly, it is thicker, and divides into two layers: of these one becomes attached to the orbital margin; the other is reflected backwards, and covers the hinder part of the globe of the eye. From the former of these two layers expansions are given off; from the part of the fascia covering the Superior rectus this expansion blends with some deep fibres from the tendon of the Levator palpebræ; while from the part of the fascia covering the Inferior rectus the expansion is carried forwards into the inferior tarsal plate, and is sometimes described as the suspensory ligament of the eye.

(3) The fascia covering the eyeball—Tenon's capsule—will be described in the sequel.

Surgical Anatomy.—The position and exact point of insertion of the tendons of the Internal and External recti muscles into the globe should be carefully examined from the front of the eyeball, as the surgeon is often required to divide the one or the other muscle for the cure of strabismus. In convergent strabismus, which is the more common form of the disease, the eye is turned inwards, requiring the division of the Internal rectus. In the divergent form, which is more rare, the eye is turned outwards, the External rectus being especially implicated. The deformity produced in either case is to be remedied by division of one or the other muscle. The operation is thus performed: the lids are to be well separated; the eyeball being rotated outwards or inwards, the conjunctiva should be raised by a pair of forceps, and incised immediately beneath the lower border of the tendon of the muscle to be divided, a little behind its insertion into the sclerotic; the submucous areolar tissue is then divided, and into the small aperture thus made, a blunt hook is passed upwards between the muscle and the globe, and the tendon of the muscle and conjunctiva covering it, divided by a pair of blunt-pointed scissors. Or the tendon may be divided by a subconjunctival incision, one blade of the scissors being passed upwards between the tendon and the conjunctiva, and the other between the tendon and the sclerotic. The student, when dissecting these muscles, should remove on one side of the subject the conjunctiva from the front of the eye, in order to see more accurately the position of the tendons, while on the opposite side the operation may be performed.

V. Nasal Region (fig. 306)

Pyramidalis nasi.	Dilatator naris anterior.
Levator labii superioris alæque nasi.	Compressor nasi.
Dilatator naris posterior.	Compressor narium minor.

Depressor alæ nasi.

The **Pyramidalis nasi** is a small pyramidal slip placed over the nasal bone. Its origin is by tendinous fibres from the fascia covering the lower part of the nasal bone and upper part of the cartilage, where it blends with the Compressor nasi, and it is inserted into the skin over the lower part of the forehead between the two eyebrows, its fibres decussating with those of the Occipito-frontalis.

Relations.—By its *upper surface*, with the skin. By its *under surface*, with the frontal and nasal bones.

The **Levator labii superioris alæque nasi** is a thin triangular muscle, placed by the side of the nose, and extending between the inner margin of the orbit and upper lip. It arises by a pointed extremity from the upper part of the nasal process of the superior maxillary bone, and, passing obliquely downwards and outwards, divides into two slips, one of which is inserted into the cartilage of the ala of the nose; the other is prolonged into the upper lip, becoming blended with the Orbicularis oris and Levator labii superioris proprius.

Relations.—In front, with the integument; and with a small part of the Orbicularis palpebrarum above.

The **Dilatator naris posterior** is a small muscle, which is placed partly beneath the elevator of the nose and lip. It arises from the margin of the nasal notch of the superior maxilla, and from the sesamoid cartilages, and is inserted into the skin near the margin of the nostril.

The **Dilatator naris anterior** is a thin delicate fasciculus, passing from the cartilage of the ala of the nose to the integument near its margin. This muscle is situated in front of the preceding.

The **Compressor naris** is a small, thin, triangular muscle, arising by its apex from the superior maxillary bone, above and a little external to the incisive fossa; its fibres proceed upwards and inwards, expanding into a thin aponeurosis which is attached to the fibro-cartilage of the nose, and is continuous on the bridge of the nose with that of the muscle of the opposite side, and with the aponeurosis of the Pyramidalis nasi.

The **Compressor narium minor** is a small muscle, attached by one end to the alar cartilage, and by the other to the integument at the end of the nose.

The **Depressor alæ nasi** is a short, radiated muscle, arising from the incisive fossa of the superior maxilla; its fibres ascend to be inserted into the septum, and back part of the ala of the nose. This muscle lies between the mucous membrane and muscular structure of the lip.

Nerves.—All the muscles of this group are supplied by the facial nerve.

Actions.—The Pyramidalis nasi draws down the inner angle of the eyebrows and produces transverse wrinkles over the bridge of the nose. The Levator labii superioris alæque nasi draws upwards the upper lip and ala of the nose; its most important action is upon the nose, which it dilates to a considerable extent. The action of this muscle produces a marked influence over the countenance, and it is the principal agent in the expression of contempt and disdain. The two Dilatatores nasi enlarge the aperture of the nose. Their action in ordinary breathing is to resist the tendency of the nostrils to close from atmospheric pressure, but in difficult breathing they may be noticed to be in violent action, as well as in some emotions, as anger. The Depressor alæ nasi is a direct antagonist of the other muscles of the nose, drawing the ala of the nose downwards, and thereby constricting the aperture of the nares. The Compressor nasi depresses the cartilaginous part of the nose and draws the alæ together.

VI. Superior Maxillary Region (fig. 306)

Levator labii superioris.	Zygomaticus major.
Levator anguli oris.	Zygomaticus minor.

The **Levator labii superioris (proprius)** is a thin muscle of a quadrilateral form. It arises from the lower margin of the orbit immediately above the infra-orbital foramen, some of its fibres being attached to the superior maxilla, others to the malar bone; its fibres converge to be inserted into the muscular substance of the upper lip.

Relations.—By its *superficial surface* above, with the lower segment of the Orbicularis palpebrarum; below, it is subcutaneous. By its *deep surface*, it conceals the origin of the Compressor nasi and Levator anguli oris muscles,

and the infra-orbital vessels and nerve, as they escape from the infra-orbital foramen.

The **Levator anguli oris** arises from the canine fossa, immediately below the infra-orbital foramen; its fibres incline downwards and a little outwards, to be inserted into the angle of the mouth, intermingling with those of the Zygomaticus major, the Depressor anguli oris, and the Orbicularis.

Relations.—By its *superficial surface*, with the Levator labii superioris and the infra-orbital vessels and nerves. By its *deep surface*, with the superior maxilla, the Buccinator, and the mucous membrane.

The **Zygomaticus major** is a slender fasciculus, which arises from the malar bone, in front of the zygomatic suture, and descending obliquely downwards and inwards, is inserted into the angle of the mouth, where it blends with the fibres of the Levator anguli oris, the Orbicularis oris, and the Depressor anguli oris.

Relations.—By its *superficial surface*, with the subcutaneous adipose tissue. By its *deep surface*, with the Masseter and Buccinator muscles and the facial artery and vein.

The **Zygomaticus minor** arises from the malar bone, immediately behind the maxillary suture, and passing downwards and inwards, is continuous with the Orbicularis oris at the outer margin of the Levator labii superioris. It lies in front of the preceding.

Relations.—By its *superficial surface*, with the integument and the Orbicularis palpebrarum above. By its *deep surface*, with the Masseter, Buccinator, and Levator anguli oris, and the facial artery and vein.

Nerves.—This group of muscles is supplied by the facial nerve.

Actions.—The Levator labii superioris is the proper elevator of the upper lip, carrying it at the same time a little forwards. It assists in forming the naso-labial ridge, which passes from the side of the nose to the upper lip and gives to the face an expression of sadness. The Levator anguli oris raises the angle of the mouth and assists the Levator labii superioris in producing the naso-labial ridge. The Zygomaticus major draws the angle of the mouth backwards and upwards, as in laughing; whilst the Zygomaticus minor, being inserted into the outer part of the upper lip and not into the angle of the mouth, draws it backwards, upwards, and outwards, and thus gives to the face an expression of sadness.

VII. Inferior Maxillary Region (fig. 306)

Levator labii inferioris (Levator menti).
Depressor labii inferioris (Quadratus menti).
Depressor anguli oris (Triangularis menti).

Dissection.—The Muscles in this region may be dissected by making a vertical incision through the integument from the margin of the lower lip to the chin: a second incision should then be carried along the margin of the lower jaw as far as the angle, and the integument carefully removed in the direction shown in fig. 305.

The **Levator labii inferioris (Levator menti)** is to be dissected by everting the lower lip and raising the mucous membrane. It is a small conical fasciculus, placed on the side of the frænum of the lower lip. It arises from the incisive fossa, external to the symphysis of the lower jaw: its fibres descend to be inserted into the integument of the chin.

Relations.—On its *inner surface*, with the mucous membrane; in the *median line*, it is blended with the muscle of the opposite side; and on its *outer side*, with the Depressor labii inferioris.

The **Depressor labii inferioris (Quadratus menti)** is a small quadrilateral muscle. It arises from the external oblique line of the lower jaw, between the symphysis and mental foramen, and passes obliquely upwards and inwards, to be inserted into the integument of the lower lip, its fibres blending with the Orbicularis oris, and with those of its fellow of the opposite side. It is continuous

with the fibres of the Platysma at its origin. This muscle contains much yellow fat intermingled with its fibres.

Relations.—By its *superficial surface*, with part of the Depressor anguli oris, and with the integument, to which it is closely connected. By its *deep surface*, with the mental vessels and nerves, the mucous membrane of the lower lip, the labial glands, and the Levator menti, with which it is intimately united.

The **Depressor anguli oris (Triangularis menti)** is triangular in shape, arising, by its broad base, from the external oblique line of the lower jaw, whence its fibres pass upwards, to be inserted, by a narrow fasciculus, into the angle of the mouth. It is continuous with the Platysma at its origin, and with the Orbicularis oris and Risorius at its insertion, and some of its fibres are directly continuous with those of the Levator anguli oris.

Relations.—By its *superficial surface*, with the integument. By its *deep surface*, with the Depressor labii inferioris and Buccinator.

Nerves.—This group of muscles is supplied by the facial nerve.

Actions.—The Levator labii inferioris raises the lower lip, and protrudes it forwards, and at the same time wrinkles the integument of the chin, expressing doubt or disdain. The Depressor labii inferioris draws the lower lip directly downwards and a little outwards, as in the expression of irony. The Depressor anguli oris depresses the angle of the mouth, being the antagonist to the Levator anguli oris and Zygomaticus major; acting with these muscles, it will draw the angle of the mouth directly backwards.

VIII. Intermaxillary Region

Orbicularis oris. Buccinator. Risorius.

Dissection.—The dissection of these muscles may be considerably facilitated by filling the cavity of the mouth with tow, so as to distend the cheeks and lips; the mouth should then be closed by a few stitches, and the integument carefully removed from the surface.

The **Orbicularis oris** (fig. 306) is not a sphincter muscle like the Orbicularis palpebrarum, but consists of numerous strata of muscular fibres, having different directions, which surround the orifice of the mouth. These fibres are partially derived from the other facial muscles which are inserted into the lips, and are partly fibres proper to the lips themselves. Of the former, a considerable number are derived from the Buccinator and form the deeper stratum of the Orbicularis. Some of them, namely, those near the middle of the muscle, decussate at the angle of the mouth, those arising from the upper jaw passing to the lower lip, and those from the lower jaw to the upper lip. Other fibres of the muscle, situated at its upper and lower part, pass across the lips from side to side without interruption. Superficial to this stratum is a second, formed by the Levator and Depressor anguli oris, which cross each other at the angle of the mouth; those from the Depressor passing to the upper lip, and those from the Levator to the lower lip, along which they run to be inserted into the skin near the median line. In addition to these there are fibres from the other muscles inserted into the lips, the Levator labii superioris, the Levator labii superioris alæque nasi, the Zygomatici, and the Depressor labii inferioris; these intermingle with the transverse fibres above described, and have principally an oblique direction. The proper fibres of the lips are oblique, and pass from the under surface of the skin to the mucous membrane, through the thickness of the lip. And in addition to these are fibres by which the muscle is connected directly with the maxillary bones and the septum of the nose. These consist, in the upper lip, of four bands, two of which (*Musculus incisivus superior*) arise from the alveolar border of the superior maxilla, opposite the lateral incisor tooth, and arching outwards on each side are continuous at the angles of the mouth with the other muscles inserted into this part. The two remaining muscular slips, called the *Naso-labialis*, connect the upper lip to the back of the septum of the nose: as they descend

from the septum, an interval is left between them. It is this interval which forms the depression seen on the surface of the skin beneath the septum of the nose. The additional fibres for the lower segment (*Musculus incisivus inferior*) arise from the inferior maxilla, externally to the Levator labii inferioris, and arch outwards to the angles of the mouth, to join the Buccinator and the other muscles attached to this part.

Relations.—By its *superficial surface*, with the integument, to which it is closely connected. By its *deep surface*, with the buccal mucous membrane, the labial glands, and coronary vessels. By its *outer circumference*, it is blended with the numerous muscles which converge to the mouth from various parts of the face. Its *inner circumference* is free, and covered by the mucous membrane.

The **Buccinator** (fig. 319) is a broad, thin muscle, quadrilateral in form, which occupies the interval between the jaws at the side of the face. It arises from the outer surface of the alveolar processes of the upper and lower jaws, corresponding to the three molar teeth ; and behind, from the anterior border of the pterygo-maxillary ligament. The fibres converge towards the angle of the mouth, where the central fibres intersect each other, those from below being continuous with the upper segment of the Orbicularis oris ; and those from above with the inferior segment; the highest and lowest fibres continue forward uninterruptedly into the corresponding segment of the lip without decussation.

Relations.—By its *superficial surface*, behind, with a large mass of fat, which separates it from the ramus of the lower jaw, the Masseter, and a small portion of the Temporal muscle ; anteriorly, with the Zygomatici, Risorius, Levator anguli oris, Depressor anguli oris, and Stenson's duct, which pierces it opposite the second molar tooth of the upper jaw ; the facial artery and vein cross it from below upwards ; it is also crossed by the branches of the facial and buccal nerves. By its *internal surface*, with the buccal glands and mucous membrane of the mouth.

The *pterygo-maxillary ligament* separates the Buccinator muscle from the Superior constrictor of the pharynx. It is a tendinous band, attached by one extremity to the apex of the internal pterygoid plate, and by the other to the posterior extremity of the internal oblique line of the lower jaw. Its *inner surface* corresponds to the cavity of the mouth, and is lined by mucous membrane. Its *outer surface* is separated from the ramus of the jaw by a quantity of adipose tissue. Its *posterior border* gives attachment to the Superior constrictor of the pharynx ; its *anterior border*, to the fibres of the Buccinator (see fig. 319).

The **Risorius (Santorini)** (fig. 306) consists of a narrow bundle of fibres, which arises in the fascia over the Masseter muscle and, passing horizontally forwards, is inserted into the skin at the angle of the mouth. It is placed superficial to the Platysma, and is broadest at its outer extremity. This muscle varies much in its size and form.

Nerves.—The muscles in this group are all supplied by the facial nerve. The buccal branch of the inferior maxillary nerve pierces the Buccinator muscle, and by some anatomists is regarded as partly supplying this muscle. Probably it merely pierces it on its way to the mucous membrane of the cheek.

Actions.—The Orbicularis oris in its ordinary action produces the direct closure of the lips ; by its deep fibres, assisted by the oblique ones, it closely applies the lips to the alveolar arch. The superficial part, consisting principally of the decussating fibres, brings the lips together and also protrudes them forwards. The Buccinators contract and compress the cheeks, so that, during the process of mastication, the food is kept under the immediate pressure of the teeth. When the cheeks have been previously distended with air, the Buccinator muscles expel it from between the lips, as in blowing a trumpet. Hence the name (*buccina*, a trumpet). The Risorius retracts the angles of the mouth, and produces the unpleasant expression which is sometimes seen in tetanus, and is known as 'risus sardonicus.'

IX. Temporo-maxillary Region

Masseter. Temporal.

Masseteric Fascia.—Covering the Masseter muscle, and firmly connected with it, is a strong layer of fascia, derived from the deep cervical fascia. Above, this fascia is attached to the lower border of the zygoma, and behind it covers the parotid gland, constituting the *parotid fascia.*

The **Masseter** is exposed by the removal of this fascia (fig. 306); it is a short, thick muscle, somewhat quadrilateral in form, consisting of two portions, superficial and deep. The *superficial portion*, the larger, arises by a thick, tendinous aponeurosis from the malar process of the superior maxilla, and from the anterior two-thirds of the lower border of the zygomatic arch: its fibres pass downwards and backwards, to be inserted into the angle and lower half of the outer surface of the ramus of the jaw. The *deep portion* is much smaller, and more muscular in texture; it arises from the posterior third of the lower border and the whole of the inner surface of the zygomatic arch; its fibres pass downwards and forwards, to be inserted into the upper half of the ramus and outer surface of the coronoid process of the jaw. The deep portion of the muscle is partly concealed, in front, by the superficial portion; behind, it is covered by the parotid gland. The fibres of the two portions are united at their insertion.

Relations.—By its *superficial surface*, with the Zygomatici, the Socia parotidis, and Stenson's duct; the branches of the facial nerve and the transverse facial vessels, which cross it; the masseteric fascia; the Risorius Santorini, Platysma myoides, and the integument. By its *deep surface*, with the Temporal muscle at its insertion, the ramus of the jaw, and the Buccinator, from which it is separated by a mass of fat. The masseteric nerve and artery enter it on its under surface. Its *posterior margin* is overlapped by the parotid gland. Its *anterior margin* projects over the Buccinator muscle; and the facial vein lies on it below.

The *temporal fascia* is seen, at this stage of the dissection, covering in the Temporal muscle. It is a strong, fibrous investment, covered, on its outer surface, by the Attrahens and Attollens aurem muscles, the aponeurosis of the Occipito-frontalis, and by part of the Orbicularis palpebrarum. The temporal vessels and the auriculo-temporal nerve cross it from below upwards. Above, it is a single layer, attached to the entire extent of the upper temporal ridge; but below, where it is attached to the zygoma, it consists of two layers, one of which is inserted into the outer, and the other into the inner border of the zygomatic arch. A small quantity of fat, the orbital branch of the temporal artery, and a filament from the orbital, or temporo-malar, branch of the superior maxillary nerve, are contained between these two layers. It affords attachment by its inner surface to the superficial fibres of the Temporal muscle.

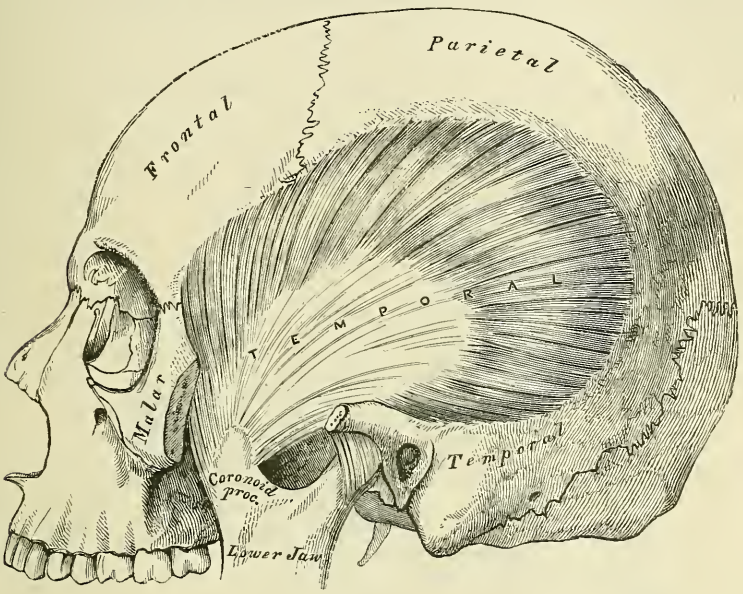
Dissection.—In order to expose the Temporal muscle, remove the temporal fascia, which may be effected by separating it at its attachment along the upper border of the zygoma, and dissecting it upwards from the surface of the muscle. The zygomatic arch should then be divided, in front, at its junction with the malar bone; and, behind, near the external auditory meatus, and drawn downwards with the Masseter, which should be detached from its insertion into the ramus and angle of the jaw. The whole extent of the Temporal muscle is then exposed.

The **Temporal** (fig. 310) is a broad, radiating muscle, situated at the side of the head, and occupying the entire extent of the temporal fossa. It arises from the whole of the temporal fossa except that portion of it that is formed by the malar bone. Its attachment extends from the external angular process of the frontal in front, to the mastoid portion of the temporal behind; and from the curved line on the frontal and parietal bones above, to the pterygoid ridge on the great wing of the sphenoid below. It is also attached to the inner surface of the temporal fascia. Its fibres converge as they descend, and terminate in an aponeurosis, the fibres of which, radiated at its commencement, converge into a

thick and flat tendon, which is inserted into the inner surface, apex, and anterior border of the coronoid process of the jaw, nearly as far forwards as the last molar tooth.

Relations.—By its *superficial surface*, with the integument, the Attrahens and Attollens aurem muscles, the temporal vessels and nerves, the aponeurosis of the Occipito-frontalis, the temporal fascia, the zygoma, and Masseter. By its *deep surface*, with the temporal fossa, the External pterygoid and part of the Buccinator muscles, the internal maxillary artery, its deep temporal branches, and the deep temporal nerves. Behind the tendon are the masseteric vessels and nerve, and

Fig. 310.—The Temporal muscle, the zygoma and Masseter having been removed.



in front of it the buccal vessels and nerve. Its anterior border is separated from the malar bone by a mass of fat.

Nerves.—Both muscles are supplied by the inferior maxillary nerve.

X. Pterygo-maxillary Region (fig. 311)

External Pterygoid. Internal Pterygoid.

Dissection.—The Temporal muscle having been examined, saw through the base of the coronoid process, and draw it upwards, together with the Temporal muscle, which should be detached from the surface of the temporal fossa. Divide the ramus of the jaw just below the condyle, and also, by a transverse incision extending across the middle, just above the dental foramen; remove the fragment of bone, and the Pterygoid muscles will be exposed.

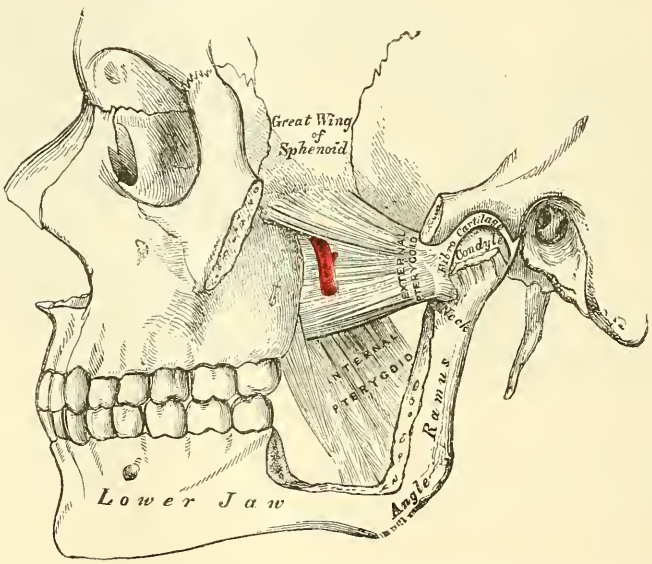
The **External pterygoid** is a short, thick muscle, somewhat conical in form, which extends almost horizontally between the zygomatic fossa and the condyle of the jaw. It arises by two heads, separated by a slight interval: the *upper* arises from the external surface of the greater wing of the sphenoid and from the pterygoid ridge, which separates the zygomatic from the temporal fossa; the *lower* from the outer surface of the external pterygoid plate. Its fibres pass horizontally backwards and outwards, to be inserted into a depression in front of the neck of the condyle of the lower jaw, and into the corresponding part of the interarticular fibro-cartilage.

Relations.—By its *external surface*, with the ramus of the lower jaw, the

internal maxillary artery, which crosses it,* the tendon of the Temporal muscle and the Masseter. By its *internal surface*, it rests against the upper part of the Internal pterygoid, the internal lateral ligament, the middle meningeal artery, and inferior maxillary nerve; by its *upper border* it is in relation with the temporal and masseteric branches of the inferior maxillary nerve; by its lower border it is in relation with the inferior dental and gustatory nerves, and it is pierced by the buccal nerve. In the interval between the two portions of the muscle the internal maxillary artery passes, when this vessel lies on the muscle (see fig. 311).

The **Internal pterygoid** is a thick, quadrilateral muscle, and resembles the Masseter in form. It arises from the pterygoid fossa, being attached to the inner surface of the external pterygoid plate, and to the grooved surface of the tuberosity of the palate bone, and by a second slip from the outer surface of the tuberosities of the palate and superior maxillary bones; its fibres pass downwards, outwards, and backwards, to be inserted, by a strong tendinous lamina into

Fig. 311.—The Pterygoid muscles; the zygomatic arch and a portion of the ramus of the jaw having been removed.



the lower and back part of the inner side of the ramus and angle of the lower jaw, as high as the dental foramen.

Relations.—By its *external surface*, with the ramus of the lower jaw, from which it is separated, at its upper part, by the External pterygoid, the internal lateral ligament, the internal maxillary artery, the dental vessels and nerves, and the lingual nerve. By its *internal surface*, with the Tensor palati, being separated from the Superior constrictor of the pharynx by a cellular interval.

Nerves.—These muscles are supplied by the inferior maxillary nerve.

Actions.—The Temporal, Masseter and Internal pterygoid raise the lower jaw against the upper with great force. The superficial portion of the Masseter assists the External pterygoid in drawing the lower jaw forwards upon the upper; the jaw being drawn back again by the deep fibres of the Masseter, and posterior fibres of the Temporal. The External pterygoid muscles are the direct agents in the trituration of the food, drawing the lower jaw directly forwards, so as to make the lower teeth project beyond the upper. If the muscle of one side acts, the corresponding side of the jaw is drawn forwards, and the other condyle remain-

* This is the usual relation, but in many cases the artery will be found below the muscle.

ing fixed, the symphysis deviates to the opposite side. The alternation of these movements on the two sides produces trituration.

Surface Form.—The outline of the muscles of the head and face cannot be traced on the surface of the body, except in the case of two of the masticatory muscles. Those of the head are thin, so that the outline of the bone is perceptible beneath them. Those in the face are small, covered by soft skin, and often by a considerable layer of fat, so that their outline is concealed; but they serve to round off and smooth prominent borders, and to fill up what would be otherwise unsightly angular depressions. Thus, the Orbicularis palpebrarum rounds off the prominent margin of the orbit, and the Pyramidalis nasi fills in the sharp depression beneath the glabella, and thus softens and tones down the abrupt depression which is seen on the unclothed bone. In like manner, the labial muscles, converging to the lips, and assisted by the superimposed fat, fill in the sunken hollow of the lower part of the face. Although the muscles of the face are usually described as arising from the bones, and inserted into the nose, lips, and corners of the mouth, they have fibres inserted into the skin of the face along their whole extent, so that almost every point of the skin of the face has its muscular fibre to move it; hence it is that when in action the facial muscles produce alterations in the skin-surface, giving rise to the formation of various folds or wrinkles, or otherwise altering the relative position of parts, so as to produce the varied expressions with which the face is endowed; hence these muscles are termed the 'Muscles of expression.' The only two muscles in this region which greatly influence surface-form are the Masseter and the Temporal. The Masseter is a quadrilateral muscle, which imparts fulness to the hinder part of the cheek. When the muscle is firmly contracted, as when the teeth are clenched, its outline is plainly visible; the anterior border forms a prominent vertical ridge, behind which is a considerable fulness, especially marked at the lower part of the muscle; this fulness is entirely lost when the mouth is opened, and the muscle no longer in a state of contraction. The Temporal muscle is fan-shaped, and fills the Temporal fossa, substituting for it a somewhat convex form, the anterior part of which, on account of the absence of hair over the temple, is more marked than the posterior, and stands out in strong relief when the muscle is in a state of contraction.

MUSCLES AND FASCIÆ OF THE NECK

The muscles of the Neck may be arranged into groups, corresponding with the region in which they are situated.

These groups are nine in number:—

I. Superficial Region.
II. Depressors of the Os Hyoides and Larynx.
III. Elevators of the Os Hyoides and Larynx.
IV. Muscles of the Tongue.
V. Muscles of the Pharynx.
VI. Muscles of the Soft Palate.
VII. Muscles of the Anterior Vertebral Region.
VIII. Muscles of the Lateral Vertebral Region.
IX. Muscles of the Larynx.

The muscles contained in each of these groups are the following:—

I. Superficial Region.

Platysma myoides.
Sterno-cleido-mastoid.

Infra-hyoid Region.

II. Depressors of the Os hyoides and Larynx

Sterno-hyoid.
Sterno-thyroid.
Thyro-hyoid.
Omo-hyoid.

Supra-hyoid Region.

III. Elevators of the Os hyoides and Larynx.

Digastric.
Stylo-hyoid.
Mylo-hyoid.
Genio-hyoid.

Lingual Region.

IV. Muscles of the Tongue.

Genio-hyo-glossus.
Hyo-glossus.
Lingualis.
Stylo-glossus.
Palato-glossus.

V. Muscles of the Pharynx.

Constrictor inferior.
Constrictor medius.
Constrictor superior.
Stylo-pharyngeus.
Palato-pharyngeus.

VI. Muscles of the Soft Palate.

Levator palati.
Tensor palati.
Azygos uvulæ.
Palato-glossus.
Palato-pharyngeus.

VII. Muscles of the Anterior Vertebral Region.

Rectus capitis anticus major.
Rectus capitis anticus minor.
Rectus lateralis.
Longus colli.

VIII. Muscles of the Lateral Vertebral Region.

Scalenus anticus.
Scalenus medius.
Scalenus posticus.

IX. Muscles of the Larynx.

Included in the description of the Larynx.

I. Superficial Cervical Region

Platysma myoides. Sterno-cleido-mastoid.

Dissection.—A block having been placed at the back of the neck, and the face turned to the side opposite that to be dissected, so as to place the parts upon the stretch, make two transverse incisions: one from the chin, along the margin of the lower jaw, to the mastoid process; and the other along the upper border of the clavicle. Connect these by an oblique incision made in the course of the Sterno-mastoid muscle, from the mastoid process to the sternum; the two flaps of integument having been removed in the direction shown in fig. 305, the superficial fascia will be exposed.

The **Superficial cervical fascia** is a thin, aponeurotic lamina, which is hardly demonstrable as a separate membrane. Beneath it is found the Platysma myoides muscle.

The **Platysma myoides** (fig. 306) is a broad, thin plane of muscular fibres, placed immediately beneath the superficial fascia on each side of the neck. It arises by thin, fibrous bands from the fascia covering the upper part of the Pectoral and Deltoid muscles; its fibres proceed obliquely upwards and inwards along the side of the neck. The anterior fibres interlace, in front of the jaw, with the fibres of the muscle of the opposite side; the posterior fibres pass over the lower jaw, some of them being attached to the bone below the external oblique line, others passing on to be inserted into the skin and subcutaneous tissue of the lower part of the face, many of these fibres blending with the muscles about the angle and lower part of the mouth. Sometimes fibres can be traced to the Zygomatic muscles, or to the margin of the Orbicularis palpebrarum. Beneath the Platysma, the external jugular vein may be seen descending from the angle of the jaw to the clavicle.

Surgical Anatomy.—It is essential to remember the direction of the fibres of the Platysma, in connection with the operation of bleeding from the external jugular vein; for if the point of the lancet is introduced in the direction of the muscular fibres, the orifice made will be filled up by the contraction of the muscle, and blood will not flow; but if the incision is made across the course of the fibres, they will retract, and expose the orifice in the vein, and so allow the flow of blood.

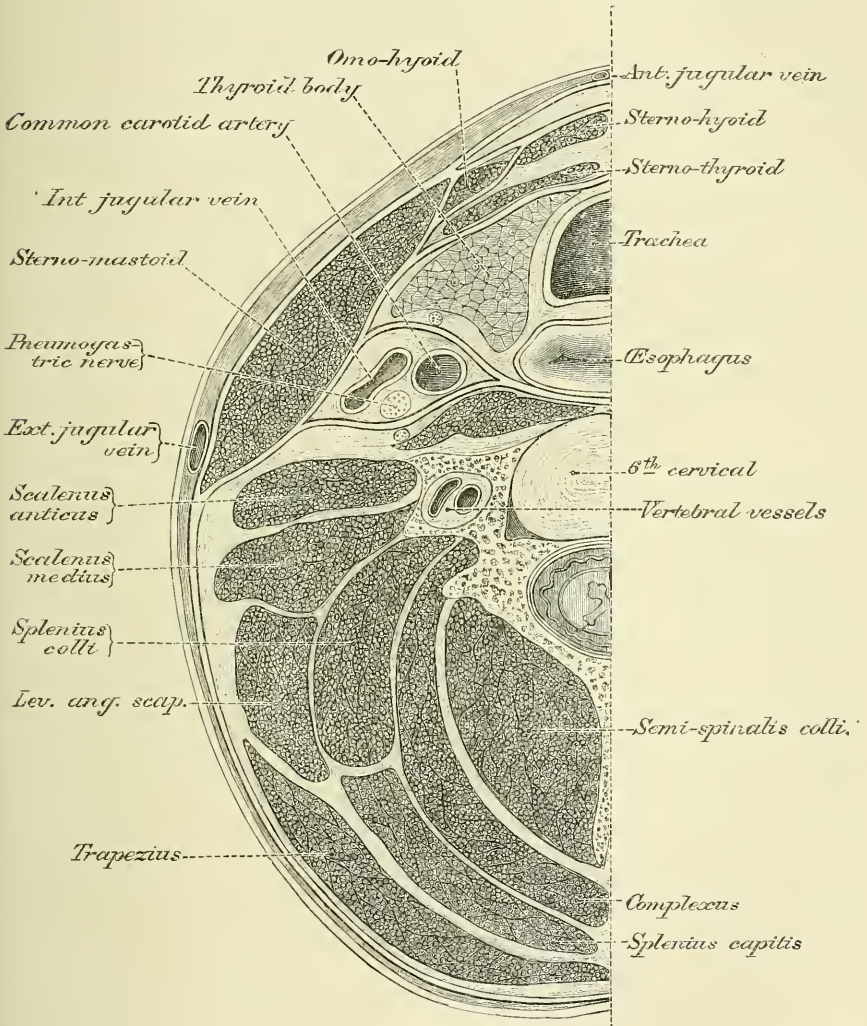
Relations.—By its *external surface*, with the integument, to which it is united more closely below than above. By its *internal surface*, with the Pectoralis major, Deltoid, and Trapezius, and with the clavicle. In the *neck*, with the external and anterior jugular veins, the deep cervical fascia, the superficial branches of the cervical plexus, the Sterno-mastoid, Sterno-hyoid, Omo-hyoid, and Digastric muscles. Behind the Sterno-mastoid muscle, it covers the Scaleni muscles and the nerves of the brachial plexus. On the *face*, it is in relation with the parotid gland, the facial artery and vein, and the Masseter and Buccinator muscles.

Action.—The Platysma myoides produces a slight wrinkling of the surface of the skin of the neck, in an oblique direction, when the entire muscle is brought

into action. Its anterior portion, the thickest part of the muscle, depresses the lower jaw; it also serves to draw down the lower lip and angle of the mouth on each side, being one of the chief agents in the expression of melancholy.

The **Deep cervical fascia** (fig. 312) is a strong, fibrous layer, which invests the muscles of the neck, and encloses the vessels and nerves. It commences, as an extremely thin layer, at the back part of the neck, where it is attached to the ligamentum nuchæ and to the spinous process of the seventh cervical vertebræ, and, passing forwards, invests the Trapezius muscle; from the anterior border

FIG. 312.—Section of the neck at about the level of the sixth cervical vertebra. Showing the arrangement of the deep cervical fascia.



of this muscle it forms a layer, which covers in the posterior triangle of the neck; and, passing forwards to the posterior border of the Sterno-mastoid muscle, divides into two layers, one of which passes in front, and the other behind, that muscle. The layer which passes in front of the muscle is continued forwards to the front of the neck, and blends with the fascia of the opposite side, covering the anterior triangle. It is joined on its under surface, except for about an inch below, by a lamella derived from the layer covering the posterior surface of the

Sterno-mastoid muscle. Where these two layers do not meet, a little space is left between them, as they both pass inwards to the middle line of the neck. This is *Burns's space*, and contains a little areolar tissue and fat, and occasionally a small lymphatic gland. If traced upwards the anterior layer of the cervical fascia is found to pass over the parotid gland and Masseter muscle, forming the *parotid* and *masseteric fasciæ*, and is attached to the lower border of the zygoma, and, more anteriorly, to the lower border of the body of the jaw; if traced downwards, it is seen to pass to the upper border of the clavicle and sternum, being pierced just above the former bone by the external jugular vein. In the middle line of the neck, the fascia is connected to the symphysis of the inferior maxilla, and, lower down, to the hyoid bone, between which points it is thin; below the hyoid bone it becomes thicker, and is attached below to the anterior margin of the upper border of the sternum. The layer of the deep cervical fascia which passes behind the Sterno-mastoid covers the anterior surface of the Scalenus anticus muscle. At the outer side of the carotid vessels it divides into two, one layer passing in front of the vessels, the other behind them. The layer which passes in front of the vessels again divides into three lamellæ. Of these, the anterior lamella, except for an inch below where it forms the posterior boundary of Burns's space, joins the layer of cervical fascia passing in front of the Sterno-mastoid, and with it passes to the middle line covering the anterior surface of the Depressor muscles of the hyoid bone. The portion of this lamella which invests the Omo-hyoid is continued downwards as a distinct process, which descends to be inserted into the sternum and cartilage of the first rib, and becomes connected with the Costo-coracoid membrane. The middle lamella passes behind the depressors of the hyoid bone and in front of the thyroid body to meet its fellow of the opposite side, in front of the trachea. At the root of the neck this middle lamella can be traced downwards into the thorax to become continuous with the fibrous layer of the pericardium. The posterior lamella passes on the inner side of the carotid vessels, and speedily joins the layer passing behind them, thus enclosing them in a sheath. The layer of cervical fascia which passes behind the carotid vessels, having been joined by the posterior of the three lamellæ from the layer of fascia passing in front of the vessels, is prolonged inwards, behind the pharynx and œsophagus, forming a sheath for the Prevertebral muscles, the *prevertebral fascia*. To the inner side of the carotid vessels, a special layer of fascia, derived from the prevèrtebral fascia, is continued inwards towards the middle line, closely covering the constrictor muscles: this is called the *pharyngeal fascia*, and between it and the prevertebral fascia is a space, the *retro-pharyngeal space*, filled in by a quantity of loose connective tissue. This space is continued downwards behind the œsophagus into the thorax, where it becomes continuous with the posterior mediastinum. Above, the pharyngeal fascia is prolonged forwards over the Superior constrictor of the pharynx to the pterygo-maxillary ligament (p. 399), where it becomes continuous with the fascia covering the Buccinator muscle. Finally, from the layer of the deep cervical fascia, which passes behind the Sterno-mastoid, is given off another lamella, which may be regarded as a prolongation of the prevertebral fascia; this passes downwards and outwards over the brachial plexus and subclavian vessels, to assist in forming the axillary sheath. The two layers of the deep cervical fascia, where they unite opposite the angle of the lower jaw, bind the Sterno-mastoid muscle to this part of the bone. From that portion of the cervical fascia which is attached to the angle of the jaw, a process of extreme density is found passing backwards to the inner side of the parotid gland, to be attached to the apex of the styloid process of the temporal bone; this is termed the *Stylo-maxillary ligament*.

Surgical Anatomy.—The cervical fascia is of considerable importance from a surgical point of view. As will be seen from the foregoing description, it may be divided into three layers: (1) A superficial layer; (2) a layer passing in front of the trachea, and

forming with the superficial layer a sheath for the depressors of the hyoid bone; (3) a prevertebral layer passing in front of the bodies of the cervical vertebræ, and forming with the second layer a space in which is contained the trachea, œsophagus, &c. The superficial layer forms a complete investment for the neck. It is attached behind to the ligamentum nuchæ and the spine of the seventh cervical vertebra: above it is attached to the external occipital protuberance, to the superior curved line of the occiput, to the mastoid process, to the zygoma and the lower jaw; below it is attached to the manubrium sterni, the clavicle, the acromion process, and the spine of the scapula; in front it blends with the fascia of the opposite side. This layer would oppose the extension of abscesses or new growths towards the surface, and pus forming beneath it would have a tendency to extend laterally. If it is in the posterior triangle, it might extend backwards under the Trapezius, forwards under the Sterno-mastoid, or downwards under the clavicle for some distance, until stopped by the junction of the cervical fascia to the Costo-coracoid membrane. If the pus is contained in the anterior triangle, it might find its way into the anterior mediastinum, being situated in front of the layer of fascia which passes down into the thorax to become continuous with the pericardium; but owing to the less density and thickness of the fascia in this situation it more frequently finds its way through it and points above the sternum. The second layer of fascia is connected above with the hyoid bone. It passes down beneath the depressors and in front of the thyroid body and trachea to become continuous with the fibrous layer of the pericardium. Laterally it invests the great vessels of the neck and is connected with the superficial layer beneath the sterno-mastoid. Pus forming beneath this layer would in all probability find its way into the posterior mediastinum. The third layer (the prevertebral fascia) is connected above to the base of the skull. Pus forming beneath this layer, in cases, for instance, of caries of the bodies of the cervical vertebræ, might extend towards the posterior and lateral part of the neck and point in this situation, or might perforate this layer of fascia and the pharyngeal fascia and point into the pharynx (post-pharyngeal abscess).

In cases of cut throat the cervical fascia is of considerable importance. In cases where the wound involves only the superficial layer the injury is usually trivial, the only special danger being injury to the external jugular vein, and the only special complication being diffuse cellulitis. But where the second of the two layers has been opened up, important structures may have been injured, which may lead to serious results.

It may be worth while mentioning that in Burns's space is contained the sternal head of origin of the Sterno-mastoid muscle, so that this space is opened in division of this tendon. The anterior jugular vein is also contained in the same space.

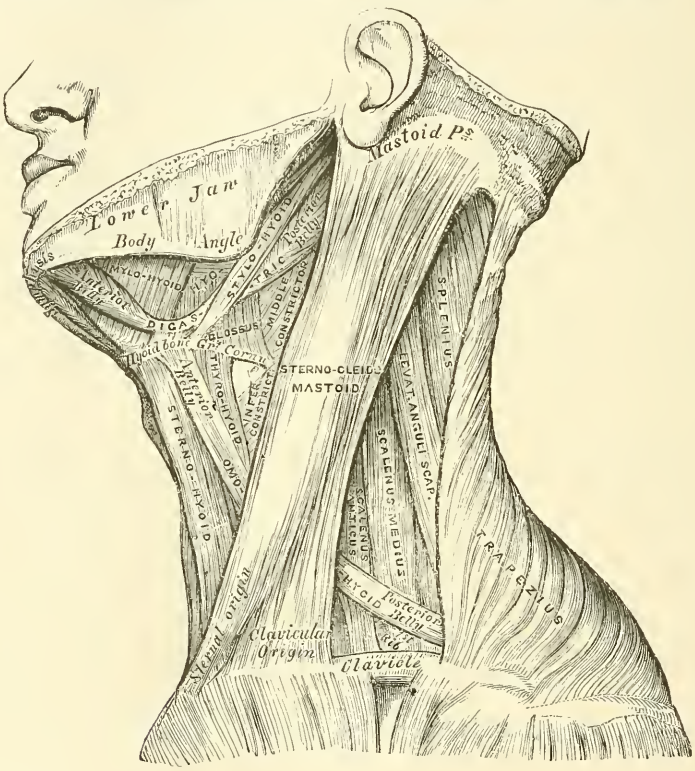
The **Sterno-mastoid** or **Sterno-cleido-mastoid** (fig. 313) is a large, thick muscle, which passes obliquely across the side of the neck, being enclosed between the two layers of the deep cervical fascia. It is thick and narrow at its central part, but is broader and thinner at each extremity. It arises, by two heads, from the sternum and clavicle. The *sternal portion* is a rounded fasciculus, tendinous in front, fleshy behind, which arises from the upper and anterior part of the first piece of the sternum, and is directed upwards, outwards, and backwards. The *clavicular portion* arises from the inner third of the superior border of the clavicle, being composed of fleshy and aponeurotic fibres; it is directed almost vertically upwards. These two portions are separated from one another, at their origin, by a triangular cellular interval; but become gradually blended, below the middle of the neck, into a thick, rounded muscle, which is inserted, by a strong tendon, into the outer surface of the mastoid process, from its apex to its superior border, and by a thin aponeurosis into the outer half of the superior curved line of the occipital bone. The Sterno-mastoid varies much in its extent of attachment to the clavicle: in one case the clavicular may be as narrow as the sternal portion; in another, as much as three inches in breadth. When the clavicular origin is broad, it is occasionally subdivided into numerous slips, separated by narrow intervals. More rarely, the corresponding margins of the Sterno-mastoid and Trapezius have been found in contact. In the application of a ligature to the third part of the subclavian artery, it will be necessary, where the muscles come close together, to divide a portion of one or of both.

This muscle divides the quadrilateral space at the side of the neck into two triangles, an anterior and a posterior. The boundaries of the *anterior triangle* are, in front, the median line of the neck; above, the lower border of the body of the jaw, and an imaginary line drawn from the angle of the jaw to the mastoid process; behind, the anterior border of the Sterno-mastoid muscle. The boundaries of the *posterior triangle* are, in front, the posterior border of the

Sterno-mastoid; below, the upper border of the clavicle; behind, the anterior margin of the Trapezius.*

Relations.—By its *superficial surface*, with the integument and Platysma, from which it is separated by the external jugular vein, the superficial branches of the cervical plexus, and the anterior layer of the deep cervical fascia. By its *deep surface*, it is in relation with the Sterno-clavicular articulation; a process of the deep cervical fascia; the Sterno-hyoid, Sterno-thyroid, Omo-hyoid, posterior belly of the Digastric, Levator anguli scapulæ, Splenius and Scaleni muscles; common carotid artery, internal jugular vein, commencement of the internal and external carotid arteries, the occipital, subclavian, transversalis colli and suprascapular arteries and veins; the pneumogastric, hypoglossal, descendens and communicans hypoglossi nerves and the spinal accessory nerve, which pierces

Fig. 313.—Muscles of the neck, and boundaries of the triangles.



its upper third; the cervical plexus, part of the parotid gland and deep lymphatic glands.

Nerves.—The Platysma myoides is supplied by the facial and superficial branches of the cervical plexus; the Sterno-cleido-mastoid by the spinal accessory and deep branches of the cervical plexus.

Actions.—When only one Sterno-mastoid muscle acts, it flexes the head and draws it towards the shoulder of the same side, assisted by the Splenius and the Obliquus capitis inferior of the opposite side. At the same time it rotates the head so as to carry the face towards the opposite side. When both muscles are brought into action, they serve to depress the head upon the neck, and the neck upon the chest. If the head is fixed, they assist in elevating the thorax in forced inspiration.

* The anatomy of these triangles will be more exactly described with that of the vessels of the neck.

Surface Form.—The anterior edge of the muscle forms a very prominent ridge beneath the skin, which it is important to notice, as it forms a guide to the surgeon in making the necessary incisions for ligature of the common carotid artery, and for œsophagotomy.

Surgical Anatomy.—The relations of the sternal and clavicular parts of the Sterno-mastoid should be carefully examined, as the surgeon is sometimes required to divide one or both portions of the muscle in *wry-neck*. One variety of this distortion is produced by spasmodic contraction or rigidity of the Sterno-mastoid; the head being carried down towards the shoulder of the same side, and the face turned to the opposite side, and fixed in that position. When there is permanent shortening, subcutaneous division of the muscle is resorted to. This is performed by introducing a tenotomy knife beneath it, close to its origin, and dividing it from behind forwards whilst the muscle is put well upon the stretch. There is seldom any difficulty in dividing the sternal portion, by making a puncture on the inner side of the tendon, and then pushing a blunt tenotome behind it, and cutting forwards. In dividing the clavicular portion care must be taken to avoid wounding the external jugular vein, which runs parallel with the posterior border of the muscle in this situation, or the anterior jugular vein, which crosses beneath it. If the external jugular vein lies near the muscle, it is safer to make the first puncture at the outer side of the tendon, and introduce a blunt tenotome from without inwards. Many surgeons prefer dividing the muscle by the open method. An incision is made over either origin of the muscle, the tendon is exposed and a director is passed underneath it, and it is then divided. With care and attention to asepsis this plan of treatment is devoid of risk, and in this way the accidental division of the vessels can be avoided. Some of the fibres of the Sterno-mastoid muscle are occasionally torn during birth, especially in breech presentations; this is accompanied by hæmorrhage and formation of a swelling within the substance of the muscle. This by some is believed to be one of the causes of wry-neck.

II. Infra-hyoid Region (figs. 313, 314)

Depressors of the Os Hyoides and Larynx

Sterno-hyoid.	Thyro-hyoid.
Sterno-thyroid.	Omo-hyoid.

Dissection.—The muscles in this region may be exposed by removing the deep fascia from the front of the neck. In order to see the entire extent of the Omo-hyoid, it is necessary to divide the Sterno-mastoid at its centre, and turn its ends aside, and to detach the Trapezius from the clavicle and scapula. This, however, should not be done until the Trapezius has been dissected.

The **Sterno-hyoid** is a thin, narrow, riband-like muscle, which arises from the inner extremity of the clavicle, the posterior sterno-clavicular ligament, and the upper and posterior part of the first piece of the sternum; passing upwards and inwards, it is inserted, by short, tendinous fibres, into the lower border of the body of the os hyoides. This muscle is separated, below, from its fellow by a considerable interval; but they approach one another in the middle of their course, and again diverge as they ascend. It sometimes presents, immediately above its origin, a transverse tendinous intersection, like those in the Rectus abdominis.

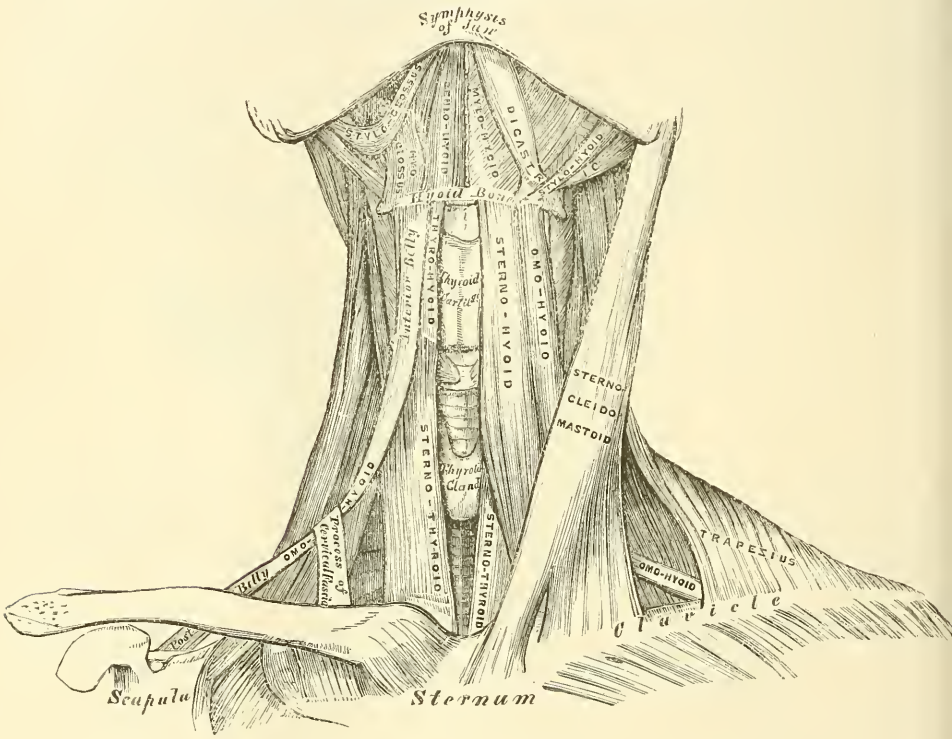
Relations.—By its *superficial surface*, below, with the sternum, the sternal end of the clavicle, and the Sterno-mastoid; and above, with the Platysma and deep cervical fascia. By its *deep surface*, with the Sterno-thyroid, Crico-thyroid, and Thyro-hyoid muscles, the thyroid gland, the superior thyroid vessels, the thyroid cartilage, the crico-thyroid and thyro-hyoid membranes.

The **Sterno-thyroid** is shorter and wider than the preceding muscle, beneath which it is situated. It arises from the posterior surface of the first bone of the sternum, below the origin of the Sterno-hyoid, and from the edge of the cartilage of the first rib, and occasionally of the second rib also; and is inserted into the oblique line on the side of the ala of the thyroid cartilage. This muscle is in close contact with its fellow at the lower part of the neck; and is occasionally traversed by a transverse or oblique tendinous intersection like those in the Rectus abdominis.

Relations.—By its *anterior surface*, with the Sterno-hyoid, Omo-hyoid, and Sterno-mastoid. By its *posterior surface*, from below upwards, with the trachea, vena innominata, common carotid (and on the right side the arteria innominata), the thyroid gland and its vessels, and the lower part of the larynx. The middle thyroid vein lies along its inner border, a relation which it is important to remember in the operation of tracheotomy.

The **Thyro-hyoid** is a small, quadrilateral muscle appearing like a continuation of the Sterno-thyroid. It arises from the oblique line on the side of the thyroid cartilage, and passes vertically upwards to be inserted into the lower border of the body and greater cornu of the hyoid bone.

Fig. 314.—Muscles of the neck. Anterior view.



Relations.—By its *external surface*, with the Sterno-hyoid and Omo-hyoid muscles. By its *internal surface*, with the thyroid cartilage, the thyro-hyoid membrane, and the superior laryngeal vessels and nerve.

The **Omo-hyoid** passes across the side of the neck, from the scapula to the hyoid bone. It consists of two fleshy bellies, united by a central tendon. It arises from the upper border of the scapula, and occasionally from the transverse ligament which crosses the suprascapular notch; its extent of attachment to the scapula varying from a few lines to an inch. From this origin, the posterior belly forms a flat, narrow fasciculus, which inclines forwards and slightly upwards across the lower part of the neck, behind the Sterno-mastoid muscle, where it becomes tendinous; it then changes its direction, forming an obtuse angle, and terminates in the anterior belly, which passes almost vertically upwards, close to the outer border of the Sterno-hyoid, to be inserted into the lower border of the body of the os hyoides, just external to the insertion of the Sterno-hyoid. The central tendon of this muscle, which varies much in length and form, is held in position by a process of the deep cervical fascia, which includes it in a sheath. This process is prolonged down, to be attached to the cartilage of the first rib

and the sternum. It is by this means that the angular form of the muscle is maintained.

This muscle subdivides each of the two large triangles at the side of the neck into two smaller triangles; the two posterior ones being the *posterior superior* or *occipital*, and the *posterior inferior* or *subclavian*; the two anterior, the *anterior superior* or *superior carotid*, and the *anterior inferior* or *inferior carotid triangle*.

Relations.—By its *superficial surface*, with the Trapezius, the Sterno-mastoid, deep cervical fascia, Platysma, and integument. By its *deep surface*, with the Scaleni muscles, phrenic nerve, lower cervical nerves, which go to form the brachial plexus, the suprascapular vessels and nerve, sheath of the common carotid artery and internal jugular vein, the Sterno-thyroid and Thyro-hyoid muscles.

Nerves.—The Thyro-hyoid is supplied by the hypoglossal; the other muscles of this group by branches from the loop of communication between the descendens and communicans hypoglossi.

Actions.—These muscles depress the larynx and hyoid bone, after they have been drawn up with the pharynx in the act of deglutition. The Omo-hyoid muscles not only depress the hyoid bone, but carry it backwards, and to one or the other side. It is concerned especially in prolonged inspiratory efforts; for by tensing the lower part of the cervical fascia it lessens the inward suction of the soft parts, which would otherwise compress the great vessels and the apices of the lungs. The Thyro-hyoid may act as an elevator of the thyroid cartilage, when the hyoid bone ascends, drawing upwards the thyroid cartilage, behind the os hyoides.* The Sterno-thyroid acts as a depressor of the thyroid cartilage.

III. Supra-hyoid Region (figs. 313, 314)

Elevators of the Os Hyoides—Depressors of the Lower Jaw

Digastric.	Mylo-hyoid.
Stylo-hyoid.	Genio-hyoid.

Dissection.—To dissect these muscles, a block should be placed beneath the back of the neck, and the head drawn backwards, and retained in that position. On the removal of the deep fascia, the muscles are at once exposed.

The **Digastric** consists of two fleshy bellies united by an intermediate, rounded tendon. It is a small muscle, situated below the side of the body of the lower jaw, and extending, in a curved form, from the side of the head to the symphysis of the jaw. The *posterior belly*, longer than the anterior, arises from the digastric groove on the inner side of the mastoid process of the temporal bone, and passes downwards, forwards, and inwards. The *anterior belly* arises from a depression on the inner side of the lower border of the jaw, close to the symphysis, and passes downwards and backwards. The two bellies terminate in the central tendon which perforates the Stylo-hyoid, and is held in connection with the side of the body and the greater cornu of the hyoid bone by a fibrous loop, lined by a synovial membrane. A broad aponeurotic layer is given off from the tendon of the Digastric on each side, which is attached to the body and great cornu of the hyoid bone; this is termed the *supra-hyoid aponeurosis*. It forms a strong layer of fascia between the anterior portion of the two muscles, and a firm investment for the other muscles of the supra-hyoid region which lie deeper.

The Digastric muscle divides the anterior superior triangle of the neck into two smaller triangles; the upper, or *submaxillary*, being bounded, above, by the

* It is this action of the Thyro-hyoid muscle which, as Dr. Buchanan has pointed out, 'causes or permits the folding back of the epiglottis over the upper orifice of the larynx.' *Journ. of Anat. and Phys.* 2nd series. No. III. p. 255.

lower border of the body of the jaw, and a line drawn from its angle to the mastoid process; below, by the posterior belly of the Digastric and the Stylo-hyoid muscles; in front, by the middle line of the neck, and anterior belly of the Digastric: the lower or *superior carotid triangle* being bounded above by the posterior belly of the Digastric, behind by the Sterno-mastoid, below by the Omo-hyoid.

Relations.—By its *superficial surface*, with the Platysma, Sterno-mastoid, part of the Splenius, Trachelo-mastoid, and Stylo-hyoid muscles, and the parotid gland. By its *deep surface*, the anterior belly lies on the Mylo-hyoid; the posterior belly on the Stylo-glossus, Stylo-pharyngeus, and Hyo-glossus muscles, the external carotid artery and its lingual and facial branches, the internal carotid artery, internal jugular vein, and hypoglossal nerve.

The **Stylo-hyoid** is a small, slender muscle, lying in front of, and above, the posterior belly of the Digastric. It arises from the back and outer surface of the styloid process, near the base; and, passing downwards and forwards, is inserted into the body of the hyoid bone, just at its junction with the greater cornu, and immediately above the Omo-hyoid. This muscle is perforated, near its insertion, by the tendon of the Digastric.

Relations.—By its *superficial surface*, above with the parotid gland and deep cervical fascia; below it is superficial, being situated immediately beneath the deep cervical fascia. By its *deep surface*, with the posterior belly of the Digastric, the external carotid artery, with its lingual and facial branches and the Hyo-glossus muscle.

The Stylo-hyoid ligament.—In connection with the Stylo-hyoid muscle may be described a ligamentous band, the *Stylo-hyoid ligament*. It is a fibrous cord, often containing a little cartilage in its centre, which continues the styloid process down to the hyoid bone, being attached to the tip of the former and the small cornu of the latter. It is often more or less ossified, and in many animals forms a distinct bone, the *epihyal*.

The Digastric and Stylo-hyoid should be removed, in order to expose the next muscle.

The **Mylo-hyoid** is a flat, triangular muscle, situated immediately beneath the anterior belly of the Digastric, and forming, with its fellow of the opposite side, a muscular floor for the cavity of the mouth. It arises from the whole length of the mylo-hyoid ridge, extending from the symphysis in front to the last molar tooth behind. The posterior fibres pass inwards and slightly downwards, to be inserted into the body of the os hyoides. The middle and anterior fibres are inserted into a median fibrous raphé, extending from the symphysis of the lower jaw to the hyoid bone, where they join at an angle with the fibres of the opposite muscle. This median raphé is sometimes wanting; the muscular fibres of the two sides are then directly continuous with one another.

Relations.—By its *cutaneous* or *under surface*, with the Platysma, the anterior belly of the Digastric, the supra-hyoid aponeurosis, the submaxillary gland, submental vessels, and mylo-hyoid vessels and nerve. By its *deep* or *superior surface*, with the Genio-hyoid, part of the Hyo-glossus, and Stylo-glossus muscles, the hypo-glossal and lingual nerves, the submaxillary ganglion, the sublingual gland, the deep portion of the submaxillary gland and Wharton's duct; the sublingual and ranine vessels, and the buccal mucous membrane.

Dissection.—The Mylo-hyoid should now be removed, in order to expose the muscles which lie beneath; this is effected by detaching it from its attachments to the hyoid bone and jaw, and separating it by a vertical incision from its fellow of the opposite side.

The **Genio-hyoid** is a narrow, slender muscle, situated immediately beneath* the inner border of the preceding. It arises from the inferior genial tubercle on the inner side of the symphysis of the jaw, and passes downwards and backwards,

* This refers to the depth of the muscles from the skin in the order of dissection. In the erect position of the body each of these muscles lies above the preceding.

to be inserted into the anterior surface of the body of the os hyoides. This muscle lies in close contact with its fellow of the opposite side, and increases slightly in breadth as it descends.

Relations.—It is covered by the Mylo-hyoid, and lies on the Genio-hyo-glossus.

Nerves.—The Digastric is supplied: its anterior belly, by the mylo-hyoid branch of the inferior dental; its posterior belly, by the facial; the Stylo-hyoid, by the facial; the Mylo-hyoid, by the mylo-hyoid branch of the inferior dental; the Genio-hyoid, by the hypoglossal.

Actions.—This group of muscles performs two very important actions. They raise the hyoid bone, and with it the base of the tongue, during the act of deglutition; or, when the hyoid bone is fixed by its depressors and those of the larynx, they depress the lower jaw. During the first act of deglutition, when the mass is being driven from the mouth into the pharynx, the hyoid bone, and with it the tongue, is carried upwards and forwards by the anterior belly of the Digastric, the Mylo-hyoid, and Genio-hyoid muscles. In the second act, when the mass is passing through the pharynx, the direct elevation of the hyoid bone takes place by the combined action of all the muscles; and after the food has passed, the hyoid bone is carried upwards and backwards by the posterior belly of the Digastric and Stylo-hyoid muscles, which assist in preventing the return of the morsel into the mouth.

IV. Lingual Region

Genio-hyo-glossus. Stylo-glossus.
Hyo-glossus. Palato-glossus.
Chondro-glossus.

Dissection.—After completing the dissection of the preceding muscles, saw through the lower jaw just external to the symphysis. Then draw the tongue forwards, and attach it, by a stitch, to the nose; when its muscles, which are thus put on the stretch, may be examined.

The **Genio-hyo-glossus** has received its name from its triple attachment to the jaw, hyoid bone, and tongue, but it would be better named the *Genio-glossus*, since its attachment to the hyoid bone is very slight or altogether absent. It is a flat, triangular muscle, placed vertically on either side of the middle line, its apex corresponding with its point of attachment to the lower jaw, its base with its insertion into the tongue and hyoid bone. It arises by a short tendon from the superior genial tubercle on the inner side of the symphysis of the jaw, immediately above the Genio-hyoid; from this point the muscle spreads out in a fan-like form, a few of the inferior fibres passing downwards, to be attached by a thin aponeurosis into the upper part of the body of the hyoid bone, a few fibres passing between the Hyo-glossus and Chondro-glossus to blend with the constrictor muscles of the pharynx; the middle fibres passing backwards, and the superior ones upwards and forwards, to enter the whole length of the under surface of the tongue, from the base to the apex. The two muscles lie on either side of the median plane; behind, they are quite distinct from each other, and are separated at their insertion into the under surface of the tongue by a tendinous raphé, which extends through the middle of the organ; in front, the two muscles are more or less blended: distinct fasciculi are to be seen passing off from one muscle, crossing the middle line, and intersecting with bundles of fibres derived from the muscle on the other side (fig. 316).

Relations.—By its *internal surface* it is in contact with its fellow of the opposite side. By its *external surface*, with the Inferior lingualis, the Hyo-glossus, the lingual artery and hypoglossal nerve, the lingual nerve, and sublingual gland. By its *upper border*, with the mucous membrane of the floor of the mouth (frænum linguæ). By its *lower border*, with the Genio-hyoid.

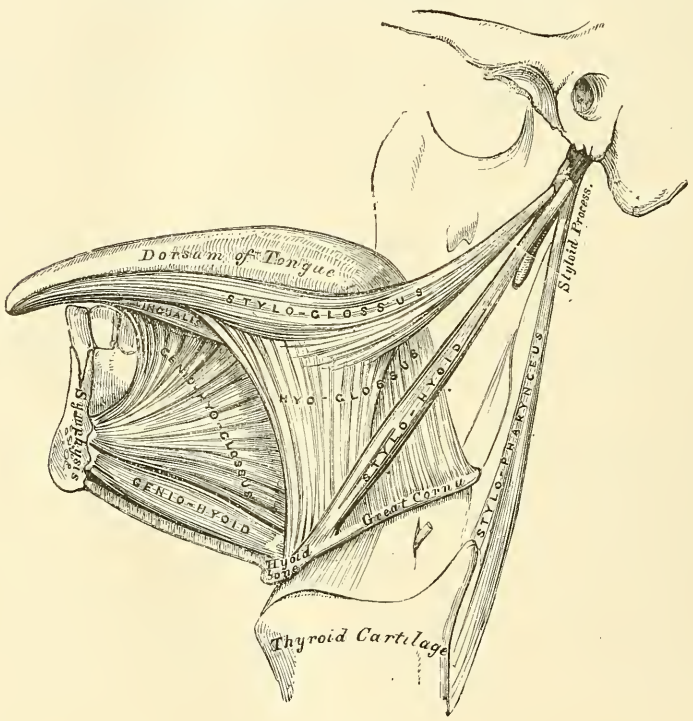
The **Hyo-glossus** is a thin, flat, quadrilateral muscle, which arises from the

side of the body, and whole length of the greater cornu of the hyoid bone, and passes almost vertically upwards to enter the side of the tongue, between the Stylo-glossus and Lingualis. Those fibres of this muscle which arise from the body are directed upwards and backwards, overlapping those arising from the greater cornu, which are directed upwards and forwards.

Relations.—By its *external surface*, with the Digastric, the Stylo-hyoid, Stylo-glossus, and Mylo-hyoid muscles, the submaxillary ganglion, the lingual and hypoglossal nerves, Wharton's duct, and the deep portion of the submaxillary gland. By its *deep surface*, with the Stylo-hyoid ligament, the Genio-hyo-glossus, Lingualis, and Middle constrictor, the lingual vessels, and the glosso-pharyngeal nerve.

The **Chondro-glossus** is a distinct muscular slip, though it is sometimes described as a part of the Hyo-glossus, from which, however, it is separated by

Fig. 315.—Muscles of the tongue. Left side.



the fibres of the Genio-hyo-glossus, which pass to the side of the pharynx. It is about three-quarters to an inch in length, and arises from the inner side and base of the lesser cornu and contiguous portion of the body of the hyoid bone, and passes directly upwards to blend with the intrinsic muscular fibres of the tongue, between the Hyo-glossus and Genio-hyo-glossus. A small slip of muscular fibre is occasionally found, arising from the cartilago triticea in the thyro-hyoid ligament, and passing upwards and forwards to enter the tongue with the hindermost fibres of the Hyo-glossus.

The **Stylo-glossus,** the shortest and smallest of the three styloid muscles, arises from the anterior and outer side of the styloid process, near its apex, and from the stylo-maxillary ligament, to which its fibres, in most cases, are attached by a thin aponeurosis. Passing downwards and forwards between the internal and external carotid arteries, and becoming nearly horizontal in its direction, it divides upon the side of the tongue into two portions : one longitudinal, which enters the side of the tongue near its dorsal surface, blending with the fibres of the Lingualis in

front of the Hyo-glossus; the other oblique which overlaps the Hyo-glossus muscle and decussates with its fibres.

Relations.—By its *external surface*, from above downwards, with the parotid gland, the Internal pterygoid muscle, the lingual nerve, and the mucous membrane of the mouth. By its *internal surface*, with the tonsil, the Superior constrictor, and the Hyo-glossus muscle.

The **Palato-glossus**, or **Constrictor isthmi faucium**, although it is one of the muscles of the tongue, serving to draw its base upwards during the act of deglutition, is more nearly associated with the soft palate, both in its situation and function; it will, consequently, be described with that group of muscles.

Nerves.—The Palato-glossus is probably innervated by the spinal accessory nerve, through the pharyngeal plexus; the remaining muscles of this group by the hypoglossal.

Muscular substance of tongue.—The muscular fibres of the tongue run in various directions. These fibres are divided into two sets—Extrinsic and

Fig. 316.—Muscles of the tongue from below. From a preparation in the Museum of the Royal College of Surgeons of England.

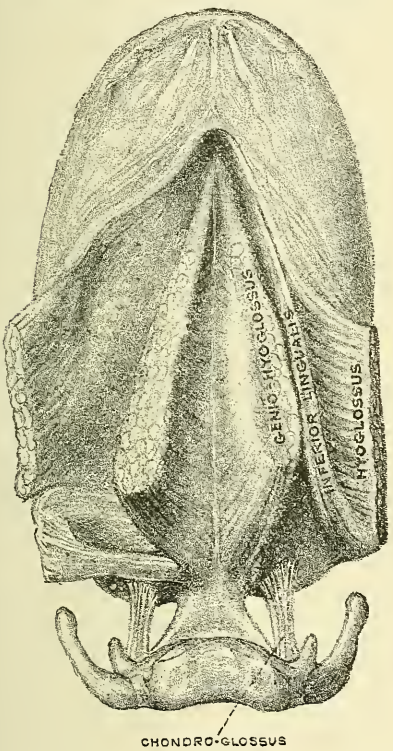


Fig. 317.—Muscles on the dorsum of the tongue.

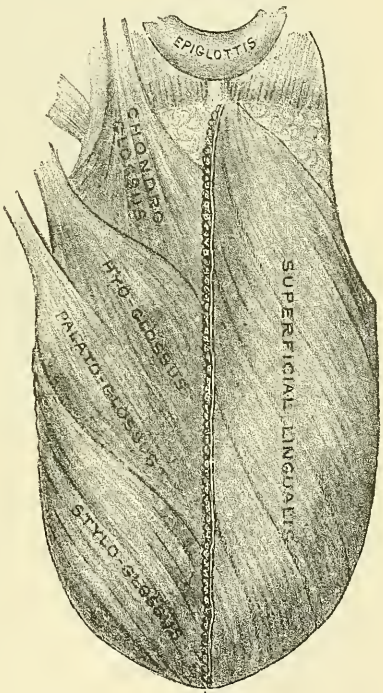


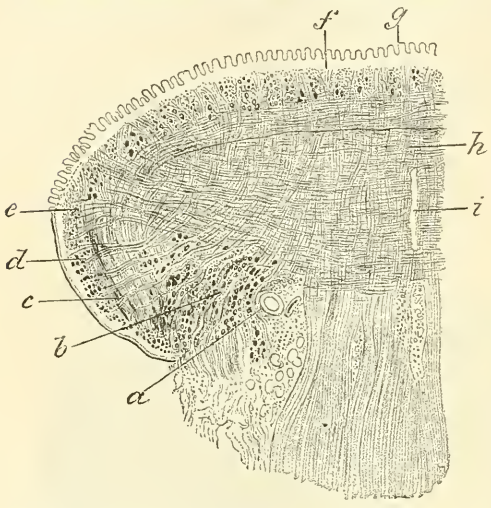
Intrinsic. The extrinsic muscles of the tongue are those which have their origin external and only their terminal fibres contained in the substance of the organ. They are: the Stylo-glossus, the Hyo-glossus, the Palato-glossus, the Genio-hyo-glossus, and part of the Superior constrictor of the pharynx (Pharyngeo-glossus). The intrinsic are those which are contained entirely within the tongue, and form the greater part of its muscular structure.

The tongue consists of symmetrical halves separated from each other in the middle line by a fibrous septum. Each half is composed of muscular fibres arranged in various directions, containing much interposed fat, and supplied by vessels and nerves.

To demonstrate the various fibres of the tongue, the organ should be subjected

to prolonged boiling, in order to soften the connective tissue; the dissection may then be commenced from the dorsum (fig. 317). Immediately beneath the mucous membrane is a submucous, fibrous layer, into which the muscular fibres which terminate on the surface of the tongue are inserted. Upon removing this, with the mucous membrane, the first stratum of muscular fibres is exposed. This belongs to the group of intrinsic muscles, and has been named the *Superior lingualis*. It consists of a thin layer of oblique and longitudinal fibres, which arise from the submucous fibrous layer, close to the Epiglottis, and from the fibrous septum, and pass forwards and outwards to the edges of the tongue. Between its fibres pass some vertical fibres derived from the Genio-hyo-glossus and from the vertical intrinsic muscle, which will be described later on. Beneath this layer is the second stratum of muscular fibres, derived principally from the extrinsic muscles. In front, it is formed by the fibres derived from the Stylo-glossus, running along the side of the tongue, and sending one set of fibres over the dorsum which runs obliquely forwards and inwards to the middle line, and another set of fibres, seen at a later period of the dissection, on to the under surface of the sides of the anterior part of the tongue, which runs forwards and inwards, between the fibres of the Hyo-glossus, to the middle line. Behind this layer of fibres, derived from the Stylo-glossus, are fibres derived from the Hyo-glossus, assisted by some few fibres of the Palato-glossus. The Hyo-glossus, entering the side of the under surface of the tongue, between the Stylo-glossus and Inferior lingualis, passes round its margin and spreads out into a layer on the dorsum, which occupies the middle third of the organ, and runs almost transversely inwards to the septum. It is reinforced by some fibres from the Palato-glossus; other fibres of this muscle pass more deeply and intermingle with the next layer. The posterior part of the second layer of the muscular fibres of the tongue is derived from those fibres of the Hyo-glossus which arise from the lesser cornu of the hyoid bone, and are here described as a separate muscle—the Chondro-glossus. The fibres of this muscle are arranged in a fan-shaped manner, and spread out over the posterior third of the tongue. Beneath this layer is the great mass of the intrinsic muscles of the tongue, intersected at right angles by the terminal fibres of one of the extrinsic muscles—the Genio-hyo-glossus. This portion of the tongue is paler in colour and softer in texture than that already described, and is sometimes designated the medullary portion in contradistinction to the firmer superficial part, which is termed the cortical portion. It consists largely of transverse fibres, the *Transverse lingualis*, and of vertical fibres, the *Vertical lingualis*. The Transverse lingualis forms the largest portion of the third layer of muscular fibres of the tongue. The fibres arise from the median septum, and pass outwards to be inserted into the submucous fibrous layer at the sides of the tongue. Intermingled with these transverse intrinsic fibres are transverse extrinsic fibres derived from the Palato-glossus and the Superior constrictor of the pharynx. These transverse extrinsic fibres, however, run in the opposite direction, passing inwards towards

Fig. 318.—Coronal section of tongue. Showing intrinsic muscles. (Altered from Krause.)



a, lingual artery; *b*, Inferior lingualis, cut through; *c*, fibres of Hyo-glossus; *d*, oblique fibres of Stylo-glossus; *e*, insertion of Transverse lingualis; *f*, Superior lingualis; *g*, papillæ of tongue; *h*, vertical fibres of Genio-hyo-glossus intersecting Transverse lingualis; *i*, septum.

the septum. Intersecting the transverse fibres are a large number of vertical fibres derived partly from the Genio-hyo-glossus and partly from intrinsic fibres, the *Vertical lingualis*. The fibres derived from the Genio-hyo-glossus enter the under surface of the tongue on each side of the median septum from base to apex. They ascend in a radiating manner to the dorsum, being inserted into the submucous fibrous layer covering the tongue on each side of the middle line. The Vertical lingualis is found only at the borders of the fore part of the tongue, external to the fibres of the Genio-hyo-glossus. Its fibres extend from the upper to the under surface of the organ, decussating with the fibres of the other muscles, and especially with the Transverse lingualis. The fourth layer of muscular fibres of the tongue consists partly of extrinsic fibres derived from the Stylo-glossus, and partly of intrinsic fibres, the *Inferior lingualis*. At the sides of the under surface of the organ are some fibres derived from the Stylo-glossus, which, as it runs forwards at the side of the tongue, gives off fibres which, passing forwards and inwards between the fibres of the Hyo-glossus, form an inferior oblique stratum which joins in front with the anterior fibres of the Inferior lingualis. The Inferior lingualis is a longitudinal band, situated on the under surface of the tongue, and extending from the base to the apex of the organ. Behind, some of its fibres are connected with the body of the hyoid bone. It lies between the Hyo-glossus and the Genio-hyo-glossus, and in front of the Hyo-glossus it gets into relation with the Stylo-glossus, with the fibres of which it blends. It is in relation by its under surface with the ranine artery.

Surgical Anatomy.—The fibrous septum which exists between the two halves of the tongue is very complete, so that the anastomosis between the two lingual arteries is not very free, a fact often illustrated by injecting one-half of the tongue with coloured size, while the other half is left uninjected, or is injected with size of a different colour.

This is a point of considerable importance in connection with removal of one-half of the tongue for cancer, an operation which is now frequently resorted to when the disease is strictly confined to one side of the tongue. If the mucous membrane is divided longitudinally exactly in the middle line, the tongue can be split into halves along the median raphé, without any appreciable hæmorrhage, and the diseased half can then be removed.

Actions.—The movements of the tongue, although numerous and complicated, may be understood by carefully considering the direction of the fibres of its muscles. The *Genio-hyo-glossi* muscles, by means of their posterior fibres, draw the base of the tongue forwards, so as to protrude the apex from the mouth. The anterior fibres draw the tongue back into the mouth. The whole length of these two muscles acting along the middle line of the tongue draw it downwards, so as to make it concave from side to side, forming a channel along which fluids may pass towards the pharynx, as in sucking. The *Hyo-glossi* muscles depress the tongue, and draw down its sides, so as to render it convex from side to side. The *Stylo-glossi* muscles draw the tongue upwards and backwards. The *Palato-glossi* muscles draw the base of the tongue upwards. With regard to the intrinsic muscles, both the Superior and Inferior linguales tend to shorten the tongue, but the former, in addition, turn the tip and sides upwards so as to render the dorsum concave, while the latter pull the tip downwards and cause the dorsum to become convex. The Transverse lingualis narrows and elongates the tongue, and the Vertical lingualis flattens and broadens it. The complex arrangement of the muscular fibres of the tongue, and the various directions in which they run, give to this organ the power of assuming the various forms necessary for the enunciation of the different consonantal sounds; and Dr. Macalister states 'there is reason to believe that the musculature of the tongue varies in different races owing to the hereditary practice and habitual use of certain motions required for enunciating the several vernacular languages.'

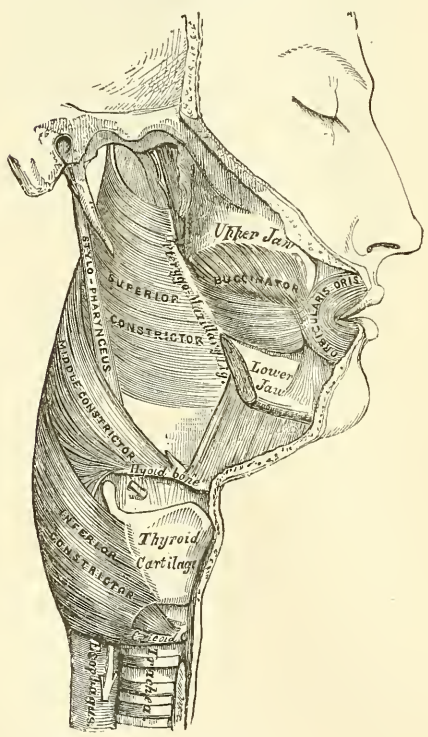
V. Pharyngeal Region

Inferior constrictor.	Superior constrictor.
Middle constrictor.	Stylo-pharyngeus.
Palato-pharyngeus.	(See next section.)
Salpingo-pharyngeus.	

Dissection (fig. 319).—In order to examine the muscles of the pharynx, cut through the trachea and œsophagus just above the sternum, and draw them upwards by dividing the loose areolar tissue connecting the pharynx with the front of the vertebral column. The parts being drawn well forwards, apply the edge of the saw immediately behind the styloid processes, and saw the base of the skull through from below upwards. The pharynx and mouth should then be stuffed with tow, in order to distend its cavity and render the muscles tense and easier of dissection.

The **Inferior constrictor**, the most superficial and thickest of the three constrictors, arises from the sides of the cricoid and thyroid cartilages. To the cricoid cartilage it is attached in the interval between the Crico-thyroid muscle in front, and the articular facet for the thyroid cartilage behind. To the thyroid cartilage it is attached to the oblique line on the side of the great ala, to the cartilaginous surface behind it, nearly as far as its posterior border, and to the inferior cornu. From these attachments the fibres spread backwards and inwards, to be inserted into the fibrous raphé in the posterior median line of the pharynx. The inferior fibres are horizontal, and continuous with the fibres of the œsophagus; the rest ascend, increasing in obliquity, and overlap the Middle constrictor.

Fig. 319.—Muscles of the pharynx. External view.



Relations.—It is covered by a dense cellular membrane which surrounds the entire pharynx (pharyngeal fascia). *Behind*, it is in relation with the vertebral column and the prevertebral muscles; *laterally*, with the thyroid gland, the common carotid artery, and the Sterno-thyroid muscle; by its *internal surface*, with the Middle constrictor, the Stylo-pharyngeus, Palato-pharyngeus, the fibrous coat and mucous membrane of the pharynx. The superior laryngeal nerve and artery pass near the upper border, and the inferior, or recurrent laryngeal, beneath the lower border of this muscle, previous to their entering the larynx.

The **Middle constrictor** is a flattened, fan-shaped muscle, smaller than the preceding. It arises from the whole length of the upper border of the greater cornu of the hyoid bone, from the lesser cornu, and from the stylo-hyoid ligament. The fibres diverge from their origin: the lower ones descending beneath the Inferior constrictor, the middle fibres passing transversely, and the upper fibres ascending and overlapping the Superior constrictor. The muscle is inserted into

the posterior median fibrous raphé, blending in the middle line with the one of the opposite side.

Relations.—This muscle is separated from the Superior constrictor by the glosso-pharyngeal nerve and the Stylo-pharyngeus muscle; and from the Inferior constrictor by the superior laryngeal nerve. *Behind*, it lies on the vertebral column, the Longus colli, and the Rectus capitis anticus major. *On each side* it is in relation with the carotid vessels, the pharyngeal plexus, and some lymphatic glands. Near its origin it is covered by the Hyo-glossus, from which it is separated by the lingual vessels. It lies upon the Superior constrictor, the Stylo-pharyngeus, the Palato-pharyngeus, the fibrous coat, and the mucous membrane of the pharynx.

The **Superior constrictor** is a quadrilateral muscle, thinner and paler than the other constrictors, and situated at the upper part of the pharynx. It arises from the lower third of the posterior margin of the internal pterygoid plate and its hamular process, from the contiguous portion of the palate bone and the reflected tendon of the Tensor palati muscle, from the pterygo-maxillary ligament, from the alveolar process above the posterior extremity of the mylo-hyoid ridge, and by a few fibres from the side of the tongue. From these points the fibres curve backwards, to be inserted into the median raphé, being also prolonged by means of a fibrous aponeurosis to the pharyngeal spine on the basilar process of the occipital bone. The superior fibres arch beneath the Levator palati and the Eustachian tube, the interval between the upper border of the muscle and the basilar process being deficient in muscular fibres, and closed by fibrous membrane. This interval is known as the *sinus of Morgagni*.

Relations.—By its *outer surface*, with the vertebral column, the internal carotid artery, the internal jugular vein, the glosso-pharyngeal, pneumogastric, spinal accessory, hypoglossal, and sympathetic nerves, the Middle constrictor which overlaps it, and the Stylo-pharyngeus. By its *internal surface*, with the Palato-pharyngeus, the tonsil, the fibrous coat and mucous membrane of the pharynx.

The **Stylo-pharyngeus** is a long, slender muscle, round above, broad and thin below. It arises from the inner side of the base of the styloid process, passes downwards along the side of the pharynx between the Superior and Middle constrictors, and spreads out beneath the mucous membrane, where some of its fibres are lost in the Constrictor muscles; and others, joining with the Palato-pharyngeus, are inserted into the posterior border of the thyroid cartilage. The glosso-pharyngeal nerve runs on the outer side of this muscle, and crosses over it in passing forward to the tongue.

Relations.—*Externally*, with the Stylo-glossus muscle, the parotid gland, the external carotid artery, and the Middle constrictor. *Internally*, with the internal carotid, the internal jugular vein, the Superior constrictor, Palato-pharyngeus and mucous membrane.

Nerves.—The Constrictors are supplied by branches from the pharyngeal plexus, the Stylo-pharyngeus by the glosso-pharyngeal nerve, and the Inferior constrictor by additional branches from the external and recurrent laryngeal nerves.

Actions.—When deglutition is about to be performed, the pharynx is drawn upwards and dilated in different directions, to receive the morsel propelled into it from the mouth. The Stylo-pharyngei, which are much farther removed from one another at their origin than at their insertion, draw the sides of the pharynx upwards and outwards, and so increase its transverse diameter; its breadth in the antero-posterior direction being increased by the larynx and tongue being carried forwards in their ascent. As soon as the morsel is received in the pharynx, the Elevator muscles relax, the bag descends, and the Constrictors contract upon the morsel, and convey it gradually downwards into the œsophagus. Besides its action in deglutition, the pharynx also exerts an important influence in the modulation of the voice, especially in the production of the higher tones.

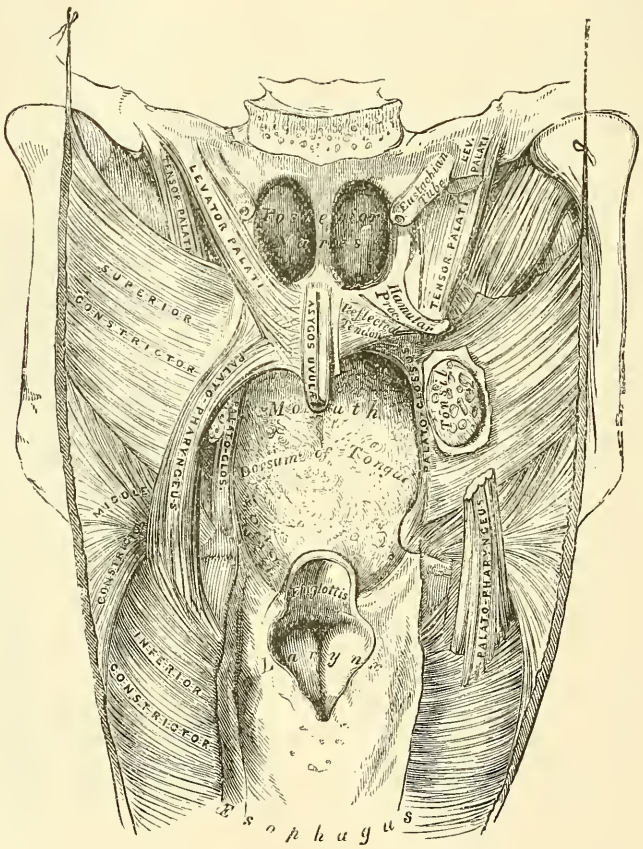
VI. Palatal Region

Levator palati.	Palato-glossus.
Tensor palati.	Palato-pharyngeus.
Azygos uvulæ.	Salpingo-pharyngeus.

Dissection (fig. 320).—Lay open the pharynx from behind, by a vertical incision extending from its upper to its lower part, and partially divide the occipital attachment by a transverse incision on each side of the vertical one; the posterior surface of the soft palate is then exposed. Having fixed the uvula so as to make it tense, the mucous membrane and glands should be carefully removed from the posterior surface of the soft palate and the muscles of this part are at once exposed.

The **Levator palati** is a long, thick, rounded muscle, placed on the outer side of the posterior nares. It arises from the under surface of the apex of the petrous

Fig. 320.—Muscles of the soft palate. The pharynx being laid open from behind.



portion of the temporal bone, and from the adjoining cartilaginous portion of the Eustachian tube; after passing into the pharynx, above the upper concave margin of the Superior constrictor, it passes obliquely downwards and inwards, its fibres spreading out in the soft palate as far as the middle line, where they blend with those of the opposite side.

Relations.—*Externally*, with the Tensor palati and Superior constrictor. *Internally*, with the mucous membrane of the pharynx. *Posteriorly*, with the posterior fasciculus of the Palato-pharyngeus, the Azygos uvulæ, and the mucous lining of the soft palate.

The **Circumflexus** or **Tensor palati** is a broad, thin, riband-like muscle, placed on the outer side of the Levator palati, and consisting of a vertical and a horizontal portion. The vertical portion arises by a broad, thin, and flat lamella from the scaphoid fossa at the base of the internal pterygoid plate; from the spine of the sphenoid: the vaginal process of the temporal bone and the outer side of the cartilaginous portion of the Eustachian tube: descending vertically between the internal pterygoid plate and the inner surface of the Internal pterygoid muscle, it terminates in a tendon, which winds round the hamular process, being retained in this situation by some of the fibres of origin of the Internal pterygoid muscle. Between the hamular process and the tendon is a small bursa. The tendon or horizontal portion then passes horizontally inwards, and is inserted into a broad aponeurosis, the *palatine aponeurosis*, and into the transverse ridge on the horizontal portion of the palate bone.

Relations.—*Externally*, with the Internal pterygoid. *Internally*, with the Levator palati, from which it is separated by the Superior constrictor, and with the internal pterygoid plate. In the soft palate, its tendon and the palatine aponeurosis is anterior to that of the Levator palati, being covered by the Palato-glossus and the mucous membrane.

Palatine Aponeurosis.—Attached to the posterior border of the hard palate is a thin, firm, fibrous lamella which supports the muscles and gives strength to the soft palate. It is thicker above than below, where it becomes very thin and difficult to define. Laterally, it is continuous with the pharyngeal aponeurosis.

The **Azygos uvulæ** is not a single muscle, as would be inferred from its name, but a pair of narrow cylindrical fleshy fasciculi, placed on either side of the median line of the soft palate. Each muscle arises from the posterior nasal spine of the palate bone, and from the contiguous tendinous aponeurosis of the soft palate, and descends to be inserted into the uvula.

Relations.—*Anteriorly*, with the tendinous expansion of the Levatores palati; *behind*, with the posterior fasciculus of the Palato-pharyngeus and the mucous membrane.

The two next muscles are exposed by removing the mucous membrane from the pillars of the soft palate throughout nearly their whole extent.

The **Palato-glossus** (**Constrictor isthmi faucium**) is a small fleshy fasciculus, narrower in the middle than at either extremity, forming, with the mucous membrane covering its surface, the anterior pillar of the soft palate. It arises from the anterior surface of the soft palate on each side of the uvula, and, passing downwards, forwards, and outwards in front of the tonsil, is inserted into the side of the tongue, some of its fibres spreading over the dorsum, and others passing deeply into the substance of the organ to intermingle with the Transversus linguæ. In the soft palate, the fibres of this muscle are continuous with those of the muscle of the opposite side.

The **Palato-pharyngeus** is a long, fleshy fasciculus, narrower in the middle than at either extremity, forming, with the mucous membrane covering its surface, the posterior pillar of the soft palate. It is separated from the Palato-glossus by an angular interval, in which the tonsil is lodged. It arises from the soft palate by an expanded fasciculus, which is divided into two parts by the Levator palati and Azygos uvulæ. The *posterior fasciculus* lies in contact with the mucous membrane, and joins with the corresponding muscle in the middle line; the *anterior fasciculus*, the thicker, lies in the soft palate between the Levator and Tensor, and joins in the middle line the corresponding part of the opposite muscle. Passing outwards and downwards behind the tonsil, the Palato-pharyngeus joins the Stylo-pharyngeus, and is inserted with that muscle into the posterior border of the thyroid cartilage, some of its fibres being lost on the side of the pharynx, and others passing across the middle line posteriorly, to decussate with the muscle of the opposite side.

Relations.—In the soft palate, its *posterior surface* is covered by mucous

membrane, from which it is separated by a layer of palatine glands. By its *anterior surface* it is in relation with the Tensor palati. Where it forms the posterior pillars of the fauces, it is covered by mucous membrane, excepting on its outer surface. In the *pharynx* it lies between the mucous membrane and the Constrictor muscles.

The Salpingo-pharyngeus.—This muscle arises from the inferior part of the Eustachian tube near its orifice; it passes downwards and blends with the posterior fasciculus of the Palato-pharyngeus.

In a dissection of the soft palate from its posterior or nasal surface to its anterior or oral surface, the muscles would be exposed in the following order: viz. the posterior fasciculus of the Palato-pharyngeus, covered over by the mucous membrane reflected from the floor of the nasal fossæ; the Azygos uvulæ; the Levator palati; the anterior fasciculus of the Palato-pharyngeus; the aponeurosis of the Tensor palati, and the Palato-glossus covered over by a reflection from the oral mucous membrane.

Nerves.—The Tensor palati is supplied by a branch from the otic ganglion; the remaining muscles of this group are in all probability supplied by the internal branch of the spinal accessory, whose fibres are distributed along with certain branches of the pneumogastric through the pharyngeal plexus.*

Actions.—During the *first stage* of deglutition, the morsel of food is driven back into the fauces by the pressure of the tongue against the hard palate: the base of the tongue being, at the same time, retracted, and the larynx raised with the pharynx, and carried forwards under it. During the *second stage*, the epiglottis is pressed over the superior aperture of the larynx, and the morsel glides past it; then the Palato-glossi muscles, the constrictors of the fauces, contract behind the food; the soft palate is slightly raised by the Levator palati, and made tense by the Tensor palati; and the Palato-pharyngei, by their contraction, pull the pharynx upwards over the morsel of food, and at the same time come nearly together, the uvula filling up the slight interval between them. By these means the food is prevented passing into the upper part of the pharynx or the posterior nares; at the same time, the latter muscles form an inclined plane, directed obliquely downwards and backwards, along the under surface of which the morsel descends into the lower part of the pharynx. The Salpingo-pharyngeus raises the upper and lateral part of the pharynx; i.e. that part which is above the point where the Stylo-pharyngeus is attached to the pharynx.

Surgical Anatomy.—The muscles of the soft palate should be carefully dissected, the relations they bear to the surrounding parts especially examined, and their action attentively studied upon the dead subject, as the surgeon is required to divide one or more of these muscles in the operation of staphyloraphy. Sir W. Fergusson was the first to show that in the congenital deficiency called *cleft palate*, the edges of the fissure are forcibly separated by the action of the Levatores palati and Palato-pharyngei muscles, producing very considerable impediment to the healing process after the performance of the operation for uniting their margins by adhesion; he, consequently, recommended the division of these muscles as one of the most important steps in the operation. This he effected by an incision made with a curved knife introduced behind the soft palate. The incision is to be half-way between the hamular process and Eustachian tube, and perpendicular to a line drawn between them. This incision perfectly accomplishes the division of the Levator palati. The Palato-pharyngeus may be divided by cutting across the posterior pillar of the soft palate, just below the tonsil, with a pair of blunt-pointed curved scissors; and the anterior pillar may be divided also. To divide the Levator palati, the plan recommended by Mr. Pollock is to be greatly preferred. The soft palate being put upon the stretch, a double-edged knife is passed through it just on the inner side of the hamular process, and above the line of the Levator palati. The handle being now alternately raised and depressed, a sweeping cut is made along the posterior surface of the soft palate, and the knife withdrawn, leaving only a small opening in the mucous membrane on the anterior surface. If this operation is performed on the dead body, and the parts afterwards dissected, the Levator palati will be found completely divided. In the present day, however, this division of the muscles, as part of the operation of staphyloraphy, is not so much insisted upon. All tension is prevented by making longitudinal incisions, on either side,

* *Journal of Anatomy and Physiology*, vol. xxiii. p. 523.

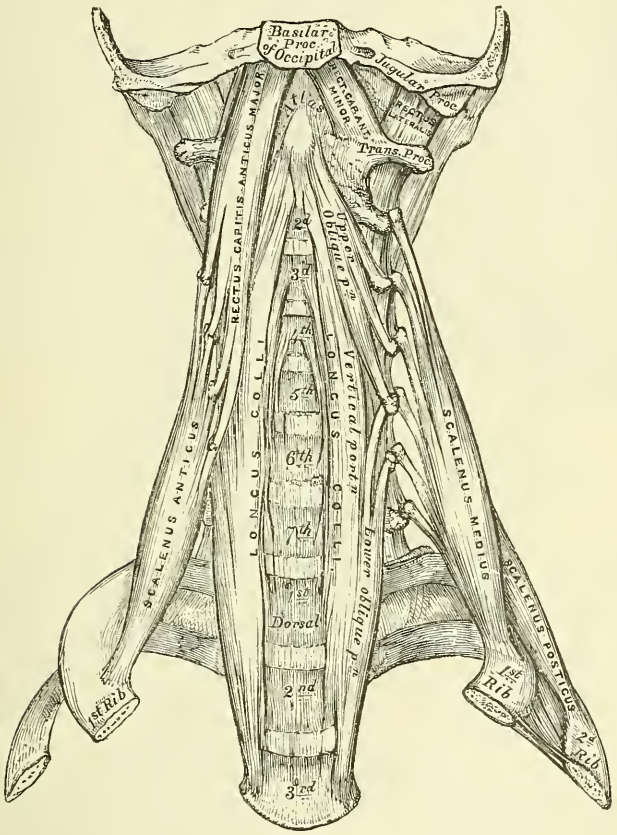
parallel to the cleft and just internal to the hamular process, in such a position as to avoid the posterior palatine artery.

VII. Anterior Vertebral Region

Rectus capitis anticus major.
Rectus capitis anticus minor.
Rectus capitis lateralis.
Longus colli.

The **Rectus capitis anticus major** (fig. 321), broad and thick above, narrow below, appears like a continuation upwards of the Scalenus anticus. It arises by four tendinous slips from the anterior tubercles of the transverse processes of

Fig. 321.—The prevertebral muscles.



the third, fourth, fifth, and sixth cervical vertebræ, and ascends, converging towards its fellow of the opposite side, to be inserted into the basilar process of the occipital bone.

Relations.—By its *anterior surface*, with the pharynx, the sympathetic nerve, and the sheath enclosing the internal and common carotid artery, internal jugular vein, and pneumogastric nerve. By its *posterior surface*, with the Longus colli, the Rectus capitis anticus minor, and the upper cervical vertebræ.

The **Rectus capitis anticus minor** is a short, flat muscle, situated immediately behind the upper part of the preceding. It arises from the anterior surface of the lateral mass of the atlas, and from the root of its transverse process, and passing obliquely upwards and inwards, is inserted into the basilar process immediately behind the preceding muscle.

Relations.—By its *anterior surface*, with the Rectus capitis anticus major. By its *posterior surface*, with the front of the occipito-atlantal articulation.

The **Rectus capitis lateralis** is a short, flat muscle, which arises from the upper surface of the transverse process of the atlas, and is inserted into the under surface of the jugular process of the occipital bone.

Relations.—By its *anterior surface*, with the internal jugular vein. By its *posterior surface*, with the vertebral artery. On its *outer side* lies the occipital artery; on its *inner side* the suboccipital nerve.

The **Longus colli** is a long, flat muscle, situated on the anterior surface of the spine, between the atlas and the third dorsal vertebra. It is broad in the middle, narrow and pointed at each extremity, and consists of three portions: a superior oblique, an inferior oblique, and a vertical portion. The *superior oblique portion* arises from the anterior tubercles of the transverse processes of the third, fourth, and fifth cervical vertebræ; and, ascending obliquely inwards, is inserted by a narrow tendon into the tubercle on the anterior arch of the atlas. The *inferior oblique portion*, the smallest part of the muscle, arises from the front of the bodies of the first two or three dorsal vertebræ; and ascending obliquely outwards, is inserted into the anterior tubercles of the transverse processes of the fifth and sixth cervical vertebræ. The *vertical portion* lies directly on the front of the spine; it arises, below, from the front of the bodies of the upper three dorsal and lower three cervical vertebræ, and is inserted above into the front of the bodies of the second, third, and fourth cervical vertebræ above.

Relations.—By its *anterior surface*, with the pharynx, the œsophagus, sympathetic nerve, the sheath of the great vessels of the neck, the inferior thyroid artery, and recurrent laryngeal nerve. By its *posterior surface*, with the cervical and dorsal portions of the spine. Its *inner border* is separated from the opposite muscle by a considerable interval below; but they approach each other above.

VIII. Lateral Vertebral Region

Scalenus anticus. Scalenus medius.
Scalenus posticus.

The **Scalenus anticus** is a conical-shaped muscle, situated deeply at the side of the neck, behind the Sterno-mastoid. It arises from the anterior tubercles of the transverse processes of the third, fourth, fifth, and sixth cervical vertebræ, and descending, almost vertically, is inserted by a narrow, flat tendon into the impression on the inner border and upper surface of the first rib. The lower part of this muscle separates the subclavian artery and vein: the latter being in front, and the former, with the brachial plexus, behind.

Relations.—*In front*, with the clavicle, the Subclavius, Sterno-mastoid, and Omo-hyoid muscles, the transversalis colli, the suprascapular and ascending cervical arteries, the subclavian vein, and the phrenic nerve. By its *posterior surface*, with the scalenus medius, pleura, the subclavian artery, and brachial plexus of nerves. It is separated from the Longus colli, on the inner side, by the vertebral artery. On the anterior tubercles of the transverse processes of the cervical vertebræ, between the attachments of the Scalenus anticus and Longus colli, lies the ascending cervical branch of the inferior thyroid artery.

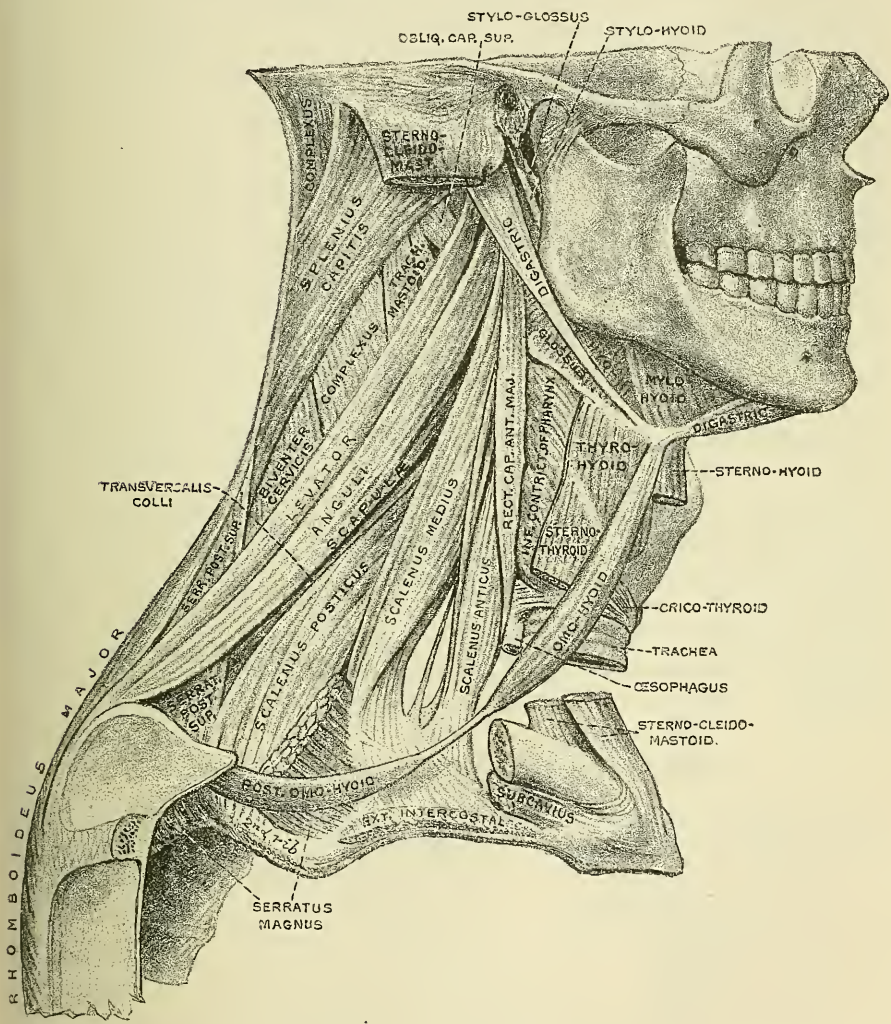
The **Scalenus medius**, the largest and longest of the three Scaleni, arises from the posterior tubercles of the transverse processes of the lower six cervical vertebræ, and descending along the side of the vertebral column is inserted by a broad attachment into the upper surface of the first rib, behind the groove for the subclavian artery, as far back as the tubercle. It is separated from the Scalenus anticus by the subclavian artery below and the cervical nerves above. The posterior thoracic, or nerve of Bell, is formed in the substance of the Scalenus medius and emerges from it.

Relations.—By its *anterior surface*, with the Sterno-mastoid; it is crossed by the clavicle, the Omo-hyoid muscle, subclavian artery, and the cervical nerves.

To its *outer side* is the Levator anguli scapulæ, and the Scalenus posticus muscle.

The **Scalenus posticus,** the smallest of the three scaleni, arises, by two or three separate tendons, from the posterior tubercles of the transverse processes of the lower two or three cervical vertebræ, and, diminishing as it descends, is inserted by a thin tendon into the outer surface of the second rib, behind the attachment of the Serratus magnus. This is the most deeply placed of the three Scaleni, and is occasionally blended with the Scalenus medius.

FIG. 322.—Muscles of the neck. (From a preparation in the Museum of the Royal College of Surgeons of England.)



Nerves.—The Rectus capitis anticus major and minor and the Rectus lateralis are supplied by the first cervical nerve, and from the loop formed between it and the second; the Longus colli and Scaleni, by branches from the anterior divisions of the lower cervical nerves (fifth, sixth, seventh, and eighth) before they form the brachial plexus. The Scalenus medius also receives a filament from the deep external branches of the cervical plexus.

Actions.—The Rectus anticus major and minor are the direct antagonists of the muscles at the back of the neck, serving to restore the head to its natural

position after it has been drawn backwards. These muscles also serve to flex the head, and from their obliquity, rotate it, so as to turn the face to one or the other side. The Longus colli flexes and slightly rotates the cervical portion of the spine. The Scaleni muscles, when they take their fixed point from above, elevate the first and second ribs, and are, therefore, inspiratory muscles. When they take their fixed point from below, they bend the spinal column to one or the other side. If the muscles of both sides act, lateral movement is prevented, but the spine is slightly flexed. The Rectus lateralis, acting on one side, bends the head laterally.

Surface Form.—The muscles in the neck, with the exception of the Platysma myoides, are invested by the deep cervical fascia, which softens down their form, and is of considerable importance in connection with deep cervical abscesses and tumours, modifying the direction of their growth and causing them to extend laterally instead of towards the surface. The *Platysma myoides* does not influence surface form except it is in action, when it produces wrinkling of the skin of the neck, which is thrown into oblique ridges parallel with the fasciculi of the muscle. Sometimes this contraction takes place suddenly and repeatedly, as a sort of spasmodic twitching, the result of a nervous habit. The *Sterno-cleido-mastoid* is the most important muscle of the neck as regards its surface form. If the muscle is put into action by drawing the chin downwards and to the opposite shoulder, its surface form will be plainly outlined. The sternal origin will stand out as a sharply defined ridge, while the clavicular origin will present a flatter and not so prominent an outline. The fleshy middle portion will appear as an oblique roll or elevation, with a thick rounded anterior border gradually becoming less marked above. On the opposite side, i.e. on the side to which the head is turned, the outline is lost, its place being occupied by an oblique groove in the integument. When the muscle is at rest its anterior border is still visible, forming an oblique rounded ridge, terminating below in the sharp outline of the sternal head. The posterior border of the muscle does not show above the clavicular head. The anterior border is defined by drawing a line from the tip of the mastoid process to the sterno-clavicular joint. It is an important surface-marking in the operation of ligature of the common carotid artery and some other operations. Between the sternal and clavicular heads is a slight depression, most marked when the muscle is in action. This is bounded below by the prominent sternal extremity of the clavicle. Between the sternal origins of the two muscles is a V-shaped space, the *suprasternal notch*, more pronounced below, and becoming toned down above, where the Sterno-hyoid and Sterno-thyroid muscles, lying upon the trachea, become more prominent. Above the hyoid bone, in the middle line, the anterior belly of the *Digastric* to a certain extent influences surface form. It corresponds to a line drawn from the symphysis of the lower jaw to the side of the body of the hyoid bone, and renders this part of the hyo-mental region convex. In the posterior triangle of the neck, the posterior belly of the *Omo-hyoid*, when in action, forms a conspicuous object, especially in thin necks, presenting a cord-like form running across this region, almost parallel with, and a little above, the clavicle.

MUSCLES AND FASCIÆ OF THE TRUNK

The muscles of the Trunk may be arranged in four groups, corresponding with the region in which they are situated.

I. The Back
II. The Thorax
III. The Abdomen
IV. The Perinæum

I. Muscles of the Back

The muscles of the back are very numerous, and may be subdivided into five layers.

First Layer

Trapezius.
Latissimus dorsi

Second Layer

Levator anguli scapulæ.
Rhomboideus minor.
Rhomboideus major.

Third Layer

Serratus posticus superior.
Serratus posticus inferior.
Splenius capitis.
Splenius colli.

Fourth Layer

Sacral and Lumbar Regions

Erector spinæ.

Dorsal Region

Ilio-costalis.
Musculus accessorius ad ilio-costalem.
Longissimus dorsi.
Spinalis dorsi.

Cervical Region

Cervicalis ascendens.
Transversalis colli.
Trachelo-mastoid.
Complexus.
Biventer cervicis.
Spinalis colli.

Fifth Layer

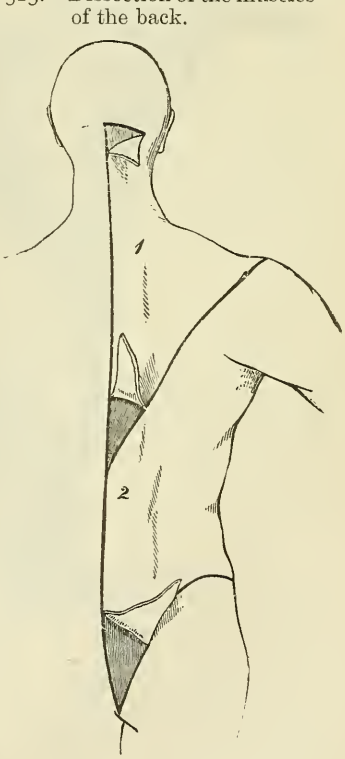
Semispinalis dorsi.
Semispinalis colli.
Multifidus spinæ.
Rotatores spinæ.
Supraspinales.
Interspinales.
Extensor coccygis.
Intertransversales.
Rectus capitis posticus major.
Rectus capitis posticus minor.
Obliquus capitis superior.
Obliquus capitis inferior.

First Layer

Trapezius. Latissimus dorsi.

Dissection (fig. 323).—Place the body in the prone position, with the arms extended over the sides of the table, and the chest and abdomen supported by several blocks, so as to render the muscles tense. Then make an incision along the middle line of the back from the occipital protuberance to the coccyx. Make a transverse incision from the upper end of this to the mastoid process; and a third incision from its lower end, along the crest of the ilium to about its middle. This large intervening space should, for convenience of dissection, be subdivided by a fourth incision, extending obliquely from the spinous process of the last dorsal vertebra, upwards and outwards, to the acromion process. This incision corresponds with the lower border of the Trapezius muscle. The flaps of integument are then to be removed in the direction shown in the figure.

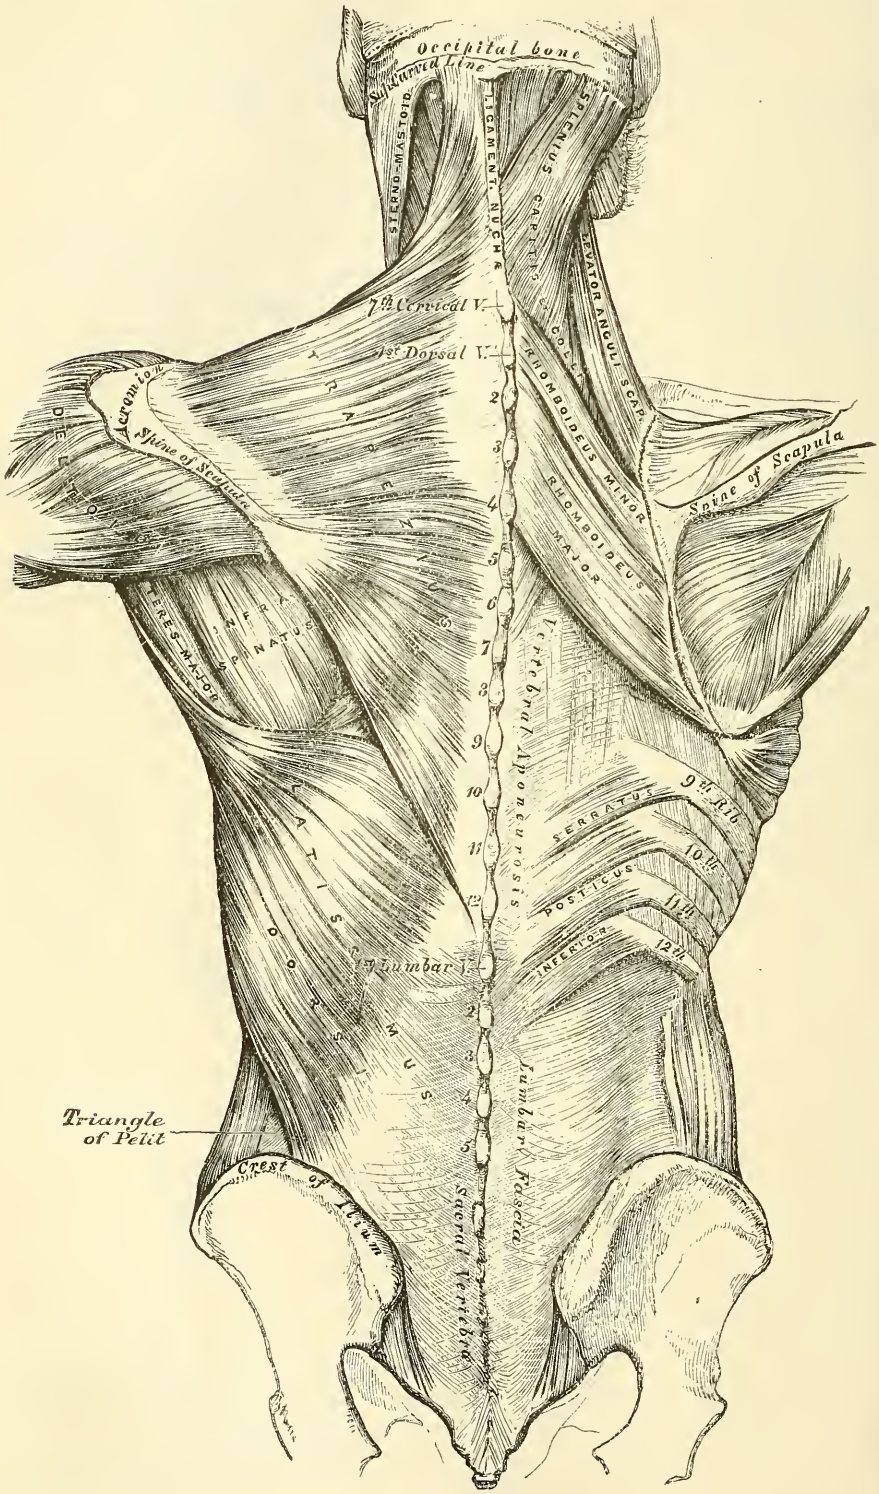
Fig. 323.—Dissection of the muscles of the back.



The **superficial fascia** is exposed upon removing the skin from the back. It forms a layer of considerable thickness and strength, in which a quantity of granular pinkish fat is contained. It is continuous with the superficial fascia in other parts of the body. The **deep fascia** is a dense fibrous layer, attached to the occipital bone, the spines of the vertebræ, the crest of the ilium, and the spine of the scapula. It covers over the superficial muscles, forming sheaths for them, and in the neck forms the posterior part of the deep cervical fascia; in the thorax it is continuous with the deep fascia of the axilla and chest, and in the abdomen with that covering the abdominal muscles.

The **Trapezius** (fig. 324) is a broad, flat, triangular muscle, placed immediately beneath the skin and fascia, and covering the upper and back part of the neck and shoulders. It arises from the external occipital protuberance and the inner third of the superior curved line of the occipital bone; from the ligamentum nuchæ, the spinous process of the seventh cervical, and those of all the dorsal vertebræ; and from the corresponding portion of the supraspinous ligament.

FIG. 324.—Muscles of the back. On the left side is exposed the first layer; on the right side, the second layer and part of the third.



From this origin, the superior fibres proceed downwards and outwards, the inferior ones upwards and outwards; and the middle fibres, horizontally; and are inserted, the superior ones into the outer third of the posterior border of the clavicle; the middle fibres into the inner margin of the acromion process, and into the superior lip of the posterior border or crest of the spine of the scapula; the inferior fibres converge near the scapula, and terminate in a triangular aponeurosis, which glides over a smooth surface at the inner extremity of the spine, to be inserted into a tubercle at the outer part of this smooth surface. The Trapezius is fleshy in the greater part of its extent, but tendinous at its origin and insertion. At its occipital origin, it is connected to the bone by a thin fibrous lamina, firmly adherent to the skin, and wanting the lustrous, shining appearance of aponeuroses. At its origin from the spines of the vertebræ, it is connected to the bones by means of a broad semi-elliptical aponeurosis, which occupies the space between the sixth cervical and the third dorsal vertebræ, and forms, with the aponeurosis of the opposite muscle, a tendinous ellipse. The rest of the muscle arises by numerous short tendinous fibres. If the Trapezius is dissected on both sides, the two muscles resemble a trapezium, or diamond-shaped quadrangle: two angles corresponding to the shoulders; a third to the occipital protuberance; and the fourth to the spinous process of the last dorsal vertebra.

The clavicular insertion of this muscle varies as to the extent of its attachment: it sometimes advances as far as the middle of the clavicle, and may even become blended with the posterior edge of the Sterno-mastoid, or overlap it. This should be borne in mind in the operation for tying the third part of the subclavian artery.

Relations.—By its *superficial surface*, with the integument. By its *deep surface*, in the neck, with the Complexus, Splenius, Levator anguli scapulæ, and Rhomboideus minor; in the back, with the Rhomboideus major, Supraspinatus, Infraspinatus, the Vertebral aponeurosis (which separates it from the prolongations of the Erector spinæ), and the Latissimus dorsi. The spinal accessory nerve and the superficial cervical artery pass beneath the anterior border of this muscle, near the clavicle. The anterior margin of its cervical portion forms the posterior boundary of the posterior triangle of the neck, the other boundaries being the Sterno-mastoid in front, and the clavicle below.

The **Ligamentum nuchæ** (fig. 324) is a thin band of condensed cellulo-fibrous membrane, placed in the line of union between the two Trapezii in the neck. It extends from the external occipital protuberance to the spinous process of the seventh cervical vertebra, where it is continuous with the supraspinous ligament. From its anterior surface a fibrous lamina is given off, which is attached to the spinous process of each of the cervical vertebræ, excepting the atlas, so as to form a septum between the muscles on each side of the neck. In man it is merely the rudiment of an important elastic ligament, which, in some of the lower animals, serves to sustain the weight of the head.

The **Latissimus dorsi** is a broad flat muscle, which covers the lumbar and the lower half of the dorsal regions, and is gradually contracted into a narrow fasciculus at its insertion into the humerus. It arises by tendinous fibres from the spinous processes of the six inferior dorsal and from the posterior layer of the lumbar fascia (see page 432), by which it is attached to the spines of the lumbar and sacral vertebræ, and to the supraspinous ligament. It also arises from the external lip of the crest of the ilium, behind the origin of the External oblique, and by fleshy digitations from the three or four lower ribs, which are interposed between similar processes of the External oblique muscle (fig. 329, page 448). From this extensive origin the fibres pass in different directions, the upper ones horizontally, the middle obliquely upwards, and the lower vertically upwards, so as to converge and form a thick fasciculus, which crosses the inferior angle of the scapula, and occasionally receives a few fibres from it. The muscle then curves around the lower border of the Teres major, and is twisted upon

itself, so that the superior fibres become at first posterior and then inferior, and the vertical fibres at first anterior and then superior. It then terminates in a short quadrilateral tendon, about three inches in length, which, passing in front of the tendon of the Teres major, is inserted into the bottom of the bicipital groove of the humerus; its insertion extending higher on the humerus than that of the tendon of the Pectoralis major. The lower border of the tendon of this muscle is united with that of the Teres major, the surfaces of the two being separated by a bursa; another bursa is sometimes interposed between the muscle and the inferior angle of the scapula. This muscle at its insertion gives off an expansion to the deep fascia of the arm.

A muscular slip, varying from 3 to 4 inches in length, and from $\frac{1}{4}$ to $\frac{3}{4}$ of an inch in breadth, occasionally arises from the upper edge of the Latissimus dorsi about the middle of the posterior fold of the axilla, and crosses the axilla in front of the axillary vessels and nerves, to join the under surface of the tendon of the Pectoralis major, the Coraco-brachialis, or the fascia over the Biceps. The position of this abnormal slip is a point of interest in its relation to the axillary artery, as it crosses the vessel just above the spot usually selected for the application of a ligature, and may mislead the surgeon during the operation. It may be easily recognised by the transverse direction of its fibres. Dr. Struther found it, in 8 out of 105 subjects, occurring seven times on both sides.

Relations.—Its *superficial surface* is subcutaneous, excepting at its upper part, where it is covered by the Trapezius, and at its insertion, where its tendon is crossed by the axillary vessels and the brachial plexus of nerves. By its *deep surface*, it is in relation with the Lumbar fascia, the Serratus posticus inferior, the lower external intercostal muscles and ribs, inferior angle of the scapula, Rhomboideus major, Infraspinatus, and Teres major. Its outer margin is separated below from the External oblique by a small triangular interval; and another triangular interval exists between its upper border and the margin of the Trapezius, in which the Rhomboideus major muscle is exposed.

Nerves.—The Trapezius is supplied by the spinal accessory, and by branches from the anterior divisions of the third and fourth cervical nerves; the Latissimus dorsi by the middle or long subscapular nerve.

Second Layer

Levator anguli scapulæ. Rhomboideus minor.
Rhomboideus major.

Dissection.—The Trapezius must be removed, in order to expose the next layer; to effect this, detach the muscle from its attachment to the clavicle and spine of the scapula, and turn it back towards the spine.

The **Levator anguli scapulæ** is situated at the back part and side of the neck. It arises by tendinous slips from the posterior tubercles of the transverse processes of the four upper cervical vertebræ; these, becoming fleshy, are united so as to form a flat muscle, which, passing downwards and backwards, is inserted into the posterior border of the scapula, between the superior angle and the triangular smooth surface at the root of the spine.

Relations.—By its *superficial surface*, with the integument, Trapezius, and Sterno-mastoid. By its *deep surface*, with the Splenius colli, Transversalis colli, Cervicalis ascendens, and Serratus posticus superior muscles, and with the transversalis colli and posterior scapular arteries.

The **Rhomboideus minor** arises from the ligamentum nuchæ and spinous processes of the seventh cervical and first dorsal vertebræ. Passing downwards and outwards, it is inserted into the margin of the triangular smooth surface at the root of the spine of the scapula. This small muscle is usually separated from the Rhomboideus major by a slight cellular interval.

Relations.—By its *superficial* (*posterior*) *surface*, with the Trapezius. By its *deep surface*, with the same structures as the Rhomboideus major.

The **Rhomboideus major** is situated immediately below the preceding, the adjacent margins of the two being occasionally united. It arises by tendinous fibres from the spinous processes of the four or five upper dorsal vertebræ and the supraspinous ligament, and is inserted into a narrow tendinous arch, attached above to the lower part of the triangular surface at the root of the spine; below, to the inferior angle, the arch being connected to the border of the scapula by a thin membrane. When the arch extends, as it occasionally does, but a short distance, the muscular fibres are inserted into the scapula itself.

Relations.—By its *superficial* (*posterior*) *surface*, with the Latissimus dorsi. By its *deep* (*anterior*) *surface*, with the Serratus posticus superior, posterior scapular artery, the vertebral aponeurosis which separates it from the prolongations from the Erector spinæ, the Intercostal muscles, and ribs.

Nerves.—The Rhomboid muscles are supplied by branches from the anterior division of the fifth cervical nerve; the Levator anguli scapulæ by the anterior division of the third and fourth cervical nerves.

Actions.—The movements effected by the preceding muscles are numerous, as may be conceived from their extensive attachment. The whole of the *Trapezius* when in action retracts the scapula and rotates it on a sagittal axis; if the head is fixed, the upper part of the Trapezius will elevate the point of the shoulder, as in supporting weights; when the lower fibres are brought into action they assist in depressing the bone. If the scapula is prevented from gliding on the chest, the middle and lower fibres of the muscle cause it to rotate, so that the acromion is raised. If the shoulders are fixed, both Trapezii, acting together, will draw the head directly backwards; or if only one acts, the head is drawn to the corresponding side.

The *Latissimus dorsi*, when it acts upon the humerus, draws it backwards, adducts, and at the same time rotates it inwards. It is the muscle which is principally employed in giving a downward blow, as in felling a tree or in sabre practice. If the arm is fixed, the muscle may act in various ways upon the trunk: thus, it may raise the lower ribs and assist in forcible inspiration; or, if both arms are fixed, the two muscles may assist the Abdominal and great Pectoral muscles in suspending and drawing the whole trunk forwards, as in climbing or walking on crutches.

The *Levator anguli scapulæ* raises the superior angle of the scapula, assisting the Trapezius in bearing weights or in shrugging the shoulders. If the shoulder be fixed, the Levator anguli scapulæ inclines the neck to the corresponding side and rotates it in the same direction. The Rhomboid muscles carry the inferior angle backwards and upwards, thus producing a slight rotation of the scapula upon the side of the chest, the Rhomboideus major acting especially on the lower angle of the scapula, through the tendinous arch by which it is inserted. The Rhomboid muscles acting together with the middle and inferior fibres of the Trapezius will draw the scapula directly backwards towards the spine.

Third Layer

Serratus posticus superior. Serratus posticus inferior.

Splenius { Splenius capitis. / Splenius colli.

Dissection.—To bring into view the third layer of muscles, remove the whole of the second, together with the Latissimus dorsi; by cutting through the Levator anguli scapulæ and Rhomboid muscles near their insertion, and reflecting them upwards, and by dividing the Latissimus dorsi in the middle by a vertical incision carried from its upper to its lower part, and reflecting the two halves of the muscle.

The **Serratus posticus superior** is a thin, flat, quadrilateral muscle, situated at the upper and back part of the thorax. It arises by a thin and broad aponeurosis from the ligamentum nuchæ, and from the spinous processes of the last cervical and two or three upper dorsal vertebræ and from the supraspinous ligament.

Inclining downwards and outwards, it becomes muscular, and is inserted, by four fleshy digitations, into the upper borders of the second, third, fourth, and fifth ribs, a little beyond their angles.

Relations.—By its *superficial surface*, with the Trapezius, Rhomboidei, and Levator anguli scapulæ. By its *deep surface*, with the Splenius, and the vertebral aponeurosis, which separates it from the prolongations of the Erector spinæ, and with the Intercostal muscles and ribs.

The **Serratus posticus inferior** is situated at the junction of the dorsal and lumbar regions: it is of an irregularly quadrilateral form, broader than the preceding, and separated from it by a considerable interval. It arises by a thin aponeurosis from the spinous processes of the last two dorsal and two or three upper lumbar vertebræ, and from the supraspinous ligaments. Passing obliquely upwards and outwards, it becomes fleshy, and divides into four flat digitations, which are inserted into the lower borders of the four lower ribs, a little beyond their angles. The thin aponeurosis of origin is intimately blended with the lumbar fascia.

Relations.—By its *superficial surface*, with the Latissimus dorsi. By its *deep surface*, with the Erector spinæ, ribs, and Intercostal muscles. Its upper margin is continuous with the vertebral aponeurosis.

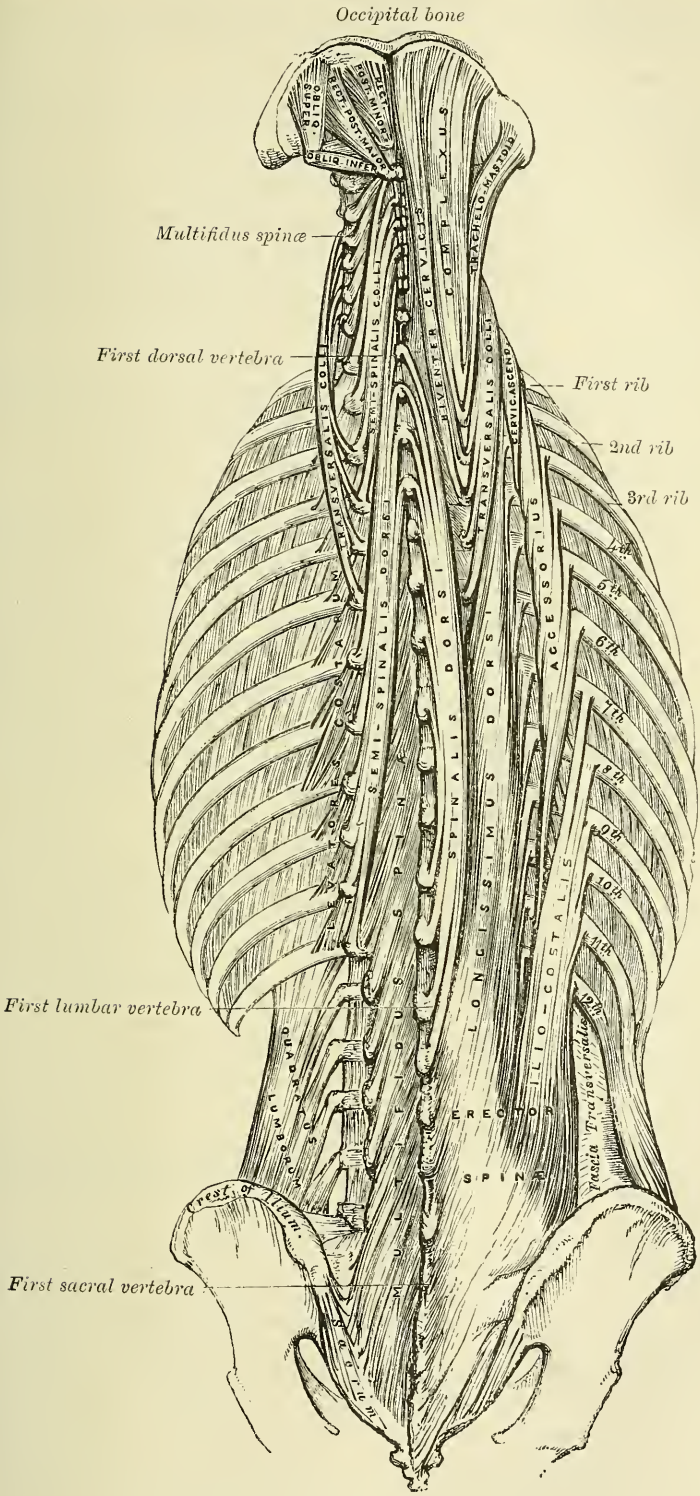
The *Vertebral aponeurosis* is a thin, fibrous lamina, extending along the whole length of the back part of the thoracic region, serving to bind down the long extensor muscles of the back which support the spine and head, and separate them from those muscles which connect the spine to the upper extremity. It consists of longitudinal and transverse fibres blended together, forming a thin lamella, which is attached in the median line to the spinous processes of the dorsal vertebræ; externally, to the angles of the ribs; and below, to the upper border of the Serratus posticus inferior and portion of the lumbar fascia, which gives origin to the Latissimus dorsi; above, it passes beneath the Serratus posticus superior and the Splenius, and blends with the deep fascia of the neck.

The *Lumbar fascia* (fig. 324) is a thick and strong lamella occupying the interval between the last rib and the crest of the ilium. It is attached internally to the spinous processes of the lumbar and sacral vertebræ; above, to the last rib, and to the cartilage of the eleventh rib; below, to the posterior third of the crest of the ilium. Externally, it blends with the Transversalis abdominis muscle. The posterior or superficial surface of this fascia gives attachment to part of the origin of the Latissimus dorsi, to the Serratus posticus inferior, and to the Internal oblique muscle of the abdomen. The anterior or deep surface gives off two layers: one lies between the Erector spinæ and Quadratus lumborum, and is attached to the tips of the transverse processes of the lumbar vertebræ; the other lies on the anterior or internal surface of the Quadratus lumborum, and is attached to the front part of the same transverse processes. The upper portion of this layer, which extends from the transverse process of the first lumbar vertebra to the apex and lower border of the last rib, constitutes the ligamentum arcuatum externum. Therefore these three layers of the lumbar fascia form two spaces: between the posterior and middle layer is situated the Erector spinæ and the Multifidus spinæ; between the middle and anterior layers is situated the Quadratus lumborum.

Now detach the Serratus posticus superior from its origin, and turn it outwards, when the Splenius muscle will be brought into view.

The **Splenius** is situated at the back of the neck and upper part of the dorsal region. At its origin, it is a single muscle, narrow, and pointed in form; but it soon becomes broader, and divides into two portions, which have separate insertions. It arises, by tendinous fibres, from the lower half of the ligamentum nuchæ, from the spinous processes of the last cervical and of the six upper dorsal vertebræ, and from the supraspinous ligament. From this origin, the fleshy fibres proceed obliquely upwards and outwards forming a broad flat muscle,

Fig. 325.—Muscles of the back. Deep layers



which divides as it ascends into two portions, the Splenius capitis and Splenius colli.

The **Splenius capitis** is inserted into the mastoid process of the temporal bone, and into the rough surface on the occipital bone just beneath the superior curved line.

The **Splenius colli** is inserted, by tendinous fasciculi, into the posterior tubercles of the transverse processes of the two or three upper cervical vertebræ.

The Splenius is separated from its fellow of the opposite side by a triangular interval, in which is seen the Complexus.

Relations.—By its *superficial surface*, with the Trapezius, from which it is separated below by the Rhomboidei and the Serratus posticus superior. It is covered at its insertion by the Sterno-mastoid, and at the lower and back part of the neck by the Levator anguli scapulæ. By its *deep surface*, with the Spinalis dorsi, Longissimus dorsi, Semispinalis colli, Complexus, Trachelo-mastoid, and Transversalis colli.

Nerves.—The Splenius is supplied from the external branches of the posterior divisions of the cervical nerves; the Serratus posticus superior is supplied by the external branches of the posterior divisions of the upper dorsal nerves; the Serratus posticus inferior by the external branches of the posterior divisions of the lower dorsal nerves.

Actions.—The Serrati are respiratory muscles. The Serratus posticus superior elevates the ribs; it is therefore an inspiratory muscle; while the Serratus inferior draws the lower ribs downwards and backwards, and thus elongates the thorax. It also fixes the lower ribs, thus aiding the downward action of the diaphragm and resisting the tendency which it has to draw the lower ribs upwards and forwards. It must therefore be regarded as a muscle of inspiration. This muscle is also probably a tensor of the vertebral aponeurosis. The Splenii muscles of the two sides, acting together, draw the head directly backwards, assisting the Trapezius and Complexus; acting separately, they draw the head to one or the other side, and slightly rotate it, turning the face to the same side. They also assist in supporting the head in the erect position.

Fourth Layer

Sacral and Lumbar Regions	*Cervical Region*
Erector spinæ.	Cervicalis ascendens.
Dorsal Region	Transversalis colli.
Ilio-costalis.	Trachelo-mastoid.
Musculus accessorius ad ilio-costalem.	Complexus.
Longissimus dorsi.	Biventer cervicis.
Spinalis dorsi.	Spinalis colli.

Dissection.—To expose the muscles of the fourth layer, remove entirely the Serrati and the vertebral and lumbar fasciæ. Then detach the Splenius by separating its attachment to the spinous processes and reflecting it outwards.

The **Erector spinæ** (fig. 325), and its prolongations in the dorsal and cervical regions, fill up the vertebral groove on each side of the spine. It is covered in the lumbar region by the lumbar fascia; in the dorsal region by the Serrati muscles and the vertebral aponeurosis; and in the cervical region by a layer of cervical fascia continued beneath the Trapezius and the Splenius. This large muscular and tendinous mass varies in size and structure at different parts of the spine. In the sacral region, the Erector spinæ is narrow and pointed, and its origin chiefly tendinous in structure. In the lumbar region, the muscle becomes enlarged, and forms a large fleshy mass. In the dorsal region, it subdivides into two parts, which gradually diminish in size as they ascend to be inserted into the vertebræ and ribs. In the cervical region, it divides into a number

of small muscles which are continued upwards to the head and support it upon the spine.

The Erector spinæ arises from the sacro-iliac groove, and from the anterior surface of a very broad and thick tendon, which is attached, internally, to the spines of the sacrum, to the spinous processes of the lumbar and the eleventh and twelfth dorsal vertebræ, and the supraspinous ligament; externally, to the back part of the inner lip of the crest of the ilium, and to the series of eminences on the posterior part of the sacrum, which represent the transverse processes, where it blends with the great sacro-sciatic and posterior sacro-iliac ligaments. Some of its fibres are continuous with the fibres of origin of the Gluteus maximus. The muscular fibres form a single large fleshy mass, bounded in front by the transverse processes of the lumbar vertebræ, and by the middle lamella of the lumbar fascia. Opposite the last rib it divides into two parts, the Ilio-costalis and the Longissimus dorsi.

The **Ilio-costalis** (*Sacro-lumbalis*), the external and smaller portion of the Erector spinæ, is inserted, generally, by six or seven flattened tendons, into the angles of the six or seven lower ribs. The number of the tendons of this muscle is, however, very variable, and therefore the number of ribs into which it is inserted. Frequently it is found to possess nine or ten tendons, and sometimes as many tendons as there are ribs, and is then inserted into the angles of all the ribs. If this muscle is reflected outwards, it will be seen to be reinforced by a series of muscular slips, which arise from the angles of the ribs; by means of these the Ilio-costalis is continued upwards to the upper ribs, and the cervical portion of the spine. The accessory portions form two additional muscles, the Musculus accessorius and the Cervicalis ascendens.

The **Musculus accessorius ad ilio-costalem** arises, by separate flattened tendons, from the angles of the six lower ribs: these become muscular, and are finally inserted, by separate tendons, into the angles of the six upper ribs and into the back of the transverse process of the seventh cervical vertebra.

The **Cervicalis ascendens** * is the continuation of the Accessorius upwards into the neck; it is situated on the inner side of the tendons of the Accessorius, arising from the angles of the four or five upper ribs, and is inserted by a series of slender tendons into the posterior tubercles of the transverse processes of the fourth, fifth, and sixth cervical vertebræ.

The **Longissimus dorsi** is the inner and larger portion of the Erector spinæ. In the lumbar region, where it is as yet blended with the Ilio-costalis, some of the fibres are attached to the whole length of the posterior surface of the transverse processes and the accessory processes of the lumbar vertebræ, and to the middle layer of the lumbar fascia. In the dorsal region, the Longissimus dorsi is inserted, by long thin tendons, into the tips of the transverse processes of all the dorsal vertebræ, and into from seven to eleven of the lower ribs between their tubercles and angles. This muscle is continued upwards, to the cranium and cervical portion of the spine, by means of two additional muscles, the Transversalis colli and Trachelo-mastoid.

The **Transversalis colli** (or **cervicis**), placed on the inner side of the Longissimus dorsi, arises by long thin tendons from the summits of the transverse processes of the six upper dorsal vertebræ, and is inserted by similar tendons into the posterior tubercles of the transverse processes of the cervical vertebræ from the second to the sixth inclusive.

The **Trachelo-mastoid** lies on the inner side of the preceding, between it and the Complexus muscle. It arises, by four tendons, from the transverse processes of the five or six upper dorsal vertebræ, and by additional separate tendons from the articular processes of the three or four lower cervical. The fibres form a small muscle, which ascends to be inserted into the posterior margin of the

* This muscle is sometimes called 'Cervicalis descendens.' The student should remember that these long muscles take their fixed point from above or from below, according to circumstances.

mastoid process, beneath the Splenius and Sterno-mastoid muscles. This small muscle is almost always crossed by a tendinous intersection near its insertion into the mastoid process.*

Relations.—The Erector spinæ and its prolongations are bound down to the vertebræ and ribs in the lumbar and dorsal regions by the lumbar fascia and the vertebral aponeurosis. The inner part of these muscles covers the muscles of the fifth layer. In the neck, they are in relation, by their *superficial surface*, with the Trapezius and Splenius; by their *deep surface*, with the Semispinalis dorsi et colli, and the Recti and Obliqui.

The **Spinalis dorsi** connects the spinous processes of the upper lumbar and the dorsal vertebræ together by a series of muscular and tendinous slips, which are intimately blended with the Longissimus dorsi. It is situated at the inner side of the Longissimus dorsi, arising, by three or four tendons, from the spinous processes of the first two lumbar and the last two dorsal vertebræ: these, uniting, form a small muscle, which is inserted, by separate tendons, into the spinous processes of the dorsal vertebræ, the number varying from four to eight. It is intimately united with the Semispinalis dorsi, which lies beneath it.

The **Spinalis colli** is a small muscle, connecting together the spinous processes of the cervical vertebræ, and analogous to the Spinalis dorsi in the dorsal region. It varies considerably in its size, and in its extent of attachment to the vertebræ, not only in different bodies, but on the two sides of the same body. It usually arises by fleshy or tendinous slips, varying from two to four in number, from the spinous processes of the fifth, sixth, and seventh cervical vertebræ, and occasionally from the first and second dorsal, and is inserted into the spinous process of the axis, and occasionally into the spinous processes of the two vertebræ below it. This muscle was found absent in five cases out of twenty-four.

The **Complexus** is a broad thick muscle, situated at the upper and back part of the neck, beneath the Splenius, and internal to the Transversalis colli and Trachelo-mastoid. It arises, by a series of tendons, about seven in number, from the tips of the transverse processes of the upper three dorsal and seventh cervical vertebræ, and from the articular processes of the three cervical above this. The tendons, uniting, form a broad muscle, which passes obliquely upwards and inwards, and is inserted into the innermost depression between the two curved lines of the occipital bone. This muscle, about its middle, is traversed by a transverse tendinous intersection.

The **Biventer cervicis** is a small fasciculus, situated on the inner side of the preceding, and in the majority of cases blended with it; it has received its name from having a tendon intervening between two fleshy bellies. It is sometimes described as a part of the Complexus. It arises by from two to four tendinous slips, from the transverse processes of as many of the upper dorsal vertebræ, and is inserted, on the inner side of the Complexus, into the superior curved line of the occipital bone.

Relations.—The Complexus is covered by the Splenius and the Trapezius. It lies on the Rectus capitis posticus major and minor, the Obliquus capitis superior and inferior, and on the Semispinalis colli, from which it is separated by the profunda cervicis artery, the princeps cervicis artery, and branches of the posterior cervical plexus of nerves. The Biventer cervicis is separated from its fellow of the opposite side by the ligamentum nuchæ.

Nerves.—The Erector spinæ and its subdivisions in the dorsal region are supplied by the external branches of the posterior divisions of the lumbar and dorsal nerves; while its subdivisions in the cervical region, the Transversalis colli and Trachelo-mastoid, are supplied by the external branches of the posterior divisions of the cervical nerves; the Complexus, by the internal branches of the

* These two muscles (Transversalis colli and Trachelo-mastoid) are sometimes described as one, having a common origin, but dividing above at their insertion. The Trachelo-mastoid is then termed the *Transversalis capitis*.

posterior divisions of the cervical nerves, the suboccipital and great occipital. The Spinalis colli is supplied by the internal branches of the posterior divisions of the cervical nerves; and the Spinalis dorsi by the internal branches of the posterior divisions of the dorsal nerves.

Fifth Layer

Semispinalis dorsi.	Extensor coccygis.
Semispinalis colli.	Intertransversales.
Multifidus spinæ.	Rectus capitis posticus major.
Rotatores spinæ.	Rectus capitis posticus minor.
Supraspinales.	Obliquus capitis superior.
Interspinales.	Obliquus capitis inferior.

Dissection.—Remove the muscles of the preceding layer by dividing and turning aside the Complexus; then detach the Spinalis and Longissimus dorsi from their attachments, divide the Erector spinæ at its connection below to the sacral and lumbar spines, and turn it outwards. The muscles filling up the interval between the spinous and transverse processes are then exposed.

The **Semispinalis dorsi** (fig. 325) consists of thin, narrow, fleshy fasciculi, interposed between tendons of considerable length. It arises by a series of small tendons from the transverse processes of the lower dorsal vertebræ, from the tenth or eleventh to the fifth or sixth; and is inserted, by five or six tendons, into the spinous processes of the upper four dorsal and lower two cervical vertebræ.

The **Semispinalis colli**, thicker than the preceding, arises by a series of tendinous and fleshy fibres from the transverse processes of the upper four dorsal vertebræ and from the articular processes of the lower four cervical vertebræ; and is inserted into the spinous processes of four cervical vertebræ, from the axis to the fifth cervical. The fasciculus connected with the axis is the largest, and chiefly muscular in structure.

Relations.—By their *superficial surface*, from below upwards, with the Spinalis dorsi, Longissimus dorsi, Splenius, Complexus, the profunda cervicis artery, the princeps cervicis artery, and the internal branches of the posterior divisions of the first, second, and third cervical nerves. By their *deep surface*, with the Multifidus spinæ.

The **Multifidus spinæ** consists of a number of fleshy and tendinous fasciculi, which fill up the groove on either side of the spinous processes of the vertebræ, from the sacrum to the axis. In the sacral region, these fasciculi arise from the back of the sacrum, as low as the fourth sacral foramen, and from the aponeurosis of origin of the Erector spinæ; in the iliac region, from the inner surface of the posterior superior spine of the ilium, and posterior sacro-iliac ligaments; in the lumbar regions, from the articular processes; in the dorsal region, from the transverse processes; and in the cervical region, from the articular processes. Each fasciculus, passing obliquely upwards and inwards, is inserted into the amina and whole length of the spinous process of one of the vertebræ above. These fasciculi vary in length: the most superficial, the longest, pass from one vertebra to the third or fourth above; those next in order pass from one vertebra to the second or third above; whilst the deepest connect two contiguous vertebræ.

Relations.—By its *superficial surface*, with the Longissimus dorsi, Spinalis dorsi, Semispinalis dorsi, and Semispinalis colli. By its *deep surface*, with the laminæ and spinous processes of the vertebræ, and with the Rotatores spinæ in the dorsal region.

The **Rotatores spinæ** are found only in the dorsal region of the spine, beneath the Multifidus spinæ; they are eleven in number on each side. Each muscle is small and somewhat quadrilateral in form; it arises from the upper and back part of the transverse process, and is inserted into the lower border and outer

surface of the lamina of the vertebra above, the fibres extending as far inwards as the root of the spinous process. The first is found between the first and second dorsal; the last, between the eleventh and twelfth. Sometimes the number of these muscles is diminished by the absence of one or more from the upper or lower end.

The **Supraspinales** consist of a series of fleshy bands which lie on the spinous processes in the cervical region of the spine.

The **Interspinales** are short muscular fasciculi, placed in pairs between the spinous processes of the contiguous vertebræ, one on each side of the interspinous ligament. In the *cervical region*, they are most distinct, and consist of six pairs, the first being situated between the axis and third vertebra, and the last between the last cervical and the first dorsal. They are small narrow bundles, attached, above and below, to the apices of the spinous processes. In the *dorsal region*, they are found between the first and second vertebræ, and occasionally between the second and third; and below, between the eleventh and twelfth. In the *lumbar region*, there are four pairs of these muscles in the intervals between the five lumbar vertebræ. There is also occasionally one in the interspinous space, between the last dorsal and first lumbar, and between the fifth lumbar and the sacrum.

The **Extensor coccygis** is a slender muscular fasciculus, occasionally present, which extends over the lower part of the posterior surface of the sacrum and coccyx. It arises by tendinous fibres from the last bone of the sacrum, or first piece of the coccyx, and passes downwards to be inserted into the lower part of the coccyx. It is a rudiment of the Extensor muscle of the caudal vertebræ of the lower animals.

The **Intertransversales** are small muscles placed between the transverse processes of the vertebræ. In the *cervical region* they are most developed, consisting of rounded muscular and tendinous fasciculi, which are placed in pairs, passing between the two anterior and the two posterior tubercles of the transverse processes of two contiguous vertebræ, separated from one another by the anterior division of the cervical nerve, which lies in the groove between them. In this region there are seven pairs of these muscles, the first pair being between the atlas and axis, and the last pair between the seventh cervical and first dorsal vertebræ. In the *dorsal region* they are least developed, consisting chiefly of rounded tendinous cords in the intertransverse spaces of the upper dorsal vertebræ; but between the transverse processes of the lower three dorsal vertebræ, and between the transverse processes of the last dorsal and the first lumbar, they are muscular in structure. In the *lumbar region* they are arranged in pairs, on either side of the spine; one set occupying the entire interspace between the transverse processes of the lumbar vertebræ, the *intertransversales laterales*; the other set, *intertransversales mediales*, passing from the accessory process of one vertebra to the mammillary process of the next.

The **Rectus capitis posticus major** arises by a pointed tendinous origin from the spinous process of the axis, and, becoming broader as it ascends, is inserted into the inferior curved line of the occipital bone and the surface of bone immediately below it. As the muscles of the two sides pass upwards and outwards, they leave between them a triangular space, in which are seen the Recti capitis postici minores muscles.

Relations.—By its *superficial surface*, with the Complexus; and, at its insertion, with the Superior oblique. By its *deep surface*, with part of the Rectus capitis posticus minor, the posterior arch of the atlas, the posterior occipito-atlantal ligament, and part of the occipital bone.

The **Rectus capitis posticus minor**, the smallest of the four muscles in this region, is of a triangular shape; it arises by a narrow pointed tendon from the tubercle on the posterior arch of the atlas, and, becoming broader as it ascends, is inserted into the rough surface beneath the inferior curved line, nearly as far as the foramen magnum, nearer to the middle line than the preceding.

Relations.—By its *superficial surface*, with the Complexus and the Rectus capitis posticus major. By its *deep surface*, with the posterior occipito-atlantal ligament.

The **Obliquus capitis inferior**, the larger of the two Oblique muscles, arises from the apex of the spinous process of the axis, and passes almost horizontally outwards, to be inserted into the lower and back part of the transverse process of the atlas.

Relations.—By its *superficial surface*, with the Complexus and with the posterior division of the second cervical nerve which crosses it. By its *deep surface*, with the vertebral artery, and posterior atlanto-axial ligament.

The **Obliquus capitis superior**, narrow below, wide and expanded above, arises by tendinous fibres from the upper surface of the transverse process of the atlas, joining with the insertion of the preceding, and, passing obliquely upwards and inwards, is inserted into the occipital bone, between the two curved lines, external to the Complexus.

Relations.—By its *superficial surface*, with the Complexus and Trachelo-mastoid. By its *deep surface*, with the posterior occipito-atlantal ligament.

The Suboccipital triangle.—Between the two oblique muscles and the Rectus capitis posticus major a triangular interval exists, the *suboccipital triangle*. This triangle is bounded, above and internally, by the Rectus capitis posticus major; above and externally, by the Obliquus capitis superior; below and externally, by the Obliquus capitis inferior. It is covered in by a layer of dense fibro-fatty tissue, situated beneath the Complexus muscle. The floor is formed by the posterior occipito-atlantal ligament, the posterior arch of the atlas, and the posterior atlanto-axial ligament. It contains the vertebral artery, as it runs in a deep groove on the upper surface of the posterior arch of the atlas; and the posterior division of the suboccipital nerve.

Nerves.—The Semispinalis dorsi and Rotatores spinæ are supplied by the internal branches of the posterior divisions of the dorsal nerves; the Semispinalis colli, by the internal branches of the posterior divisions of the cervical nerves; the Supraspinales and Interspinales are supplied by the internal branches of the posterior divisions of the cervical, dorsal, and lumbar nerves in the respective regions; the Intertransversales, by the internal branches of the posterior divisions of the cervical, dorsal, and lumbar nerves; the Multifidus spinæ, by the same, with the addition of the internal branches of the posterior divisions of the sacral nerves. The Recti and Obliqui muscles are all supplied by the suboccipital nerve; the Inferior oblique is also supplied by the great occipital nerve.

Actions.—When both the Spinales dorsi contract, they extend the dorsal region of the spine; when only one muscle contracts, it helps to bend the dorsal portion of the spine to one side. The Erector spinæ, comprising the Ilio-costalis and the Longissimus dorsi with their accessory muscles, serves, as its name implies, to maintain the spine in the erect posture; it also serves to bend the trunk backwards when it is required to counterbalance the influence of any weight at the front of the body—as, for instance, when a heavy weight is suspended from the neck, or when there is any great abdominal distension, as in pregnancy or dropsy; the peculiar gait under such circumstances depends upon the spine being drawn backwards, by the counterbalancing action of the Erector spinæ muscles. The muscles which form the continuation of the Erector spinæ upwards steady the head and neck, and fix them in the upright position. If the Ilio-costalis and Longissimus dorsi of one side act, they serve to draw down the chest and spine to the corresponding side. The Cervicales ascendens, taking their fixed points from the cervical vertebræ, elevate those ribs to which they are attached; taking their fixed points from the ribs, both muscles help to extend the neck; while one muscle bends the neck to its own side. The Transversalis colli, when both muscles act, taking their fixed point from below, bend the neck backwards. The Trachelo-mastoid, when both muscles act, taking their fixed point

from below, bend the head backwards; while, if only one muscle acts, the face is turned to the side on which the muscle is acting, and then the head is bent to the shoulder. The two Recti muscles draw the head backwards. The Rectus capitis posticus major, owing to its obliquity, rotates the cranium, with the atlas, round the odontoid process, turning the face to the same side. The Multifidus spinæ acts successively upon the different parts of the spine; thus, the sacrum furnishes a fixed point from which the fasciculi of this muscle act upon the lumbar region; these then become the fixed points for the fasciculi moving the dorsal region, and so on throughout the entire length of the spine; it is by the successive contraction and relaxation of the separate fasciculi of this and other muscles that the spine preserves the erect posture without the fatigue that would necessarily have been produced had this position been maintained by the action of a single muscle. The Multifidus spinæ, besides preserving the erect position of the spine, serves to rotate it, so that the front of the trunk is turned to the side opposite to that from which the muscle acts, this muscle being assisted in its action by the Obliquus externus abdominis. The Complexi draw the head directly backward; if one muscle acts, it draws the head to one side, and rotates it so that the face is turned to the opposite side. The Superior oblique draws the head backwards; and, from the obliquity in the direction of its fibres, will slightly rotate the cranium, turning the face to the opposite side. The Obliquus capitis inferior rotates the atlas, and with it the cranium, round the odontoid process, turning the face to the same side. The Semispinales, when the muscles of the two sides act together, help to extend the spine; when the muscles of one side only act, they rotate the dorsal and cervical parts of the spine, turning the body to the opposite side. The Supraspinales and Interspinales by approximating the spinous process help to extend the spine. The Intertransversales approximate the transverse processes, and help to bend the spine to one side. The Rotatores spinæ assist the Multifidus spinæ to rotate the spine, so that the front of the trunk is turned to the side opposite to that from which the muscle acts.

Surface Form.—The surface forms produced by the muscles of the back are numerous and difficult to analyse unless they are considered in systematic order. The most superficial layer, consisting of large strata of muscular substance, influences to a certain extent the surface form, and at the same time reveals the forms of the layers beneath. The *Trapezius* at the upper part of the back, and in the neck, covers over and softens down the outline of the underlying muscles. Its anterior border forms the posterior boundary of the posterior triangle of the neck. It forms a slight undulating ridge which passes downwards and forwards from the occiput to the junction of the middle and outer third of the clavicle. The tendinous ellipse formed by a part of the origin of the two muscles at the back of the neck is always to be seen as an oval depression, more marked when the muscle is in action. A slight dimple on the skin opposite the interval between the spinous processes of the third and fourth dorsal vertebræ marks the triangular aponeurosis by which the inferior fibres are inserted into the root of the spine of the scapula. From this point the inferior border of the muscle may be traced as an undulating ridge to the spinous process of the twelfth dorsal vertebra. In like manner, the *Latissimus dorsi* softens down and modulates the underlying structures at the lower part of the back and lower part of the side of the chest. In this way it modulates the outline of the Erector spinæ; of the Serratus posticus inferior, which is sometimes to be discerned through it, and is sometimes entirely obscured by it; of part of the Serratus magnus and Superior oblique, which it covers, and of the convex oblique ridges formed by the ribs with the intervening intercostal spaces. The anterior border of the muscle is the only part which gives a distinct surface form. This border may be traced, when the muscle is in action, as a rounded edge, starting from the crest of the ilium, and passing obliquely forwards and upwards to the posterior border of the axilla, where it combines with the Teres major in forming a thick rounded fold, the posterior boundary of the axillary space. The muscles in the second layer influence to a very considerable extent the surface form of the back of the neck and upper part of the trunk. The *Levator anguli scapulæ* reveals itself as a prominent divergent line, running downwards and outwards, from the transverse processes of the upper cervical vertebræ to the angle of the scapula, covered over and toned down by the overlying Trapezius. The *Rhomboidei* produce, when in action, a vertical eminence between the internal border of the scapula and the spinal furrow, varying in intensity according to the condition of contraction or relaxation of the Trapezius muscle, by which they are for the most part covered. The lowermost part of the Rhomboideus major is

uncovered by the Trapezius and forms on the surface an oblique ridge running upwards and inwards from the inferior angle of the scapula. Of the muscles of the third layer of the back, the *Serratus posticus superior* does not in any way influence surface form. The *Serratus posticus inferior*, when in strong action, may occasionally be revealed as an elevation beneath the Latissimus dorsi. The *Splenii* by their divergence serve to broaden out the upper part of the back of the neck and produce a local fulness in this situation, but do not otherwise influence surface form. Beneath all these muscles those of the fourth layer—the *Erector spinæ* and its continuations—influence the surface form in a decided manner. In the loins, the Erector spinæ, bound down by the lumbar fascia, forms a rounded vertical eminence, which determines the depth of the spinal furrow, and which below tapers to a point on the posterior surface of the sacrum and becomes lost there. In the back it forms a flattened plane which gradually becomes lost. In the neck the only part of this group of muscles which influences surface form is the *Trachelo-mastoid*, which produces a short convergent line across the upper part of the posterior triangle of the neck, appearing from under cover of the posterior border of the Sterno-mastoid and being lost below beneath the Trapezius.

II. Muscles and Fasciæ of the Thorax

The Muscles belonging exclusively to this region are few in number. They are the

Intercostales externi.	Triangularis sterni.
Intercostales interni.	Levatores costarum.
Infracostales.	Diaphragm.

Intercostal fasciæ.—A thin but firm layer of fascia covers the outer surface of the External intercostal and the inner surface of the Internal intercostal muscles; and a third layer, the middle intercostal fascia, more delicate, is interposed between the two planes of muscular fibres. These are the intercostal fasciæ: they are best marked in those situations where the muscular fibres are deficient, as between the External intercostal muscles and sternum, in front; and between the Internal intercostals and spine, behind.

The **Intercostal muscles** (fig. 341) are two thin planes of muscular and tendinous fibres, placed one over the other, filling up the intercostal spaces, and being directed obliquely between the margins of the adjacent ribs. They have received the name 'external' and 'internal,' from the position they bear to one another. The tendinous fibres are longer and more numerous than the muscular: hence the walls of the intercostal spaces possess very considerable strength, to which the crossing of the muscular fibres materially contributes.

The **External intercostals** are eleven in number on each side. They extend from the tubercles of the ribs, behind, to the commencement of the cartilages of the ribs, in front, where they terminate in a thin membranous aponeurosis, which is continued forwards to the sternum. They arise from the lower border of each rib, and are inserted into the upper border of the rib below. In the two lowest spaces they extend to the end of the cartilages, and in the upper two or three spaces they do not quite extend to the ends of the ribs. Their fibres are directed obliquely downwards and forwards, in a similar direction with those of the External oblique muscle of the abdomen. They are thicker than the internal intercostals.

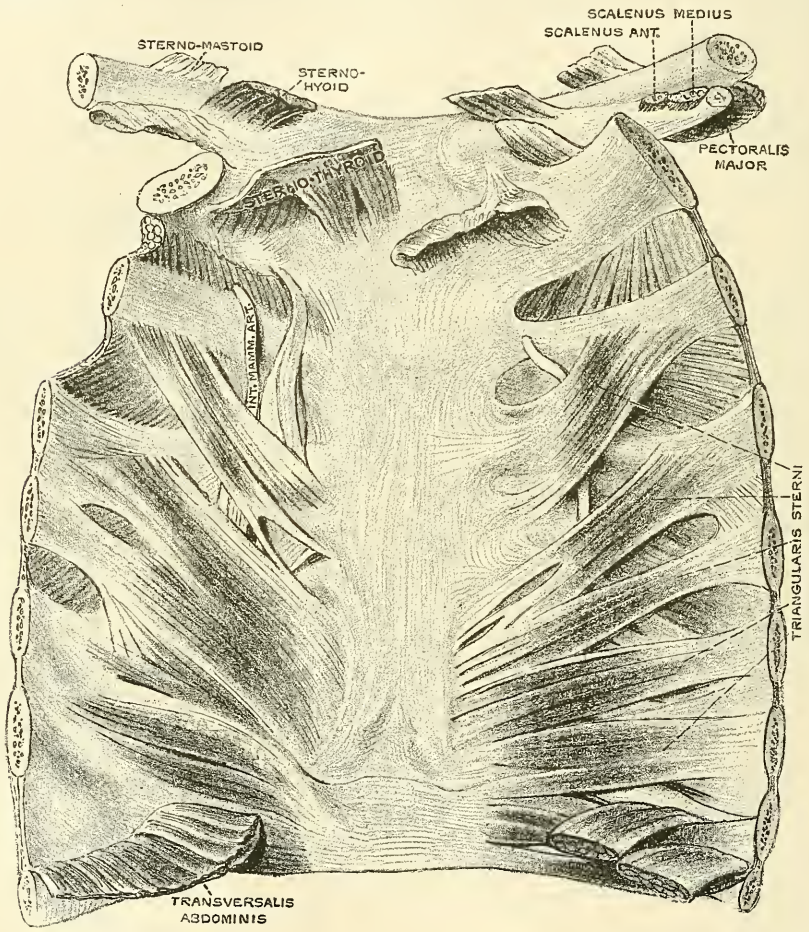
Relations.—By their *outer surface*, with the muscles which immediately invest the chest, viz. the Pectoralis major and minor, Serratus magnus, and Rhomboideus major, Serratus posticus superior and inferior, Scalenus posticus, Ilio-costalis, Longissimus dorsi, Cervicalis ascendens, Transversalis colli, Levatores costarum, and the Obliquus externus abdominis. By their *internal surface*, with the middle intercostal fascia, which separates them from the intercostal vessels and nerve, and the Internal intercostal muscles, and, behind, from the pleura.

The **Internal intercostals** are also eleven in number on each side. They commence anteriorly at the sternum, in the interspaces between the cartilages of the true ribs, and from the anterior extremities of the cartilages of the false ribs,

and extend backwards as far as the angles of the ribs; whence they are continued to the vertebral column by a thin aponeurosis. They arise from the ridge on the inner surface of each rib, as well as from the corresponding costal cartilage, and are inserted into the upper border of the rib below. Their fibres are directed obliquely downwards and backwards, passing in the opposite direction to the fibres of the External intercostal muscles.

Relations.—By their *external surface*, with the intercostal vessels and nerves, and the middle intercostal fascia, which separates them from the External inter-

Fig. 326.—Posterior surface of sternum and costal cartilages, showing Triangularis sterni muscle. (From a preparation in the Museum of the Royal College of Surgeons of England.)



costal muscles. By their *internal surface*, with the internal intercostal fascia, which separates them from the pleura costalis, Triangularis sterni, and Diaphragm.

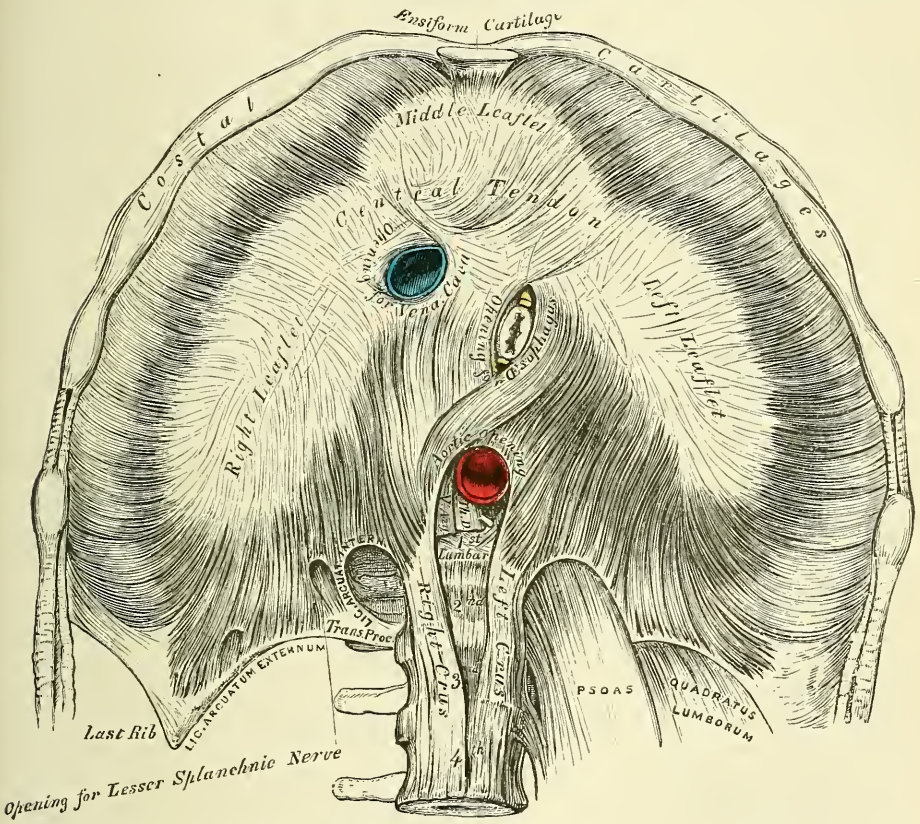
The **Infracostales (subcostales)** consist of muscular and aponeurotic fasciculi, which vary in number and length: they are placed on the inner surface of the ribs, where the Internal intercostal muscles cease; they arise from the inner surface of one rib, and are inserted into the inner surface of the first, second, or third rib below. Their direction is most usually oblique, like the Internal intercostals. They are most frequent between the lower ribs.

The **Triangularis sterni** (fig. 326) is a thin plane of muscular and tendinous fibres, situated upon the inner wall of the front of the chest. It arises from the

lower third of the posterior surface of the sternum, from the posterior surface of the ensiform cartilage, and from the sternal ends of the costal cartilages of the three or four lower true ribs. Its fibres diverge upwards and outwards, to be inserted by fleshy digitations into the lower border and inner surfaces of the costal cartilages of the second, third, fourth, fifth, and sixth ribs. The lowest fibres of this muscle are horizontal in their direction, and are continuous with those of the Transversalis: those which succeed are oblique, whilst the superior fibres are almost vertical. This muscle varies much in its attachment, not only in different bodies, but on opposite sides of the same body.

Relations.—*In front*, with the sternum, ensiform cartilage, costal cartilages, Internal intercostal muscles, and internal mammary vessels. *Behind*, with the pleura, pericardium, and anterior mediastinum.

Fig. 327.—The Diaphragm. Under surface.



The **Levatores costarum** (fig. 325), twelve in number on each side, are small tendinous and fleshy bundles, which arise from the extremities of the transverse processes of the seventh cervical and eleven upper dorsal vertebræ, and, passing obliquely downwards and outwards, are inserted into the upper border of the rib below them, between the tubercle and the angle. The Inferior levatores divide into two fasciculi, one of which is inserted as above described; the other fasciculus passes down to the second rib below its origin; thus, each of the lower ribs receives fibres from the transverse processes of two vertebræ.

Nerves.—The muscles of this group are supplied by the intercostal nerves.

The **Diaphragm** (*διάφραγμα, a partition wall*) (fig. 327) is a thin musculo-fibrous septum, consisting of muscular fibres externally, which arise from the circumference of the thoracic cavity and pass upwards and inwards to converge to a central tendon. It is placed obliquely at the junction of the upper with the

middle third of the trunk, and separates the thorax from the abdomen, forming the floor of the former cavity and the roof of the latter. It is elliptical, its longest diameter being from side to side, and somewhat fan-shaped; the broad elliptical portion being horizontal, the narrow part, the *crura*, which represents the handle of the fan, vertical, and joined at right angles to the former. It is from this circumstance that some anatomists describe it as consisting of two portions, the upper or great muscle of the Diaphragm, and the lower or lesser muscle. It arises from the whole of the internal circumference of the thorax: being attached, in front, by fleshy fibres to the ensiform cartilage; on either side, to the inner surface of the cartilages and bony portions of the six or seven inferior ribs, interdigitating with the Transversalis; and behind, to two aponeurotic arches, named the *ligamentum arcuatum externum et internum*; and by the crura, to the lumbar vertebræ. The fibres from these sources vary in length; those arising from the ensiform appendix are very short and occasionally aponeurotic; those from the ligamenta arcuata, and more especially those from the cartilages of the ribs at the side of the chest, are longer, describe well-marked curves as they ascend, and finally converge to be inserted into the circumference of the central tendon. Between the sides of the muscular slip from the ensiform appendix and the cartilages of the adjoining ribs, the fibres of the Diaphragm are deficient, the interval being filled by areolar tissue, covered on the thoracic side by the pleuræ; on the abdominal, by the peritoneum. This is, consequently, a weak point, and a portion of the contents of the abdomen may protrude into the chest, forming phrenic or diaphragmatic hernia, or a collection of pus in the mediastinum may descend through it, so as to point at the epigastrium.

The *ligamentum arcuatum internum* is a tendinous arch, thrown across the upper part of the Psoas magnus muscle, on each side of the spine. It is connected, by one end, to the outer side of the body of the first lumbar vertebra, being continuous with the outer side of the tendon of the corresponding crus; and, by the other end, to the front of the transverse process of the first and sometimes also to that of the second, lumbar vertebra.

The *ligamentum arcuatum externum* is the thickened upper margin of the anterior lamella of the lumbar fascia; it arches across the upper part of the Quadratus lumborum, being attached, by one extremity, to the front of the transverse process of the first lumbar vertebra; and, by the other, to the apex and lower margin of the last rib.

The Crura.—The Diaphragm is connected to the spine by two *crura* or *pillars*, which are situated on the bodies of the lumbar vertebræ, on each side of the aorta. The crura, at their origin, are tendinous in structure: the right crus, larger and longer than the left, arising from the anterior surface of the bodies and intervertebral substances of the three or four upper lumbar vertebræ; the left, from the two upper; both blending with the anterior common ligament of the spine. These tendinous portions of the crura pass forwards and inwards and gradually converge to meet in the middle line, forming an arch, beneath which passes the aorta, vena azygos major, and thoracic duct. From this tendinous arch muscular fibres arise, which diverge, the outermost portion being directed upwards and outwards to the central tendon; the innermost decussating in front of the aorta, and then diverging, so as to surround the œsophagus before ending in the central tendon. The fibres derived from the right crus are the most numerous, and pass in front of those derived from the left.

The *Central* or *Cordiform Tendon* of the Diaphragm is a thin but strong tendinous aponeurosis, situated at the centre of the vault formed by the muscle, immediately below the pericardium, with which its circumference is blended. It is shaped somewhat like a trefoil leaf, consisting of three divisions, or leaflets, separated from one another by slight indentations. The right leaflet is the largest; the middle one, directed towards the ensiform cartilage, the next in size; and the left, the smallest. In structure, the tendon is composed of several planes of fibres, which intersect one another at various angles, and unite

into straight or curved bundles—an arrangement which affords it additional strength.

The *Openings* connected with the Diaphragm are three large and several smaller apertures. The former are the aortic, the œsophageal, and the opening for the vena cava.

The *aortic opening* is the lowest and the most posterior of the three large apertures connected with this muscle, being at the level of the first lumbar vertebra. It is situated in the middle line, immediately in front of the bodies of the vertebræ; and is, therefore, *behind* the Diaphragm, not in it. It is an osseo-aponeurotic aperture, formed by a tendinous arch thrown across the front of the bodies of the vertebræ, from the crus on one side to that on the other, and transmits the aorta, vena azygos major, thoracic duct, and sometimes the left cord of the sympathetic. Occasionally some tendinous fibres are prolonged across the bodies of the vertebræ from the inner part of the lower end of the crura, passing behind the aorta, and thus converting the opening into a fibrous ring.

The *œsophageal opening* is situated at the level of the tenth dorsal vertebra; it is elliptical in form, muscular in structure, and, formed by the two crura, is placed above, and, at the same time, anterior, and a little to the left of the preceding. It transmits the œsophagus and pneumogastric nerves and some small œsophageal arteries. The anterior margin of this aperture is occasionally tendinous, being formed by the margin of the central tendon.

The *opening for the vena cava* (*foramen quadratum*) is the highest, about on the level of the disc between the eighth and ninth dorsal vertebræ; it is quadrilateral in form, tendinous in structure, and placed at the junction of the right and middle leaflets of the central tendon, its margins being bounded by four bundles of tendinous fibres, which meet at right angles.

The *right crus* transmits the sympathetic and the greater and lesser splanchnic nerves of the right side; the *left crus* transmits the sympathetic, when it does not pass through the aortic opening, the greater and lesser splanchnic nerves of the left side, and the vena azygos minor.

The *Serous Membranes* in relation with the Diaphragm are four in number: three lining its upper or thoracic surface; one, its abdominal. The three serous membranes on its upper surface are the pleura on either side, and the serous layer of the pericardium, which covers the middle portion of the tendinous centre. The serous membrane covering its under surface is a portion of the general peritoneal membrane of the abdominal cavity.

The Diaphragm is arched, being convex towards the chest, and concave to the abdomen. The *right portion* forms a complete arch from before backwards, being accurately moulded over the convex surface of the liver, and having resting upon it the concave base of the right lung. The *left portion* is arched from before backwards in a similar manner; but the arch is narrower in front, being encroached upon by the pericardium, and lower than the right, at its summit, by about three-quarters of an inch. It supports the base of the left lung, and covers the great end of the stomach, the spleen, and left kidney. At its circumference the Diaphragm is higher in the mesial line of the body than at either side; but in the middle of the thorax, the central portion, which supports the heart, is on a lower level than the two lateral portions.

Nerves.—The Diaphragm is supplied by the phrenic nerves and phrenic plexus of the sympathetic.

Actions.—The Intercostals are the chief agents in the movement of the ribs in ordinary respiration. When the first rib is elevated and fixed by the Scaleni, the External intercostals raise the other ribs, especially their fore part, and so increase the capacity of the chest from before backwards; at the same time they evert their lower borders, and so enlarge the thoracic cavity transversely. The Internal intercostals, at the side of the thorax, depress the ribs, and invert their lower borders, and so diminish the thoracic cavity; but at the fore part of

the chest these muscles assist the External intercostals in raising the cartilages.* The Levatores costarum assist the External intercostals in raising the ribs. The Triangularis sterni draws down the costal cartilages; it is therefore an expiratory muscle.

The Diaphragm is the principal muscle of inspiration. When in a condition of rest the muscle presents a domed surface, concave towards the abdomen; and consists of a circumferential muscular and a central tendinous part. When the muscular fibres contract, they become less arched, or nearly straight, and thus cause the central tendon to descend, and in consequence the level of the chest wall is lowered, the vertical diameter of the chest being proportionately increased. In this descent the different parts of the tendon move unequally. The left leaflet descends to the greatest extent; the right to a less extent, on account of the liver; and the central leaflet the least, because of its connection to the pericardium. In descending the Diaphragm presses on the abdominal viscera, and so to a certain extent causes a projection of the abdominal wall; but in consequence of these viscera not yielding completely, the central tendon becomes a fixed point, and enables the circumferential muscular fibres to act *from* it, and so elevate the lower ribs and expand the lower part of the thoracic cavity; and Duchenne has shown that the Diaphragm has the power of elevating the ribs, to which it is attached, by its contraction, if the abdominal viscera are *in situ*, but that if these organs are removed, this power is lost. When at the end of inspiration, the Diaphragm relaxes, the thoracic walls return to their natural position in consequence of their elastic reaction and of the elasticity and weight of the displaced viscera.†

In all expulsive acts the Diaphragm is called into action, to give additional power to each expulsive effort. Thus, before sneezing, coughing, laughing, and crying; before vomiting; previous to the expulsion of the urine and fæces, or of the fœtus from the womb, a deep inspiration takes place.

The height of the Diaphragm is constantly varying during respiration, the muscle being carried upwards or downwards from the average level; its height also varies according to the degree of distension of the stomach and intestines, and the size of the liver. After a forced expiration, the right arch is on a level, in front with the fourth costal cartilage; at the side, with the fifth, sixth, and seventh ribs; and behind with the eighth rib; the left arch being usually from one to two ribs' breadth below the level of the right one. In a forced inspiration, it descends from one to two inches; its slope would then be represented by a line drawn from the ensiform cartilage towards the tenth rib.

Muscles of Inspiration and Expiration.—The muscles which assist the action of the Diaphragm in ordinary tranquil inspiration are the Intercostals and the Levatores costarum, as above stated, and the Scaleni. When the need for more forcible action exists, the shoulders and the base of the scapula are fixed, and

* The view of the action of the Intercostal muscles given in the text is that which is taught by Hutchinson (*Cycl. of Anat. and Phys.* art. 'Thorax'), and is usually adopted in our schools. It is, however, much disputed. Hamberger believed that the External intercostals act as elevators of the ribs, or muscles of inspiration, while the Internal act in expiration. Haller taught that both sets of muscles act in common—viz. as muscles of inspiration—and this view is adopted by many of the best anatomists of the Continent, and appears supported by many observations made on the human subject under various conditions of disease, and on living animals after the muscles have been exposed under chloroform. The reader may consult an interesting paper by Dr. Cleland in the *Journal of Anat. and Phys.* No. II., May 1867, p. 209, 'On the Hutchinsonian Theory of the Action of the Intercostal Muscles.' He refers to Henle, Luschka, Budge, and Bäumler, *Observations on the Action of the Intercostal Muscles*. Erlangen, 1860. (In *New Syd. Soc.'s Year-Book for* 1861, p. 69.) Dr. W. W. Keen has come to the conclusion, from experiments made upon a criminal executed by hanging, that the External intercostals are muscles of expiration, as they pulled the ribs down, while the Internal intercostals pulled the ribs up, and are muscles of inspiration. (*Trans. Coll. Phys. Philadelphia*, Third Series, vol. i., 1875, p. 97.)

† For a detailed description of the general relations of the Diaphragm, and its action, refer to Dr. Sibson's *Medical Anatomy*.

then the powerful muscles of forced inspiration come into play; the chief of these are the Trapezius, the Pectoralis minor, the Serratus posticus superior and inferior, and the Rhomboidei. The lower fibres of the Serratus magnus may possibly assist slightly in dilating the chest by raising and everting the ribs. The Sterno-mastoid also, when the head is fixed, assists in forced inspiration, by drawing up the sternum, and by fixing the clavicle, and thus affording a fixed point for the action of the muscles of the chest. The Ilio-costalis and Quadratus lumborum assist in forced inspiration by fixing the last rib (see page 458).

The ordinary action of expiration is hardly effected by muscular force, but results from a return of the walls of the thorax to a condition of rest, owing to their own elasticity and to that of the lungs. Forced expiratory actions are performed mainly by the flat muscles (Obliqui and Transversalis) of the abdomen, assisted also by the Rectus. Other muscles of forced expiration are the Internal intercostals and Triangularis sterni (as above mentioned), the Quadratus lumborum, and the Ilio-costalis.

III. Muscles of the Abdomen

The muscles of the abdomen may be divided into two groups :—1. The superficial muscles of the abdomen ; and 2. The deep muscles of the abdomen.

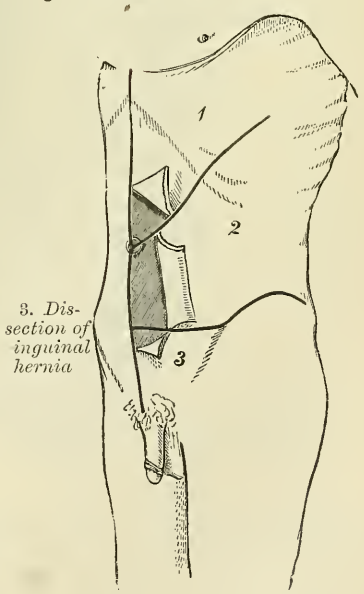
1. Superficial Muscles

The Muscles in this region are, the

Obliquus Externus.
Obliquus Internus.
Transversalis.
Rectus.
Pyramidalis.

Dissection (fig. 328).—To dissect the abdominal muscles, make a vertical incision from the ensiform cartilage to the symphysis pubis; a second incision from the umbilicus obliquely upwards and outwards to the outer surface of the chest, as high as the lower border of the fifth or sixth rib; and a third, commencing midway between the umbilicus and pubes, transversely outwards to the anterior superior iliac spine, and along the crest of the ilium as far as its posterior third. Then reflect the three flaps included between these incisions from within outwards, in the lines of direction of the muscular fibres. If necessary, the abdominal muscles may be made tense by inflating the peritoneal cavity through the umbilicus.

Fig. 328.—Dissection of abdomen.

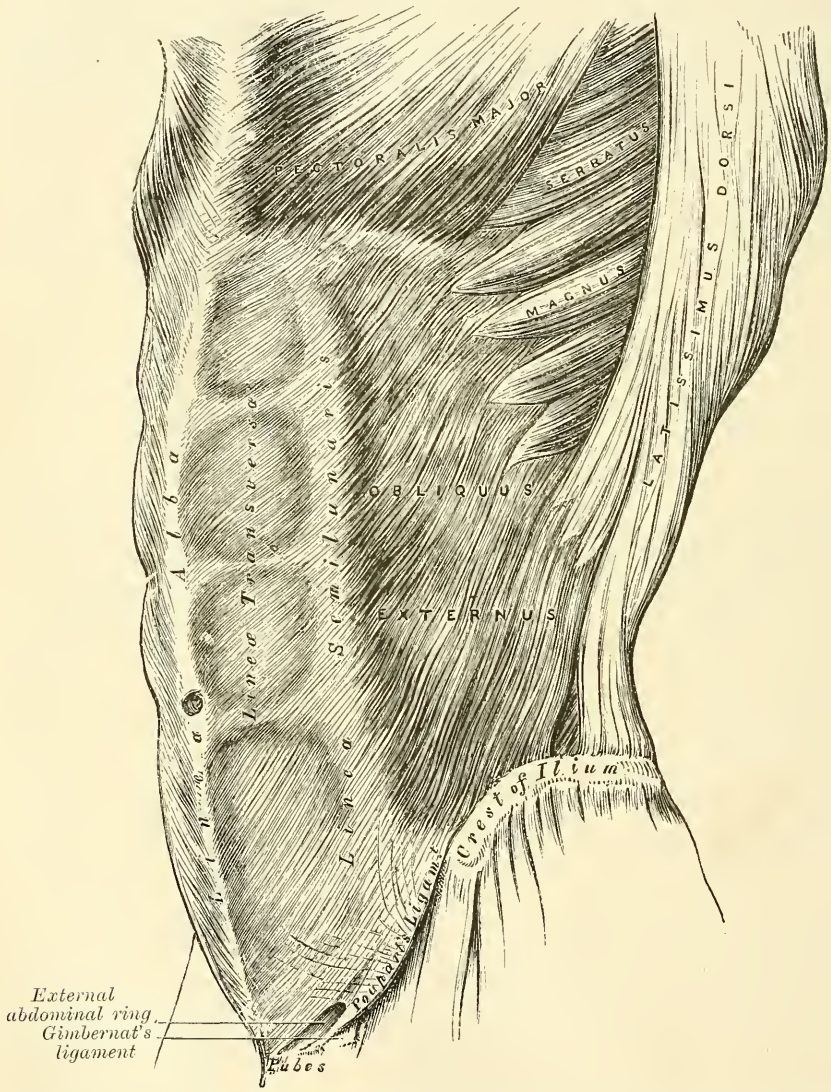


3. *Dissection of inguinal hernia*

The **Superficial fascia** of the abdomen consists over the greater part of the abdominal wall of a single layer of fascia, which contains a variable amount of fat; but as this layer approaches the groin it is easily divisible into two layers, between which are found the superficial vessels and nerves and the superficial inguinal lymphatic glands. The superficial layer is thick, areolar in texture, containing adipose tissue in its meshes, the quantity of which varies in different subjects. Below it passes over Poupart's ligament, and is continuous with the outer layer of the superficial fascia of the thigh. In the male this fascia is continued over the penis and outer surface of the cord to the scrotum, where it helps to form the dartos. As it passes to the scrotum it changes its character, becoming thin, destitute of adipose tissue and of a pale reddish colour, and in the scrotum it acquires some involuntary muscular fibres. From the scrotum it may

be traced backwards to be continuous with the superficial fascia of the perinæum. In the female, this fascia is continued into the labia majora. The deeper layer (*fascia of Scarpa*) is thinner and more membranous in character than the superficial layer. In the middle line, it is intimately adherent to the linea alba and to the symphysis pubis, and is prolonged on to the dorsum of the penis, forming the suspensory ligament; above, it is continuous with the superficial fascia over the rest of the trunk; below, it blends with the fascia lata of the thigh a little below Poupart's ligament; and below and internally, it is continued over the penis and

Fig. 329.—The External oblique muscle.



spermatic cord to the scrotum, where it helps to form the dartos. From the scrotum it may be traced backwards to be continuous with the deep layer of the superficial fascia of the perinæum. In the female, it is continued into the labia majora.

The **External** or **Descending oblique muscle** (fig. 329) is situated on the side and fore part of the abdomen; being the largest and the most superficial of the three flat muscles in this region. It is broad, thin, and irregularly quadrilateral, its muscular portion occupying the side, its aponeurosis the anterior wall of the

abdomen. It arises, by eight fleshy digitations, from the external surface and lower borders of the eight inferior ribs; these digitations are arranged in an oblique line running downwards and backwards; the upper ones being attached close to the cartilages of the corresponding ribs; the lowest to the apex of the cartilage of the last rib; the intermediate ones, to the ribs at some distance from their cartilages. The five superior serrations increase in size from above downwards, and are received between corresponding processes of the Serratus magnus; the three lower ones diminish in size from above downwards, receiving between them corresponding processes from the Latissimus dorsi. From these attachments the fleshy fibres proceed in various directions. Those from the lowest ribs pass nearly vertically downwards, to be inserted into the anterior half of the outer lip of the crest of the ilium; the middle and upper fibres, directed downwards and forwards, terminate in an aponeurosis, opposite a line drawn from the prominence of the ninth costal cartilage to the anterior superior spinous process of the ilium.

The **Aponeurosis of the External oblique** is a thin but strong membranous aponeurosis, the fibres of which are directed obliquely downwards and inwards. It is joined with that of the opposite muscle along the median line, covers the whole of the front of the abdomen; above, it is connected with the lower border of the Pectoralis major; below, its fibres are closely aggregated together, and extend obliquely across from the anterior superior spine of the ilium to the spine of the os pubis and the linea ilio-pectinea. In the median line, it interlaces with the aponeurosis of the opposite muscle, forming the linea alba, which extends from the ensiform cartilage to the symphysis pubis.

That portion of the aponeurosis which extends between the anterior superior spine of the ilium and the spine of the os pubis is a broad band, folded inwards, and continuous below with the fascia lata; it is called *Poupart's ligament*. The portion which is reflected from Poupart's ligament at the spine of the os pubis along the pectineal line is called *Gimbernat's ligament*. From the point of attachment of the latter to the pectineal line, a few fibres pass upwards and inwards, behind the inner pillar of the ring, to the linea alba. They diverge as they ascend, and form a thin triangular fibrous layer, which is called the *triangular fascia of the abdomen*.

In the aponeurosis of the External oblique, immediately above the crest of the os pubis, is a triangular opening, the *external abdominal ring*, formed by a separation of the fibres of the aponeurosis in this situation.

Relations.—By its *external surface*, with the superficial fascia, superficial epigastric and circumflex iliac vessels, and some cutaneous nerves. By its *internal surface*, with the Internal oblique, the lower part of the eight inferior ribs, and Intercostal muscles, the Cremaster, the spermatic cord in the male, and round ligament in the female. Its *posterior border*, extending from the last rib to the crest of the ilium, is fleshy throughout and free; it is occasionally overlapped by the Latissimus dorsi, though generally a triangular interval exists between the two muscles near the crest of the ilium in which is seen a portion of the Internal oblique. This triangle, *Petit's triangle*, is therefore bounded in front by the External oblique, behind by the Latissimus dorsi, below by the crest of the ilium, while its floor is formed by the Internal oblique (fig. 324).

The following parts of the aponeurosis of the External oblique muscle require to be further described, viz. the external abdominal ring, the intercolumnar fibres and fascia, Poupart's ligament, Gimbernat's ligament, and the triangular ligament of the abdomen.

The **External abdominal ring**.—Just above, and to the outer side of the crest of the os pubis, an interval is seen in the aponeurosis of the External oblique, called the *External abdominal ring*. The aperture is oblique in direction, somewhat triangular in form, and corresponds with the course of the fibres of the aponeurosis. It usually measures from base to apex about an inch, and transversely about half an inch. It is bounded below by the crest of the os pubis;

above, by a series of curved fibres, the *intercolumnar*, which pass across the upper angle of the ring, so as to increase its strength; and on each side, by the margins of the opening in the aponeurosis, which are called the columns or pillars of the ring.

The external pillar, which is at the same time inferior from the obliquity of its direction, is the stronger; it is formed by that portion of Poupart's ligament which is inserted into the spine of the os pubis; it is curved so as to form a kind of groove, upon which the spermatic cord rests. The internal or superior pillar is a broad, thin, flat band which is attached to the front of the symphysis pubis, interlacing with its fellow of the opposite side, that of the right side being superficial.

The external abdominal ring gives passage to the spermatic cord in the male, and round ligament in the female: it is much larger in men than in women, on account of the large size of the spermatic cord, and hence the greater frequency of inguinal hernia in men.

The **intercolumnar fibres** are a series of curved tendinous fibres, which arch across the lower part of the aponeurosis of the External oblique. They have received their name from stretching across between the two pillars of the external ring, describing a curve with the convexity downwards. They are much thicker and stronger at the outer margin of the external ring, where they are connected to the outer third of Poupart's ligament, than internally, where they are inserted into the linea alba. They are more strongly developed in the male than in the female. The intercolumnar fibres increase the strength of the lower part of the aponeurosis, and prevent the divergence of the pillars from one another.

These intercolumnar fibres, as they pass across the external abdominal ring, are themselves connected together by delicate fibrous tissue, thus forming a fascia which, as it is attached to the pillars of the ring, covers it in, and is called the *intercolumnar fascia*. This **intercolumnar fascia** is continued down as a tubular prolongation around the outer surface of the cord and testis, and encloses them in a distinct sheath, hence it is also called the external spermatic fascia.

The sac of an inguinal hernia, in passing through the external abdominal ring, receives an investment from the intercolumnar fascia.

If the finger is introduced a short distance into the external abdominal ring and the limb is then extended and rotated outwards, the aponeurosis of the External oblique, together with the iliac portion of the fascia lata, will be felt to become tense, and the external ring much contracted; if the limb is on the contrary flexed upon the pelvis and rotated inwards, this aponeurosis will become lax and the external abdominal ring sufficiently enlarged to admit the finger with comparative ease; hence the patient should always be put in the latter position when the taxis is applied for the reduction of an inguinal hernia, in order that the abdominal walls may be relaxed as much as possible.

Poupart's ligament, or the **crural arch**, is the lower border of the aponeurosis of the External oblique muscle, which extends from the anterior superior spine of the ilium to the spine of the os pubis. From this latter point it is reflected outwards to be attached to the pectineal line for about half an inch, forming Gimbernat's ligament. Its general direction is curved downwards towards the thigh, where it is continuous with the fascia lata. Its outer half is rounded and oblique in direction. Its inner half gradually widens at its attachment to the os pubis, is more horizontal in direction, and lies beneath the spermatic cord.

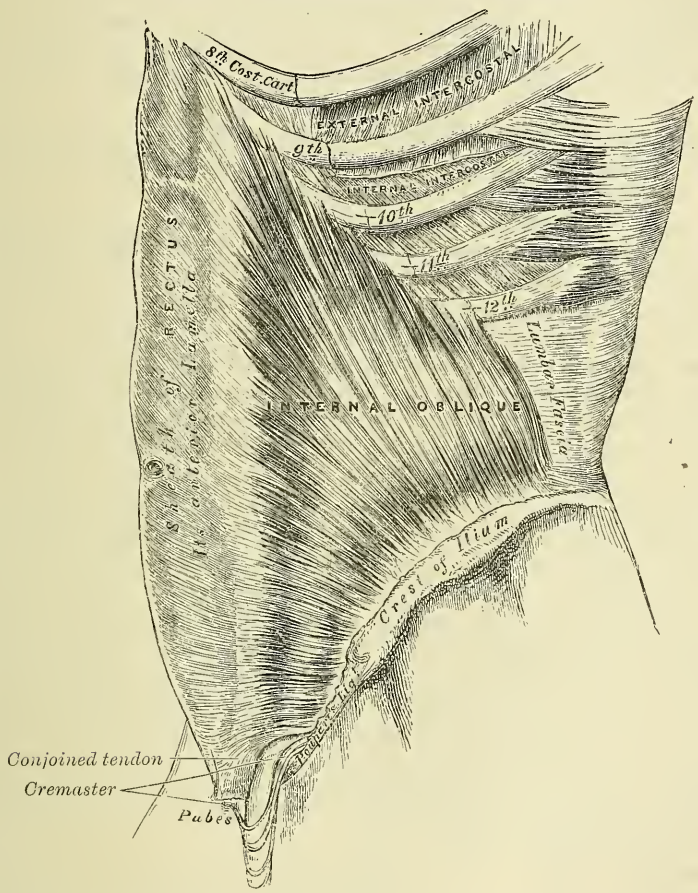
Nearly the whole of the space included between the crural arch and the innominate bone is filled in by the parts which descend from the abdomen into the thigh. These will be referred to again on a subsequent page.

Gimbernat's ligament is that part of the aponeurosis of the External oblique muscle which is reflected downwards and outwards from the spine of the os pubis to be inserted into the pectineal line. It is about half an inch in length, larger in the male than in the female, almost horizontal in direction in the erect posture,

and of a triangular form with the base directed outwards. Its base, or outer margin, is concave, thin, and sharp, and lies in contact with the crural sheath; forming the inner boundary of the femoral ring. Its apex corresponds to the spine of the os pubis. Its posterior margin is attached to the pectineal line, and is continuous with the pubic portion of the fascia lata. Its anterior margin is continuous with Poupart's ligament.

The **triangular fascia** of the abdomen is a layer of tendinous fibres of a triangular shape, which is attached by its apex to the pectineal line, where it is continuous with Gimbernat's ligament. It passes inwards beneath the spermatic cord, and expands into a somewhat fan-shaped fascia, lying behind the inner

Fig. 330.—The Internal oblique muscle.



pillar of the external abdominal ring, and in front of the conjoined tendon, and interlaces with the ligament of the other side at the linea alba.

Dissection.—Detach the External oblique by dividing it across, just in front of its attachment to the ribs, as far as its posterior border, and separate it below from the crest of the ilium as far as the anterior superior spine; then separate the muscle carefully from the Internal oblique, which lies beneath, and turn it towards the opposite side.

The **Internal** or **Ascending oblique muscle** (fig. 330), thinner and smaller than the preceding, beneath which it lies, is of an irregularly quadrilateral form, and situated at the side and fore part of the abdomen. It arises, by fleshy fibres, from the outer half of Poupart's ligament, being attached to the groove on its upper surface; from the anterior two-thirds of the middle lip of the crest of the ilium, and from the posterior lamella of the lumbar fascia. From this origin the fibres diverge: those from Poupart's ligament, few in number, and paler in colour

than the rest, arch downwards and inwards across the spermatic cord in the male and the round ligament in the female, and, becoming tendinous, are inserted, conjointly with those of the Transversalis, into the crest of the os pubis and pectineal line, to the extent of half an inch, forming what is known as the conjoined tendon of the Internal oblique and Transversalis; those from the anterior third of the iliac origin are horizontal in their direction, and, becoming tendinous along the lower fourth of the linea semilunaris, pass in front of the Rectus muscle to be inserted into the linea alba; those which arise from the middle third of the origin from the crest of the ilium pass obliquely upwards and inwards, and terminate in an aponeurosis, which divides at the outer border of the Rectus muscle into two lamellæ, which are continued forwards, in front and behind this muscle to the linea alba: the posterior lamella being also connected to the cartilages of the seventh, eighth, and ninth ribs; the most posterior fibres pass almost vertically upwards, to be inserted into the lower borders of the cartilages of the three lower ribs, being continuous with the Internal intercostal muscles.

The conjoined tendon of the Internal oblique and Transversalis is inserted into the crest of the os pubis and pectineal line, immediately behind the external abdominal ring, serving to protect what would otherwise be a weak point in the abdominal wall. Sometimes this tendon is insufficient to resist the pressure from within, and is carried forward in front of the protrusion through the external ring, forming one of the coverings of direct inguinal hernia; or the hernia forces its way through the fibres of the conjoined tendon.

The aponeurosis of the Internal oblique is continued forward to the middle line of the abdomen, where it joins with the aponeurosis of the opposite muscle at the linea alba, and extends from the margin of the thorax to the os pubis. At the outer margin of the Rectus muscle, this aponeurosis, for the upper three-fourths of its extent, divides into two lamellæ, which pass, one in front and the other behind the muscle, enclosing it in a kind of sheath, and reuniting on its inner border at the linea alba; the anterior layer is blended with the aponeurosis of the External oblique muscle; the posterior layer with that of the Transversalis. Along the lower fourth, the aponeurosis passes altogether in front of the Rectus without any separation. Where the aponeurosis ceases to split, and passes altogether in front of the Rectus muscle, a deficiency is left in the sheath of the muscle behind; this is marked above by a sharp lunated margin, having its concavity downwards. This is known as the *semilunar fold of Douglas.*

Relations.—By its *external surface,* with the External oblique, Latissimus dorsi, spermatic cord, and external ring. By its *internal surface,* with the Transversalis muscle, the lower intercostal vessels and nerves, the ilio-hypogastric and the ilio-inguinal nerves. Near Poupart's ligament, it lies on the fascia transversalis, internal ring, and spermatic cord. Its lower border forms the upper boundary of the spermatic canal.

The **Cremaster muscle** is a thin muscular layer, composed of a number of fasciculi which arise from the inner part of Poupart's ligament where its fibres are continuous with those of the Internal oblique and also occasionally with the Transversalis. It passes along the outer side of the spermatic cord, descends with it through the external abdominal ring upon the front and sides of the cord, and forms a series of loops which differ in thickness and length in different subjects. Those at the upper part of the cord are exceedingly short, but they become in succession longer and longer, the longest reaching down as low as the testicle, where a few are inserted into the tunica vaginalis. These loops are united together by areolar tissue, and form a thin covering over the cord and testis, the *fascia cremasterica.* The fibres ascend along the inner side of the cord, and are inserted by a small pointed tendon into the crest of the os pubis and front of the sheath of the Rectus muscle.

It will be observed that the origin and insertion of the Cremaster is precisely similar to that of the lower fibres of the Internal oblique. This fact affords an

easy explanation of the manner in which the testicle and cord are invested by this muscle. At an early period of fœtal life the testis is placed at the lower and back part of the abdominal cavity, but during its descent towards the scrotum, which takes place before birth, it passes beneath the arched fibres of the Internal oblique. In its passage beneath this muscle some fibres are derived from its lower part which accompany the testicle and cord into the scrotum. It occasionally happens that the loops of the Cremaster surround the cord, some lying behind as well as in front. It is probable that under these circumstances the testis, in its descent, passed through instead of beneath the fibres of the Internal oblique.

In the descent of an oblique inguinal hernia, which takes the same course as the spermatic cord, the Cremaster muscle forms one of its coverings. This muscle becomes largely developed in cases of hydrocele and large, old scrotal hernia. The Cremaster muscle is only found in the male, but almost constantly in the female a few muscular fibres may be found on the surface of the round ligament, which correspond to this muscle, and in cases of oblique inguinal hernia in the female a considerable amount of muscular fibre may be found covering the sac.

Dissection.—Detach the Internal oblique in order to expose the Transversalis beneath. This may be effected by dividing the muscle above, at its attachment to the ribs; below, at its connection with Poupart's ligament and the crest of the ilium; and behind, by a vertical incision extending from the last rib to the crest of the ilium. The muscle should previously be made tense by drawing upon it with the fingers of the left hand, and if its division is carefully effected, the cellular interval between it and the Transversalis, as well as the direction of the fibres of the latter muscle, will afford a clear guide to their separation; along the crest of the ilium the circumflex iliac vessels are interposed between them, and form an important guide in separating them. The muscle should then be thrown inwards towards the linea alba.

The **Transversalis muscle** (fig. 331), so called from the direction of its fibres, is the most internal flat muscle of the abdomen, being placed immediately beneath the Internal oblique. It arises by fleshy fibres from the outer third of Poupart's ligament; from the inner lip of the crest of the ilium, for its anterior three-fourths; from the inner surface of the cartilages of the six lower ribs, interdigitating with the Diaphragm; and by the lumbar fascia from the spinous and transverse processes of the lumbar vertebræ. The muscle terminates in front in a broad aponeurosis, the lower fibres of which curve downwards and inwards, and are inserted, together with those of the Internal oblique, into the lower part of the linea alba, the crest of the os pubis and pectineal line, forming what is known as the conjoined tendon of the Internal oblique and Transversalis. Throughout the rest of its extent the aponeurosis passes horizontally inwards, and is inserted into the linea alba; its upper three-fourths passing behind the Rectus muscle, blending with the posterior lamella of the Internal oblique; its lower fourth passing in front of the Rectus.

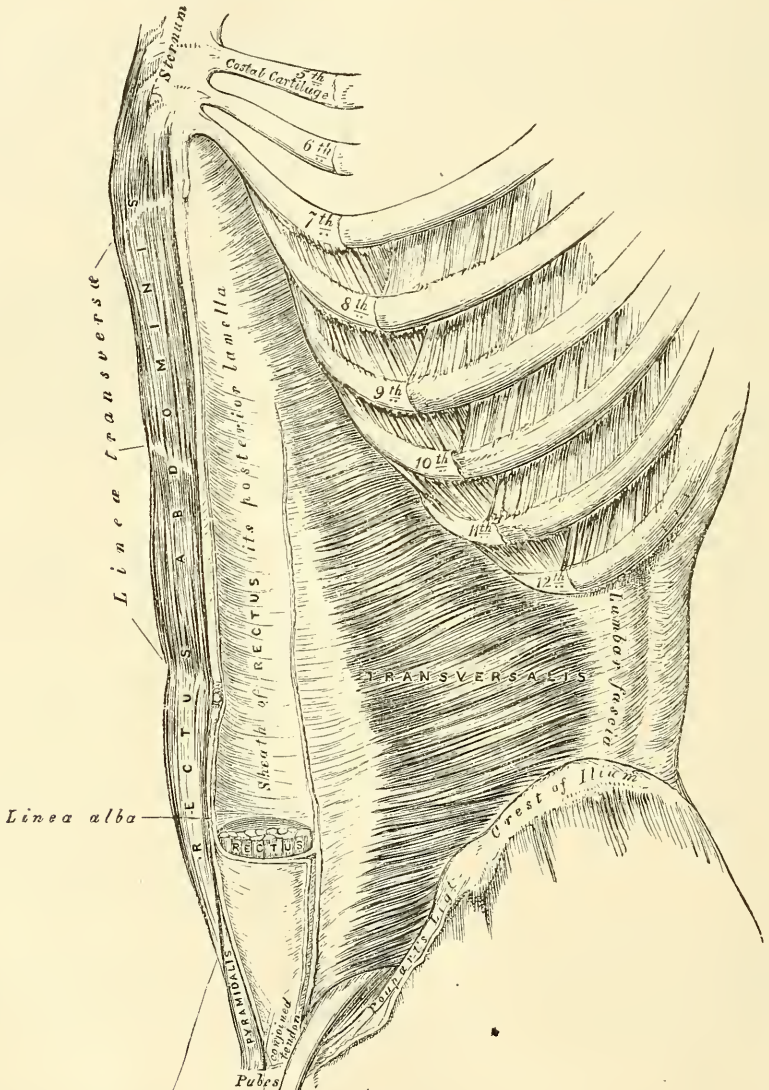
Relations.—By its *external surface*, with the Internal oblique, and the inner surface of the cartilages of the lower ribs. By its *internal surface*, with the fascia transversalis, which separates it from the peritoneum. Its lower border forms the upper boundary of the spermatic canal.

Dissection.—To expose the Rectus muscle, open its sheath by a vertical incision extending from the margin of the thorax to the os pubis, and then reflect the two portions from the surface of the muscle, which is easily done, excepting at the lineæ transversæ, where so close an adhesion exists that the greatest care is requisite in separating them. Now raise the outer edge of the muscle, in order to examine the posterior layer of the sheath. By dividing the muscle in the centre, and turning its lower part downwards, the point where the posterior wall of the sheath terminates in a thin curved margin will be seen.

The **Rectus abdominis** is a long flat muscle, which extends along the whole length of the front of the abdomen, being separated from its fellow of the

opposite side by the linea alba. It is much broader, but thinner, above than below, and arises by two tendons, the external or larger being attached to the crest of the os pubis; the internal, smaller portion, interlacing with its fellow of the opposite side, and being connected with the ligaments covering the front of the symphysis pubis. The fibres ascend, and the muscle is inserted by three portions of unequal size into the cartilages of the fifth, sixth, and seventh ribs. The upper portion, attached principally to the cartilage of the fifth rib, also

Fig. 331.—The Transversalis, Rectus, and Pyramidalis muscles.



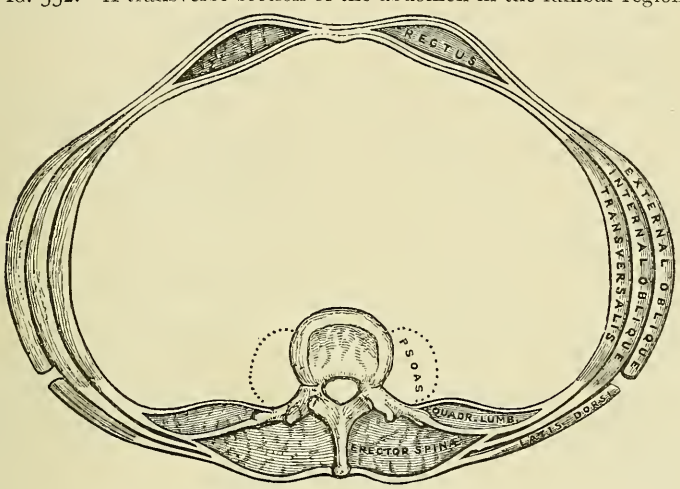
usually has some fibres of insertion into the anterior extremity of the rib itself. Some fibres are occasionally connected with the costo-xiphoid ligaments, and side of the ensiform cartilage.

The Rectus muscle is traversed by tendinous intersections, three in number, which have received the name of *lineæ transversæ*. One of these is usually situated opposite the umbilicus, and two above that point; of the latter, one corresponds to the extremity of the ensiform cartilage, and the other is about

midway between the ensiform cartilage and the umbilicus. These intersections pass transversely or obliquely across the muscle in a zigzag course; they rarely extend completely through its substance, sometimes pass only half-way across it, and are intimately adherent in front to the sheath in which the muscle is enclosed. Sometimes one or two additional lines may be seen, one usually below the umbilicus; the position of the other, where it exists, is variable. These additional lines are for the most part incomplete.

The Rectus is enclosed in a sheath (fig. 332) formed by the aponeuroses of the Oblique and Transversalis muscles, which are arranged in the following manner. When the aponeurosis of the Internal oblique arrives at the outer margin of the Rectus, it divides into two lamellæ, one of which passes in front of the Rectus, blending with the aponeurosis of the External oblique; the other, behind it, blending with the aponeurosis of the Transversalis; and these, joining again at its inner border, are inserted into the linea alba. This arrangement of the aponeurosis exists along the upper three-fourths of the muscle: at the commencement of the lower fourth, the posterior wall of the sheath terminates in a thin curved margin, the *semilunar fold of Douglas*, the concavity of which looks downwards towards the pubes: the aponeuroses of all three muscles passing in

Fig. 332.—A transverse section of the abdomen in the lumbar region.



front of the Rectus without any separation. The extremities of the fold of Douglas descend as pillows to the os pubis. The inner pillar is attached to the symphysis pubis; the outer pillar, which is named by Braune the ligament of Hesselbach, divides below to enclose the internal abdominal ring; the interna. fibres are attached to the ascending ramus of the os pubis and the pectineal fascia; the external ones pass to the Psoas fascia and to the Transversalis where it arises from Poupart's ligament on the outer side of the ring. The Rectus muscle, in the situation where its sheath is deficient, is separated from the peritoneum by the transversalis fascia.

The **Pyramidalis** is a small muscle, triangular in shape, placed at the lower part of the abdomen, in front of the Rectus, and contained in the same sheath with that muscle. It arises by tendinous fibres from the front of the os pubis and the anterior pubic ligament; the fleshy portion of the muscle passes upwards, diminishing in size as it ascends, and terminates by a pointed extremity, which is inserted into the linea alba, midway between the umbilicus and the os pubis. This muscle is sometimes found wanting on one or both sides; the lower end of the Rectus then becomes proportionately increased in size. Occasionally it has been found double on one side, or the muscles of the two sides are of unequal size. Sometimes its length exceeds what is stated above.

Nerves.—The abdominal muscles are supplied by the lower intercostal nerves. The Internal oblique also receives a filament from the ilio-inguinal nerve. The Cremaster is supplied by the genital branch of the Genito-crural.

In the description of the abdominal muscles, mention has frequently been made of the linea alba, lineæ semilunares, and lineæ transversæ; when the dissection of the muscles is completed, these structures should be examined.

The **linea alba** is a tendinous raphé seen along the middle line of the abdomen, extending from the ensiform cartilage to the symphysis pubis, to which it is attached. It is placed between the inner borders of the Recti muscles, and is formed by the blending of the aponeuroses of the Obliqui and Transversales muscles. It is narrow below, corresponding to the narrow interval existing between the Recti; but broader above, as these muscles diverge from one another in their ascent, becoming of considerable breadth after great distension of the abdomen from pregnancy or ascites. It presents numerous apertures for the passage of vessels and nerves; the largest of these is the umbilicus, which in the fœtus transmits the umbilical vessels, but in the adult is obliterated, the cicatrix being stronger than the neighbouring parts; hence umbilical hernia occurs in the adult *near* the umbilicus, whilst in the fœtus it occurs *at* the umbilicus. The linea alba is in relation, in front, with the integument, to which it is adherent, especially at the umbilicus; behind, it is separated from the peritoneum by the transversalis fascia; and below, by the urachus, and the bladder when that organ is distended.

The **lineæ semilunares** are two curved tendinous lines placed one on each side of the linea alba. Each corresponds with the outer border of the Rectus muscle, extends from the cartilage of the ninth rib to the pubic spine, and is formed by the aponeurosis of the Internal oblique at its point of division to enclose the Rectus, where it is reinforced in front by the External oblique, and behind by the Transversalis.

The **lineæ transversæ** are narrow transverse lines which intersect the Recti muscles, as already mentioned; they connect the lineæ semilunares with the linea alba.

Actions.—The abdominal muscles perform a threefold action.

When the pelvis and thorax are fixed, they compress the abdominal viscera, by constricting the cavity of the abdomen, in which action they are materially assisted by the descent of the diaphragm. By these means assistance is given in expelling the fœtus from the uterus, the fæces from the rectum, the urine from the bladder, and the contents of the stomach in vomiting.

If the pelvis and spine are fixed, these muscles compress the lower part of the thorax, materially assisting expiration. If the pelvis alone is fixed, the thorax is bent directly forward, when the muscles of both sides act, or to either side when those of the two sides act alternately, rotation of the trunk at the same time taking place to the opposite side.

If the thorax is fixed, these muscles, acting together, draw the pelvis upwards, as in climbing; or, acting singly, they draw the pelvis upwards, and bend the vertebral column to one side or the other. The Recti muscles, acting from below, depress the thorax, and consequently flex the vertebral column; when acting from above, they flex the pelvis upon the vertebral column. The Pyramidales are tensors of the linea alba.

The **fascia transversalis** is a thin aponeurotic membrane which lies between the inner surface of the Transversalis muscle and the peritoneum. It forms part of the general layer of fascia which lines the interior of the abdominal and pelvic cavities, and is directly continuous with the iliac and pelvic fasciæ. In the inguinal region, the transversalis fascia is thick and dense in structure and joined by fibres from the aponeurosis of the Transversalis muscle, but it becomes thin and cellular as it ascends to the Diaphragm, and blends with the fascia covering this muscle. In front, it unites across the middle line with the fascia on the opposite side of the body, and behind it becomes lost in the fat which

covers the posterior surfaces of the kidneys. Below, it has the following attachments: posteriorly, it is connected to the whole length of the crest of the ilium, between the attachments of the Transversalis and Iliacus muscles; between the anterior superior spine of the ilium and the femoral vessels it is connected to the posterior margin of Poupart's ligament, and is there continuous with the iliac fascia. Internal to the femoral vessels it is thin and attached to the os pubis and pectineal line, behind the conjoined tendon, with which it is united; and, corresponding to the point where the femoral vessels pass into the thigh, this fascia descends in front of them, forming the anterior wall of the crural sheath. Beneath Poupart's ligament it is strengthened by a dense band of fibrous tissue, which is only loosely connected to Poupart's ligament, and is specialised as the *deep crural arch*. The spermatic cord in the male and the round ligament in the female pass through this fascia; the point where they pass through is called the *internal abdominal ring*. This opening is not visible externally owing to a prolongation of the transversalis fascia on these structures, forming the infundibuliform process.

The **Internal** or **deep abdominal ring** is situated in the transversalis fascia, midway between the anterior superior spine of the ilium and the symphysis pubis, and about half an inch above Poupart's ligament. It is of an oval form, the extremities of the oval directed upwards and downwards, varies in size in different subjects, and is much larger in the male than in the female. It is bounded, above and externally, by the arched fibres of the Transversalis; below and internally, by the deep epigastric vessels. It transmits the spermatic cord in the male and the round ligament in the female. From its circumference a thin funnel-shaped membrane, the *infundibuliform fascia*, is continued round the cord and testis, enclosing them in a distinct pouch.

When the sac of an oblique inguinal hernia passes through the internal or deep abdominal ring, the infundibuliform process of the transversalis fascia forms one of its coverings.

The **inguinal** or **spermatic canal** contains the spermatic cord in the male and the round ligament in the female. It is an oblique canal about an inch and a half in length, directed downwards and inwards, and placed parallel to and a little above Poupart's ligament. It commences above at the internal or deep abdominal ring, which is the point where the cord enters the spermatic canal, and terminates below at the external ring. It is bounded in front by the integument and superficial fascia, by the aponeurosis of the External oblique throughout its whole length, and by the Internal oblique for its outer third; behind, by the triangular fascia, the conjoined tendon of the Internal oblique and Transversalis, transversalis fascia, and the subperitoneal fat and peritoneum; above, by the arched fibres of the Internal oblique and Transversalis; below, by the union of the fascia transversalis with Poupart's ligament.

That form of protrusion in which the intestine follows the course of the spermatic cord along the spermatic canal is called oblique inguinal hernia.

The **deep crural arch.**—Curving over the vessels, just at the point where they become femoral, on the abdominal side of Poupart's ligament and loosely connected with it, is a thickened band of fibres called the deep crural arch. It is apparently a thickening of the fascia transversalis, joining externally to the centre of Poupart's ligament, and arching across the front of the crural sheath to be inserted by a broad attachment into the spine of the os pubis and ilio-pectineal line, behind the conjoined tendons. In some subjects this structure is not very prominently marked, and not unfrequently it is altogether wanting.

Surface Form.—The only two muscles of this group which have any considerable influence on surface form are the External oblique and Rectus muscles of the abdomen. With regard to the External oblique, the upper digitations of its origin from the ribs are well marked, intermingled with the serrations of the Serratus magnus; the lower digitations are not visible, being covered by the thick border of the Latissimus dorsi. Its attachment to the

crest of the ilium, in conjunction with the Internal oblique, forms a thick oblique roll, which determines the iliac furrow. Sometimes on the front of the lateral region of the abdomen an undulating outline marks the spot where the muscular fibres terminate and the aponeurosis commences. The outer border of the Rectus is defined by the *linea semilunaris*, which may be exactly defined by putting the muscle into action. It corresponds with a curved line, with its convexity outwards, drawn from the end of the cartilage of the ninth rib to the spine of the os pubis, so that the centre of the line, at or near the umbilicus, is three inches from the median line. The inner border of the Rectus corresponds to the *linea alba*, marked on the surface of the body by a groove, the *abdominal furrow*, which extends from the infrasternal fossa to, or to a little below, the umbilicus, where it gradually becomes lost. The surface of the Rectus presents three transverse furrows, the *lineæ transversæ*. The upper two of these, one opposite or a little below the tip of the ensiform cartilage, and another, midway between this point and the umbilicus, are usually well marked; the third, opposite the umbilicus, is not so distinct. The umbilicus, situated in the linea alba, varies very much in position as regards its height. It is always situated above a zone drawn round the body opposite the highest point of the crest of the ilium, generally being about three-quarters of an inch to an inch above this line. It generally corresponds, therefore, to the fibro-cartilage between the third and fourth lumbar vertebræ.

2. Deep Muscles of the Abdomen

Psoas parvus.	Iliacus.
Psoas magnus.	Quadratus lumborum.

The Psoas magnus, the Psoas parvus, and the Iliacus muscles, with the fascia covering them, will be described with the Muscles of the Lower Extremity (see page 507).

The fascia covering the Quadratus lumborum.—This is the most internal of the two layers of fascia which are given off from the anterior or deep surface of the lumbar fascia. It is a thin layer of fascia which, passing over the anterior surface of the Quadratus lumborum, is attached, internally, to the anterior surface of the transverse processes of the lumbar vertebræ; below, to the ilio-lumbar ligament; and above, to the apex and lower border of the last rib.

The portion of this fascia which extends from the transverse process of the first lumbar vertebra to the apex and lower border of the last rib, constitutes the ligamentum arcuatum externum.

The **Quadratus lumborum** (fig. 325, page 433) is situated in the lumbar region. It is irregularly quadrilateral in shape, and broader below than above. It arises by aponeurotic fibres from the ilio-lumbar ligament and the adjacent portion of the crest of the ilium for about two inches, and is inserted into the lower border of the last rib for about half its length and, by four small tendons, into the apices of the transverse processes of the four upper lumbar vertebræ. Occasionally a second portion of this muscle is found situated in front of the preceding. It arises from the upper borders of the transverse processes of three or four of the lower lumbar vertebræ, and is inserted into the lower margin of the last rib. The Quadratus lumborum is contained in a sheath formed by the anterior and middle lamellæ of the lumbar fasciæ.

Relations.—Its *anterior surface* (or rather the fascia which covers its anterior surface) is in relation with the colon, the kidney, the Psoas muscle, and the Diaphragm. Its *posterior surface* is in relation with the middle lamella of the lumbar fascia, which separates it from the Erector spinæ. The Quadratus lumborum extends, however, beyond the outer border of the Erector spinæ.

Nerve-supply.—The anterior branches of the last dorsal and first lumbar nerves.

Actions.—The Quadratus lumborum draws down the last rib, and acts as a muscle of forced expiration; but, at the same time, by fixing the last rib it opposes the tendency of the Diaphragm to draw it upwards, and thus it becomes an assistant to inspiration. If the thorax and spine are fixed, it may act upon the pelvis, raising it towards its own side when only one muscle is put in action; and when both muscles act together, either from below or above, they flex the trunk.

IV. Muscles of the Pelvic Outlet

The muscles of this region are situated at the pelvic outlet in the ischio-rectal region and the perinæum. They include the following:

I. Muscles of the ischio-rectal region.

II. Muscles of the perinæum: A. In the Male; B. In the Female.

I. Muscles of the Ischio-Rectal Region

Corrugator cutis ani. Internal sphincter ani.
External sphincter ani. Levator ani.
Coccygeus.

The Corrugator cutis ani.—Around the anus is a thin stratum of involuntary muscular fibre, which surrounds it in a radiating manner. Internally, the fibres fade off into the submucous tissue, whilst externally they blend with the true skin. By its contraction it raises the skin into ridges radiating from the margin of the anus.

The **External sphincter ani** is a thin, flat plane of muscular fibres, elliptical in shape and intimately adherent to the integument surrounding the margin of the anus. It measures about three or four inches in length, from its anterior to its posterior extremity, being about an inch in breadth, opposite the anus. It arises from the tip of the coccyx, by a narrow tendinous band, and from the superficial fascia in front of that bone; and is inserted into the central tendinous point of the perinæum, joining with the Transversus perinæi, the Levator ani, and the Accelerator urinæ. Like other sphincter muscles, it consists of two planes of muscular fibre, which surround the margin of the anus, and join in a commissure in front and behind, some fibres crossing from side to side in front and behind the anus.

Nerve-supply.—A branch from the anterior division of the fourth sacral and the inferior hæmorrhoidal branch of the internal pudic.

Actions.—The action of this muscle is peculiar: 1. It is, like other muscles, always in a state of tonic contraction, and having no antagonistic muscle it keeps the anal orifice closed. 2. It can be put into a condition of greater contraction under the influence of the will, so as to more firmly occlude the anal aperture in other expiratory efforts, unconnected with defæcation. 3. Taking its fixed point at the coccyx, it helps to fix the central point of the perinæum, so that the Accelerator may act from this fixed point.

The **Internal sphincter** is a muscular ring which surrounds the lower extremity of the rectum for about an inch; its inferior border being contiguous to, but quite separate from, the External sphincter. This muscle is about two lines in thickness, and is formed by an aggregation of the involuntary circular fibres of the intestine. It is paler in colour and less coarse in texture than the External sphincter.

Actions.—Its action is entirely involuntary. It helps the External sphincter to occlude the anal aperture.

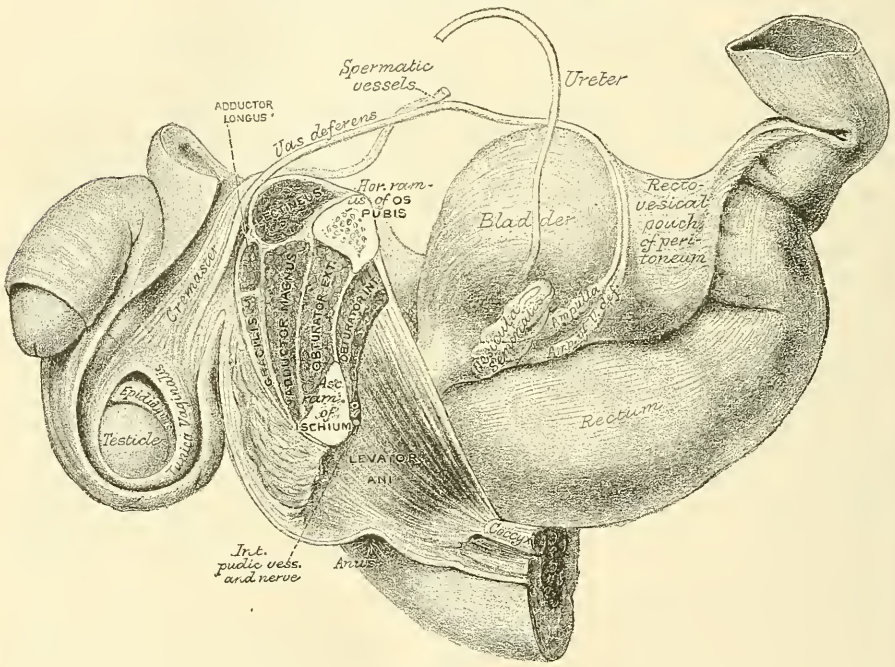
The **Levator ani** (fig. 333) is a broad, thin muscle, situated on each side of the pelvis. It is attached to the inner surface of the sides of the true pelvis, and descending unites with its fellow of the opposite side to form the floor of the pelvic cavity. It supports the viscera in this cavity and surrounds the various structures which pass through it. It arises, in front, from the posterior surface of the body of the os pubis on the outer side of the symphysis; posteriorly, from the inner surface of the spine of the ischium; and between these two points, from the angle of division between the obturator and recto-vesical layers of the pelvic fascia at their under part. The fibres pass downwards to the middle line of the floor of the pelvis, and are inserted, the most posterior into the sides of the apex of the coccyx; those placed more anteriorly unite with the muscle of

the opposite side, in a median fibrous raphé, which extends between the coccyx and the margin of the anus. The middle fibres, which form the larger portion of the muscle, are inserted into the side of the rectum, blending with the fibres of the Sphincter muscles; lastly, the anterior fibres, the longest, descend upon the side of the prostate gland to unite beneath it with the muscle of the opposite side, blending with the fibres of the External sphincter and Transversus perinæi muscles at the central tendinous point of the perinæum.

The anterior portion is occasionally separated from the rest of the muscle by connective tissue. From this circumstance, as well as from its peculiar relation with the prostate gland, descending by its side, and surrounding it as in a sling, it has been described by Santorini and others as a distinct muscle, under the name of Levator prostatæ. In the female, the anterior fibres of the Levator ani descend upon the side of the vagina.

Relations.—By its *inner* or *pelvic surface*, with the recto-vesical fascia, which

Fig. 333.—Side view of pelvis, showing Levator ani. (From a preparation in the Museum of the Royal College of Surgeons.)



separates it from the viscera of the pelvis and from the peritoneum. By its *outer* or *perineal surface*, it forms the inner boundary of the ischio-rectal fossa, and is covered by a thin layer of fascia, the *ischio-rectal* or *anal fascia*, given off from the obturator fascia. Its *posterior border* is free and separated from the Coccygeus muscle by a cellular interspace. Its *anterior border* is separated from the muscle of the opposite side by a triangular space, through which the urethra, and in the female the vagina, passes from the pelvis.

Nerve-supply.—A branch from the anterior division of the fourth sacral nerve and a branch from the pudic nerve, which is sometimes derived from the perineal, sometimes from the inferior hæmorrhoidal division.

Actions.—This muscle supports the lower end of the rectum and vagina, and also the bladder during the efforts of expulsion. It elevates and inverts the lower end of the rectum after it has been protruded and everted during the expulsion of the fæces. It is also a muscle of forced expiration.

The **Coccygeus** is situated behind and parallel with the preceding. It is a triangular plane of muscular and tendinous fibres, arising, by its apex, from the

spine of the ischium and lesser sacro-sciatic ligament, and inserted, by its base, into the margin of the coccyx and into the side of the lower piece of the sacrum. It assists the Levator ani and Pyriformis in closing in the back part of the outlet of the pelvis.

Relations.—By its *inner* or *pelvic surface*, with the rectum. By its *external surface*, with the lesser sacro-sciatic ligament. The *lower border* is in relation with the posterior border of the Levator ani, but separated from it by a cellular interval: its *upper border* is in relation with the lower border of the Pyriformis, but separated from it by the sciatic and internal pudic vessels and nerve.

Nerve-supply.—A branch from the fourth and fifth sacral nerves.

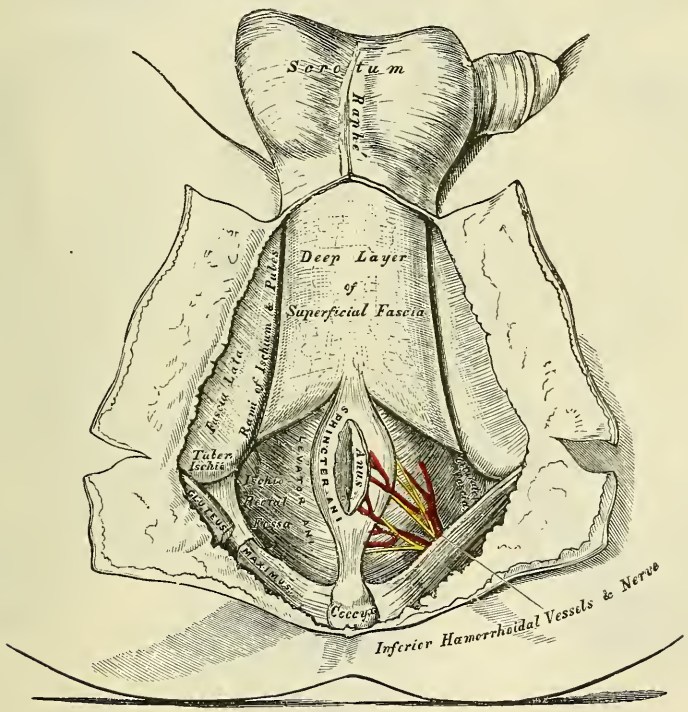
Action.—The Coccygei muscles raise and support the coccyx, after it has been pressed backwards during defæcation or parturition.

II. A. Muscles and Fasciæ of the Perinæum in the Male

Transversus perinæi.	Erector penis.
Accelerator urinæ.	Compressor urethræ.

Superficial fascia.—The superficial fascia of the perinæum consists of two layers, superficial and deep, as in other regions of the body.

Fig. 334.—The perinæum. The integument and superficial layer of superficial fascia reflected.

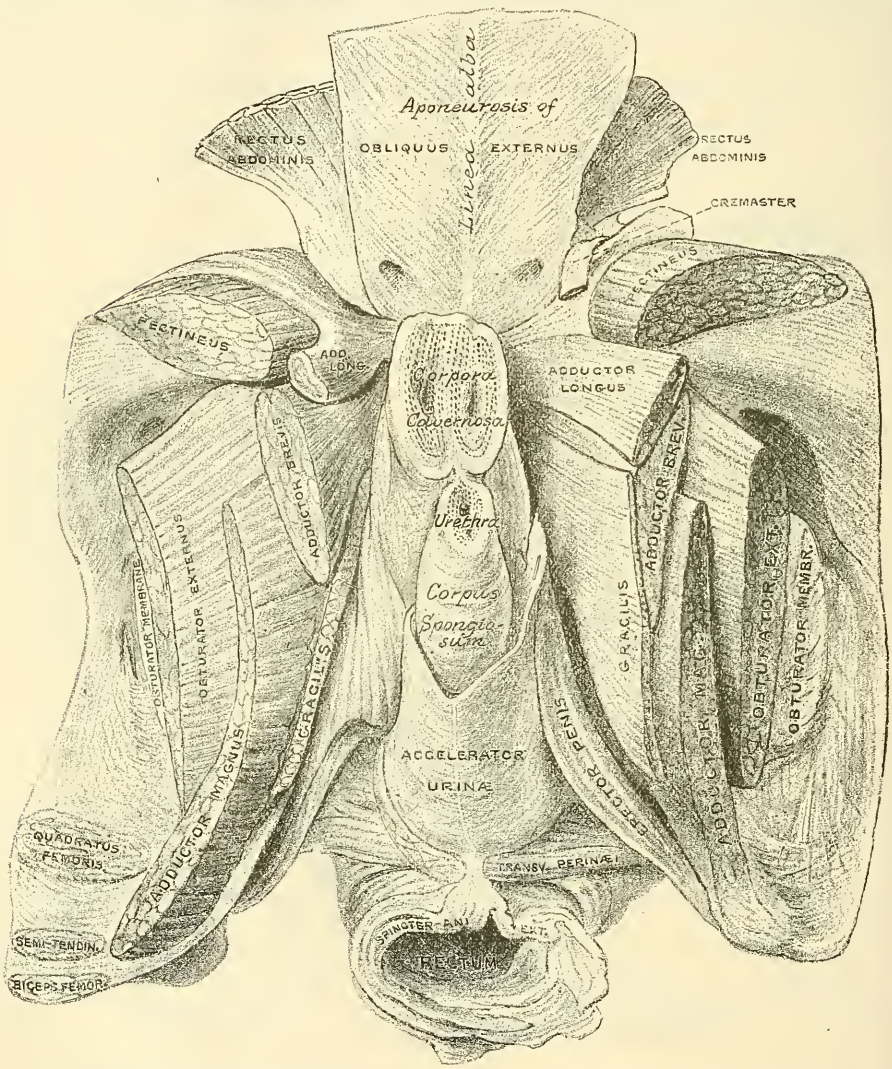


The *superficial layer* is thick, loose, areolar in texture, and contains much adipose tissue in its meshes, the amount of which varies in different subjects. In front, it is continuous with the dartos of the scrotum; behind, it is continuous with the subcutaneous areolar tissue surrounding the anus; and, on either side, with the same fascia on the inner side of the thighs. This layer should be carefully removed after it has been examined, when the deep layer will be exposed.

The *deep layer of superficial fascia* (Fascia of Colles) is thin, aponeurotic in structure, and of considerable strength, serving to bind down the muscles of

the root of the penis. It is continuous, in front, with the dartos of the scrotum; on either side it is firmly attached to the margins of the rami of the os pubis and ischium, external to the crus penis, and as far back as the tuberosity of the ischium; posteriorly, it curves down behind the Transversus perinæi muscles to join the lower margin of the deep perineal fascia. This fascia not only covers the muscles in this region, but sends down a vertical septum from its under surface, which separates the back part of the subjacent space into two, being incomplete in front.

Fig. 335.—The muscles attached to the front of the pelvis. (From a preparation in the Museum of the Royal College of Surgeons of England.)



The central tendinous point of the Perinæum.—This is a fibrous point in the middle line of the perinæum, between the urethra and the rectum, being about half an inch in front of the anus. At this point four muscles converge and are attached: viz. the External sphincter ani, the Accelerator urinæ, and the two Transversus perinæi; so that by the contraction of these muscles, which extend in opposite directions, it serves as a fixed point of support.

The **Transversus perinæi** is a narrow muscular slip, which passes more or less transversely across the back part of the perineal space. It arises by a small

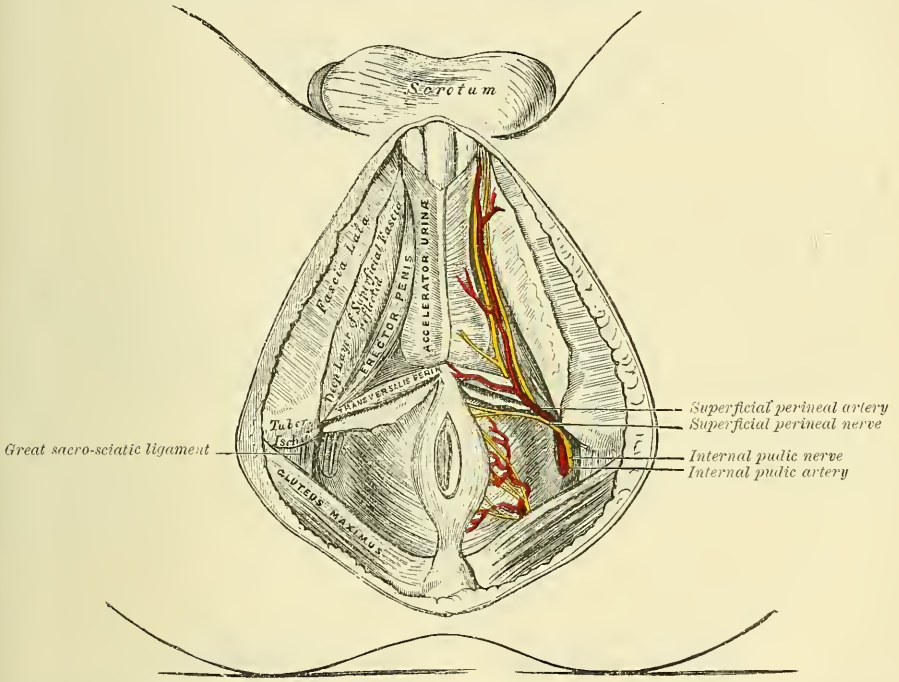
tendon from the inner and fore part of the tuberosity of the ischium, and, passing inwards, is inserted into the central tendinous point of the perinæum, joining in this situation with the muscle of the opposite side, the External sphincter ani behind, and the Accelerator urinæ in front.

Nerve-supply.—The perineal branch of the internal pudic.

Actions.—By their contraction they serve to fix the central tendinous point of the perinæum.

The **Accelerator urinæ** (*Ejaculator seminis*, or *Bulbo-cavernosus*) is placed in the middle line of the perinæum, immediately in front of the anus. In consists of two symmetrical halves, united along the median line by a tendinous raphé. It arises from the central tendon of the perinæum, and from the median raphé in front. From this point its fibres diverge like the plumes of a pen; the most posterior form a thin layer, which are lost on the anterior surface of the triangular ligament; the middle fibres encircle the bulb and adjacent parts of the corpus

Fig. 336.—The superficial muscles and vessels of the perinæum.



spongiosum, and join with the fibres of the opposite side, on the upper part of the corpus spongiosum, in a strong aponeurosis; the anterior fibres, the longest and most distinct, spread out over the sides of the corpus cavernosum, to be inserted partly into that body, anterior to the Erector penis, occasionally extending to the os pubis; partly terminating in a tendinous expansion, which covers the dorsal vessels of the penis. The latter fibres are best seen by dividing the muscle longitudinally, and dissecting it outwards from the surface of the urethra.

Action.—This muscle serves to empty the canal of the urethra, after the bladder has expelled its contents; during the greater part of the act of micturition its fibres are relaxed, and it only comes into action at the end of the process. The middle fibres are supposed, by Krause, to assist in the erection of the corpus spongiosum, by compressing the erectile tissue of the bulb. The anterior fibres, according to Tyrrel, also contribute to the erection of the penis, as they are inserted into, and continuous with, the fascia of the penis, compressing the dorsal vein during the contraction of the muscle.

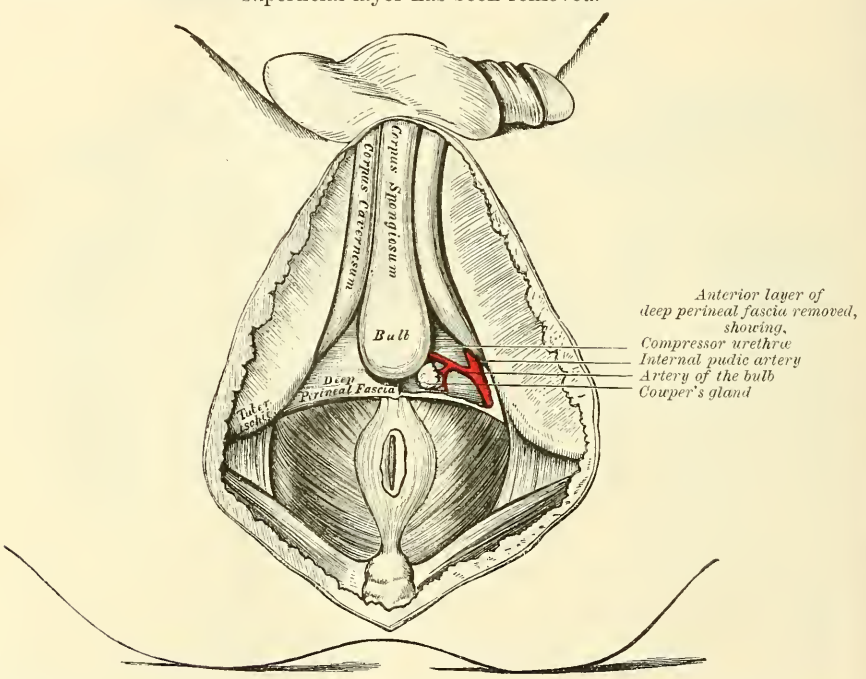
The **Erector penis** (*ischio-cavernosus*) covers part of the crus penis. It is an elongated muscle, broader in the middle than at either extremity, and situated on either side of the lateral boundary of the perinæum. It arises by tendinous and fleshy fibres from the inner surface of the tuberosity of the ischium, behind the crus penis; from the surface of the crus; and from the adjacent portion of the ramus of the ischium. From these points fleshy fibres succeed, which end in an aponeurosis which is inserted into the sides and under surface of the crus penis.

Nerve-supply.—The perineal branch of the internal pudic.

Actions.—It compresses the crus penis, and retards the return of the blood through the veins, and thus serves to maintain the organ erect.

Between the muscles just examined a triangular space exists, bounded internally by the Accelerator urinæ, externally by the Erector penis, and behind by the Transversus perinæi. The floor of this space is formed by the triangular ligament of the urethra (deep perineal fascia), and running from behind forwards

Fig. 337.—Triangular ligament or deep perineal fascia. On the left side the superficial layer has been removed.



in it are the superficial perineal vessels and nerve, and the transverse perineal artery coursing along the posterior boundary of the space on the Transversus perinæi muscle.

The **triangular ligament** (*Deep perineal fascia*) is stretched across the pubic arch, so as to close in the front part of the outlet of the pelvis. It consists of two dense membranous laminæ, which are united along their posterior borders, but are separated in front by intervening structures. The superficial of these two layers, the *inferior layer of the triangular ligament*, is triangular in shape, about an inch and a half in depth, attached above, by its apex, to the under surface of the symphysis pubis and subpubic ligament; and on each side to the rami of the ischium and os pubis, beneath the crura penis. Its inferior margin, or base, is directed towards the rectum, and connected to the central tendinous point of the perinæum. It is continuous with the deep layer of the superficial fascia behind the Transversus perinæi muscle, and with a thin fascia which covers the cutaneous surface of the Levator ani muscle (*anal* or *ischio-rectal* fascia).

This layer of the triangular ligament is perforated by the urethra, about an inch below the symphysis pubis. The aperture is circular in form, and about three or four lines in diameter. Above this is the aperture for the dorsal vein of the penis; and, outside the latter, branches of the pudic nerve and artery pierce it.

If this superficial or inferior layer of the triangular ligament is detached on either side, the following structures will be seen between it and the deep layer: the subpubic ligament above, close to the pubes; the dorsal vein of the penis; the membranous portion of the urethra, and the Compressor urethræ muscle; Cowper's glands and their ducts; the pudic vessels and nerve; the artery and nerve of the bulb, and a plexus of veins.

The deep layer of the ligament (*superior layer of the triangular ligament*) is derived from the obturator fascia and stretches across the pubic arch. If the obturator fascia is traced inwards after covering the Obturator internus muscle, it will be found to be attached by some of its deeper or anterior fibres to the inner margin of the ischio-pubic ramus, while its superficial or posterior fibres pass over this attachment to become the superior layer of the triangular ligament. Behind, this layer of the fascia is continuous with the inferior layer and with the fascia of Colles, and in front it is separated from the apex of the prostate gland through the intervention of a prolongation of the recto-vesical fascia. It is pierced by the urethra, or rather consists of two halves which are separated in the middle line by the urethra passing between them.

The **Compressor urethræ** (*Constrictor urethræ*) surrounds the whole length of the membranous portion of the urethra, and is contained between the two layers of the triangular ligament. It arises, by aponeurotic fibres, from the upper part of the descending ramus of the os pubis on each side, to the extent of half or three-quarters of an inch: each segment of the muscle passes inwards, and divides into two fasciculi, which surround the urethra from the prostate gland behind, to the bulbous portion of the urethra in front; and unite, at the upper and lower surfaces of this tube, with the muscle of the opposite side, by means of a tendinous raphé.

Actions.—The muscles of both sides act together as a sphincter, compressing the membranous portion of the urethra. During the transmission of fluids they, like the Acceleratores urinæ, are relaxed, and only come into action at the end of the process to eject the last of the fluid.

II. B. Muscles of the Perinæum in the Female (fig. 338)

Transversus perinæi.	Erector clitoridis.
Sphincter vaginæ.	Compressor urethræ.

The **Transversus perinæi** in the **female** is a narrow muscular slip, which passes more or less transversely across the back part of the perineal space. It arises by a small tendon from the inner and fore part of the tuberosity of the ischium, and, passing inwards, is inserted into the central line of the perinæum, joining in this situation with the muscle of the opposite side, the External sphincter ani behind, and the Sphincter vaginæ in front.

Nerve-supply.—The perineal branch of the internal pudic.

Actions.—By their contraction they serve to fix the central tendinous point of the perinæum.

The **Sphincter vaginæ** surrounds the orifice of the vagina, and is analogous to the Accelerator urinæ in the male. It is attached posteriorly to the central tendinous point of the perinæum, where it blends with the External sphincter ani. Its fibres pass forwards on each side of the vagina, to be inserted into the corpora cavernosa of the clitoris, a fasciculus crossing over the body of the organ so as to compress the dorsal vein.

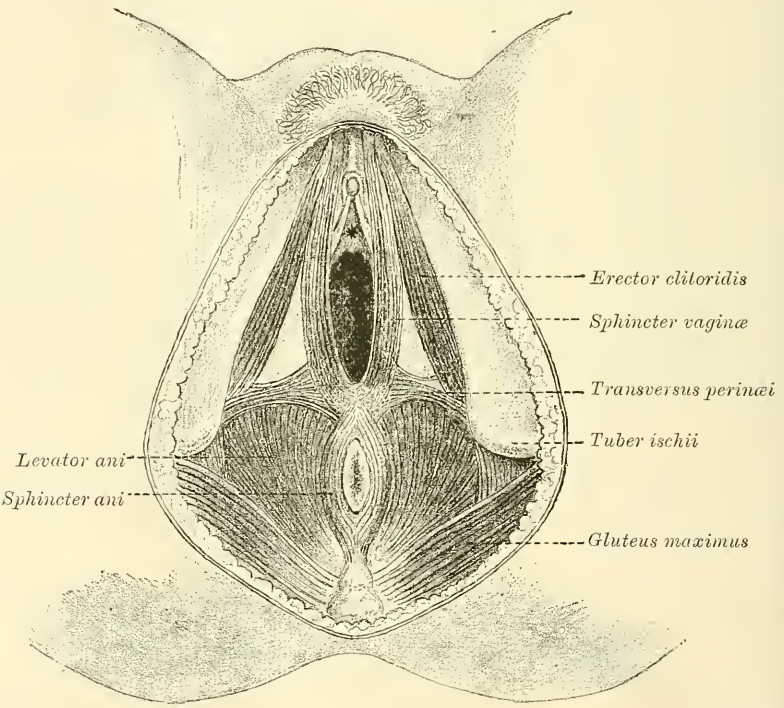
Nerve-supply.—The perineal branch of the internal pudic.

Actions.—It diminishes the orifice of the vagina. The anterior fibres contribute to the erection of the clitoris, as they are inserted into and are continuous with the fascia of the clitoris; compressing the dorsal vein during the contraction of the muscle.

The **Erector clitoridis** resembles the Erector penis in the male, but is smaller than it. It covers the unattached part of the crus clitoridis. It is an elongated muscle, broader at the middle than at either extremity, and situated on either side of the lateral boundary of the perinæum. It arises by tendinous and fleshy fibres from the inner surface of the tuberosity of the ischium, behind the crus clitoridis; from the surface of the crus; and from the adjacent portion of the ramus of the ischium. From these points fleshy fibres succeed, which end in an aponeurosis, which is inserted into the sides and under surface of the crus clitoridis.

Nerve-supply.—The perineal branch of the internal pudic.

Fig. 338.—Muscles of the female perinæum.



Actions.—It compresses the crus clitoridis and retards the return of blood through the veins, and thus serves to maintain the organ erect.

The **triangular ligament** (*deep perineal fascia*) in the female is not so strong as in the male. It is attached to the pubic arch, its apex being connected with the symphysis pubis. It is divided in the middle line by the aperture of the vagina, with the external coat of which it becomes blended, and in front of this is perforated by the urethra. Its posterior border is continuous, as in the male, with the deep layer of the superficial fascia around the Transversus perinæi muscle.

Like the triangular ligament in the male it consists of two layers, between which are to be found the following structures: the subpubic ligament above, the dorsal vein of the clitoris, a portion of the urethra and the Compressor urethræ muscle, the glands of Bartholin and their ducts; the pudic vessels and the dorsal nerve of the clitoris; the artery of the bulbi vestibuli, and a plexus of veins.

The **Compressor urethræ** (*Constrictor urethræ*) arises on each side from the margin of the descending ramus of the os pubis. The fibres, passing inwards, divide into two sets: those of the fore part of the muscle are directed across the subpubic arch in front of the urethra to blend with the muscular fibres of the opposite side; while those of the hinder and larger part pass inwards to blend with the wall of the vagina behind the urethra.

MUSCLES AND FASCIÆ OF THE UPPER EXTREMITY

The Muscles of the Upper Extremity are divisible into groups, corresponding with the different regions of the limb.

I. Of the Thoracic Region

1. *Anterior Thoracic Region*

Pectoralis major. Pectoralis minor.
Subclavius.

2. *Lateral Thoracic Region*

Serratus magnus.

II. Of the Shoulder and Arm

3. *Acromial Region*

Deltoid.

4. *Anterior Scapular Region*

Subscapularis.

5. *Posterior Scapular Region*

Supraspinatus. Teres minor.
Infraspinatus. Teres major.

6. *Anterior Humeral Region*

Coraco-brachialis. Biceps.
Brachialis anticus.

7. *Posterior Humeral Region*

Triceps. Subanconeus.

III. Of the Forearm

8. *Anterior Radio-Ulnar Region*

Superficial Layer.
- Pronator radii teres.
- Flexor carpi radialis.
- Palmaris longus.
- Flexor carpi ulnaris.
- Flexor sublimis digitorum.

Deep Layer.
- Flexor profundus digitorum.
- Flexor longus pollicis.
- Pronator quadratus.

9. *Radial Region*

Supinator longus.
Extensor carpi radialis longior.
Extensor carpi radialis brevior.

10. *Posterior Radio-Ulnar Region*

Superficial Layer.
- Extensor communis digitorum.
- Extensor minimi digiti.
- Extensor carpi ulnaris.
- Anconeus.

Deep Layer.
- Supinator brevis.
- Extensor ossis metacarpi pollicis.
- Extensor brevis pollicis.
- Extensor longus pollicis.
- Extensor indicis.

IV. Of the Hand

11. *Radial Region*

Abductor pollicis.
Flexor ossis metacarpi pollicis (Opponens pollicis).
Flexor brevis pollicis.
Adductor pollicis.

12. *Ulnar Region*

Palmaris brevis.
Abductor minimi digiti.
Flexor brevis minimi digiti.
Flexor ossis metacarpi minimi digiti (Opponens minimi digiti).

13. *Palmar Region*

Lumbricales.
Interossei palmares.
Interossei dorsales.

Dissection of Pectoral Region and Axilla (fig. 339).—The arm being drawn away from the side nearly at right angles with the trunk, and rotated outwards, make a vertical incision through the integument in the median line of the chest, from the upper to the lower part of the sternum; a second incision along the lower border of the Pectoral muscle, from the ensiform cartilage to the inner side of the axilla; a third, from the sternum along the clavicle, as far as its centre; and a fourth, from the middle of the clavicle obliquely downwards, along the interspace between the Pectoral and Deltoid muscles, as low as the fold of the armpit. The flap of integument is then to be dissected off in the direction indicated in the figure, but not entirely removed, as it should be replaced on completing the dissection. If a transverse incision is now made from the

lower end of the sternum to the side of the chest, as far as the posterior fold of the armpit, and the integument reflected outwards, the axillary space will be more completely exposed.

I. Muscles and Fasciæ of the Thoracic Region

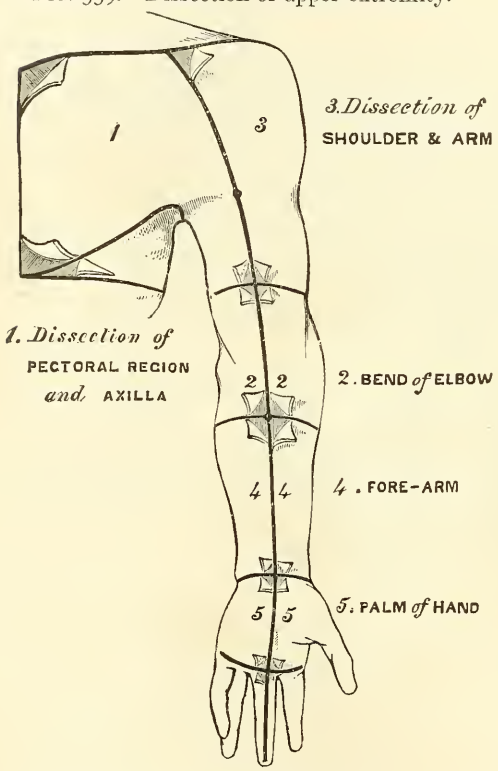
1. *Anterior Thoracic Region*

Pectoralis major. Pectoralis minor.

Subclavius.

The **superficial fascia** of the thoracic region is a loose cellulo-fibrous layer, enclosing masses of fat in its spaces. It is continuous with the superficial fascia of the neck and upper extremity above, and of the abdomen below. Opposite the mamma, it divides into two layers, one of which passes in front, the other behind that gland; and from both of these layers numerous septa pass into its substance, supporting its various lobes: from the anterior layer, fibrous processes pass forwards to the integument and nipple. These processes were called by Sir A. Cooper the *ligamenta suspensoria*, from the support they afford to the gland in this situation.

Fig. 339.—Dissection of upper extremity.



The **deep fascia** of the thoracic region is a thin aponeurotic lamina, covering the surface of the great Pectoral muscle, and sending numerous prolongations between its fasciculi: it is attached, in the middle line, to the front of the sternum; and, above, to the clavicle; externally and below it becomes continuous with the fascia over the shoulder, axilla, and thorax. It is very thin over the upper part of the muscle, thicker in the interval between the Pectoralis major and Latissimus dorsi, where it closes in the axillary space, and divides at the outer margin of the latter muscle into two layers, one of which passes in front, and the other behind it; these proceed as far as the spinous processes of the dorsal vertebræ, to which they are attached. At the lower part of the thoracic region this fascia is well-developed, and is continuous with the fibrous sheath of the Recti muscles.

The **Pectoralis major** (fig. 340) is a broad, thick, triangular muscle, situated at the upper and fore part of the chest, in front of the axilla. It arises from the anterior surface of the sternal half of the clavicle; from half the breadth of the anterior surface of the sternum, as low down as the attachment of the cartilage of the sixth or seventh rib; this portion of its origin consists of aponeurotic fibres, which intersect with those of the opposite muscle; it also arises from the cartilages of all the true ribs, with the exception, frequently, of the first, or of the seventh, or both; and from the aponeurosis of the External oblique muscle of the abdomen. The fibres from this extensive origin converge towards its insertion, giving to the muscle a radiated appearance. Those fibres which arise from the clavicle pass obliquely outwards and downwards, and are usually separated from

the rest by a cellular interval: those from the lower part of the sternum, and the cartilages of the lower true ribs, pass upwards and outwards; whilst the middle fibres pass horizontally. They all terminate in a flat tendon, about two inches broad, which is inserted into the anterior bicipital ridge of the humerus. This tendon consists of two laminæ, placed one in front of the other, and usually blended together below. The anterior, the thicker, receives the clavicular and upper half of the sternal portion of the muscle; and its fibres are inserted in the same order as that in which they arise; that is to say, the outermost fibres of

Fig. 340.—Muscles of the chest and front of the arm. Superficial view.

origin from the clavicle are inserted at the uppermost part of the tendon; the upper fibres of origin from the sternum pass down to the lowermost part of this anterior lamina of the tendon and extend as low as the tendon of the Deltoid and join with it. The posterior lamina of the tendon receives the attachment of the lower half of the sternal portion and the deeper part of the muscle from the costal cartilages. These deep fibres, and particularly those from the lower costal cartilages, ascend the higher, turning backwards successively behind the superficial and upper ones, so that the tendon appears to be twisted. The

posterior lamina reaches higher on the humerus than the anterior one, and from it an expansion is given off which covers the bicipital groove and blends with the capsule of the shoulder-joint. From the deepest fibres of this lamina at its insertion an expansion is given off which lines the bicipital groove of the humerus, whilst from the lower border of the tendon a third expansion passes downwards to the fascia of the arm.

Relations.—By its *anterior surface*, with the integument, the superficial fascia, the Platysma, the mammary gland, and the deep fascia. By its *posterior surface*; its *thoracic portion*, with the sternum, the ribs and costal cartilages, the costo-coracoid membrane, the Subclavius, Pectoralis minor, Serratus magnus, and the Intercostals; its *axillary portion* forms the anterior wall of the axillary space, and covers the axillary vessels and nerves, the Biceps and Coraco-brachialis muscles. Its *upper border* lies parallel with the Deltoid, from which it is separated by a slight interspace in which lie the cephalic vein and descending branch of the acromial thoracic artery. Its *lower border* forms the anterior margin of the axilla, being at first separated from the Latissimus dorsi by a considerable interval; but both muscles gradually converge towards the outer part of the space.

Dissection.—Detach the Pectoralis major by dividing the muscle along its attachment to the clavicle, and by making a vertical incision through its substance a little external to its line of attachment to the sternum and costal cartilages. The muscle should then be reflected outwards, and its tendon carefully examined. The Pectoralis minor is now exposed, and immediately above it, in the interval between its upper border and the clavicle, a strong fascia, the *costo-coracoid membrane*.

The **costo-coracoid membrane** is a strong fascia, placed between the clavicle and the upper border of the Pectoralis minor muscle, which protects the axillary vessels and nerves. Above, it is attached to the anterior margin of the Subclavian groove on the under surface of the clavicle, and is connected with a layer of cervical fascia which overlies the Omo-hyoid muscle, and forms the posterior layer of the sheath of the Subclavius muscle. Internally, it blends with the fascia covering the first two intercostal spaces, and is attached also to the first rib internal to the origin of the Subclavius muscle. Externally, it is very thick and dense, and is attached to the coracoid process. The portion extending from its attachment to the first rib to the coracoid process is often whiter and denser than the rest; this is sometimes called the *costo-coracoid ligament*. Below this, it is thin, and at the upper border of the Pectoralis minor it splits into two layers to invest the muscle; from the lower border of the Pectoralis minor it is continued downwards to join the axillary fascia, and outwards to join the fascia over the short head of the Biceps. The costo-coracoid membrane is pierced by the cephalic vein, the acromial thoracic artery and vein, superior thoracic artery, and anterior thoracic nerves.

The **Pectoralis minor** (fig. 341) is a thin, flat, triangular muscle, situated at the upper part of the thorax, beneath the Pectoralis major. It arises by three tendinous digitations, from the upper margin and outer surface of the third, fourth, and fifth ribs, near their cartilages, and from the aponeurosis covering the Intercostal muscles; the fibres pass upwards and outwards, and converge to form a flat tendon, which is inserted into the inner border and upper surface of the coracoid process of the scapula.

Relations.—By its *anterior surface*, with the Pectoralis major, and the superior thoracic vessels and nerves. By its *posterior surface*, with the ribs, Intercostal muscles, Serratus magnus, the axillary space, and the axillary vessels and brachial plexus of nerves. Its upper border is separated from the clavicle by a triangular interval, broad internally, narrow externally, bounded in front by the costo-coracoid membrane, and internally by the ribs. In this space are the first part of the axillary vessels and nerves.

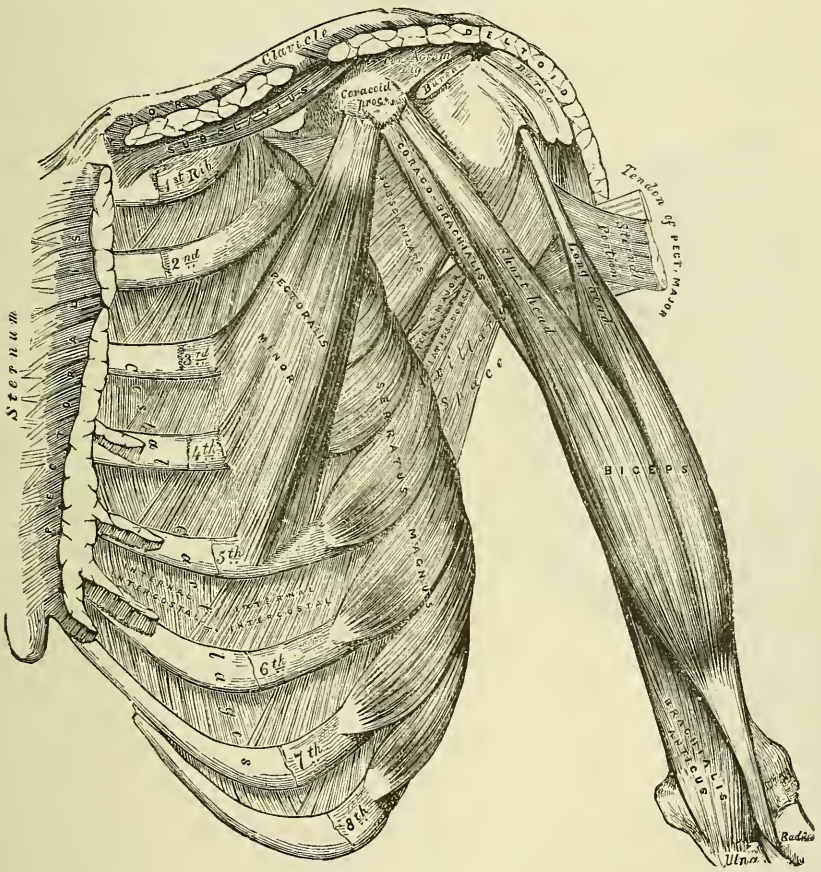
The costo-coracoid membrane should now be removed, when the Subclavius muscle will be seen.

The **Subclavius** is a long, thin, spindle-shaped muscle, placed in the interval between the clavicle and the first rib. It arises by a short, thick tendon from the first rib and its cartilage at their junction, in front of the rhomboid ligament; the fleshy fibres proceed obliquely upwards and outwards, to be inserted into a deep groove on the under surface of the middle third of the clavicle.

Relations.—By its *upper surface*, with the clavicle. By its *under surface*, it is separated from the first rib by the subclavian vessels and brachial plexus of nerves. Its *anterior surface* is separated from the Pectoralis major by the costo-coracoid membrane, which, with the clavicle and a part of the cervical fascia, forms an osseo-fibrous sheath in which the muscle is enclosed.

If the costal attachment of the Pectoralis minor is divided across, and the muscle reflected outwards, the axillary vessels and nerves are brought fully into view, and should be examined.

Fig. 341.—Muscles of the chest and front of the arm, with the boundaries of the axilla.



Nerves.—The Pectoral muscles are supplied by the anterior thoracic nerves; the Pectoralis major through these nerves receives filaments from all the spinal nerves entering into the formation of the brachial plexus; the Pectoralis minor receives its fibres from the seventh and eighth cervical and first dorsal nerves. The Subclavius is supplied by a filament from the cord formed by the union of the fifth and sixth cervical nerves.

Actions.—If the arm has been raised by the Deltoid, the Pectoralis major will, conjointly with the Latissimus dorsi and Teres major, depress it to the side of the chest. If acting alone, it adducts and draws forwards the arm, bringing

it across the front of the chest, and at the same time rotates it inwards. The Pectoralis minor depresses the point of the shoulder, drawing the scapula downwards and inwards to the thorax, and throwing the inferior angle backwards. The Subclavius depresses the shoulder, drawing the clavicle downwards and forwards. When the arms are fixed, all three muscles act upon the ribs, drawing them upwards and expanding the chest, and thus becoming very important agents in forced inspiration. Asthmatic patients always assume an attitude which fixes the shoulders, so that all these muscles may be brought into action to assist in dilating the cavity of the chest.

2. *Lateral Thoracic Region*

Serratus magnus.

The **Serratus magnus** (fig. 342) is a broad, thin, and irregularly quadrilateral muscle, situated at the upper part and side of the chest. It consists of two triangular or fan-shaped portions: the upper one has the apex of the triangle attached to the first and second ribs, and the base to the upper angle and vertebral border of the scapula; the lower one has its apex behind, attached to the inferior angle of the scapula, and its base in front connected with the ribs from the second to the eighth. It arises by nine fleshy digitations from the outer surface and upper border of the eight upper ribs (the second rib having two), and from the aponeurosis covering the upper Intercostal muscles, and is inserted into the whole length of the anterior aspect of the posterior border of the scapula. The upper fan-shaped portion is attached to the fore part of the outer surfaces of the first and second ribs; its fibres spread out, the upper ones forming a thick fasciculus, which passes upwards and backwards, and is attached to the triangular smooth surface on the anterior aspect of the superior angle of the scapula; the remaining fibres proceed backwards and downwards to be attached to the posterior border of the scapula between the superior and inferior angles. The lower fan-shaped portion is attached posteriorly by its apex to the anterior surface of the inferior angle of the scapula, partly by muscular, partly by tendinous fibres; it spreads out like a fan, the upper fibres passing forwards and upwards, the lower horizontally forwards to be inserted into the outer surface of the fore part of the ribs from the second to the eighth, by a series of muscular digitations. In the intervals between the four lower of these are received corresponding processes of the External oblique.

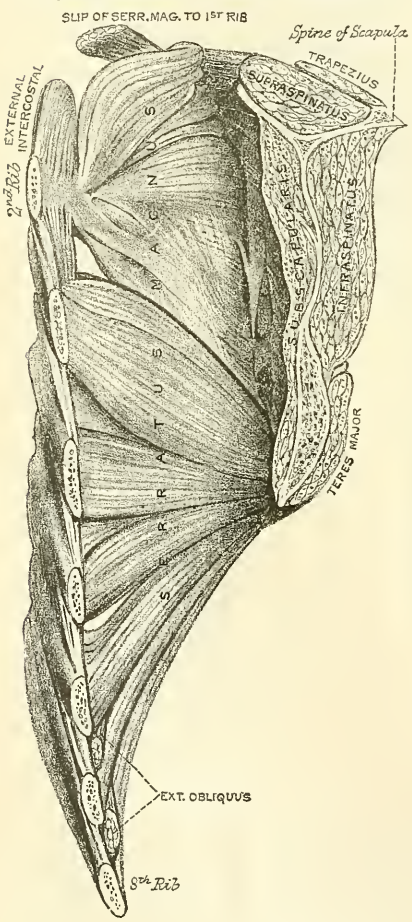


Fig. 342.—Serratus magnus. (From a preparation in the Museum of the Royal College of Surgeons of England.)

Relations.—This muscle is covered, in front, by the Pectoral muscles; behind, by the Subscapularis; above, by the axillary vessels and nerves. Its *deep surface* rests upon the ribs and Intercostal muscles.

Nerves.—The Serratus magnus is supplied by the posterior thoracic nerve which is derived from the fifth, sixth and generally the seventh cervical nerves.

Actions.—The Serratus magnus, as a whole, carries the scapula forwards, and at the same time raises the vertebral border of the bone. It is therefore concerned in the action of pushing. Its lower and stronger fibres move forwards the lower angle and assist the Trapezius in rotating the bone round an axis through its centre, and thus assists this muscle in raising the acromion and supporting weights upon the shoulder. It is also an assistant to the Deltoid in raising the arm, inasmuch as during the action of this latter muscle it fixes the scapula and so the glenoid cavity on which the head of the humerus rotates. After the Deltoid has raised the arm to a right angle with the trunk, the Serratus magnus and the Trapezius, by rotating the scapula, raise the arm into an almost vertical position. It is possible that when the shoulders are fixed the lower fibres of the Serratus magnus may assist in raising and everting the ribs; but it is not the important inspiratory muscle which it was formerly believed to be.

Surgical Anatomy.—When the muscle is paralysed, the vertebral border, and especially the lower angle, leave the ribs and stand out prominently on the surface, giving a peculiar 'winged' appearance to the back. The patient is unable to raise the arm, and an attempt to do so is followed by a further projection of the lower angle of the scapula from the back of the thorax.

Dissection.—After completing the dissection of the axilla, if the muscles of the back have been dissected, the upper extremity should be separated from the trunk. Saw through the clavicle at its centre, and then cut through the muscles which connect the scapula and arm with the trunk, viz. the Pectoralis minor in front, Serratus magnus at the side, and the Levator anguli scapulæ, the Rhomboids, Trapezius, and Latissimus dorsi behind. These muscles should be cleaned and traced to their respective insertions. Then make an incision through the integument, commencing at the outer third of the clavicle, and extending along the margin of that bone, the acromion process, and spine of the scapula; the integument should be dissected from above downwards and outwards, when the fascia covering the Deltoid is exposed (fig. 339, 3).

II. Muscles and Fasciæ of the Shoulder and Arm

The **superficial fascia** of the upper extremity is a thin cellulo-fibrous layer, containing the superficial veins and lymphatics, and the cutaneous nerves. It is most distinct in front of the elbow, and contains very large superficial veins and nerves; in the hand it is hardly demonstrable, the integument being closely adherent to the deep fascia by dense fibrous bands. Small subcutaneous bursæ are found in this fascia over the acromion, the olecranon, and the knuckles. The deep fascia of the upper extremity comprises the aponeurosis of the shoulder, arm, and forearm, the anterior and posterior annular ligaments of the carpus, and the palmar fascia. These will be considered in the description of the muscles of the several regions.

3. *Acromial Region*

Deltoid

The **deep fascia** covering the Deltoid (deltoid aponeurosis) is a fibrous layer, which covers the outer surface of the muscle, thick and strong behind, where it is continuous with the infraspinatus fascia, thinner over the rest of its extent. It sends down numerous prolongations between the fasciculi of the muscle. In front, it is continuous with the fascia covering the great Pectoral muscle; behind, with that covering the Infraspinatus; above, it is attached to the clavicle, the acromion, and spine of the scapula; below, it is continuous with the deep fascia of the arm.

The **Deltoid** (fig. 340) is a large, thick, triangular muscle, which gives the rounded outline to the shoulder, and has received its name from its resemblance to the Greek letter Δ reversed. It surrounds the shoulder-joint in the greater part of its extent, covering it on its outer side, and in front and behind. It arises

from the outer third of the anterior border and upper surface of the clavicle; from the outer margin and upper surface of the acromion process; and from the lower lip of the posterior border of the spine of the scapula, as far back as the triangular surface at its inner end. From this extensive origin the fibres converge towards their insertion, the middle passing vertically, the anterior obliquely backwards, the posterior obliquely forwards; they unite to form a thick tendon, which is inserted into a rough prominence on the middle of the outer side of the shaft of the humerus. At its insertion the muscle gives off an expansion to the deep fascia of the arm. This muscle is remarkably coarse in texture, and the arrangement of its muscular fibres is somewhat peculiar; the central portion of the muscle—that is to say, the part arising from the acromion process—consists of oblique fibres, which arise in a bipenniform manner from the sides of tendinous intersections, generally four in number, which are attached above to the acromion process and pass downwards parallel to one another in the substance of the muscle. The oblique muscular fibres thus formed are inserted into similar tendinous intersections, generally three in number, which pass upwards from the insertion of the muscle into the humerus and alternate with the descending septa. The lateral portions of the muscle—that is to say, the fibres arising from the clavicle and spine of the scapula—are not arranged in this manner, but consist of parallel fasciculi passing from their origin above, to be inserted into the margins of the inferior tendon.

Relations.—By its *superficial surface*, with the integument, the superficial fascia, Platysma, and supra-acromial nerves. Its *deep surface* is separated from the head of the humerus by a large sacculated synovial bursa, and covers the coracoid process, coraco-acromial ligament, Pectoralis minor, Coraco-brachialis, both heads of the Biceps, the tendon of the Pectoralis major, the insertions of the Supraspinatus, Infraspinatus, and Teres minor, the scapular and external heads of the Triceps, the circumflex vessels and nerve, and the humerus. Its *anterior border* is separated at its upper part from the Pectoralis major by a cellular interspace, which lodges the cephalic vein and descending branch of the acromial thoracic artery: lower down the two muscles are in close contact. Its *posterior border* rests on the Infraspinatus and Triceps muscles.

Nerves.—The Deltoid is supplied by the fifth and sixth cervical through the circumflex nerve.

Actions.—The Deltoid raises the arm directly from the side, so as to bring it at right angles with the trunk. Its anterior fibres, assisted by the Pectoralis major, draw the arm forwards; and its posterior fibres, aided by the Teres major and Latissimus dorsi, draw it backwards.

Surgical Anatomy.—The Deltoid is very liable to atrophy, and when in this condition simulates dislocation of the shoulder-joint, as there is flattening of the shoulder and apparent prominence of the acromion process; upon examination, however, it will be found that the relative position of the great tuberosity of the humerus to the acromion and coracoid process is unchanged. Atrophy of the Deltoid may be due to disuse or loss of trophic influence, either from injury to the circumflex nerve or cord lesions, as in infantile paralysis.

Dissection.—Divide the Deltoid across, near its upper part, by an incision carried along the margin of the clavicle, the acromion process, and spine of the scapula, and reflect it downwards: the bursa will be seen on its under surface, as well as the circumflex vessels and nerve.

4. *Anterior Scapular Region*

Subscapularis.

The **subscapular fascia** is a thin membrane attached to the entire circumference of the subscapular fossa, and affording attachment by its inner surface to some of the fibres of the Subscapularis muscle: when this is removed, the Subscapularis muscle is exposed.

The **Subscapularis** (fig. 341) is a large triangular muscle, which fills up the

subscapular fossa, arising from its internal two-thirds, with the exception of a narrow margin along the posterior border, and the surfaces at the superior and inferior angles which afford attachment to the Serratus magnus: it also arises from the lower two-thirds of the groove on the axillary border of the bone. Some fibres arise from tendinous laminæ, which intersect the muscle, and are attached to ridges on the bone; and others from an aponeurosis, which separates the muscle from the Teres major and the long head of the Triceps. The fibres pass outwards, and, gradually converging, terminate in a tendon, which is inserted into the lesser tuberosity of the humerus. Those fibres which arise from the axillary border of the scapula are inserted into the neck of the humerus to the extent of an inch below the tuberosity. The tendon of the muscle is in close contact with the capsular ligament of the shoulder-joint, and glides over a large bursa, which separates it from the base of the coracoid process. This bursa communicates with the cavity of the joint by an aperture in the capsular ligament.

Relations.—By its *anterior surface* with the Serratus magnus, Coracobrachialis, and Biceps, the axillary vessels and brachial plexus of nerves, and the subscapular vessels and nerves. By its *posterior surface*, with the scapula and the capsular ligament of the shoulder-joint. Its *lower border* is contiguous with the Teres major and Latissimus dorsi.

Nerves.—It is supplied by the fifth and sixth cervical nerves through the upper and lower subscapular nerves.

Actions.—The Subscapularis rotates the head of the humerus inwards; when the arm is raised, it draws the humerus forwards and downwards. It is a powerful defence to the front of the shoulder-joint, preventing displacement of the head of the bone forwards.

5. *Posterior Scapular Region* (fig. 343)

Supraspinatus.	Teres minor.
Infraspinatus.	Teres major.

Dissection.—To expose these muscles, and to examine their mode of insertion into the humerus, detach the Deltoid and Trapezius from their attachment to the spine of the scapula and acromion process. Remove the clavicle by dividing the ligaments connecting it with the coracoid process, and separate it at its articulation with the scapula: divide the acromion process near its root with a saw. The fragments being removed, the tendons of the posterior Scapular muscles will be fully exposed, and can be examined. A block should be placed beneath the shoulder-joint, so as to make the muscles tense.

The **supraspinous fascia** is a thick and dense membranous layer, which completes the osseo-fibrous case in which the Supraspinatus muscle is contained; affording attachment, by its inner surface, to some of the fibres of the muscle. It is thick internally, but thinner externally under the coraco-acromial ligament. When this fascia is removed, the Supraspinatus muscle is exposed.

The **Supraspinatus muscle** occupies the whole of the supraspinous fossa, arising from its internal two-thirds, and from the strong fascia which covers its surface. The muscular fibres converge to a tendon, which passes across the capsular ligament of the shoulder-joint, to which it is intimately adherent, and is inserted into the highest of the three facets on the great tuberosity of the humerus.

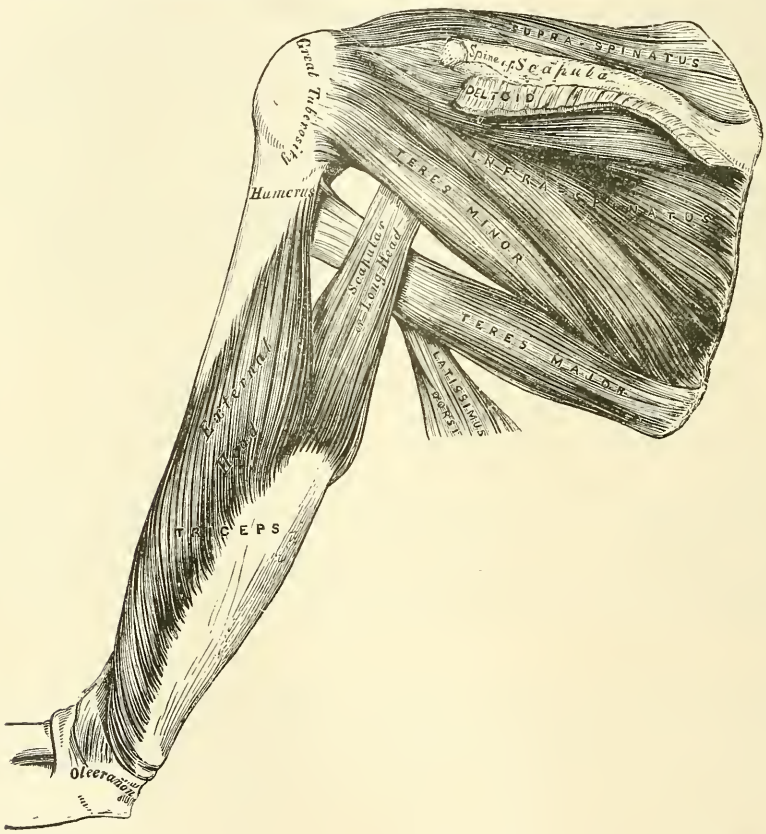
Relations.—By its *upper surface*, with the Trapezius, the clavicle, the acromion, the coraco-acromial ligament, and the Deltoid. By its *under surface*, with the scapula, the suprascapular vessels and nerve, and upper part of the shoulder-joint.

The **infraspinous fascia** is a dense fibrous membrane, covering in the Infraspinatus muscle and attached to the circumference of the infraspinous fossa; it affords attachment, by its inner surface, to some fibres of that muscle. At the point where the Infraspinatus commences to be covered by the Deltoid, this

fascia divides into two layers: one layer passes over the Deltoid muscle, helping to form the Deltoid fascia already described; the other passes beneath the Deltoid to the shoulder-joint.

The **Infraspinatus** is a thick triangular muscle, which occupies the chief part of the infraspinous fossa, arising by fleshy fibres from its internal two-thirds; and by tendinous fibres from the ridges on its surface: it also arises from a strong fascia which covers it externally, and separates it from the Teres major and minor. The fibres converge to a tendon, which glides over the external border of the spine of the scapula, and, passing across the capsular ligament of the shoulder-joint, is inserted into the middle facet on the great tuberosity of the humerus. The tendon of this muscle is occasionally separated from the spine of the scapula by a synovial bursa, which communicates with the synovial cavity of the shoulder-joint.

Fig. 343.—Muscles on the dorsum of the scapula and the Triceps.



Relations.—By its *posterior surface*, with the Deltoid, the Trapezius, Latissimus dorsi, and the integument. By its *anterior surface*, with the scapula, from which it is separated by the suprascapular and dorsalis scapulæ vessels, and with the capsular ligament of the shoulder-joint. Its *lower border* is in contact with the Teres minor, and occasionally united with it, and with the Teres major.

The **Teres minor** is a narrow, elongated muscle, which lies along the inferior border of the scapula. It arises from the dorsal surface of the axillary border of the scapula for the upper two-thirds of its extent, and from two aponeurotic laminæ, one of which separates this muscle from the Infraspinatus, the other from the Teres major; its fibres pass obliquely upwards and outwards, and terminate in a tendon, which is inserted into the lowest of the three facets on

the great tuberosity of the humerus, and, by fleshy fibres, into the humerus immediately below it. The tendon of this muscle passes across the capsular ligament of the shoulder-joint.

Relations.—By its *posterior surface*, with the Deltoid, and the integument. By its *anterior surface*, with the scapula, the dorsal branch of the subscapular artery, the long head of the Triceps, and the shoulder-joint. By its *upper border*, with the Infraspinatus. By its *lower border*, with the Teres major, from which it is separated anteriorly by the long head of the Triceps.

The **Teres major** is a broad and somewhat flattened muscle, which arises from the flat oval surface on the dorsal aspect of the inferior angle of the scapula, and from the fibrous septa interposed between it and the Teres minor and Infraspinatus; the fibres are directed upwards and outwards, and terminate in a flat tendon, about two inches in length, which is inserted into the posterior bicipital ridge of the humerus. The tendon of this muscle, at its insertion into the humerus, lies behind that of the Latissimus dorsi, from which it is separated by a synovial bursa, the two tendons being, however, united along their lower borders for a short distance.

Relations.—By its *posterior surface*, with the integument, from which it is separated, internally, by the Latissimus dorsi; and externally, by the long head of the Triceps. By its *anterior surface*, with the Subscapularis, Latissimus dorsi, Coraco-brachialis, short head of the Biceps, the axillary vessels, and brachial plexus of nerves. Its *upper border* is at first in relation with the Teres minor, from which it is afterwards separated by the long head of the Triceps. Its *lower border* forms, in conjunction with the Latissimus dorsi, part of the posterior boundary of the axilla.

Nerves.—The Supra- and Infraspinatus muscles are supplied by the fifth and sixth cervical nerves through the suprascapular nerve; the Teres minor, by the fifth cervical, through the circumflex; and the Teres major, by the fifth and sixth cervical, through the lower subscapular.

Actions.—The Supraspinatus assists the Deltoid in raising the arm from the side, and fixes the head of the humerus in its socket. The Infraspinatus and Teres minor rotate the head of the humerus outwards: when the arm is raised, they assist in retaining it in that position and carrying it backwards. One of the most important uses of these three muscles is the great protection they afford to the shoulder-joint, the Supraspinatus supporting it above, and preventing displacement of the head of the humerus upwards, whilst the Infraspinatus and Teres minor protect it behind, and prevent dislocation backwards. The Teres major assists the Latissimus dorsi in drawing the humerus downwards and backwards, when previously raised, and rotating it inwards; when the arm is fixed it may assist the Pectoral and Latissimus dorsi muscles in drawing the trunk forwards.

6. *Anterior Humeral Region* (fig. 341)

Coraco-brachialis. Biceps. Brachialis anticus.

Dissection.—The arm being placed on the table, with the front surface uppermost, make a vertical incision through the integument along the middle line, from the outer extremity of the anterior fold of the axilla, to about two inches below the elbow-joint, where it should be joined by a transverse incision, extending from the inner to the outer side of the forearm; the two flaps being reflected on either side, the fascia should be examined (fig. 339).

The **deep fascia** of the arm is continuous with that covering the shoulder and front of the great Pectoral muscle, by means of which it is attached, above, to the clavicle, acromion, and spine of the scapula; it forms a thin, loose, membranous sheath investing the muscles of the arm, sending down septa between them, and composed of fibres disposed in a circular or spiral direction, and connected together by vertical and oblique fibres. It differs in thickness at different parts, being thin over the Biceps, but thicker where it covers the

Triceps, and over the condyles of the humerus: it is strengthened by fibrous aponeuroses, derived from the Pectoralis major and Latissimus dorsi on the inner side, and from the Deltoid externally. On either side it gives off a strong intermuscular septum, which is attached to the condyloid ridge and condyle of the humerus. These septa serve to separate the muscles of the anterior from those of the posterior brachial region. The *external intermuscular septum* extends from the lower part of the anterior bicipital ridge, along the external condyloid ridge, to the outer condyle; it is blended with the tendon of the Deltoid, gives attachment to the Triceps behind, to the Brachialis anticus, Supinator longus, and Extensor carpi radialis longior, in front; and is perforated by the musculo-spiral nerve and superior profunda artery. The *internal intermuscular septum*, thicker than the preceding, extends from the lower part of the posterior lip of the bicipital groove below the Teres major, along the internal condyloid ridge to the inner condyle; it is blended with the tendon of the Coraco-brachialis, and affords attachment to the Triceps behind and the Brachialis anticus in front. It is perforated by the ulnar nerve and the inferior profunda and anastomotic arteries. At the elbow, the deep fascia is attached to all the prominent points round the joint, viz. the condyles of the humerus and the olecranon process of the ulna, and is continuous with the deep fascia of the forearm. Just below the middle of the arm, on its inner side, in front of the internal intermuscular septum, is an oval opening in the deep fascia, which transmits the basilic vein and some lymphatic vessels. On the removal of this fascia, the muscles, vessels, and nerves of the anterior humeral region are exposed.

The **Coraco-brachialis**, the smallest of the three muscles in this region, is situated at the upper and inner part of the arm. It arises by fleshy fibres from the apex of the coracoid process, in common with the short head of the Biceps, and from the intermuscular septum between the two muscles; the fibres pass downwards, backwards, and a little outwards, to be inserted by means of a flat tendon into a rough ridge at the middle of the inner surface and internal border of the shaft of the humerus between the origins of the Triceps and Brachialis anticus. It is perforated by the musculo-cutaneous nerve. The inner border of the muscle forms a guide to the position of the brachial artery in tying the vessel in the upper part of its course.

Relations.—By its *anterior surface*, with the Pectoralis major above, and at its insertion with the brachial vessels and median nerve which cross it. By its *posterior surface*, with the tendons of the Subscapularis, Latissimus dorsi, and Teres major, the inner head of the Triceps, the humerus, and the anterior circumflex vessels. By its *inner border*, with the brachial artery and the median and musculo-cutaneous nerves. By its *outer border*, with the short head of the Biceps and Brachialis anticus.

The **Biceps** (*Biceps flexor cubiti*) is a long fusiform muscle, occupying the whole of the anterior surface of the arm, and divided above into two portions or heads, from which circumstance it has received its name. The short head arises by a thick flattened tendon from the apex of the coracoid process, in common with the Coraco-brachialis. The long head arises from the supraglenoid tubercle on the upper margin of the glenoid cavity, by a long rounded tendon, which is continuous with the glenoid ligament. This tendon arches over the head of the humerus, being enclosed in a special sheath of the synovial membrane of the shoulder-joint; it then passes through an opening in the capsular ligament at its attachment to the humerus, and descends in the bicipital groove, in which it is retained by a fibrous prolongation from the tendon of the Pectoralis major. The fibres from this tendon form a rounded belly, and, about the middle of the arm, join with the portion of the muscle derived from the short head. The belly of the muscle, narrow and somewhat flattened, terminates above the elbow in a flattened tendon, which is inserted into the back part of the tuberosity of the radius, a synovial bursa being interposed between the tendon and the front

of the tuberosity. The tendon of the muscle is thin and broad; as it approaches the radius it becomes narrow and twisted upon itself, so that its anterior surface becomes external and is applied to the tuberosity of the radius at its insertion: opposite the bend of the elbow the tendon gives off, from its inner side, a broad aponeurosis, the *bicipital fascia* (*semilunar fascia*), which passes obliquely downwards and inwards across the brachial artery, and is continuous with the deep fascia of the forearm (fig. 340). The inner border of this muscle forms a guide to the position of the vessel, in tying the brachial artery in the middle of the arm.*

Relations.—Its *anterior surface* is overlapped above by the Pectoralis major and Deltoid; in the rest of its extent it is covered by the superficial and deep fasciæ and the integument. Its *posterior surface* rests above on the shoulder-joint and upper part of the humerus; below it rests on the Brachialis anticus, with the musculo-cutaneous nerve intervening between the two, and on the Supinator brevis. Its *inner border* is in relation with the Coraco-brachialis, the brachial vessels, and median nerve; its *outer border*, with the Deltoid and Supinator longus.

The **Brachialis anticus** is a broad muscle, which covers the elbow-joint and the lower half of the front of the humerus. It is somewhat compressed from before backwards, and is broader in the middle than at either extremity. It arises from the lower half of the outer and inner surfaces of the shaft of the humerus; and commences above at the insertion of the Deltoid, which it embraces by two angular processes. Its origin extends below, to within an inch of the margin of the articular surface, and is limited on each side by the external and internal borders of the shaft of the humerus. It also arises from the intermuscular septa on each side, but more extensively from the inner than the outer, from which it is separated below by the Supinator longus and Extensor carpi radialis longior. Its fibres converge to a thick tendon, which is inserted into a rough depression on the anterior surface of the coronoid process of the ulna, being received into an interval between two fleshy slips of the Flexor digitorum profundus.

Relations.—By its *anterior surface*, with the Biceps, the brachial vessels, musculo-cutaneous, and median nerves. By its *posterior surface*, with the humerus and front of the elbow-joint. By its *inner border*, with the Triceps, ulnar nerve, and Pronator radii teres, from which it is separated by the intermuscular septum. By its *outer border*, with the musculo-spiral nerve, radial recurrent artery, the Supinator longus, and Extensor carpi radialis longior.

Nerves.—The muscles of this group are supplied by the musculo-cutaneous nerve. The Brachialis anticus usually receives an additional filament from the musculo-spiral. The Coraco-brachialis receives its supply primarily from the seventh cervical, the Biceps and Brachialis anticus from the fifth and sixth cervical nerves.

Actions.—The Coraco-brachialis draws the humerus forwards and inwards, and at the same time assists in elevating it towards the scapula. The Biceps is a flexor of the forearm: it is also a supinator, and serves to render tense the deep fascia of the forearm by means of the broad aponeurosis given off from its tendon. The Brachialis anticus is a flexor of the forearm, and forms an important defence to the elbow-joint. When the forearm is fixed, the Biceps and Brachialis anticus flex the arm upon the forearm, as is seen in efforts of climbing.

* A third head to the Biceps is occasionally found (Theile says as often as once in eight or nine subjects), arising at the upper and inner part of the Brachialis anticus, with the fibres of which it is continuous, and inserted into the bicipital fascia and inner side of the tendon of the Biceps. In most cases this additional slip passes behind the brachial artery in its course down the arm. Occasionally the third head consists of two slips, which pass down, one in front, the other behind the artery, concealing the vessel in the lower half of the arm.

7. *Posterior Humeral Region*

Triceps. Subanconeus.

The **Triceps** (*Triceps extensor cubiti*) (fig. 343) is situated on the back of the arm, extending the entire length of the posterior surface of the humerus. It is of large size, and divided above into three parts : hence its name. These three portions have been named (1) the middle, scapular, or long head ; (2) the external, or long humeral ; and (3) the internal, or short humeral head.

The *middle* or *scapular head* arises, by a flattened tendon, from a rough triangular depression on the scapula, immediately below the glenoid cavity, being blended at its upper part with the capsular ligament ; the muscular fibres pass downwards between the two other portions of the muscle, and join with them in the common tendon of insertion.

The *external head* arises from the posterior surface of the shaft of the humerus, between the insertion of the Teres minor and the upper part of the musculo-spiral groove ; from the external border of the humerus and the external intermuscular septum : the fibres from this origin converge towards the common tendon of insertion.

The *internal head* arises from the posterior surface of the shaft of the humerus, below the groove for the musculo-spiral nerve : commencing above, narrow and pointed, below the insertion of the Teres major, and extending to within an inch of the trochlear surface : it also arises from the internal border of the humerus and from the back of the whole length of the internal and lower part of the external intermuscular septa. The fibres of this portion of the muscle are directed, some downwards to the olecranon, whilst others converge to the common tendon of insertion.

The *common tendon* of the Triceps commences about the middle of the back part of the muscle : it consists of two aponeurotic laminæ, one of which is subcutaneous and covers the posterior surface of the muscle for the lower half of its extent ; the other is more deeply seated in the substance of the muscle ; after receiving the attachment of the muscular fibres, they join together above the elbow, and are inserted, for the most part, into the back part of the upper surface of the olecranon process ; a band of fibres is, however, continued downwards, on the outer side, over the Anconeus, to blend with the deep fascia of the forearm. A small bursa, occasionally multilocular, is situated on the front part of this surface, beneath the tendon.

The long head of the Triceps descends between the Teres minor and Teres major, dividing the triangular space between these two muscles and the humerus into two smaller spaces, one triangular, the other quadrangular (fig. 343). The triangular space contains the dorsalis scapulæ vessels ; it is bounded by the Teres minor above, the Teres major below, and the scapular head of the Triceps externally : the quadrangular space transmits the posterior circumflex vessels and the circumflex nerve ; it is bounded by the Teres minor above, the Teres major below, the scapular head of the Triceps internally, and the humerus externally.

Relations.—By its *posterior surface*, with the Deltoid above : in the rest of its extent it is subcutaneous. By its *anterior surface*, with the humerus, musculo-spiral nerve, superior profunda vessels, and back part of the elbow-joint. Its *middle* or *long head* is in relation, behind, with the Deltoid and Teres minor ; in front, with the Subscapularis, Latissimus dorsi, and Teres major.

The **Subanconeus** is a name given to a few fibres from the under surface of the lower part of the Triceps muscle, which are inserted into the posterior ligament of the elbow-joint. By some authors it is regarded as the analogue of the Subcrureus in the lower limb, but it is not a separate muscle.

Nerves.—The Triceps is supplied by the seventh and eighth cervical nerves through the musculo-spiral nerve.

Actions.—The Triceps is the great extensor muscle of the forearm, serving, when the forearm is flexed, to extend the elbow-joint. It is the direct antagonist of the Biceps and Brachialis anticus. When the arm is extended, the long head of the muscle may assist the Teres major and Latissimus dorsi in drawing the humerus backwards and in adducting it to the thorax. The long head of the Triceps protects the under part of the shoulder-joint, and prevents displacement of the head of the humerus downwards and backwards. The Subanconeus draws up the posterior ligament during extension of the forearm.

Surgical Anatomy.—The existence of the band of fibres from the Triceps to the fascia of the forearm is of importance in excision of the elbow, and should always be carefully preserved from injury by the operator, as by means of these fibres the patient is enabled to extend the forearm, a movement which would otherwise mainly be accomplished by gravity, that is to say, by allowing the forearm to drop from its own weight.

III. Muscles and Fasciæ of the Forearm

Dissection.—To dissect the forearm, place the limb in the position indicated in fig. 339, make a vertical incision along the middle line from the elbow to the wrist, and a transverse incision at the extremity of this; the superficial structures being removed, the deep fascia of the forearm is exposed.

The **deep fascia** of the forearm, continuous above with that enclosing the arm, is a dense, highly glistening aponeurotic investment, which forms a general sheath enclosing the muscles in this region; it is attached, behind, to the olecranon and posterior border of the ulna, and gives off from its inner surface numerous intermuscular septa, which enclose each muscle separately. Below, it is continuous in front with the anterior annular ligament, and forms a sheath for the tendon of the Palmaris longus muscle, which passes over the annular ligament to be inserted into the palmar fascia. Behind, near the wrist-joint, it becomes much thickened by the addition of many transverse fibres, and forms the posterior annular ligament. It consists of circular and oblique fibres, connected together by numerous vertical fibres. It is much thicker on the dorsal than on the palmar surface, and at the lower than at the upper part of the forearm, and is strengthened by tendinous fibres derived from the Brachialis anticus and Biceps in front, and from the Triceps behind. Its inner surface gives origin to muscular fibres, especially at the upper part of the inner and outer sides of the forearm, and forms the boundaries of a series of conical-shaped cavities, in which the muscles are contained. Besides the vertical septa separating each muscle, transverse septa are given off both on the anterior and posterior surfaces of the forearm, separating the deep from the superficial layer of muscles. Numerous apertures exist in the fascia for the passage of vessels and nerves; one of these, of large size, situated at the front of the elbow, serves for the passage of a communicating branch between the superficial and deep veins.

The muscles of the forearm may be subdivided into groups corresponding to the region they occupy. One group occupies the inner and anterior aspect of the forearm, and comprises the Flexor and Pronator muscles. Another group occupies its outer side; and a third its posterior aspect. The two latter groups include all the Extensor and Supinator muscles.

8. *Anterior Radio-Ulnar Region*

The muscles in this region are divided for convenience of description into two groups or layers, superficial and deep.

Superficial layer

Pronator radii teres.
Flexor carpi radialis.
Palmaris longus.
Flexor carpi ulnaris.
Flexor sublimis digitorum.

These muscles take origin from the internal condyle of the humerus by a common tendon.

The **Pronator radii teres** arises by two heads. One, the larger and more superficial, arises from the humerus, immediately above the internal condyle, and from the tendon common to the origin of the other muscles; also from the fascia of the forearm, and intermuscular septum between it and the Flexor carpi radialis. The other head is a thin fasciculus, which arises from the inner side of the coronoid process of the ulna, joining the preceding at an acute angle. Between the two heads passes the median nerve. The muscle passes obliquely across the forearm from the inner to the outer side, and terminates in a flat tendon, which turns over the outer margin of the radius, and is inserted into a rough impression at the middle of the outer surface of the shaft of that bone.

Relations.—By its *anterior surface* throughout the greater part of its extent with the deep fascia; at its insertion it is crossed by the radial vessels and nerve and covered by the Supinator longus. By its *posterior surface*, with the Brachialis anticus, Flexor sublimis digitorum, the median nerve, and ulnar artery: the small, or deep, head being interposed between the two latter structures. Its *outer border* forms the inner boundary of a triangular space, in which is placed the brachial artery, median nerve, and tendon of the Biceps muscle. Its *inner border* is in contact with the Flexor carpi radialis.

Surgical Anatomy.—This muscle, when suddenly brought into very active use, as in the game of lawn tennis, is apt to be strained, producing slight swelling, tenderness, and pain on putting the muscle into action. This is known as 'lawn-tennis arm.'

The **Flexor carpi radialis** lies on the inner side of the preceding muscle. It arises from the internal condyle by the common tendon, from the fascia of the forearm, and from the intermuscular septa between it and the Pronator radii teres, on the outside; the Palmaris longus, internally; and the Flexor sublimis digitorum, beneath. Slender and aponeurotic in structure at its commencement, it increases in size, and terminates in a tendon, which forms the lower two-thirds of its length. This tendon passes through a canal on the outer side of the annular ligament, runs through a groove in the os trapezium (which is converted into a canal by a fibrous sheath, and lined by a synovial membrane), and is inserted into the base of the metacarpal bone of the index finger, and by a slip into the base of the metacarpal bone of the middle finger. The radial artery lies between the tendon of this muscle and the Supinator longus, and may easily be tied in this situation.

Relations.—By its *superficial surface*, with the deep fascia and the integument. By its *deep surface*, with the Flexor sublimis digitorum, Flexor longus pollicis, and wrist-joint. By its *outer border*, with the Pronator radii teres and the radial vessels. By its *inner border*, with the Palmaris longus above, and the median nerve below.

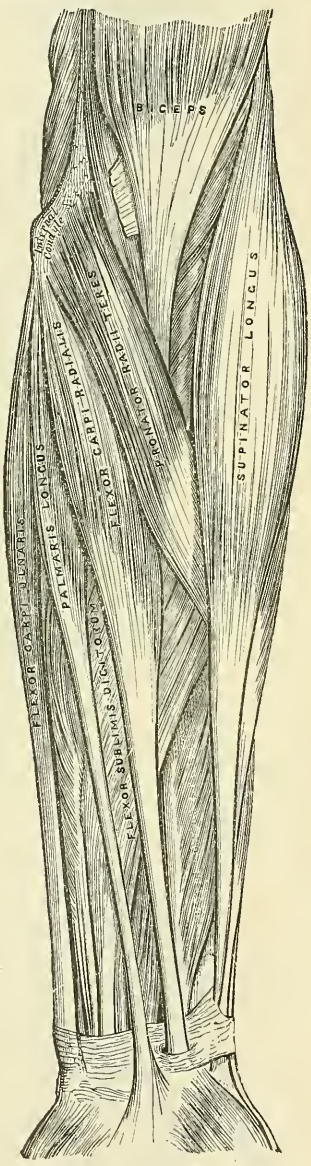
The **Palmaris longus** is a slender, fusiform muscle, lying on the inner side of the preceding. It arises from the inner condyle of the humerus by the common tendon, from the deep fascia, and the intermuscular septa between it and the adjacent muscles. It terminates in a slender, flattened tendon, which passes over the annular ligament, to end in the palmar fascia, frequently sending a tendinous slip to the short muscles of the thumb. This muscle is often absent.

Relations.—By its *superficial surface*, with the deep fascia. By its *deep surface*, with the Flexor sublimis digitorum. *Internally*, with the Flexor carpi ulnaris. *Externally*, with the Flexor carpi radialis. The median nerve lies close to the tendon, just above the wrist, on its inner and posterior side.

The **Flexor carpi ulnaris** lies along the ulnar side of the forearm. It arises by two heads, connected by a tendinous arch, beneath which pass the ulnar nerve and posterior ulnar recurrent artery. One head arises from the inner condyle of the humerus by the common tendon; the other from the inner margin of the olecranon and from the upper two-thirds of the posterior border of the ulna by

an aponeurosis, common to it and the Extensor carpi ulnaris and Flexor profundus digitorum; and from the intermuscular septum between it and the Flexor sublimis digitorum. The fibres terminate in a tendon, which occupies the anterior part of the lower half of the muscle, and is inserted into the pisiform bone, and is prolonged from this to the fifth metacarpal and unciform bones, by the piso-metacarpal and piso-uncinate ligaments: it is also attached by a few fibres to the annular ligament. The ulnar artery lies on the outer side of the tendon of this muscle, in the lower two-thirds of the forearm; the tendon forming a guide in tying the vessel in this situation.

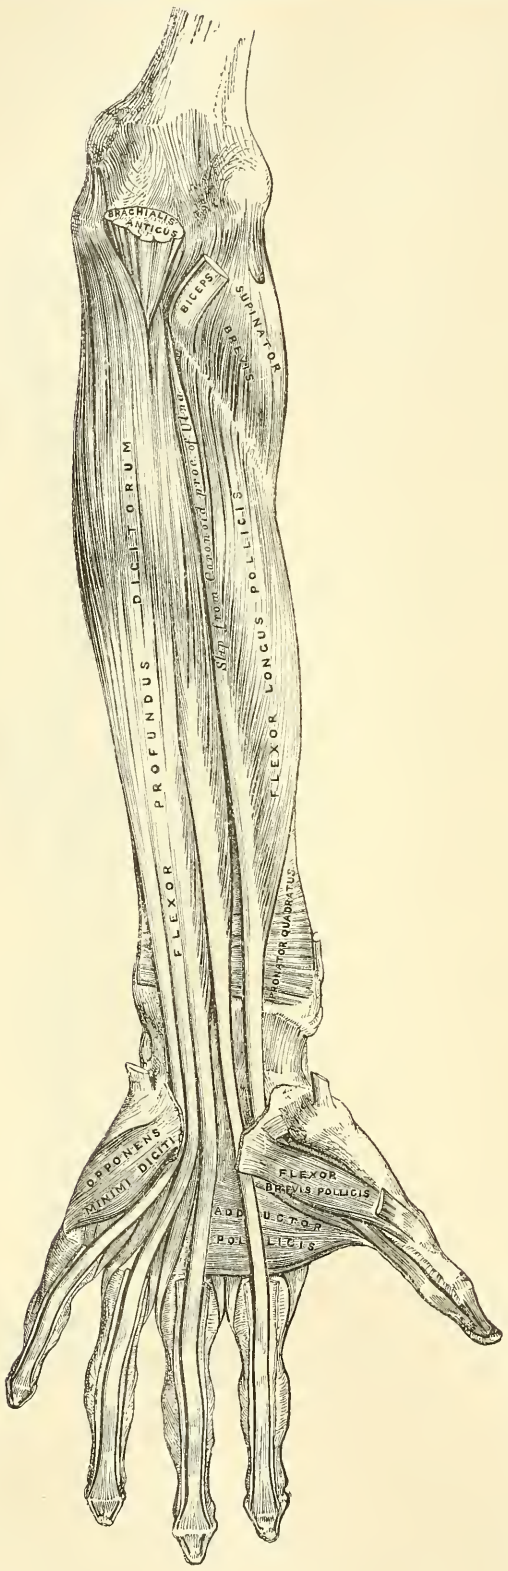
Fig. 344.—Front of the left forearm. Superficial muscles.



Relations.—By its *superficial surface*, with the deep fascia, with which it is intimately connected for a considerable extent. By its *deep surface*, with the Flexor sublimis digitorum, the Flexor profundus digitorum, the Pronator quadratus, and the ulnar vessels and nerve. By its *outer* or *radial border*, with the Palmaris longus above, and the ulnar vessels and nerve below.

The **Flexor sublimis digitorum** (*perforatus*) is placed beneath the preceding muscles, which therefore must be removed in order to bring its attachment into view. It is the largest of the muscles of the superficial layer, and arises by three heads. One head arises from the internal condyle of the humerus by the common tendon, from the internal lateral ligament of the elbow-joint, and from the intermuscular septum common to it and the preceding muscles. The second head arises from the inner side of the coronoid process of the ulna, above the ulnar origin of the Pronator radii teres (fig. 211, p. 239). The third head arises from the oblique line of the radius, extending from the tubercle to the insertion of the Pronator radii teres. The fibres pass vertically downwards, forming a broad and thick muscle, which speedily divides into two planes of muscular fibres, superficial and deep: the superficial plane divides into two parts which end in tendons for the middle and ring fingers; the deep plane also divides into two parts, which end in tendons for the index and little fingers, but previously to having done so, it gives off a muscular slip, which joins that part of the superficial plane which is intended for the ring finger. As the four tendons thus formed pass beneath the annular ligament into the palm of the hand, they are arranged in pairs, the superficial pair corresponding to the middle and ring fingers, the deep pair to the index and little fingers. The tendons diverge from one another as they pass onwards. Opposite the bases of the first phalanges each tendon divides into two slips, to allow of the passage of the corresponding tendon of the Flexor profundus digitorum; the two portions of the tendon then unite and form a grooved channel for the reception of the accompanying deep flexor tendon. Finally they subdivide a second time, to be inserted into the sides of the second phalanges about their middle. After leaving the palm, these tendons accompanied

Fig. 345.—Front of the left forearm. Deep muscles.



by the deep flexor tendons lie in osseo-aponeurotic canals (fig. 345). These canals are formed by strong fibrous bands, which arch across the tendons, and are attached on each side to the margins of the phalanges. Opposite the middle of the proximal and second phalanges the sheath is very strong, and the fibres pass transversely; but opposite the joints it is much thinner, and the fibres pass obliquely. Each sheath is lined by a synovial membrane, which is reflected on the contained tendon.

Relations.—In the forearm, by its *superficial surface*, with the deep fascia and all the preceding superficial muscles; by its *deep surface*, with the Flexor profundus digitorum, Flexor longus pollicis, the ulnar vessels and nerve, and the median nerve. In the hand, its tendons are in relation, *in front*, with the palmar fascia, superficial palmar arch, and the branches of the median nerve; *behind*, with the tendons of the deep Flexor and the Lumbricales.

Deep Layer

Flexor profundus digitorum.
Flexor longus pollicis.
Pronator quadratus.

Dissection.—Divide each of the superficial muscles at its centre, and turn either end aside; the deep layer of muscles, together with the median nerve and ulnar vessels, will then be exposed.

The **Flexor profundus digitorum** (*perforans*) (fig. 345) is situated on the ulnar side of the forearm, immediately beneath the superficial Flexors. It arises from the upper three-fourths of the anterior and inner surfaces of the shaft of the ulna, embracing the insertion of the Brachialis anticus above, and

extending, below, to within a short distance of the Pronator quadratus. It also arises from a depression on the inner side of the coronoid process; by an aponeurosis from the upper three-fourths of the posterior border of the ulna, in common with the Flexor and Extensor carpi ulnaris; and from the ulnar half of the interosseous membrane. The fibres form a fleshy belly of considerable size, which divides into four tendons: these pass under the annular ligament beneath the tendons of the Flexor sublimis digitorum. Opposite the first phalanges, the tendons pass between the two slips of the tendons of the Flexor sublimis digitorum, and are finally inserted into the bases of the last phalanges. The tendon of the index finger is distinct; the rest are connected together by cellular tissue and tendinous slips, as far as the palm of the hand. The tendons of this and those of the Flexor sublimis digitorum, whilst contained in the osseo-aponeurotic canals of the fingers, are invested in a synovial sheath, and are connected to each other, and to the phalanges, by slender, tendinous filaments, called *vincula accessoria tendinum*. One of these connects the deep tendon to the bone, before it passes through the superficial tendon; a second connects the two tendons together, after the deep tendons have passed through; and a third connects the deep tendon to the head of the second phalanx. This last consists largely of yellow elastic tissue, and may assist in drawing down the tendon after flexion of the finger.*

Four small muscles, the Lumbricales, are connected with the tendons of the Flexor profundus in the palm. They will be described with the muscles in that region.

Relations.—By its *superficial surface*, in the forearm, with the Flexor sublimis digitorum, the Flexor carpi ulnaris, the ulnar vessels and nerve, and the median nerve; and in the hand, with the tendons of the superficial Flexor. By its *deep surface*, in the forearm, with the ulna, the interosseous membrane, the Pronator quadratus; and in the hand, with the Interossei, Adductores pollicis, and deep palmar arch. By its *ulnar border*, with the Flexor carpi ulnaris. By its *radial border*, with the Flexor longus pollicis, the anterior interosseous vessels and nerve being interposed.

The **Flexor longus pollicis** is situated on the radial side of the forearm, lying on the same plane as the preceding. It arises from the grooved anterior surface of the shaft of the radius: commencing, above, immediately below the tuberosity and oblique line, and extending, below, to within a short distance of the Pronator quadratus. It also arises from the adjacent part of the interosseous membrane, and generally by a fleshy slip from the base of the coronoid process. The fibres pass downwards, and terminate in a flattened tendon, which passes beneath the annular ligament, is then lodged in the interspace between the outer head of the Flexor brevis pollicis and the Adductor obliquus pollicis, and, entering an osseo-aponeurotic canal similar to those for the other flexor tendons, is inserted into the base of the last phalanx of the thumb.

Relations.—By its *superficial surface*, with the Flexor sublimis digitorum, Flexor carpi radialis, Supinator longus, and radial vessels. By its *deep surface*, with the radius, interosseous membrane, and Pronator quadratus. By its *ulnar border*, with the Flexor profundus digitorum, from which it is separated by the anterior interosseous vessels and nerve.

The **Pronator quadratus** is a small, flat, quadrilateral muscle, extending transversely across the front of the radius and ulna, above their carpal extremities. It arises from the oblique or pronator ridge on the lower part of the anterior surface of the shaft of the ulna; from the lower fourth of the anterior surface, and the anterior border of the ulna; and from a strong aponeurosis which covers the inner third of the muscle. The fibres pass horizontally outwards, to be inserted into the lower fourth of the anterior surface and anterior border of the shaft of the radius.

Relations.—By its *superficial surface*, with the Flexor profundus digitorum,

* Marshall, *Brit. and For. Med.-Chir. Rev.*, 1853.

the Flexor longus pollicis, Flexor carpi radialis, and the radial vessels. By its *deep surface*, with the radius, ulna, and interosseous membrane.

Nerves.—All the muscles of the superficial layer are supplied by the median nerve, excepting the Flexor carpi ulnaris, which is supplied by the ulnar. The Pronator radii teres and the Flexor carpi radialis derive their supply primarily from the sixth cervical; the Palmaris longus from the eighth cervical; the Flexor sublimis digitorum from the seventh and eighth cervical and first dorsal, and the Flexor carpi ulnaris from the eighth cervical and first dorsal nerves. Of the deep layer, the Flexor profundus digitorum is supplied by the eighth cervical and first dorsal through the ulnar and anterior interosseous branch of the median. The remaining two muscles, Flexor longus pollicis and Pronator quadratus, are also supplied by the eighth cervical and first dorsal through the anterior interosseous branch of the median.

Actions.—These muscles act upon the forearm, the wrist, and hand. The Pronator radii teres helps to rotate the radius upon the ulna, rendering the hand prone; when the radius is fixed, it assists the other muscles in flexing the forearm. The Flexor carpi radialis is one of the flexors of the wrist; when acting alone, it flexes the wrist, inclining it to the radial side. It can also assist in pronating the forearm and hand, and, by continuing its action, in bending the elbow. The Flexor carpi ulnaris is one of the flexors of the wrist; when acting alone, it flexes the wrist, inclining it to the ulnar side; and by continuing to contract, it bends the elbow. The Palmaris longus is a tensor of the palmar fascia. It also assists in flexing the wrist and elbow. The Flexor sublimis digitorum flexes first the middle, and then the proximal phalanx. It assists in flexing the wrist and elbow. The Flexor profundus digitorum is one of the flexors of the phalanges. After the Flexor sublimis has bent the second phalanx, the Flexor profundus flexes the terminal one; but it cannot do so until after the contraction of the superficial muscle. It also assists in flexing the wrist. The Flexor longus pollicis is a flexor of the phalanges of the thumb. When the thumb is fixed, it also assists in flexing the wrist. The Pronator quadratus helps to rotate the radius upon the ulna, rendering the hand prone.

9. *Radial Region* (fig. 346)

Supinator longus. Extensor carpi radialis longior.
Extensor carpi radialis brevior.

Dissection.—Divide the integument in the same manner as in the dissection of the anterior brachial region; and, after having examined the cutaneous vessels and nerves and deep fascia, remove all these structures. The muscles will then be exposed. The removal of the fascia will be considerably facilitated by detaching it from below upwards. Great care should be taken to avoid cutting across the tendons of the muscles of the thumb, which cross obliquely the larger tendons running down the back of the radius.

The **Supinator longus** (brachio-radialis) is the most superficial muscle on the radial side of the forearm: it is fleshy for the upper two-thirds of its extent, tendinous below. It arises from the upper two-thirds of the external condyloid ridge of the humerus, and from the external intermuscular septum, being limited above by the musculo-spiral groove. The fibres terminate above the middle of the forearm in a flat tendon, which is inserted into the outer side of the base of the styloid process of the radius.

Relations.—By its *superficial surface*, with the integument and fascia for the greater part of its extent; near its insertion it is crossed by the Extensor ossis metacarpi pollicis and the Extensor brevis pollicis. By its *deep surface*, with the humerus, the Extensor carpi radialis longior and brevior, the insertion of the Pronator radii teres, and the Supinator brevis. By its *inner border*, above the elbow, with the Brachialis anticus, the musculo-spiral nerve, and radial recurrent artery; and in the forearm with the radial vessels and nerve.

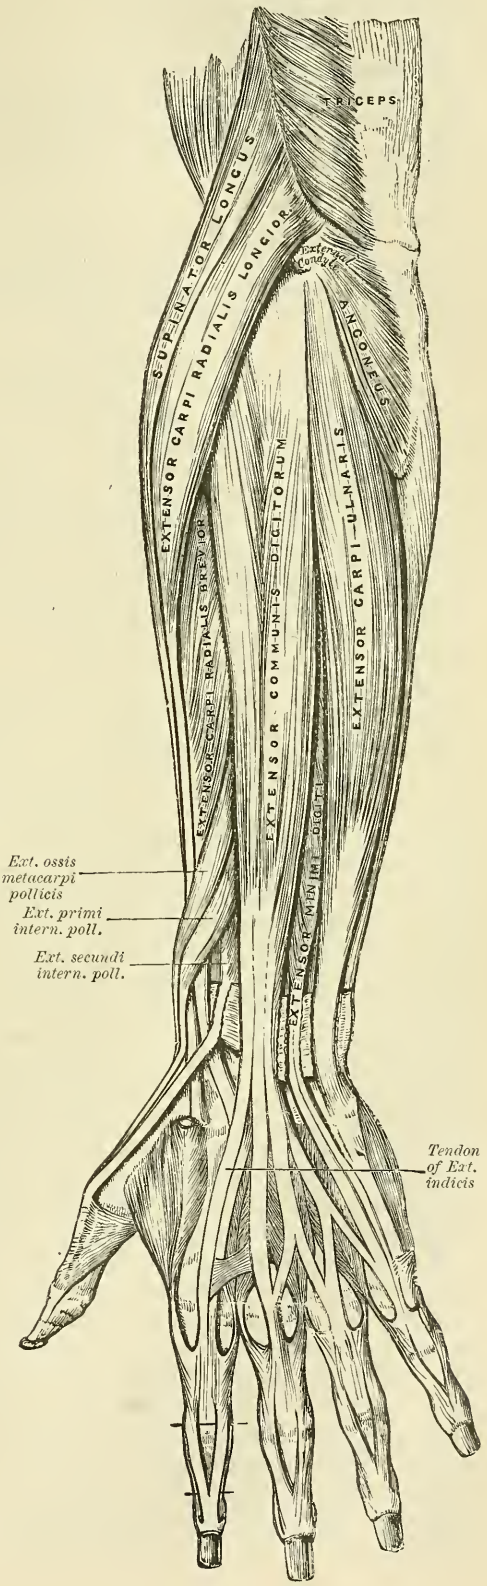
The **Extensor carpi radialis longior** is placed partly beneath the preceding muscle. It arises from the lower third of the external condyloid ridge of the humerus, from the external intermuscular septum, and by a few fibres from the common tendon of origin of the extensor muscles of the forearm. The fibres terminate at the upper third of the forearm in a flat tendon, which runs along the outer border of the radius, beneath the extensor tendons of the thumb; it then passes through a groove common to it and the Extensor carpi radialis brevior, immediately behind the styloid process, and is inserted into the base of the metacarpal bone of the index finger, on its radial side.

Relations.—By its *superficial surface*, with the Supinator longus, and fascia of the forearm. Its *outer side* is crossed obliquely by the extensor tendons of the thumb. By its *deep surface*, with the elbow-joint, the Extensor carpi radialis brevior, and back part of the wrist.

The **Extensor carpi radialis brevior** is shorter, as its name implies, and thicker than the preceding muscle, beneath which it is placed. It arises from the external condyle of the humerus, by a tendon common to it and the three following muscles: from the external lateral ligament of the elbow-joint; from a strong aponeurosis which covers its surface; and from the intermuscular septa between it and the adjacent muscles. The fibres terminate about the middle of the forearm in a flat tendon, which is closely connected with that of the preceding muscle, and accompanies it to the wrist, lying in the same groove on the posterior surface of the radius; it passes beneath the extensor tendons of the thumb, then beneath the annular ligament, and, diverging somewhat from its fellow, is inserted into the base of the metacarpal bone of the middle finger, on its radial side.

The tendons of the two preced-

Fig. 346.—Posterior surface of the forearm. Superficial muscles.



ing muscles pass through the same compartment of the annular ligament, and are lubricated by a single synovial membrane, but are separated from each other by a small vertical ridge of bone as they lie in the groove at the back of the radius.

Relations.—By its *superficial surface,* with the Extensor carpi radialis longior, and with the Extensor muscles of the thumb which cross it. By its *deep surface,* with the Supinator brevis, tendon of the Pronator radii teres, radius, and wrist-joint. By its *ulnar border,* with the Extensor communis digitorum.

10. *Posterior Radio-Ulnar Region* (fig. 346)

The muscles in this region are divided for purposes of description into two groups or layers, superficial and deep.

Superficial Layer

Extensor communis digitorum.	Extensor carpi ulnaris.
Extensor minimi digiti.	Anconeus.

The **Extensor communis digitorum** is situated at the back part of the forearm. It arises from the external condyle of the humerus, by the common tendon; from the deep fascia, and the intermuscular septa between it and the adjacent muscles. Just below the middle of the forearm it divides into three fleshy masses, from which tendons proceed; these pass, together with the Extensor indicis, through a separate compartment of the annular ligament, lubricated by a synovial membrane. The tendons then diverge, the innermost one dividing into two; and all, after passing across the back of the hand, are inserted into the second and third phalanges of the fingers in the following manner: the outermost tendon, accompanied by the Extensor indicis, goes to the index finger; the second tendon is usually connected to the first by a thin transverse band, and receives a slip from the third tendon; it goes to the middle finger; the third tendon gives off the slip to the second, and receives a very considerable part of the fourth tendon on its way to the ring finger; the fourth, or innermost tendon, divides into two parts: one goes to join the third tendon, the other, reinforced by the Extensor minimi digiti, goes to the little finger. Each tendon opposite the metacarpo-phalangeal articulation becomes narrow and thickened, and gives off a thin fasciculus upon each side of the joint, which blends with the lateral ligaments and serves as the posterior ligament; after having passed the joint, it spreads out into a broad aponeurosis, which covers the whole of the dorsal surface of the first phalanx; and is reinforced, in this situation, by the tendons of the Interossei and Lumbricales. Opposite the first phalangeal joint this aponeurosis divides into three slips, a middle and two lateral: the former is inserted into the base of the second phalanx; and the two lateral, which are continued onwards along the sides of the second phalanx, unite by their contiguous margins, and are inserted into the dorsal surface of the last phalanx. As the tendons cross the phalangeal joints, they furnish them with posterior ligaments.

Relations.—By its *superficial surface,* with the fascia of the forearm and hand, the posterior annular ligament, and integument. By its *deep surface,* with the Supinator brevis, the Extensor muscles of the thumb and index finger, the posterior interosseous vessels and nerve, the wrist-joint, carpus, metacarpus, and phalanges. By its *radial border,* with the Extensor carpi radialis brevior. By its *ulnar border,* with the Extensor minimi digiti and Extensor carpi ulnaris.

The **Extensor minimi digiti** is a slender muscle placed on the inner side of the Extensor communis, with which it is generally connected. It arises from the common tendon by a thin, tendinous slip; and from the intermuscular septa between it and the adjacent muscles. Its tendon runs through a separate compartment in the annular ligament behind the inferior radio-ulnar joint, then

divides into two as it crosses the hand, one slip being joined by the slip from the innermost tendon of the common extensor. The three slips thus formed spread into a broad aponeurosis, which after receiving a slip from the Abductor minimi digiti is inserted into the second and third phalanges. The tendon is situated on the ulnar side of, and somewhat more superficial than, the common extensor.

The **Extensor carpi ulnaris** is the most superficial muscle on the ulnar side of the forearm. It arises from the external condyle of the humerus, by the common tendon; by an aponeurosis from the posterior border of the ulna in common with the Flexor carpi ulnaris and the Flexor profundus digitorum; and from the deep fascia of the forearm. This muscle terminates in a tendon, which runs through a groove behind the styloid process of the ulna, passes through a separate compartment in the annular ligament, and is inserted into the prominent tubercle on the ulnar side of the base of the metacarpal bone of the little finger.

Relations.—By its *superficial surface*, with the deep fascia of the forearm. By its *deep surface*, with the ulna, and the muscles of the deep layer.

The **Anconeus** is a small, triangular muscle, placed behind and below the elbow-joint, and appears to be a continuation of the external portion of the Triceps. It arises by a separate tendon from the back part of the outer condyle of the humerus, and is inserted into the side of the olecranon, and upper fourth of the posterior surface of the shaft of the ulna; its fibres diverge from their origin, the upper ones being directed transversely, the lower obliquely inwards.

Relations.—By its *superficial surface*, with a strong fascia derived from the Triceps. By its *deep surface*, with the elbow-joint, the orbicular ligament, the ulna, and a small portion of the Supinator brevis.

Deep Layer (fig. 348)

Supinator brevis. Extensor brevis pollicis.
Extensor ossis metacarpi pollicis. Extensor longus pollicis.
Extensor indicis.

The **Supinator brevis** (fig. 347) is a broad muscle, of a hollow cylindrical form, curved round the upper third of the radius. It consists of two distinct planes of muscular fibres, between which lies the posterior interosseous nerve. The two planes arise in common: the superficial one by tendinous, and the deeper by muscular fibres from the external condyle of the humerus; from the external lateral ligament of the elbow-joint, and the orbicular ligament of the radius; from the ridge on the ulna, which runs obliquely downwards from the posterior extremity of the lesser sigmoid cavity; from the triangular depression in front of it; and from a tendinous expansion which covers the surface of the muscle. The superficial fibres surround the upper part of the radius, and are inserted into the outer edge of the bicipital tuberosity and to the oblique line of the radius, as low down as the insertion of the Pronator radii teres. The upper fibres of the deeper plane form a sling-like fasciculus, which encircles the neck of the radius above the tuberosity and is attached to the back part of its inner surface: the greater part of this portion of the muscle is inserted into the posterior and external surface of the shaft, midway between the oblique line and the head of the bone. Between the insertion of the two planes, the posterior interosseous nerve lies on the shaft of the bone.

Relations.—By its *superficial surface*, with the superficial Extensor and Supinator muscles, and the radial vessels and nerve. By its *deep surface*, with the elbow-joint, the interosseous membrane, and the radius.

The **Extensor ossis metacarpi pollicis** is the most external and the largest of the deep extensor muscles; it lies immediately below the Supinator brevis, with which it is sometimes united. It arises from the posterior surface of the shaft of the ulna below the insertion of the Anconeus, from the interosseous membrane, and from the middle third of the posterior surface of the shaft of the

radius. Passing obliquely downwards and outwards, it terminates in a tendon, which runs through a groove on the outer side of the styloid process of the radius, accompanied by the tendon of the Extensor brevis pollicis, and is

Fig. 347.—Supinator brevis. (From a preparation in the Museum of the Royal College of Surgeons of England.)

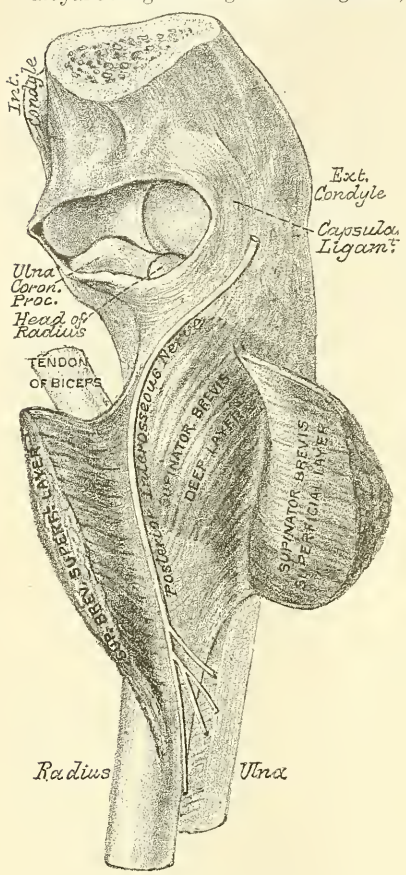


Fig. 348.—Posterior surface of the forearm. Deep muscles.

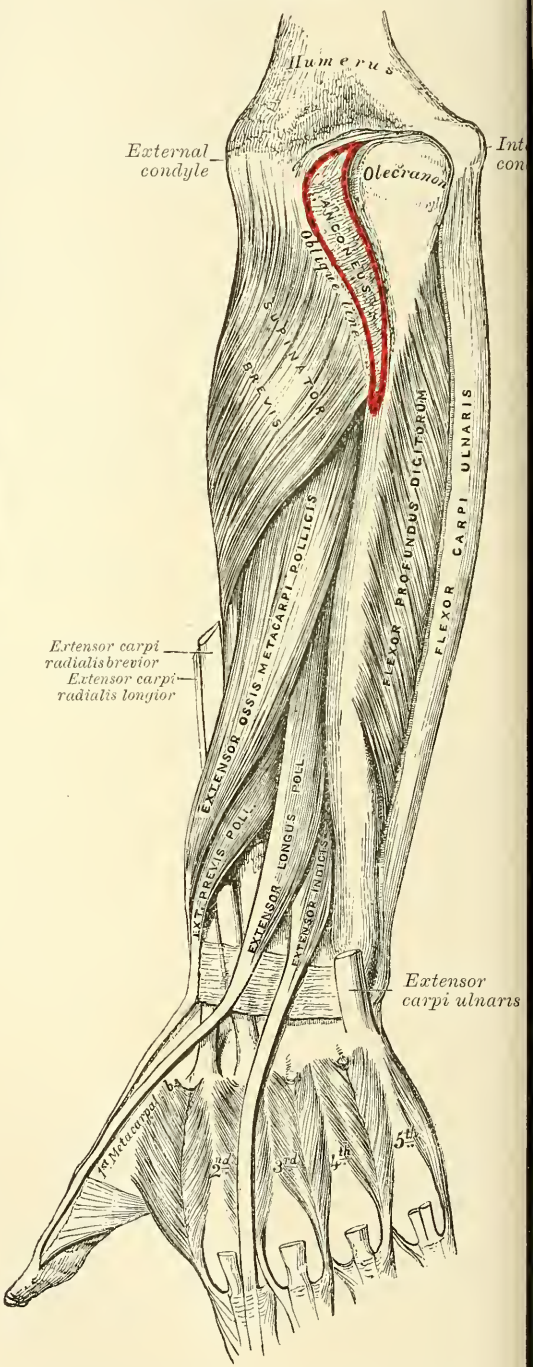

inserted into the base of the metacarpal bone of the thumb. It occasionally gives off two slips, near its insertion: one to the Trapezium, and the other to blend with the origin of the Abductor pollicis.

Relations.—By its *superficial surface*, with the Extensor communis digitorum, Extensor minimi digiti, and fascia of the forearm; and with the branches of the posterior interosseous artery and nerve which cross it. By its *deep surface*, with the ulna, interosseous membrane, radius, the tendons of the Extensor carpi radialis longior and brevior, which it crosses obliquely; and, at the outer side of the wrist, with the radial vessels. By its *upper border*, with the Supinator brevis. By its *lower border*, with the Extensor brevis pollicis.

The **Extensor brevis pollicis** (*Extensor primi internodii pollicis*), the smallest muscle of this group, lies on the inner side of the preceding. It arises from the posterior surface of the shaft of the radius, below the Extensor ossis metacarpi pollicis and from the interosseous membrane. Its direction is similar to that of the Extensor ossis metacarpi pollicis, its tendon passing through the same groove on the outer side of the styloid process, to be inserted into the base of the first phalanx of the thumb.

Relations.—The same as those of the Extensor ossis metacarpi pollicis.

The **Extensor longus pollicis** (*Extensor secundi internodii pollicis*) is much larger than the preceding muscle, the origin of which it partly covers in. It arises from the posterior surface of the shaft of the ulna, below the origin of the Extensor ossis metacarpi pollicis, and from the interosseous membrane. It terminates in a tendon, which passes through a separate compartment in the annular ligament, lying in a narrow, oblique groove at the back part of the lower end of the radius. It then crosses obliquely the tendons of the Extensor carpi radialis longior and brevior, being separated from the other extensor tendons of the thumb by a triangular interval, in which the radial artery is found; and is finally inserted into the base of the last phalanx of the thumb.

Relations.—By its *superficial surface*, with the same parts as the Extensor ossis metacarpi pollicis. By its *deep surface*, with the ulna, interosseous membrane, the posterior interosseous nerve, radius, the wrist, the radial vessels, and metacarpal bone of the thumb.

The **Extensor indicis** is a narrow, elongated muscle, placed on the inner side of, and parallel with, the preceding. It arises from the posterior surface of the shaft of the ulna, below the origin of the Extensor longus pollicis and from the interosseous membrane. Its tendon passes with the Extensor communis digitorum through the same canal in the annular ligament, and subsequently joins the tendon of the Extensor communis which belongs to the index finger, opposite the lower end of the corresponding metacarpal bone, lying to the ulnar side of the tendon from the common extensor.

Relations.—The relations are similar to those of the preceding muscles.

Nerves.—The Supinator longus is supplied by the sixth, the Extensor carpi radialis longior by the sixth and seventh, and the Anconeus by the seventh and eighth cervical nerves, all through the musculo-spiral nerve; the remaining muscles of the radial and posterior brachial region are supplied through the posterior interosseous nerve, the Supinator brevis being supplied by the sixth cervical, the Extensor carpi radialis brevior by the sixth and seventh cervicals, and all the other muscles by the seventh cervical.

Actions.—The muscles of the radial and posterior brachial regions, which comprise all the extensor and supinator muscles, act upon the forearm, wrist, and hand; they are the direct antagonists of the pronator and flexor muscles. The Anconeus assists the Triceps in extending the forearm. The chief action of the Supinator longus is that of a flexor of the elbow-joint, but in addition to this it may act both as a supinator or a pronator: that is to say, if the forearm is forcibly pronated, it will act as a supinator, and bring the bones into a position midway between supination and pronation; and, *vice versâ*, if the arm is forcibly supinated, it will act as a pronator, and bring the bones into the same position, midway between supination and pronation. The action of the muscle is therefore to throw the forearm and hand into the position they naturally occupy when placed across the chest. The Supinator brevis is a supinator: that is to say, when the radius has been carried across the ulna in pronation, and the back of the hand is directed forwards, this muscle carries the radius back again to its normal position on the outer side of the ulna, and the palm of the hand is again directed forwards. The Extensor carpi radialis longior extends the wrist and abducts the hand. It may also assist in bending the elbow-joint; at all events it serves to fix or steady this articulation. The Extensor carpi radialis brevior assists the Extensor carpi radialis longior in extending the wrist, and

may also act slightly as an abductor of the hand. The Extensor carpi ulnaris helps to extend the hand, but when acting alone inclines it towards the ulnar side: by its continued action it extends the elbow-joint. The Extensor communis digitorum extends the phalanges, then the wrist, and finally the elbow. It acts principally on the proximal phalanges, the middle and terminal phalanges being extended mainly by the Interossei and Lumbricales. It has also a tendency to separate the fingers as it extends them. The Extensor minimi digiti extends the little finger, and by its continued action it assists in extending the wrist. It is owing to this muscle that the little finger can be extended or pointed whilst the others are flexed. The chief action of the Extensor ossis metacarpi pollicis is to carry the thumb outwards and backwards from the palm of the hand, and hence it has been called the *Abductor longus pollicis*. By its continued action it helps to extend and abduct the wrist. The Extensor brevis pollicis extends the proximal phalanx of the thumb. By its continued action it helps to extend and abduct the wrist. The Extensor longus pollicis extends the terminal phalanx of the thumb. By its continued action it helps to extend and abduct the wrist. The Extensor indicis extends the index finger, and by its continued action assists in extending the wrist. It is owing to this muscle that the index finger can be extended or pointed while the others are flexed.

Surgical Anatomy.—The tendons of the Extensor muscles of the thumb are liable to become strained, and their sheaths inflamed, after excessive exercise, producing a sausage-shaped swelling along the course of the tendon and giving a peculiar creaking sensation to the finger when the muscle acts. In consequence of its often being caused by such movements as wringing clothes, it is known as 'washerwoman's sprain.'

IV. Muscles and Fasciæ of the Hand

The **Muscles of the Hand** are subdivided into three groups: 1. Those of the thumb, which occupy the radial side; 2. Those of the little finger, which occupy the ulnar side; 3. Those in the middle of the palm and within the interosseous spaces.

Dissection (fig. 349).—Make a transverse incision across the front of the wrist, and a second across the heads of the metacarpal bones: connect the two by a vertical incision in the middle line, and continue it through the centre of the middle finger. The anterior and posterior annular ligaments, and the palmar fascia, should then be dissected.

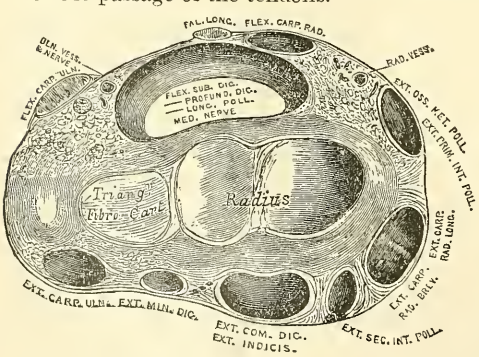

Fig. 349.—Transverse section through the wrist, showing the annular ligaments and the canals for the passage of the tendons.

The **Anterior Annular Ligament** is a strong, fibrous band, which arches over the carpus, converting the deep groove on the front of the carpal bones into a canal, beneath which pass the flexor tendons of the fingers. It is attached, internally, to the pisiform bone and unciform process of the unciform bone; and externally, to the tuberosity of the scaphoid, and to the inner part of the anterior surface and the ridge on the trapezium. It is continuous, above, with the deep fascia of the forearm, of which it may be regarded as a thickened portion; and below, with the palmar fascia. It is crossed by the ulnar vessels and nerve, and the cutaneous branches of the median and ulnar nerves. At its outer extremity is the tendon of the Flexor carpi radialis, which lies in the groove on the trapezium between the attachments of the annular ligament to the bone. It has

inserted into its anterior surface the tendon of the Palmaris longus and part of the tendon of the Flexor carpi ulnaris, and has arising from it, below, the small muscles of the thumb and little finger. Beneath it pass the tendons of the Flexor sublimis and profundus digitorum, the Flexor longus pollicis, and the median nerve.

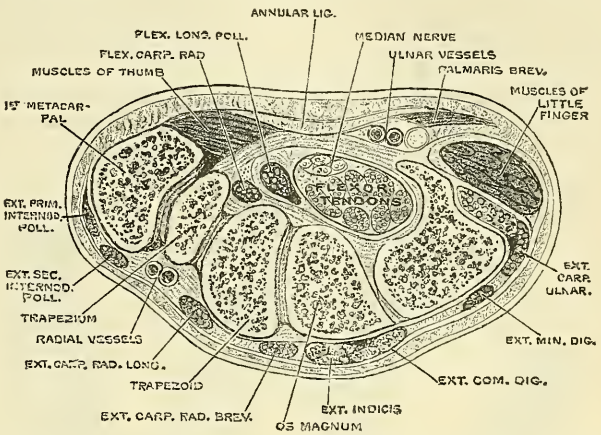

FIG. 350.—Transverse section through the carpus, showing the relative positions of the tendons, vessels, and nerves. (Henle.)

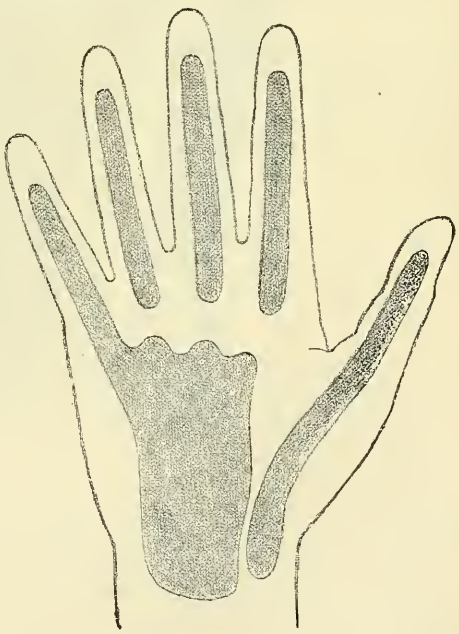
The Synovial Membranes of the Flexor Tendons at the Wrist.—There are two synovial membranes which enclose all the tendons as they pass beneath this ligament, one for the Flexor sublimis and profundus digitorum, the other for the Flexor longus pollicis. They extend up into the forearm for about an inch above the annular ligament, and downwards about half-way along the metacarpal bone, where they terminate in a blind diverticulum around each pair of tendons, with the exception of the thumb and sometimes the little finger; in these two fingers the diverticulum is continued on and communicates with the synovial sheath of the tendons. In the other three fingers the synovial sheath of the tendons in the fingers begins as a blind pouch without communication with the large synovial sac (fig. 351).

FIG. 351.—Diagram showing the arrangement of the synovial sheaths of the palm and fingers.

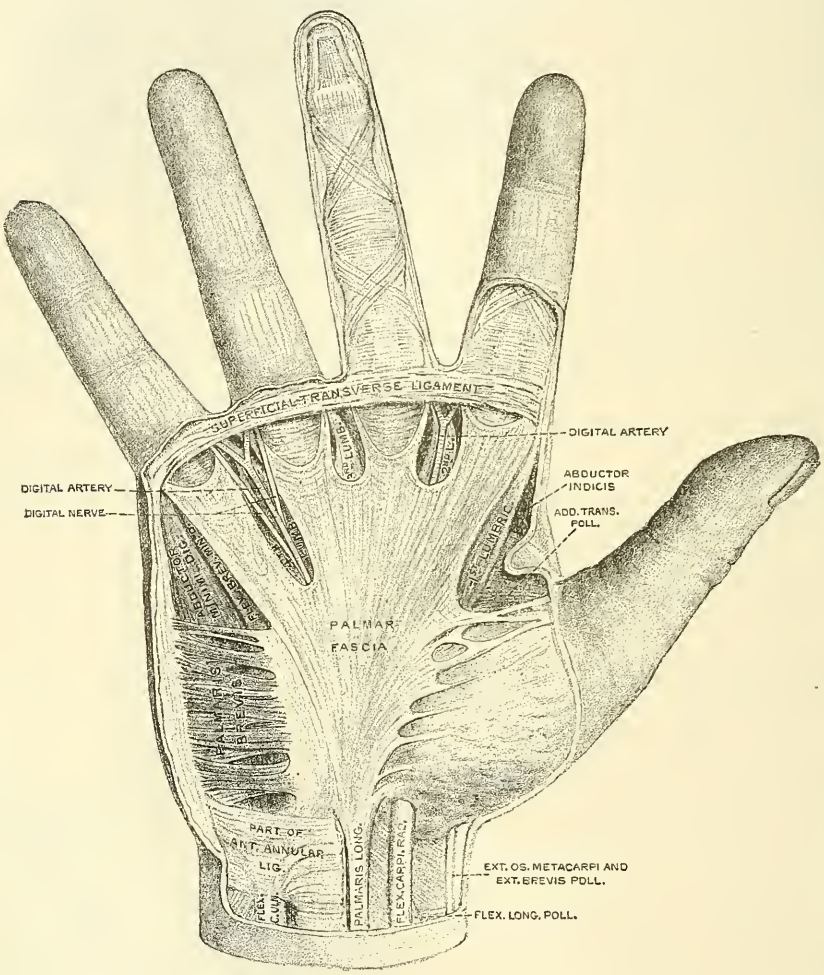


Surgical Anatomy.—This arrangement of the synovial sheaths explains the fact that thecal abscess in the thumb and little finger is liable to be followed by abscesses in the forearm, from extension of the inflammation along the continuous synovial sheaths. Ganglion is apt to occur in this situation, constituting 'compound palmar ganglion': it presents an hour-glass outline, with a swelling in front of the wrist and in the palm of the hand, and a constriction corresponding to the annular ligament between the two. The fluid can be forced from the one swelling to the other under the ligament.

The **Posterior Annular Ligament** is a strong, fibrous band, extending transversely across the back of the wrist, and consisting of the deep fascia of the back of the forearm, strengthened by the addition of some transverse fibres. It forms a sheath for the extensor tendons in their passage to the fingers, being attached, internally, to the styloid process of the ulna, the cuneiform and pisiform bones; externally, to the margin of the radius; and, in its passage across the wrist, to

the elevated ridges on the posterior surface of the radius. Its presents six compartments for the passage of tendons, each of which is lined by a separate synovial membrane. These are, from without inwards:—1. On the outer side of the styloid process, for the tendons of the Extensor ossis metacarpi and Extensor brevis pollicis. 2. Behind the styloid process, for the tendons of the Extensor carpi radialis longior and brevior. 3. About the middle of the posterior surface of the radius, for the tendon of the Extensor longus pollicis. 4. To the inner side of the latter, for the tendons of the Extensor communis digitorum and Extensor indicis. 5. Opposite the interval between the radius

Fig. 352.—Palmar fascia. (Altered from a dissection in the Museum of the Royal College of Surgeons of England.)



and ulna, for the Extensor minimi digiti. 6. Grooving the back of the ulna, for the tendon of the Extensor carpi ulnaris. The synovial membranes lining these sheaths are usually very extensive, reaching from above the annular ligament, down upon the tendons for a variable distance on the back of the hand.

The **deep palmar fascia** (fig. 352) forms a common sheath which invests the muscles of the hand. It consists of a central and two lateral portions.

The *central portion* occupies the middle of the palm, is triangular in shape, of great strength and thickness, and binds down the tendons in this situation. It is narrow above, being attached to the lower margin of the annular ligament, and receives the expanded tendon of the Palmaris longus muscle. Below, it is broad

and expanded, and divides into four slips, for the four fingers. Each slip gives off superficial fibres, which are inserted into the skin of the palm and finger, those to the palm joining the skin at the furrow corresponding to the metacarpo-phalangeal articulation, and those to the fingers passing into the skin at the transverse fold at the base of the fingers. The deeper part of each slip subdivides into two processes, which are inserted into the lateral margins of the anterior (glenoid) ligament of the metacarpo-phalangeal joint. From the sides of these processes, offsets are sent backwards, to be attached to the borders of the lateral surfaces of the metacarpal bones at their distal extremities. By this arrangement short channels are formed on the front of the lower ends of the metacarpal bones, through which the flexor tendons pass. Dr. W. W. Keen describes a fifth slip as frequently found passing to the thumb. The intervals left in the fascia, between the four fibrous slips, transmit the digital vessels and nerves, and the tendons of the Lumbricales. At the points of division of the palmar fascia into the slips above mentioned, numerous strong, transverse fibres bind the separate processes together. The palmar fascia is intimately adherent to the integument by dense fibro-areolar tissue forming the superficial palmar fascia, and gives origin by its inner margin to the Palmaris brevis; it covers the superficial palmar arch, the tendons of the flexor muscles, and the branches of the median and ulnar nerves; and on each side it gives off a vertical septum, which is continuous with the interosseous aponeurosis, and separates the lateral from the middle palmar group of muscles.

The *lateral portions* of the palmar fascia are thin, fibrous layers, which cover, on the radial side, the muscles of the ball of the thumb, and, on the ulnar side, the muscles of the little finger: they are continuous with the dorsal fascia, and in the palm with the central portion of the palmar fascia.

The **Superficial Transverse Ligament of the Fingers** is a thin, fibrous band, which stretches across the roots of the four fingers, and is closely attached to the skin of the clefts, and internally to the fifth metacarpal bone, forming a sort of rudimentary web. Beneath it the digital vessels and nerves pass onwards to their destination.

Surgical Anatomy.—The palmar fascia is liable to undergo contraction, producing a very inconvenient deformity, known as 'Dupuytren's contraction.' The ring and little fingers are most frequently implicated, but the middle, the index, and the thumb may be involved. The proximal phalanx is drawn down and cannot be straightened, and the two distal phalanges become similarly flexed as the disease advances.

11. *Radial Region* (figs. 353, 354)

Abductor pollicis.
Opponens (Flexor ossis metacarpi) pollicis.
Flexor brevis pollicis.
Adductor obliquus pollicis.
Adductor transversus pollicis.

The **Abductor pollicis** is a thin, flat muscle, placed immediately beneath the integument. It arises from the ridge of the os trapezium and annular ligament; and, passing outwards and downwards, is inserted by a thin, flat tendon into the radial side of the base of the first phalanx of the thumb, sending a slip to join the tendon of the Extensor longus pollicis.

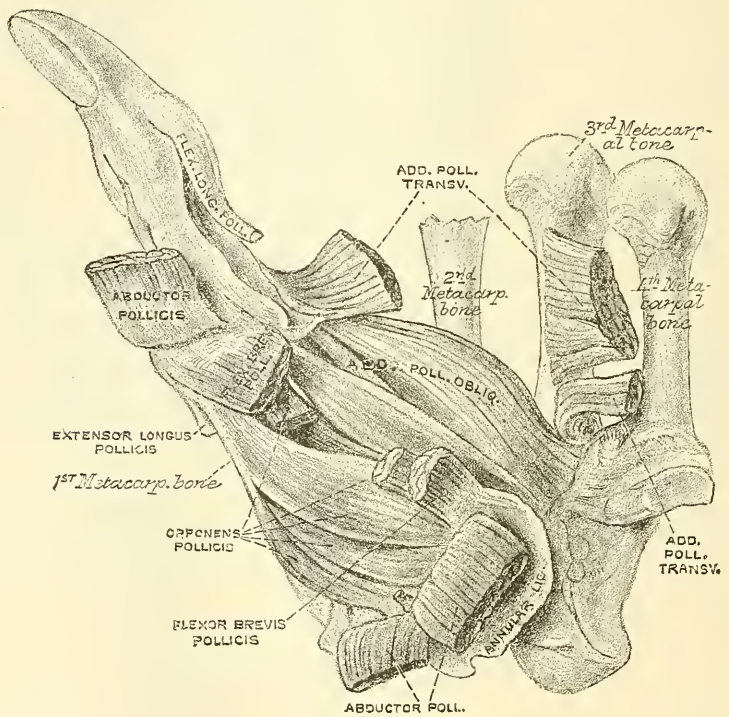
Relations.—By its *superficial surface*, with the palmar fascia. By its *deep surface*, with the Opponens pollicis, from which it is separated by a thin aponeurosis. Its *inner border* is separated from the Flexor brevis pollicis by a narrow cellular interval.

The **Opponens pollicis** is a small, triangular muscle, placed beneath the preceding. It arises from the palmar surface of the ridge on the trapezium and from the annular ligament, passes downwards and outwards, and is inserted into the whole length of the metacarpal bone of the thumb on its radial side.

Relations.—By its *superficial surface*, with the Abductor pollicis. By its *deep surface*, with the trapezio-metacarpal articulation. By its *inner border*, with the Flexor brevis pollicis.

The **Flexor brevis pollicis** is much larger than either of the two preceding muscles, beneath which it is placed. It consists of two portions, outer and inner. The outer and more superficial portion arises from the lower part of the ridge on the trapezium and outer two-thirds of the annular ligament, and passes along the outer side of the tendon of the Flexor longus pollicis; and, becoming tendinous, has a sesamoid bone developed in its tendon, and is inserted into the outer side of the base of the first phalanx of the thumb. The inner and deeper portion of the muscle is very small, and arises from the ulnar side of the first

Fig. 353.—Muscles of thumb. (From a preparation in the Museum of the Royal College of Surgeons of England.)



metacarpal bone, and is inserted into the inner side of the base of the first phalanx with the Adductor obliquus pollicis. A sesamoid bone is developed in the common tendon of insertion.

Relations.—By its *superficial surface*, with the palmar fascia. By its *deep surface*, with the tendon of the Flexor carpi radialis. By its *external surface*, with the Opponens pollicis. By its *internal surface*, with the Adductor obliquus pollicis.

The **Adductor obliquus pollicis** arises by several slips from the os magnum, the bases of the second and third metacarpal bones, the anterior carpal ligaments, and the sheath of the tendon of the Flexor carpi radialis. From this origin the greater number of fibres pass obliquely downwards and converge to a tendon, which, uniting with the tendons of the deeper portion of the Flexor brevis pollicis and the Adductor transversus, is inserted into the inner side of the base of the first phalanx of the thumb, a sesamoid bone being developed in the tendon of insertion. A considerable fasciculus, however, passes more obliquely outwards beneath the

tendon of the long flexor to join the superficial portion of the short flexor and the Abductor pollicis.*

Relations.—By its *superficial surface,* with the Flexor longus pollicis and the outer head of the Flexor brevis pollicis. Its *deep surface* covers the Adductor transversus pollicis, and is in relation with the deep palmar arch, which passes between the two adductors.

The **Adductor transversus pollicis** (fig. 353) is the most deeply seated of this group of muscles. It is of a triangular form, arising by its broad base, from the lower two-thirds of the metacarpal bone of the middle finger on its palmar surface; the fibres, proceeding outwards, converge, to be inserted, with the inner tendon of the Flexor brevis pollicis, and the Adductor obliquus pollicis, into the ulnar side of the base of the first phalanx of the thumb. From the common tendon of insertion a slip is prolonged to the Extensor longus pollicis.

Relations.—By its *superficial surface,* with the Adductor obliquus pollicis, the tendons of the Flexor profundus, and the Lumbricales. Its *deep surface* covers the first two interosseous spaces, from which it is separated by a strong aponeurosis.

Three of these muscles of the thumb, the Abductor, the Adductor transversus, and the Flexor brevis pollicis, at their insertions, give off fibrous expansions which join the tendon of the Extensor longus pollicis. This permits of flexion of the proximal phalanx and extension of the terminal phalanx at the same time. These expansions, originally figured by Albinus, have been more recently described by M. Duchenne, 'Physiologie des Mouvements.'

Nerves.—The Abductor, Opponens, and outer head of the Flexor brevis pollicis are supplied by the sixth cervical through the median nerve; the inner head of the Flexor brevis, and the Adductors, by the eighth cervical through the ulnar nerve.

Actions.—The actions of the muscles of the thumb are almost sufficiently indicated by their names. This segment of the hand is provided with three extensors—an extensor of the metacarpal bone, an extensor of the first, and an extensor of the second phalanx; these occupy the dorsal surface of the forearm and hand. There are also three flexors on the palmar surface—a flexor of the metacarpal bone, a flexor of the proximal, and a flexor of the terminal phalanx; there is also an Abductor and two Adductors. The Abductor pollicis moves the metacarpal bone of the thumb outwards, that is, away from the index finger. The Flexor ossis metacarpi pollicis flexes the metacarpal bone, that is, draws it inwards over the palm, and at the same time rotates the bone, so as to turn the ball of the thumb towards the fingers, thus producing the movement of opposition. The Flexor brevis pollicis flexes the proximal phalanx of the thumb. The Adductores pollicis move the metacarpal bone of the thumb inwards, that is, towards the index finger. These muscles give to the thumb its extensive range of motion. It will be noticed, however, that in consequence of the position of the first metacarpal bone, these movements differ from the corresponding movements of the metacarpal bones of the other fingers. Thus extension of the thumb more nearly corresponds to the motion of abduction in the other fingers, and flexion to adduction.

12. *Ulnar Region* (fig. 354)

Palmaris brevis

Abductor minimi digiti. Flexor brevis minimi digiti.

Opponens (Flexor ossis metacarpi) minimi digiti.

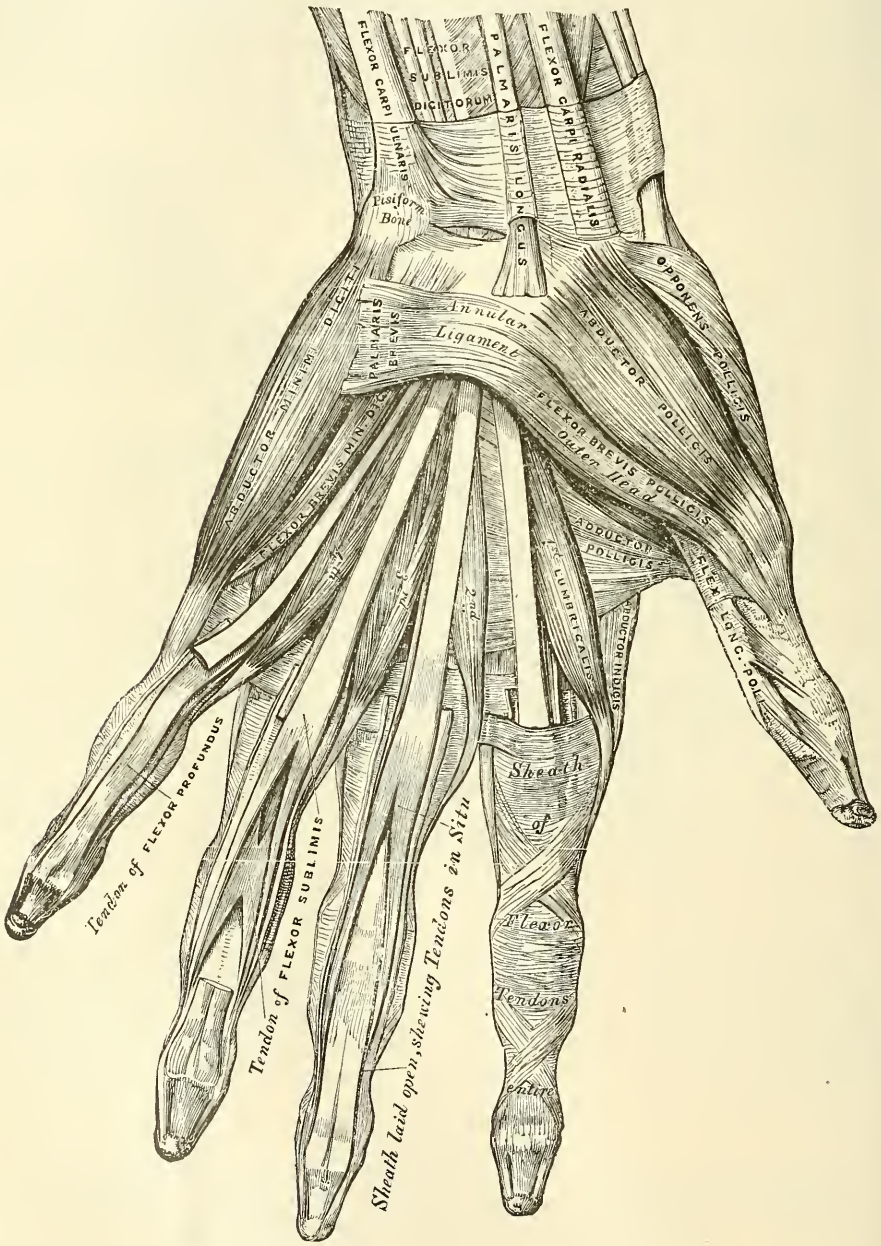
The **Palmaris brevis** is a thin quadrilateral muscle, placed beneath the integument on the ulnar side of the hand. It arises by tendinous fasciculi, from the

* This muscle was formerly described as the deep portion of the Flexor brevis pollicis.

annular ligament and palmar fascia; the fleshy fibres pass inwards, to be inserted into the skin on the inner border of the palm of the hand.

Relations.—By its *superficial surface*, with the integument, to which it is intimately adherent, especially by its inner extremity. By its *deep surface*, with the inner portion of the palmar fascia; which separates it from the ulnar vessels and nerve, and from the muscles of the ulnar side of the hand.

Fig. 354.—Muscles of the left hand. Palmar surface.



The **Abductor minimi digiti** is situated on the ulnar border of the palm of the hand. It arises from the pisiform bone, and terminates in a flat tendon, which divides into two slips; one passes under the lateral expansion of the extensor tendon, opposite the metacarpo-phalangeal articulation, and is inserted into the

ulnar side of the base of the first phalanx of the little finger. The other slip passes over the expansion, and is inserted into the ulnar border of the aponeurosis of the Extensor minimi digiti.

Relations.—By its *superficial surface*, with the inner portion of the palmar fascia, and the Palmaris brevis. By its *deep surface*, with the Flexor ossis metacarpi minimi digiti. By its *outer border*, with the Flexor brevis minimi digiti.

The **Flexor brevis minimi digiti** lies on the same plane as the preceding muscle, on its radial side. It arises from the tip of the unciform process of the unciform bone, and anterior surface of the annular ligament, and is inserted into the base of the first phalanx of the little finger. It is separated from the Abductor at its origin, by the deep branches of the ulnar artery and nerve. This muscle is sometimes wanting; the Abductor is then, usually, of large size.

Relations.—By its *superficial surface*, with the internal portion of the palmar fascia, and the Palmaris brevis. By its *deep surface*, with the Opponens.

The **Opponens minimi digiti** (fig. 345) is of a triangular form, and placed immediately beneath the preceding muscles. It arises from the unciform process of the unciform bone, and contiguous portion of the annular ligament; its fibres pass downwards and inwards, to be inserted into the whole length of the metacarpal bone of the little finger, along its ulnar margin.

Relations.—By its *superficial surface*, with the Flexor brevis, and Abductor minimi digiti. By its *deep surface*, with the Interossei muscles in the fourth metacarpal space, the metacarpal bone, and the Flexor tendons of the little finger.

Nerves.—All the muscles of this group are supplied by the eighth cervical nerve through the ulnar nerve.

Actions.—The Abductor minimi digiti abducts the little finger from the middle line of the hand. It corresponds to a dorsal interosseous muscle. It also assists in flexing the proximal phalanx. The Flexor brevis minimi digiti abducts the little finger from the middle line of the hand. It also assists in flexing the proximal phalanx. The Opponens minimi digiti draws forwards the fifth metacarpal bone, so as to deepen the hollow of the palm. The Palmaris brevis corrugates the skin on the inner side of the palm of the hand.

13. *Middle Palmar Region*

Lumbricales. Interossei palmares.
Interossei dorsales.

The **Lumbricales** (fig. 354) are four small fleshy fasciculi, accessories to the deep Flexor muscle. They arise by fleshy fibres from the tendons of the deep Flexor: the first and second, from the radial side and palmar surface of the tendons of the index and middle fingers; the third, from the contiguous sides of the tendons of the middle and ring fingers; and the fourth, from the contiguous sides of the tendons of the ring and little fingers. They pass to the radial side of the corresponding fingers, and opposite the metacarpo-phalangeal articulation each tendon is inserted into the tendinous expansion of the Extensor communis digitorum, covering the dorsal aspect of each finger.

The **Interossei muscles** (figs. 355, 356) are so named from occupying the intervals between the metacarpal bones. They are divided into two sets, a dorsal and palmar: the former are four in number, one in each metacarpal space; the latter, three in number, lie upon the metacarpal bones.

The **Dorsal interossei** are four in number, larger than the palmar, and occupy the intervals between the metacarpal bones. They are bipenniform muscles, arising by two heads from the adjacent sides of the metacarpal bones, but more extensively from the metacarpal bone which corresponds to the side of the finger in which the muscle is inserted. They are inserted into the bases of the first phalanges and into the aponeurosis of the common extensor tendon. Between the double origin of each of these muscles is a narrow triangular interval,

through the first of which passes the radial artery; through the other three passes a perforating branch from the deep palmar arch.

The *First dorsal interosseous muscle,* or *Abductor indicis,* is larger than the others. It is flat, triangular in form, and arises by two heads, separated by a fibrous arch, for the passage of the radial artery from the dorsum to the palm of the hand. The outer head arises from the upper half of the ulnar border of the first metacarpal bone; the inner head, from almost the entire length of the radial border of the second metacarpal bone; the tendon is inserted into the radial side of the index finger. The *second* and *third dorsal interossei* are inserted into the middle finger, the former into its radial, the latter into its ulnar side. The *fourth* is inserted into the ulnar side of the ring finger.

The **Palmar interossei**, three in number, are smaller than the Dorsal, and placed upon the palmar surface of the metacarpal bones, rather than between them. They arise from the entire length of the metacarpal bone of one finger, and are inserted into the side of the base of the first phalanx and aponeurotic expansion of the common extensor tendon of the same finger.

The *first* arises from the ulnar side of the second metacarpal bone, and is inserted into the same side of the first phalanx of the index finger. The *second*

Fig. 355.—The Dorsal interossei of left hand.

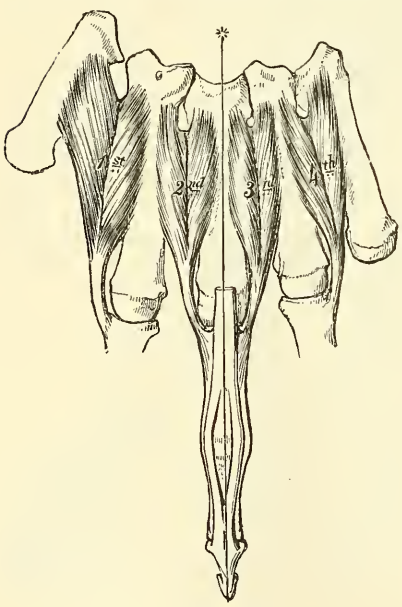


Fig. 356.—The Palmar interossei of left hand.

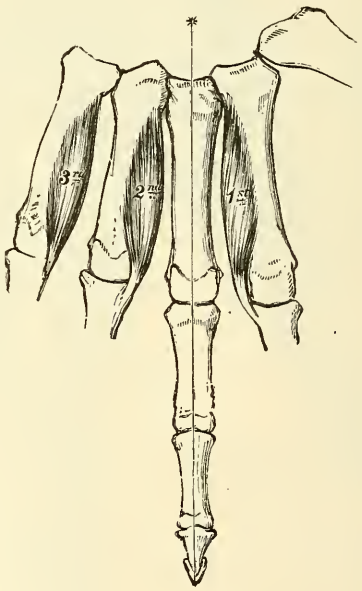


arises from the radial side of the fourth metacarpal bone, and is inserted into the same side of the ring finger. The *third* arises from the radial side of the fifth metacarpal bone, and is inserted into the same side of the little finger. From this account it may be seen that each finger is provided with two Interossei muscles, with the exception of the little finger, in which the Abductor muscle takes the place of one of the pair.

Nerves.—The two outer Lumbricales are supplied by the sixth cervical nerve, through the digital branches of the median nerve: the two inner Lumbricales and all the Interossei are supplied by the eighth cervical nerve, through the deep palmar branch of the ulnar nerve. Brooks states that the third lumbrical received a twig from the median in twelve out of twenty-one cases.

Actions.—The Palmar interossei muscles adduct the fingers to an imaginary line drawn longitudinally through the centre of the middle finger; and the Dorsal interossei abduct the fingers from that line. In addition to this the

Interossei, in conjunction with the Lumbricales, flex the first phalanx at the metacarpo-phalangeal joints, and extend the second and third phalanges in consequence of their insertion into the expansion of the extensor tendons. The Extensor communis digitorum is believed to act almost entirely on the first phalanges.

Surface Form.—The *Pectoralis major* largely influences surface form and conceals a considerable part of the thoracic wall in front. Its sternal origin presents a festooned border, which bounds and determines the width of the sternal furrow. Its clavicular origin is somewhat depressed and flattened, and between the two portions of the muscle is often an oblique depression, which differentiates the one from the other. The outer margin of the muscle is generally well marked above, and bounds the infraclavicular fossa, a triangular interval which separates the Pectoralis major from the Deltoid. It gradually becomes less marked as it approaches the tendon of insertion, and becomes more closely blended with the Deltoid muscle. The lower border of the Pectoralis major forms the rounded anterior axillary fold, and corresponds with the direction of the fifth rib. The *Pectoralis minor* influences surface form. When the arm is raised, its lowest slip of origin produces a local fulness just below the border of the anterior fold of the axilla, and so serves to break the sharp line of the lower border of the Pectoralis major muscle which is produced when the arm is in this position. The origin of the *Serratus magnus* produces a very characteristic surface marking. When the arm is raised from the side, in a well-developed subject, the five or six lower serrations are plainly discernible, forming a zigzag line, caused by the series of digitations, which diminish in size from above downwards, and have their apices arranged in the form of a curve. When the arm is lying by the side, the first serration to appear, at the lower margin of the Pectoralis major, is the one attached to the fifth rib. The *Deltoid*, with the prominence of the upper extremity of the humerus, produces the rounded outline of the shoulder. It is rounder and fuller in front than behind, where it presents a somewhat flattened form. Its anterior border, above, presents a rounded, slightly curved eminence, which bounds externally the infraclavicular fossa; below, it is closely united with the Pectoralis major. Its posterior border is thin, flattened, and scarcely marked above; below, it is thicker and more prominent. When the muscle is in action, the middle portion becomes irregular, presenting alternate longitudinal elevations and depressions: the elevations corresponding to the fleshy portions; the depressions, to the tendinous intersections of the muscle. The insertion of the Deltoid is marked by a depression on the outer side of the middle of the arm. Of the scapular muscles, the only one which materially influences surface form is the *Teres major*, which assists the Latissimus dorsi in forming the thick, rounded fold of the posterior boundary of the axilla. When the arm is raised, the Coraco-brachialis reveals itself as a long, narrow elevation, which emerges from under cover of the anterior fold of the axilla and runs downwards, internal to the shaft of the humerus. When the arm is hanging by the side, its front and inner part presents the prominence of the Biceps, bounded on either side by an intermuscular depression. This muscle determines the contour of the front of the arm, and extends from the anterior margin of the axilla to the bend of the elbow. Its upper tendons are concealed by the Pectoralis major and the Deltoid, and its lower tendon sinks into the space at the bend of the elbow. When the muscle is in a state of complete contraction—that is to say, when the forearm has been flexed and supinated—it presents a rounded convex form, bulged out laterally and its length is diminished. On each side of the Biceps, at the lower part of the arm, the *Brachialis anticus* is discernible. On the outer side it forms a narrow eminence, which extends some distance up the arm along the border of the Biceps. On the inner side it shows itself only as a little fulness just above the elbow. On the back of the arm the long head of the *Triceps* may be seen as a longitudinal eminence emerging from under cover of the Deltoid, and gradually merging into the longitudinal flattened plane of the muscle on the lower part of the back of the arm. On the anterior aspect of the elbow are to be seen two muscular elevations, one on each side, separated above, and converging below so as to form a triangular space. Of these, the inner elevation, consisting of the flexors and pronator, forms the prominence along the inner side and front of the forearm. It is a fusiform mass, pointed above at the internal condyle, and gradually tapering off below. The *Pronator radii teres*, the innermost muscle of the group, forms the boundary of the triangular space at the bend of the elbow. It is shorter, less prominent, and more oblique than the outer boundary. The most prominent part of the eminence is produced by the *Flexor carpi radialis*, the muscle next in order on the inner side of the preceding one. It forms a rounded prominence above, and can be traced downwards to its tendon, which can be felt lying on the front of the wrist, nearer to the radial than to the ulnar border and to the inner side of the radial artery. The *Palmaris longus* presents no surface marking above, but, below, is the most prominent tendon on the front of the wrist, standing out, when the muscle is in action, as a sharp tense cord beneath the skin. The *Flexor sublimis digitorum* does not directly influence surface form. The position of its four tendons on the front of the lower part of the forearm is indicated by an elongated depression between the tendons of the Palmaris longus and the Flexor carpi ulnaris. The *Flexor carpi ulnaris* occupies a small part of the posterior surface of the forearm, and is separated from the extensor and supinator

group, which occupies the greater part of this surface, by the ulnar furrow, produced by the subcutaneous posterior border of the ulna. Its tendon can be perceived along the ulnar border of the front of the forearm, and is most marked when the hand is flexed and adducted. The deep muscles of the front of the forearm have no direct influence on surface form. The external group of muscles of the forearm, consisting of the extensors and supinators, occupy the outer, and a considerable portion of the posterior, surface of this region. They form a fusiform mass, which is altogether on a higher level than the pronato-flexor group. Its apex emerges from between the Triceps and Brachialis anticus muscles some distance above the elbow-joint, and acquires its greatest breadth opposite the external condyle, and thence gradually shades off into a flattened surface. About the middle of the forearm it divides into two longitudinal eminences which diverge from each other, leaving a triangular interval between them. The outer of these two groups of muscles consists of the Supinator longus and the Extensor carpi radialis longior et brevior, which form a longitudinal eminence descending from the external condyloid ridge in the direction of the styloid process of the radius. The other and more posterior group consists of the Extensor communis digitorum, the Extensor minimi digiti, and the Extensor carpi ulnaris. It commences above as a tapering form at the external condyle of the humerus, and is separated behind at its upper part from the Anconeus by a well-marked furrow; and below, from the pronato-flexor mass, by the ulnar furrow. In the triangular interval left between these two groups, the extensors of the thumb and index finger are seen. The only two muscles of this region which require special mention, as independently influencing surface form, are the Supinator longus and the Anconeus. The inner border of the *Supinator longus* forms the outer boundary of the triangular space at the bend of the elbow. It commences as a rounded border above the condyle, and is longer, less oblique, and more prominent than the inner boundary. Lower down, the muscle forms a full fleshy mass on the outer side of the upper part of the forearm, and below tapers into a tendon, which may be traced down to the styloid process of the radius. The *Anconeus* presents a well-marked and characteristic surface form in the shape of a triangular, slightly elevated surface, immediately external to the subcutaneous posterior surface of the olecranon, and differentiated from the common extensor group by a well-marked oblique longitudinal depression. The upper angle of the triangle corresponds to the external condyle, and is marked by a depression or dimple in this situation. In the triangular interval, caused by the divergence from each other of the two groups of muscles into which the extensor and supinator group is divided at the lower part of the forearm, an oblique elongated eminence is seen, caused by the emergence of two of the extensors of the thumb from their deep origin at the back of the forearm. This eminence, full above, and becoming flattened out and partially subdivided below, runs downwards and outwards over the back and outer surface of the radius to the outer side of the wrist-joint, where it forms a ridge, especially marked when the thumb is extended, which passes onwards to the posterior aspect of the thumb. The tendons of most of the extensor muscles are to be seen and felt at the level of the wrist-joint. Most externally are the tendons of the Extensor ossis metacarpi pollicis and the Extensor brevis pollicis, forming a vertical ridge over the outer side of the joint from the styloid process of the radius to the thumb. Internal to this is the oblique ridge produced by the tendon of the Extensor longus pollicis, very noticeable when the muscle is in action. The Extensor carpi radialis longior is scarcely to be felt, but the Extensor carpi radialis brevior can be distinctly perceived, as a vertical ridge emerging from under the inner border of the tendon of the Extensor longus pollicis, when the hand is forcibly extended at the wrist. Internal to this, again, can be felt the tendons of the Extensor indicis, Extensor communis digitorum, and Extensor minimi digiti; the latter tendon being separated from those of the common extensor by a slight furrow. The muscles of the hand are principally concerned, as far as regards surface-form, in producing the thenar and hypothenar eminences, and individually are not to be distinguished, on the surface, from each other. The *Adductor transversus pollicis* is, however, an exception to this; its anterior border gives rise to a ridge across the web of skin connecting the thumb to the rest of the hand. The thenar eminence is much larger and rounder than the hypothenar one, which presents a longer and narrower eminence along the ulnar side of the hand. When the *Palmaris brevis* is in action it produces a wrinkling of the skin over the hypothenar eminence, and a deep dimple on the ulnar border of the hand. The anterior extremities of the *Lumbrical* muscles help to produce the soft eminences just behind the clefts of the fingers, separated from each other by depressions corresponding to the flexor tendons in their sheaths. Between the thenar and hypothenar eminences, at the wrist-joint, is a slight groove or depression, widening out as it approaches the fingers; beneath this we have the strong central part of the palmar fascia. Here we have some furrows, which are pretty constant in their arrangement, and bear some resemblance to the letter M. One of these furrows passes obliquely outwards from the groove between the thenar and hypothenar regions to the head of the metacarpal bone of the index finger. A second passes inwards, with a slight inclination upwards, from the termination of the first to the ulnar side of the hand. A third runs parallel with the second and about three-quarters of an inch below it. Lastly, crossing these two latter furrows is an oblique furrow parallel with the first. The skin of the palm of the hand differs considerably from that of the forearm. At the wrist it

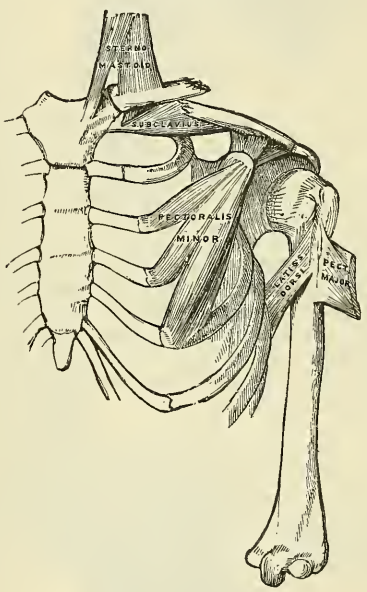
suddenly becomes hard and dense, and covered with a thick layer of cuticle. The skin in the thenar region presents these characteristics less than elsewhere. In spite of this hardness and density the skin of the palm is exceedingly sensitive and very vascular. It is destitute of hair, and no sebaceous follicles have been found in this region. Over the fingers the skin again becomes thinner, especially at the flexures of the joints, and over the terminal phalanges it is thrown into numerous parallel ridges in consequence of the arrangement of the papillæ in it. The superficial fascia in the palm is made up of dense fibro-fatty tissue. This tissue binds down the skin so firmly to the deep palmar fascia that very little movement is permitted between the two. On the back of the hand the *Dorsal interossei* produce elongated swellings between the metacarpal bones. The first dorsal interosseous (Abductor indicis), when the thumb is closely adducted to the hand, forms a prominent fusiform bulging; the other interossei are not so marked.

Surgical Anatomy.—The student, having completed the dissection of the muscles of the upper extremity, should consider the effects likely to be produced by the action of the various muscles in fracture of the bones.

In considering the actions of the various muscles upon fractures of the upper extremity, I have selected the most common forms of injury, both for illustration and description.

Fracture of the *middle of the clavicle* (fig. 357) is always attended with considerable displacement, the inner end of the outer fragment is displaced inwards and backwards, while the outer end of the same fragment is rotated forwards. The whole outer fragment is somewhat depressed.

Fig. 357.—Fracture of the middle of the clavicle.



The displacement is produced as follows: *inwards*, by the muscles passing from the chest to the outer fragment of the clavicle, to the scapula, and to the humerus, viz. the Subclavius and the Pectoralis minor and, to a less extent, the Pectoralis major and the Latissimus dorsi; *backwards*, in consequence of the rotation of the outer fragment. The Serratus magnus causes the scapula to rotate on the wall of the chest, this carries the acromion and outer end of the outer fragment of the clavicle forwards, and causes the piece of bone to rotate round a vertical axis through its centre, and so carries the inner end of the outer portion backwards. The depression of the whole outer fragment is produced by the weight of the arm and by the contraction of the Deltoid. The outer end of the inner fragment appears to be elevated, the skin being drawn tensely over it; this is owing to the depression of the outer fragment, as the inner fragment is usually kept fixed by the costo-clavicular ligament, and by the antagonism between the Sterno-mastoid and Pectoralis major muscles. But it may be raised by an unusually strong Sterno-mastoid, or by the inner end of the outer fragment getting below and behind it. The causes of displacement having been ascertained, it is easy to apply the appropriate treatment. The outer fragment is to be drawn outwards, and, together with the scapula, raised upwards to a level with the inner fragment, and retained in that position.

In fracture of the *acromial end of the clavicle*, between the conoid and trapezoid ligaments, only slight displacement occurs, as these ligaments, from their oblique insertion, serve to hold both portions of the bone in apposition. Fracture, also, of the *sternal end*, internal to the costo-clavicular ligament, is attended with only slight displacement, this ligament serving to retain the fragments in close apposition.

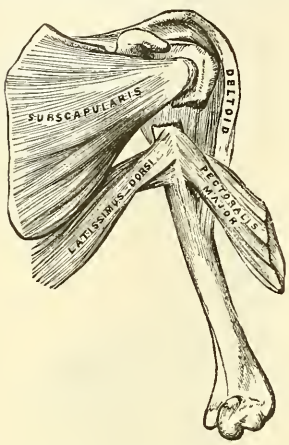
Fracture of the *acromion process* usually arises from violence applied to the upper and outer part of the shoulder; it is generally known by the rotundity of the shoulder being lost, from the Deltoid drawing the fractured portion downwards and forwards; and the displacement may easily be discovered by tracing the margin of the clavicle outwards, when the fragment will be found resting on the front and upper part of the head of the humerus. In order to relax the anterior and outer fibres of the Deltoid (the opposing muscle), the arm should be drawn forwards across the chest, and the elbow well raised, so that the head of the bone may press the acromion process upwards, and retain it in its position.

Fracture of the *coracoid process* is an extremely rare accident, and is usually caused by a sharp blow on the point of the shoulder. Displacement is here produced by the combined actions of the Pectoralis minor, short head of the Biceps, and Coraco-brachialis, the former muscle drawing the fragment inwards, and the latter directly downwards, the

amount of displacement being limited by the connection of this process to the acromion by means of the coraco-acromial ligament. In many cases there appears to have been little or no displacement, from the fact that the coraco-clavicular ligament has remained intact, and has kept the separated fragment from displacement. In order to relax these muscles and replace the fragments in close apposition, the forearm should be flexed so as to relax the Biceps, and the arm drawn forwards and inwards across the chest so as to relax the Coraco-brachialis; the humerus should then be pushed upwards against the coraco-acromial ligament, and the arm retained in that position.

Fracture of the *surgical neck of the humerus* (fig. 358) is very common, is attended with considerable displacement, and its appearances correspond somewhat with those of dislocation of the head of the humerus into the axilla. The upper fragment is slightly elevated under the coraco-acromial ligament by the muscles attached to the greater and lesser tuberosities; the lower fragment is drawn inwards by the Pectoralis major, Latissimus dorsi, and Teres major; and the humerus is thrown obliquely outwards from the side by the Deltoid, and occasionally elevated so as to cause the upper end of the lower fragment to project beneath and in front of the coracoid process. The deformity is reduced by fixing the shoulder, and drawing the arm outwards and downwards. To counteract the opposing muscles, and to keep the fragments in position, a small conical-shaped pad should be placed in the axilla, and the arm bandaged to the side by a broad roller passed round the chest, in such a manner that the elbow is carried slightly forwards, so as to throw the upper end of the lower fragment backwards and outwards towards the head of the bone. The whole is then covered with a carefully moulded guttapercha or poroplastic shoulder cap.

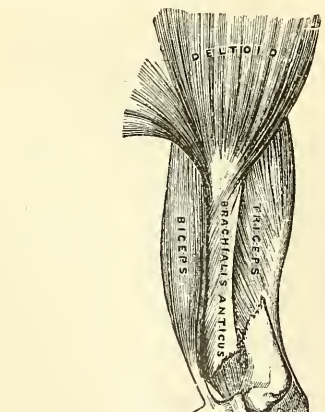
Fig. 358.—Fracture of the surgical neck of the humerus.



In fracture of the *shaft of the humerus* below the insertion of the Pectoralis major, Latissimus dorsi, and Teres major, and above the insertion of the Deltoid, there is also considerable deformity, the upper fragment being drawn inwards by the first mentioned muscles, and the lower fragment upwards and outwards by the Deltoid, producing shortening of the limb, and a considerable prominence at the seat of fracture, from the fractured ends of the bone riding over one another, especially if the fracture takes place in an oblique direction. The fragments may be brought into apposition by extension from the elbow, and retained in that position by adopting the same means as in the preceding injury.

In fractures of the *shaft of the humerus* immediately below the insertion of the Deltoid, the amount of deformity depends greatly upon the direction of the fracture. If it occurs in a transverse direction, only slight displacement takes place, the upper fragment being drawn a little forwards; but in oblique fracture, the combined actions of the Biceps and Brachialis anticus muscles in front, and the Triceps behind, draw upwards the lower fragment, causing it to glide over the upper fragment, either backwards or forwards, according to the direction of the fracture. Simple extension reduces the deformity, and the application of splints on the four sides of the arm will retain the fragments in apposition. Care should be taken not to raise the elbow; but the forearm and hand may be supported in a sling.

Fig. 359.—Fracture of the humerus above the condyles.

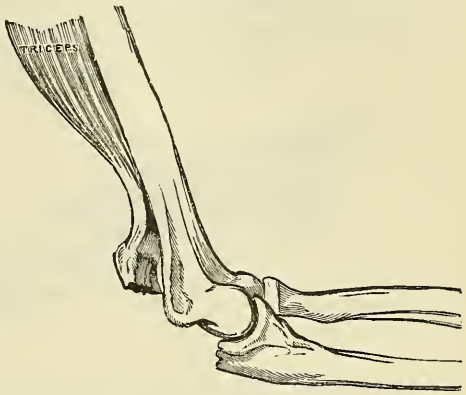


Fracture of the *humerus* (fig. 359) immediately above the condyles deserves very attentive consideration, as the general appearances correspond somewhat with those produced by separation of the epiphysis of the humerus, and with those of dislocation of the radius and ulna backwards. If the direction of the fracture is oblique from above, downwards, and forwards, the lower fragment is drawn upwards by the Brachialis anticus and Biceps in front, and the Triceps behind; and at the same time is drawn backwards behind the upper fragment by the Triceps. This injury may be diagnosed from dislocation by the increased mobility in fracture, the existence of crepitus, and the fact of the deformity being remedied by extension, on the discontinuance of which it is reproduced. The age of the patient is

of importance in distinguishing this form of injury from separation of the epiphysis. If fracture occurs in the opposite direction to that shown in the accompanying figure, the lower fragment is drawn upwards and forwards, causing a considerable prominence in front; and the upper fragment projects backwards beneath the tendon of the Triceps muscle.

Fracture of the *olecranon process* (fig. 360) is a frequent accident. The detached fragment is displaced upwards, by the action of the Triceps muscle, from half an inch to two inches; the prominence of the elbow is consequently lost, and a deep hollow is felt at the back part of the joint, which is much increased on flexing the limb. The patient at the same time loses, more or less, the power of extending the forearm. The treatment consists in relaxing the Triceps by extending the limb, and retaining it in the extended position by means of a long straight splint applied to the front of the arm; the fragments are thus brought into close apposition, and may be further approximated by drawing down the upper fragment. Union is generally ligamentous.

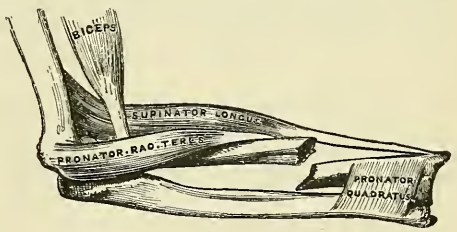
Fig. 360.—Fracture of the olecranon.



Fracture of the *neck of the radius* is an exceedingly rare accident, and is generally caused by direct violence. Its diagnosis is somewhat obscure, on account of the slight deformity visible, the injured part being surrounded by a large number of muscles; but the movements of pronation and supination are entirely lost. The upper fragment is drawn outwards by the Supinator brevis, its extent of displacement being limited by the attachment of the orbicular ligament. The lower fragment is drawn forwards and slightly upwards by the Biceps, and inwards by the Pronator radii teres, its displacement forwards and upwards being counteracted in some degree by the Supinator brevis. The treatment essentially consists in relaxing the Biceps, Supinator brevis, and Pronator radii teres muscles, by flexing the forearm, and placing it in a position midway between pronation and supination, extension having been previously made so as to bring the parts in apposition.

In fracture of the *radius* below the insertion of the Biceps, but above the insertion of the Pronator radii teres, the upper fragment is strongly supinated by the Biceps and Supinator brevis, and at the same time drawn forwards and flexed by the Biceps; the lower fragment is in a state of extreme pronation and drawn inwards towards the ulna by the pronator. Thus there is extreme displacement with very little deformity. In treating such a fracture the arm must be put up in a position of supination, otherwise union will take place with great impairment of the movements of the hand. In fractures of the radius below the insertion of the Pronator radii teres (fig. 361), the upper fragment is drawn upwards by the Biceps, and inwards by the Pronator radii teres, holding a position midway between pronation and supination, and a degree of fulness in the upper half of the forearm is thus produced: the lower fragment is drawn downwards and inwards towards the ulna by the Pronator quadratus, and thrown into a state of pronation by the same muscle; at the same time, the Supinator longus, by elevating the styloid process, into which it is inserted, will serve to depress the upper end of the lower fragment still more towards the ulna. In order to relax the opposing muscles the forearm should be bent, and the limb placed in a position midway between pronation and supination; the fracture is then easily reduced by extension from the wrist and elbow: well-padded splints should be applied on both sides of the forearm from the elbow to the wrist; the hand being allowed to fall, will, by its own weight, counteract the action of the Pronator quadratus and Supinator longus, and elevate the lower fragment to the level of the upper one.

Fig. 361.—Fracture of the shaft of the radius.

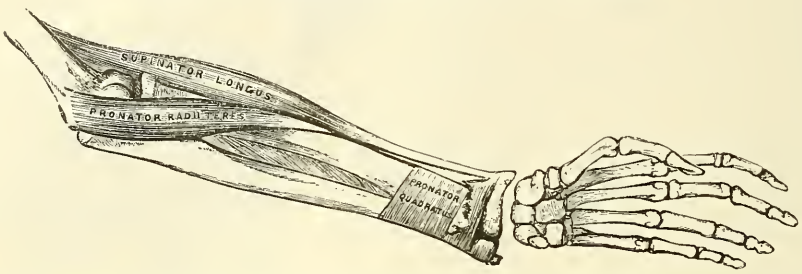


In fracture of the *shaft of the ulna* the upper fragment retains its usual position, but the lower fragment is drawn outwards towards the radius by the Pronator quadratus, producing a well-marked depression at the seat of fracture, and some fulness on the dorsal and palmar surfaces of the forearm. The fracture is easily reduced by extension from the wrist and forearm. The forearm should be flexed, and placed in a position midway between pronation and supination, and well-padded splints applied from the elbow to the ends of the fingers.

In fracture of the *shafts of the radius and ulna together*, the lower fragments are drawn upwards, sometimes forwards, sometimes backwards, according to the direction of the fracture, by the combined actions of the Flexor and Extensor muscles, producing a degree of fulness on the dorsal or palmar surface of the forearm; at the same time the two fragments are drawn into contact by the Pronator quadratus, the radius being in a state of pronation: the upper fragment of the radius is drawn upwards and inwards by the Biceps and Pronator radii teres to a higher level than the ulna; the upper portion of the ulna is slightly elevated by the Brachialis anticus. The fracture may be reduced by extension from the wrist and elbow, and the forearm should be placed in the same position as in fracture of the ulna.

In fracture of the *lower end of the radius* (fig. 362) the displacement which is produced

Fig. 362.—Fracture of the lower end of the radius.



is very considerable, and bears some resemblance to dislocation of the carpus backwards, from which it should be carefully distinguished. The lower fragment is displaced backwards and upwards, but this displacement is probably due to the force of the blow driving the portion of bone into this position and not to any muscular influence. The upper fragment projects forwards, often lacerating the substance of the Pronator quadratus, and is drawn by this muscle into close contact with the lower end of the ulna, causing a projection on the anterior surface of the forearm, immediately above the carpus, from the flexor tendons being thrust forwards. This fracture may be distinguished from dislocation by the deformity being removed on making sufficient extension, when crepitus may be occasionally detected; at the same time, on extension being discontinued, the parts immediately resume their deformed appearance (see also page 246). The age of the patient will also assist in determining whether the injury is fracture or separation of the epiphysis. The treatment consists in flexing the forearm, and making powerful extension from the wrist and elbow, depressing at the same time the radial side of the hand, and retaining the parts in that position by well-padded *pistol-shaped* splints.

MUSCLES AND FASCIÆ OF THE LOWER EXTREMITY

The muscles of the Lower Extremity are subdivided into groups, corresponding with the different regions of the limb.

I. Iliac Region

Psoas magnus.
Psoas parvus.
Iliacus.

II. Thigh

1. *Anterior Femoral Region*

Tensor vaginæ femoris.
Sartorius.
Rectus.
Vastus externus.
Vastus internus.
Crureus.
Subcrureus.

2. *Internal Femoral Region*

Gracilis
Pectineus.
Adductor longus.
Adductor brevis.
Adductor magnus.

3. *Gluteal Region*

Gluteus maximus.
Gluteus medius.
Gluteus minimus.
Pyriformis.
Gemellus superior.
Obturator internus.
Gemellus inferior.
Obturator externus.
Quadratus femoris.

4. *Posterior Femoral Region*

Biceps.
Semitendinosus.
Semimembranosus.

III. Leg

5. *Anterior Tibio-fibular Region*

Tibialis anticus.
Extensor longus digitorum.
Extensor proprius hallucis.
Peroneus tertius.

6. *Posterior Tibio-fibular Region*

Superficial Layer

Gastrocnemius.
Plantaris.
Soleus.

Deep Layer

Popliteus.
Flexor longus hallucis.
Flexor longus digitorum.
Tibialis posticus.

7. *Fibular Region.*

Peroneus longus.
Peroneus brevis.

IV. Foot

8. *Dorsal Region*

Extensor brevis digitorum.

9. *Plantar Region*

First Layer

Abductor hallucis.
Flexor brevis digitorum.
Abductor minimi digiti.

Second Layer

Flexor accessorius.
Lumbricales.

Third Layer

Flexor brevis hallucis.
Adductor obliquus hallucis.
Flexor brevis minimi digiti.
Adductor transversus pedis.

Fourth Layer

The Interossei.

I. Muscles and Fasciæ of the Iliac Region

Psoas magnus. Psoas parvus. Iliacus.

Dissection.—No detailed description is required for the dissection of these muscles. On the removal of the viscera from the abdomen, they are exposed, covered by the peritoneum and a thin layer of fascia, the iliac fascia.

The **iliac fascia** * is the aponeurotic layer which lines the back part of the abdominal cavity, and covers the Psoas and Iliacus muscles throughout their whole extent. It is thin above, and becomes gradually thicker below as it approaches the crural arch.

The *portion covering the Psoas* is attached, above, to the ligamentum arcuatum internum; internally, by a series of arched processes to the intervertebral substances, and prominent margins of the bodies of the vertebræ, and to the upper part of the sacrum; the intervals so left, opposite the constricted portions of the bodies, transmitting the lumbar arteries and filaments of the sympathetic nerve. Externally, above the crest of the ilium, this portion of the iliac fascia is continuous with the anterior lamella of the lumbar fascia (see page 432), but below the crest of the ilium it is continuous with the fascia covering the Iliacus.

The *portion investing the Iliacus* is connected, externally, to the whole length of the inner border of the crest of the ilium; and internally, to the brim of the true pelvis, where it is continuous with the periosteum, and at the ilio-pectineal eminence it receives the tendon of insertion of the Psoas parvus, when that muscle exists. External to the femoral vessels, this fascia is intimately connected to the posterior margin of Poupart's ligament, and is continuous with the fascia transversalis. Internal to the vessels it is attached to the ilio-pectineal line behind the conjoined tendon, where it is again continuous with the transversalis fascia; and corresponding to the point where the femoral vessels pass into the thigh, this fascia descends behind them forming the posterior wall of the crural sheath. This portion of the iliac fascia which passes behind the femoral vessels is also attached to the ilio-pectineal line beyond the limits

* The student must not confound this fascia with the *iliac portion of the fascia lata* (see p. 512).

of the attachment of the conjoined tendon; at this part it is continuous with the pubic portion of the fascia lata of the thigh. The external iliac vessels lie in front of the iliac fascia, but all the branches of the lumbar plexus behind it; it is separated from the peritoneum by a quantity of loose areolar tissue.

The **Psoas magnus** (fig. 364) is a long fusiform muscle placed on the side of the lumbar region of the spine and margin of the pelvis. It arises from the front of the bases and lower borders of the transverse processes of the lumbar vertebræ by five fleshy slips; also from the sides of the bodies, and the corresponding intervertebral substances of the last dorsal and all the lumbar vertebræ. The muscle is connected to the bodies of the vertebræ by five slips; each slip is attached to the upper and lower margins of two vertebræ, and to the intervertebral substance between them; the slips themselves being connected by tendinous arches which extend across the constricted part of the bodies, and beneath which pass the lumbar arteries and sympathetic nerves. These tendinous arches also give origin to muscular fibres, and protect the blood-vessels and nerves from pressure during the action of the muscle. The first slip is attached to the contiguous margins of the last dorsal and first lumbar vertebræ; the last to the contiguous margins of the fourth and fifth lumbar, and to the intervertebral substance. From these points the muscle passes down across the brim of the pelvis, and, diminishing gradually in size, passes beneath Poupart's ligament, and terminates in a tendon, which, after receiving the fibres of the Iliacus, is inserted into the lesser trochanter of the femur.

Relations.—In the lumbar region. By its *anterior surface*, which is placed behind the peritoneum, with the iliac fascia, the ligamentum arcuatum internum, the kidney, Psoas parvus, renal vessels, ureter, spermatic vessels, genito-crural nerve, and the colon. By its *posterior surface*, with the transverse processes of the lumbar vertebræ, and the Quadratus lumborum, from which it is separated by the anterior lamella of the lumbar fascia. The anterior crural nerve is at first situated in the substance of the muscle, and emerges from its outer border at the lower part. The rest of the lumbar plexus is situated in the posterior part of the substance of the muscle. By its *inner side*, the muscle is in relation with the bodies of the lumbar vertebræ, the lumbar arteries, the ganglia of the sympathetic nerve, and their branches of communication with the spinal nerves; the lumbar glands; the vena cava inferior on the right, and the aorta on the left side, and along the brim of the pelvis with the external iliac artery. In the thigh it is in relation, in front, with the fascia lata; behind, with the capsular ligament of the hip, from which it is separated by a synovial bursa, which frequently communicates with the cavity of the joint through an opening of variable size; by its *inner border*, with the Pectineus and the femoral artery, which slightly overlaps it; by its *outer border*, with the anterior crural nerve and Iliacus muscle.

The **Psoas parvus** is a long slender muscle, placed in front of the Psoas magnus. It arises from the sides of the bodies of the last dorsal and first lumbar vertebræ and from the intervertebral substance between them. It forms a small flat muscular bundle, which terminates in a long flat tendon, inserted into the ilio-pectineal eminence and, by its outer border, into the iliac fascia. This muscle is often absent, and, according to Cruveilhier, sometimes double.

Relations.—It is covered by the peritoneum, and, at its origin, by the ligamentum arcuatum internum; it rests on the Psoas magnus.

The **Iliacus** is a flat, triangular muscle, which fills up the whole of the iliac fossa. It arises from the upper two-thirds of this fossa, and from the inner margin of the crest of the ilium; behind, from the ilio-lumbar ligament, and base of the sacrum; in front, from the anterior superior and anterior inferior spinous processes of the ilium, from the notch between them, and by a few fibres from the capsule of the hip-joint. The fibres converge to be inserted

into the outer side of the tendon of the Psoas, some of them being prolonged into the oblique line which extends from the lesser trochanter to the linea aspera.*

Relations.—*Within the pelvis:* by its *anterior surface*, with the iliac fascia, which separates the muscle from the peritoneum, and with the external cutaneous nerve; on the right side, with the cæcum; on the left side with the sigmoid flexure of the colon. By its *posterior surface*, with the iliac fossa. By its *inner border*, with the Psoas magnus, and anterior crural nerve. In the thigh, it is in relation, by its *anterior surface*, with the fascia lata, Rectus, and Sartorius; behind, with the capsule of the hip-joint, a synovial bursa common to it and the Psoas magnus being interposed.

Nerves.—The Psoas magnus is supplied by the anterior branches of the second and third lumbar nerves; the Psoas parvus, when it exists, is supplied by the anterior branch of the first lumbar nerve; and the Iliacus by the anterior branches of the second and third lumbar nerves through the anterior crural.

Actions.—The Psoas and Iliacus muscles, acting from above, flex the thigh upon the pelvis: acting from below, the femur being fixed, the muscles of both sides bend the lumbar portion of the spine and pelvis forwards. They also serve to maintain the erect position, by supporting the spine and pelvis upon the femur, and assist in raising the trunk when the body is in the recumbent posture.

The *Psoas parvus* is a tensor of the iliac fascia.

Surgical Anatomy.—In the iliac fascia there is no definite septum between the portions of fascia covering the Psoas and Iliacus respectively, and the fascia is only connected to the subjacent muscles by a quantity of loose connective tissue. When abscess forms beneath this fascia, as it is very apt to do, the matter is contained in an osseo-fibrous cavity which is closed on all sides within the abdomen, and is open only at its lower part, where the fascia is prolonged over the muscle into the thigh.

Abscess within the sheath of the Psoas muscle (*Psoas abscess*) is generally due to tuberculous caries of the bodies of the lower dorsal and lumbar vertebræ. When the disease is in the dorsal region, the matter tracts down the posterior mediastinum, in front of the bodies of the vertebræ, and, passing beneath the ligamentum arcuatum internum, enters the sheath of the Psoas muscle, down which it passes as far as the pelvic brim; it then gets beneath the iliac portion of the fascia, and fills up the iliac fossa. In consequence of the attachment of the fascia to the pelvic brim, it rarely finds its way into the pelvis, but passes by a narrow opening under Poupart's ligament into the thigh, to the outer side of the femoral vessels. It thus follows that a Psoas abscess may be described as consisting of four parts: (1) a somewhat narrow channel at its upper part, in the Psoas sheath; (2) a dilated sac in the iliac fossa; (3) a constricted neck under Poupart's ligament; and (4) a dilated sac in the upper part of the thigh. When the lumbar vertebræ are the seat of the disease, the matter finds its way directly into the substance of the muscle. The muscular fibres are destroyed, and the nervous cords contained in the abscess are isolated and exposed in its interior; the femoral vessels which lie in front of the fascia remain intact, and the peritoneum seldom becomes implicated. All Psoas abscesses do not, however, pursue this course: the matter may leave the muscle above the crest of the ilium, and tracking backwards may point in the loin (*lumbar abscess*); or it may point above Poupart's ligament in the inguinal region; or it may follow the course of the iliac vessels into the pelvis, and, passing through the great sacro-sciatic notch, discharge itself on the back of the thigh; or it may open into the bladder, or find its way into the perinæum.

II. Muscles and Fasciæ of the Thigh

1. *Anterior Femoral Region*

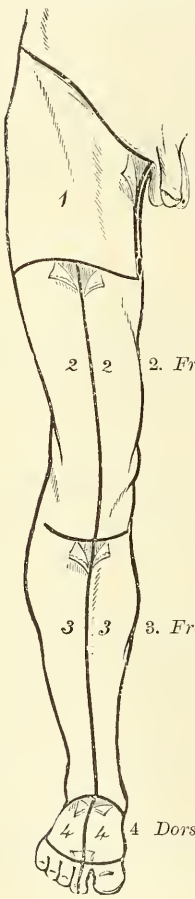
Tensor vaginæ femoris.
Sartorius.
Rectus.
Vastus externus.
Vastus internus.
Crureus.
Subcrureus.

* The Psoas and Iliacus are sometimes regarded as a single muscle, the *Ilio-psoas*, having two heads of origin and a single insertion.

Dissection.—To expose the muscles and fasciæ in this region, make an incision along Poupart's ligament, from the anterior superior spine of the ilium to the spine of the os pubis; a vertical incision from the centre of this, along the middle of the thigh to below the knee-joint; and a transverse incision from the inner to the outer side of the leg, at the lower end of the vertical incision. The flaps of integument having been removed, the superficial and deep fasciæ should be examined. The more advanced student should commence the study of this region by an examination of the anatomy of femoral hernia, and Scarpa's triangle, the incisions for the dissection of which are marked out in fig. 363.

The **superficial fascia** forms a continuous layer over the whole of the thigh, consisting of areolar tissue, containing in its meshes much fat, and capable of being separated into two or more layers, between which are found the superficial vessels and nerves. It varies in thickness in different parts of the limb; in the groin it is thick, and the two layers are separated from one another by the superficial inguinal lymphatic glands, the internal saphenous vein, and several smaller vessels. One of these two layers, the superficial, is continuous above with the superficial fascia of the abdomen. The deep layer of the superficial fascia is a very thin, fibrous layer, best marked on the inner side of the long saphenous vein and below Poupart's ligament. It is placed beneath the subcutaneous vessels and nerves and upon the surface of the fascia lata. It is intimately adherent to the fascia lata a little below Poupart's ligament. It covers the saphenous opening in the fascia lata, being closely united to its circumference, and is connected to the sheath of the femoral vessels, corresponding to its under surface. The portion of fascia covering this aperture is perforated by the internal saphenous vein and by numerous blood and lymphatic vessels, hence it has been termed the *cribriform fascia*, the openings for these vessels having been likened to the holes in a sieve. The cribriform fascia adheres closely both to the superficial fascia and to the fascia lata, so that it is described by some anatomists as part of the fascia lata, but is usually considered (as in this work) as belonging to the superficial fascia. It is not until the cribriform fascia has been cleared away that the saphenous opening is seen, so that this opening does not in ordinary cases exist naturally, but is the result of dissection. Mr. Callender, however, speaks of cases in which, probably as the result of pressure from enlarged inguinal lymphatic glands, the fascia has become atrophied, and a saphenous opening exists independent of dissection. A femoral hernia in passing through the saphenous opening receives the cribriform fascia as one of its coverings. A large subcutaneous bursa is found in the superficial fascia over the patella.

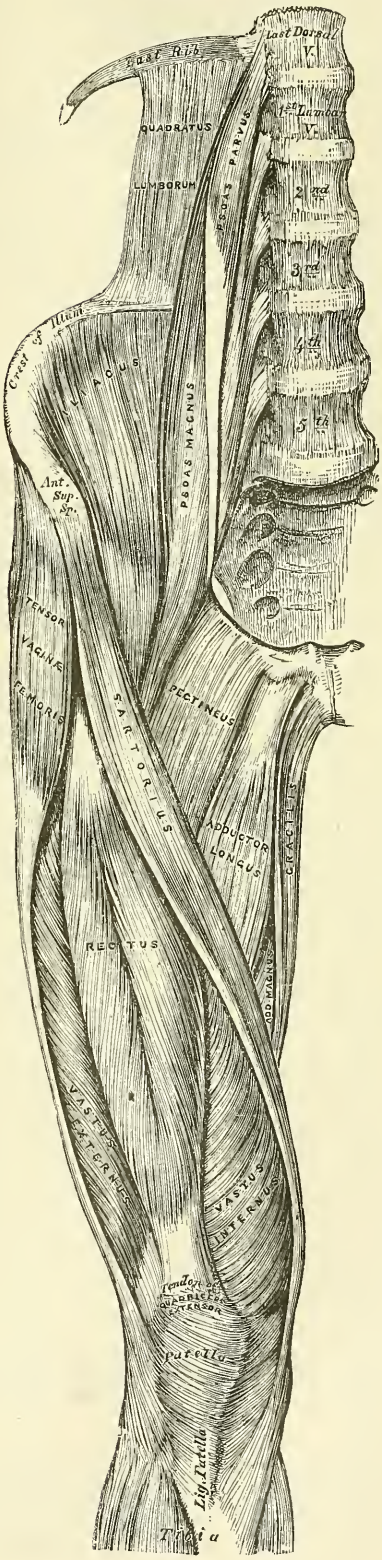
Fig. 363.—Dissection of lower extremity. Front view.



The **deep fascia** of the thigh is exposed on the removal of the superficial fascia, and is named, from its great extent, the *fascia lata*; it forms a uniform investment for the whole of this region of the limb, but varies in thickness in

different parts; thus, it is thicker in the upper and outer part of the thigh, where it receives a fibrous expansion from the Gluteus maximus muscle, and where the Tensor vaginæ femoris is inserted between its layers: it is very thin behind, and at the upper and inner part where it covers the Adductor muscles, and again becomes stronger around the knee, receiving fibrous expansions from the tendon of the Biceps externally, and from the Sartorius internally, and Quadriceps extensor cruris in front. The fascia lata is attached, above and behind, to the back of the sacrum and coccyx; externally, to the crest of the ilium; in front, to Poupart's ligament, and to the body of the os pubis; and internally, to the descending ramus of the os pubis, to the ascending ramus and tuberosity of the ischium, and to the lower border of the great sacro-sciatic ligament. From its attachment to the crest of the ilium it passes down over the Gluteus medius muscle to the upper border of the Gluteus maximus, where it splits into two layers, one passing superficial to and the other beneath this muscle. At the lower border of the muscle the two layers reunite. Externally, just below the great trochanter, the fascia lata receives the greater part of the tendon of insertion of the Gluteus maximus, and becomes proportionately thickened. The portion of the fascia lata arising from the front part of the crest of the ilium, corresponding to the origin of the Tensor vaginæ femoris, passes down the outer side of the thigh as two layers, one superficial and the other beneath this muscle; these at its lower end become blended together into a thick and strong band, having first received the insertion of the muscle. This band is continued downwards, under the name of the *ilio-tibial band*, to be inserted into the external tuberosity of the tibia. Below, the fascia lata is attached to all the prominent points around the knee-joint, viz. the condyles of the femur, tuberosities of the tibia, and head of the fibula. On each side of the patella it is strengthened by transverse fibres given off from the lower part of the Vasti muscles, which are attached to and support this bone. Of these the outer is the stronger, and is continuous with the ilio-tibial band.

Fig. 364.—Muscles of the iliac and anterior femoral regions.



From the inner surface of the fascia lata are given off two strong intermuscular septa, which are attached to the whole length of the linea aspera and its prolongations above and below: the external and stronger one, which extends from the insertion of the Gluteus maximus to the outer condyle, separates the Vastus externus in front from the short head of the Biceps behind, and gives partial origin to these muscles; the inner one, the thinner of the two, separates the Vastus internus from the Adductor and Pectineus muscles. Besides these there are numerous smaller septa, separating the individual muscles, and enclosing each in a distinct sheath.

At the upper and inner part of the thigh, a little below Poupart's ligament, a large oval-shaped aperture is observed after the superficial fascia has been cleared off: it transmits the internal saphenous vein, and other smaller vessels, and is termed the *saphenous opening*. In order more correctly to consider the mode of formation of this aperture, the fascia lata in this part of the thigh is described as consisting of two portions, an iliac portion and a pubic portion.

The *iliac portion* is all that part of the fascia lata on the outer side of the saphenous opening. It is attached, externally, to the crest of the ilium and its anterior superior spine, to the whole length of Poupart's ligament as far internally as the spine of the os pubis, and to the pectineal line in conjunction with Gimbernat's ligament. From the spine of the os pubis it is reflected downwards and outwards, forming an arched margin, the *falciform process* or boundary (*superior cornu*) of the saphenous opening; this margin overlies and is adherent to the anterior layer of the sheath of the femoral vessels: to its edge is attached the cribriform fascia; and, below, it is continuous with the pubic portion of the fascia lata.

The *pubic portion* is situated at the inner side of the saphenous opening; at the lower margin of this aperture it is continuous with the iliac portion; traced upwards, it covers the surface of the Pectineus, Adductor longus, and Gracilis muscles, and, passing behind the sheath of the femoral vessels, to which it is closely united, is continuous with the sheath of the Psoas and Iliacus muscles, and is attached above to the ilio-pectineal line, where it becomes continuous with the iliac fascia. From this description it may be observed that the iliac portion of the fascia lata passes in front of the femoral vessels, and the pubic portion behind them, so that an apparent aperture exists between the two, through which the internal saphenous joins the femoral vein.*

The fascia should now be removed from the surface of the muscles. This may be effected by pinching it up between the forceps, dividing it, and separating it from each muscle in the course of its fibres.

The **Tensor vaginæ femoris** arises from the anterior part of the outer lip of the crest of the ilium, from the outer surface of the anterior superior spinous process, and part of the outer border of the notch below it, between the Gluteus medius and Sartorius, and from the surface of the fascia covering the Gluteus medius. It is inserted between two layers of the fascia lata about one-fourth down the outer side of the thigh. From the point of insertion the fascia is continued downwards to the head of the tibia as a thickened band, the *ilio-tibial band*.

Relations.—By its *superficial surface*, with the fascia lata and the integument. By its *deep surface*, with the Gluteus medius, Rectus femoris, Vastus externus, and the ascending branches of the external circumflex artery. By its *anterior border*, with the Sartorius, from which it is separated below by a triangular space, in which is seen the Rectus femoris. By its *posterior border*, with the Gluteus medius.

The **Sartorius**, the longest muscle in the body, is flat, narrow, and ribbon-like; it arises by tendinous fibres from the anterior superior spinous process of the

* These parts will be again more particularly described with the anatomy of Hernia.

ilium and the upper half of the notch below it, passes obliquely across the upper and anterior part of the thigh, from the outer to the inner side of the limb, then descends vertically, as far as the inner side of the knee, passing behind the inner condyle of the femur, and terminates in a tendon, which, curving obliquely forwards, expands into a broad aponeurosis, inserted into the upper part of the inner surface of the shaft of the tibia, nearly as far forwards as the crest. This expansion is inserted into the bone by an inverted U-shaped aponeurosis; part of it is inserted behind the attachment of the Gracilis and Semitendinosus, and another part, arching over the upper border of the tendon of the Gracilis, is inserted into the tibia in front of these muscles. An offset is derived from the upper margin of this aponeurosis, which blends with the fibrous capsule of the knee-joint, and another, given off from its lower border, blends with the fascia on the inner side of the leg.

The relations of this muscle to the femoral artery should be carefully examined, as it constitutes the chief guide in tying the vessel. In the upper third of the thigh it forms the outer side of a triangular space, *Scarpa's triangle*, the inner side of which is formed by the Adductor longus, and the base, turned upwards, by Poupart's ligament; the femoral artery passes perpendicularly through the middle of this space from its base to its apex. In the middle third of the thigh, the femoral artery lies first along the inner border, and then behind the Sartorius.

Relations.—By its *superficial surface*, with the fascia lata and integument. By its *deep surface*, with the Rectus, Iliacus, Psoas, Vastus internus, anterior crural nerve, sheath of the femoral vessels, Adductor longus, Adductor magnus, Gracilis, Semitendinosus, long saphenous nerve, and internal lateral ligament of the knee-joint.

The **Quadriceps extensor** includes the four remaining muscles on the front of the thigh. It is the great Extensor muscle of the leg, forming a large fleshy mass, which covers the front and sides of the femur, being united below into a single tendon, attached to the patella, and above, subdivided into separate portions, which have received distinct names. Of these, one occupying the middle of the thigh, connected above with the ilium, is called the *Rectus femoris*, from its straight course. The other divisions lie in immediate connection with the shaft of the femur, which they cover from the trochanters to the condyles. The portion on the outer side of the femur is termed the *Vastus externus*; that covering the inner side, the *Vastus internus*; and that covering the front of the femur, the *Crureus*. The two latter portions are, however, so intimately blended as to form but one muscle.

The **Rectus femoris** is situated in the middle of the anterior region of the thigh; it is fusiform in shape, and its superficial fibres are arranged in a bipenniform manner, the deep fibres running straight down to the deep aponeurosis. It arises by two tendons: one, the straight tendon, or short head, from the anterior inferior spinous process of the ilium; the other is flattened, and curves outwards, to be attached to a groove above the brim of the acetabulum; this is the reflected tendon, or long head, of the Rectus; it unites with the straight tendon at an acute angle, and then spreads into an aponeurosis, from which the muscular fibres arise.* The muscle terminates in a broad and thick aponeurosis, which occupies the lower two-thirds of its posterior surface, and, gradually becoming narrowed into a flattened tendon, is inserted into the patella in common with the Vasti and Crureus.

Relations.—By its *superficial surface*, with the anterior fibres of the Gluteus minimus, the Tensor vaginæ femoris, the Sartorius, and the Psoas and Iliacus;

* Mr. W. R. Williams, in an interesting paper in the *Journ. of Anat. and Phys.* vol. xiii. p. 204, points out that the reflected tendon is the real origin of the muscle, and is alone present in early fœtal life. The direct tendon is merely an accessory band of condensed fascia. The paper will well repay perusal, though in some particulars I think the description in the text more generally accurate.—Ed.

by its lower three-fourths, with the fascia lata. By its *posterior surface*, with the hip-joint, the external circumflex vessels, and the Crureus and Vasti muscles.

The three remaining muscles have been described collectively by some anatomists, separate from the Rectus, under the name of the *Triceps extensor cruris*.

The **Vastus externus** is the largest part of the Quadriceps extensor. It arises by a broad aponeurosis, which is attached to the tubercle of the femur, to the anterior and inferior borders of the great trochanter, to a rough line leading from the trochanter major to the linea aspera, and to the outer lip of the linea aspera: this aponeurosis covers the upper three-fourths of the muscle, and from its inner surface many fibres arise. A few additional fibres arise from the tendon of the Gluteus maximus, and from the external intermuscular septum between the Vastus externus and short head of the Biceps. The fibres form a large fleshy mass, which is attached to a strong aponeurosis, placed on the under surface of the muscle at its lower part: this becomes contracted and thickened into a flat tendon, which is inserted into the outer border of the patella, blending with the great extensor tendon.

Relations.—By its *superficial surface*, with the Rectus, the Tensor vaginæ femoris, the fascia lata, and the Gluteus maximus, from which it is separated by a synovial bursa. By its *deep surface*, with the Crureus, some large branches of the external circumflex artery and anterior crural nerve being interposed.

The **Vastus internus** and **Crureus** are so inseparably connected together as to form but one muscle, as which it will be accordingly described. It is the smallest portion of the Quadriceps extensor. The anterior portion of it, covered by the Rectus, is called the Crureus; the internal portion, which lies immediately beneath the fascia lata, the Vastus internus. It arises by an aponeurosis, which is attached to the lower part of the line that extends from the inner side of the neck of the femur to the linea aspera, from the inner lip of the linea aspera, from the ridge leading from the linea aspera to the internal condyle and internal intermuscular septum. It also arises from nearly the whole of the internal, anterior, and external surfaces of the shaft of the femur, limited, above, by the line between the two trochanters, and extending, below, to within the lower fourth of the bone. From these different origins, the fibres converge to a broad aponeurosis, which covers the anterior surface of the middle portion of the muscle (the Crureus), and the deep surface of the inner division of the muscle (the Vastus internus), and which gradually narrows down to its insertion into the patella, where it blends with the other portions of the Quadriceps extensor. The muscular fibres of the Vastus internus extend lower down than those of the Vastus externus, so that the capsule of the joint is less covered with muscular fibres on the outer than on the inner side.

Relations.—By its *superficial surface*, with the Psoas and Iliacus, the Rectus, Sartorius, Pectineus, Adductors, and fascia lata, femoral vessels, and saphenous nerve. By its *deep surface*, with the femur, Subcrureus, and synovial membrane of the knee-joint.

The student will observe the striking analogy that exists between the Quadriceps extensor and the Triceps muscle in the upper extremity. So close is this similarity that M. Cruveilhier has described it under the name of the *Triceps femoralis*. Like the Triceps extensor cubiti, it consists of three distinct divisions, or heads: a middle or long head, the Rectus, analogous to the long head of the Triceps, attached to the ilium, and two other portions, which may be called the external and internal heads of the Triceps femoralis. These, it will be noticed, are strictly analogous to the outer and inner heads of the Triceps in the arm.

The *tendons* of the different portions of the Quadriceps extensor unite at the lower part of the thigh, so as to form a single strong tendon, which is inserted into the upper part of the patella, some few fibres passing over it to blend with the ligamentum patellæ. More properly, the patella may be regarded as a sesamoid bone, developed in the tendon of the Quadriceps; and the ligamentum

patellæ, which is continued from the lower part of the patella to the tuberosity of the tibia, as the proper tendon of insertion of the muscle. A synovial bursa, the *post-patellar bursa*, is interposed between the tendon and the upper part of the tuberosity of the tibia; and another, the *prepatellar bursa*, is placed over the patella itself. This latter bursa often becomes enlarged, constituting 'housemaid's knee.'

The **Subcrureus** is a small muscle, usually distinct from the Crureus, but occasionally blended with it, which arises from the anterior surface of the lower part of the shaft of the femur, and is inserted into the upper part of the *cul-de-sac* of the capsular ligament which projects upwards beneath the Quadriceps for a variable distance. It sometimes consists of several separate muscular bundles.

Nerves.—The Tensor vaginæ femoris is supplied by the fourth and fifth lumbar and first sacral nerves through the superior gluteal nerve; the other muscles of this region, by the second, third, and fourth lumbar nerves, through branches of the anterior crural.

Actions.—The Tensor vaginæ femoris is a tensor of the fascia lata; continuing its action, the oblique direction of its fibres enables it to abduct and to rotate the thigh inwards. In the erect posture, acting from below, it will serve to steady the pelvis upon the head of the femur; and by means of the ilio-tibial band it steadies the condyles of the femur on the articular surfaces of the tibia, and assists the Gluteus maximus in supporting the knee in the extended position. The Sartorius flexes the leg upon the thigh, and, continuing to act, flexes the thigh upon the pelvis; it next rotates the thigh outwards. It was formerly supposed to adduct the thigh, so as to cross one leg over the other, and hence received its name of Sartorius, or tailor's muscle (*sartor*, a tailor), because it was supposed to assist in crossing the legs in the squatting position. When the knee is bent, the Sartorius assists the Semitendinosus, Semimembranosus, and Popliteus in rotating the tibia inwards. Taking its fixed point from the leg, it flexes the pelvis upon the thigh, and, if one muscle acts, assists in rotating the pelvis. The Quadriceps extensor extends the leg upon the thigh. The Rectus muscle assists the Psoas and Iliacus in supporting the pelvis and trunk upon the femur, or in bending it forwards.

Surgical Anatomy.—A few fibres of the Rectus muscle are liable to be ruptured from severe strain. This accident is especially liable to occur during the games of football and cricket, and is sometimes known as 'cricket thigh.' The patient experiences a sudden pain in the part, as if he had been struck, and the Rectus muscle stands out and is felt to be tense and rigid. The accident is often followed by considerable swelling from inflammatory effusion. Occasionally the Quadriceps extensor may be torn away from its insertion into the patella; or the tendon of the patella may be ruptured about an inch above the bone. This accident is caused in the same manner as fracture of the patella by muscular action is produced, viz. by a violent muscular effort to prevent falling whilst the knee is in a position of semiflexion. A distinct gap can be felt above the patella, and, owing to the retraction of the muscular fibres, union may fail to take place.

2. *Internal Femoral Region*

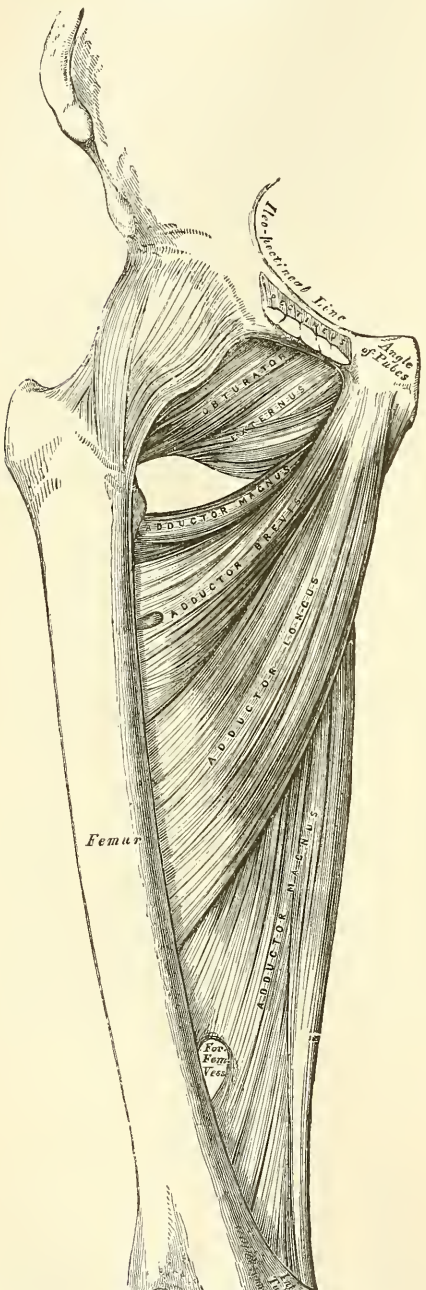
Gracilis. Adductor longus.
Pectineus. Adductor brevis.
Adductor magnus.

Dissection.—These muscles are at once exposed by removing the fascia from the fore part and inner side of the thigh. The limb should be abducted, so as to render the muscles tense and easier of dissection.

The **Gracilis** (figs. 364, 367) is the most superficial muscle on the inner side of the thigh. It is thin and flattened, broad above, narrow and tapering below. It arises by a thin aponeurosis between two and three inches in breadth, from the lower half of the margin of the symphysis and the inner margin of the descending ramus of the os pubis. The fibres pass vertically downwards, and terminate in

a rounded tendon, which passes behind the internal condyle of the femur, and, curving round the inner tuberosity of the tibia, becomes flattened, and is inserted into the upper part of the inner surface of the shaft of the tibia, below the tuberosity. A few of the fibres of the lower part of the tendon are prolonged into the deep fascia of the leg. The tendon of this muscle is situated immediately above that of the Semitendinosus, and is surrounded by the tendon of the Sartorius with which it is in part blended. As it passes across the internal lateral ligament of the knee-joint, it is separated from it by a synovial bursa common to it and the Semitendinosus muscle.

Fig. 365.—Deep muscles of the internal femoral region.



Relations.—By its *superficial surface*, with the fascia lata and the Sartorius below; the internal saphenous vein crosses it obliquely near its lower part, lying superficial to the fascia lata. The internal saphenous nerve emerges between its tendon and that of the Sartorius. By its *deep surface*, with the Adductor brevis and the Adductor magnus, and the internal lateral ligament of the knee-joint.

The **Pectineus** (fig. 364) is a flat, quadrangular muscle, situated at the anterior part of the upper and inner aspect of the thigh. It arises from the linea ilio-pectinea, from the surface of bone in front of it, between the pectineal eminence and spine of the os pubis, and from the fascia covering the anterior surface of the muscle; the fibres pass downwards, backwards, and outwards, to be inserted into a rough line leading from the lesser trochanter to the linea aspera.

Relations.—By its *anterior surface*, with the pubic portion of the fascia lata, which separates it from the femoral vessels and internal saphenous vein. By its *posterior surface*, with the capsular ligament of the hip-joint, the Adductor brevis and Obturator externus muscles, the obturator vessels and nerve being interposed. By its *outer border*, with the Psoas, a cellular interval separating them, through which passes the internal circumflex vessels. By its *inner border*, with the margin of the Adductor longus.

The **Adductor longus**, the most superficial of the three Adductors, is a flat triangular muscle, lying on the same plane as the Pectineus. It arises, by a flat narrow tendon, from the front of the os pubis, at the angle of junction of the crest with the symphysis; and

soon expands into a broad fleshy belly, which, passing downwards, backwards, and outwards, is inserted, by an aponeurosis, into the linea aspera, between the Vastus internus and the Adductor magnus, with which it is usually blended.

Relations.—By its *anterior surface*, with the fascia lata, the Sartorius, and, near its insertion, with the femoral artery and vein. By its *posterior surface*, with the Adductor brevis and magnus, the anterior branches of the obturator nerve, and with the profunda artery and vein near its insertion. By its *outer border*, with the Pectineus. By its *inner border*, with the Gracilis.

The Pectineus and Adductor longus should now be divided near their origin, and turned downwards, when the Adductor brevis and Obturator externus will be exposed.

The **Adductor brevis** is situated immediately behind the two preceding muscles. It is somewhat triangular in form, and arises by a narrow origin from the outer surface of the body and descending ramus of the os pubis, between the Gracilis and Obturator externus. Its fibres, passing backwards, outwards, and downwards, are inserted, by an aponeurosis, into the lower part of the line leading from the lesser trochanter to the linea aspera and the upper part of the linea aspera, immediately behind the Pectineus and upper part of the Adductor longus.

Relations.—By its *anterior surface*, with the Pectineus, Adductor longus, profunda femoris artery, and anterior branches of the obturator nerve. By its *posterior surface*, with the Adductor magnus, and posterior branch of the obturator nerve. By its *outer border*, with the Obturator externus, and conjoined tendon of the Psoas and Iliacus. By its *inner border*, with the Gracilis and Adductor magnus. This muscle is pierced, near its insertion, by the middle perforating branch of the profunda femoris artery.

The Adductor brevis should now be cut away near its origin, and turned outwards, when the entire extent of the Adductor magnus will be exposed.

The **Adductor magnus** is a large triangular muscle, forming a septum between the muscles on the inner and those on the back of the thigh. It arises from a small part of the descending ramus of the os pubis, from the ascending ramus of the ischium, and from the outer margin and under surface of the tuberosity of the ischium. Those fibres which arise from the ramus of the os pubis are very short, horizontal in direction, and are inserted into the rough line leading from the great trochanter to the linea aspera, internal to the Gluteus maximus; those from the ramus of the ischium are directed downwards and outwards with different degrees of obliquity, to be inserted, by means of a broad aponeurosis, into the linea aspera and the upper part of its internal prolongation below. The internal portion of the muscle, consisting principally of those fibres which arise from the tuberosity of the ischium, forms a thick fleshy mass consisting of coarse bundles which descend almost vertically, and terminate about the lower third of the thigh in a rounded tendon, which is inserted into the Adductor tubercle on the inner condyle of the femur, being connected by a fibrous expansion to the line leading upwards from the tubercle to the linea aspera. Between the two portions of the muscle an interval is left, tendinous in front, fleshy behind, for the passage of the femoral vessels into the popliteal space. The external portion of the muscle at its attachment to the femur presents three or four osseo-aponeurotic openings, formed by tendinous arches attached to the bone, from which muscular fibres arise. The three superior of these apertures are for the three perforating arteries, and the fourth, when it exists, for the terminal branch of the profunda.

Relations.—By its *anterior surface*, with the Pectineus, Adductor brevis, Adductor longus, and the femoral and profunda vessels and obturator nerve. By its *posterior surface*, with the great sciatic nerve, the Gluteus maximus, Biceps, Semitendinosus, and Semimembranosus. By its *superior* or *shortest border* it lies parallel with the Quadratus femoris, the internal circumflex artery passing

between them. By its *internal* or *longest border*, with the Gracilis, Sartorius, and fascia lata. By its *external* or *attached border*, it is inserted into the femur behind the Adductor brevis and Adductor longus, which separate it from the Vastus internus; and in front of the Gluteus maximus and short head of the Biceps, which separate it from the Vastus externus.

Nerves.—The three Adductor muscles and the Gracilis are supplied by the third and fourth lumbar nerves through the Obturator nerve; the Adductor magnus receiving an additional branch from the sacral plexus through the great sciatic. The Pectineus is supplied by the second, third, and fourth lumbar nerves through the anterior crural; from the third and fourth lumbar nerves by the obturator and by the accessory obturator, from the third lumbar, when it exists.*

Actions.—The Pectineus and three Adductors adduct the thigh powerfully; they are especially used in horse exercise, the flanks of the horse being grasped between the knees by the actions of these muscles. In consequence of the obliquity of their insertion into the linea aspera, they rotate the thigh outwards, assisting the external Rotators, and when the limb has been abducted, they draw it inwards, carrying the thigh across that of the opposite side. The Pectineus and Adductor brevis and longus assist the Psoas and Iliacus in flexing the thigh upon the pelvis. In progression, also, all these muscles assist in drawing forwards the hinder limb. The Gracilis assists the Sartorius in flexing the leg and rotating it inwards; it is also an adductor of the thigh. If the lower extremities are fixed, these muscles may take their fixed point from below and act upon the pelvis, serving to maintain the body in an erect posture; or, if their action is continued, to flex the pelvis forwards upon the femur.

Surgical Anatomy.—The Adductor longus is liable to be severely strained in those who ride much on horseback, or its tendon to be ruptured by suddenly gripping the saddle. And, occasionally, especially in cavalry soldiers, the tendon may become ossified, constituting the 'rider's bone.'

3. *Gluteal Region*

Gluteus maximus.	Gemellus superior.
Gluteus medius.	Obturator internus.
Gluteus minimus.	Gemellus inferior.
Pyriformis.	Obturator externus.

Quadratus femoris.

Dissection (fig. 328).—The subject should be turned on its face, a block placed beneath the pelvis to make the buttocks tense, and the limbs allowed to hang over the end of the table, with the foot inverted, and the thigh abducted. Make an incision through the integument along the crest of the ilium to the middle of the sacrum and thence downwards to the tip of the coccyx, and carry a second incision from that point obliquely downwards and outwards to the outer side of the thigh, four inches below the great trochanter. The portion of integument included between these incisions is to be removed in the direction shown in the figure.

The **Gluteus maximus** (fig. 367), the most superficial muscle in the gluteal region, is a very broad and thick fleshy mass, of a quadrilateral shape, which forms the prominence of the nates. Its large size is one of the most characteristic points in the muscular system in man, connected as it is with the power he has of maintaining the trunk in the erect posture. In structure the muscle is remarkably coarse, being made up of muscular fasciculi lying parallel with one another, and collected together into large bundles, separated by deep cellular intervals. It arises from the superior curved line of the ilium, and the portion of bone, including the crest, immediately behind it; from the posterior surface

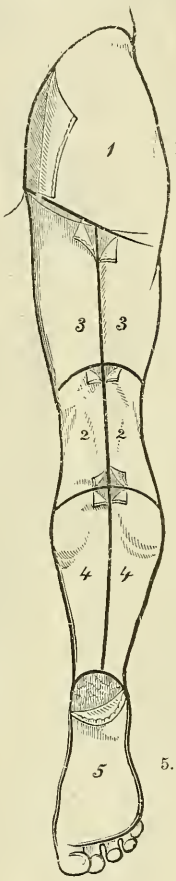
* Professor Paterson describes the Pectineus as consisting of two incompletely separated strata, of which the outer or dorsal stratum, which is constant, is supplied by the anterior crural nerve, or in its absence by the accessory obturator, with which it is intimately related; while the inner or ventral stratum, when present, is supplied by the obturator nerve. *Journal of Anatomy and Physiology*, vol. xxvi. p. 43.

of the lower part of the sacrum, the side of the coccyx, the aponeurosis of the Erector spinæ muscle, and the great sacro-sciatic ligament. The fibres are directed obliquely downwards and outwards; those forming the upper and larger portion of the muscle, together with the superficial fibres of the lower portion, terminate in a thick tendinous lamina, which passes across the great trochanter, and is inserted into the fascia lata covering the outer side of the thigh; the deeper fibres of the lower portion of the muscle are inserted into the rough line leading from the great trochanter to the linea aspera between the Vastus externus and Adductor magnus.

Three *synovial bursæ* are usually found in relation with this muscle. One of these, of large size, and generally multilocular, separates it from the great trochanter. A second, often wanting, is situated on the tuberosity of the ischium. A third is found between the tendon of this muscle and the Vastus externus.

Relations.—By its *superficial surface*, with a thin fascia, which separates it from the subcutaneous tissue. By its *deep surface*, from above downwards, with the ilium, sacrum, coccyx, and great sacro-sciatic ligament, part of the Gluteus medius, Pyriformis, Gemelli, Obturator internus, Quadratus femoris, the tuberosity of the ischium, great trochanter, the origin of the Biceps, Semitendinosus, Semimembranosus, and Adductor magnus muscles. The gluteal vessels and superior gluteal nerve are seen issuing from the pelvis above the Pyriformis muscle, the sciatic and internal pudic vessels and nerves, and muscular branches from the sacral plexus below it. Its *upper border* is thin, and connected with the Gluteus medius by the fascia lata. Its *lower border* is free and prominent.

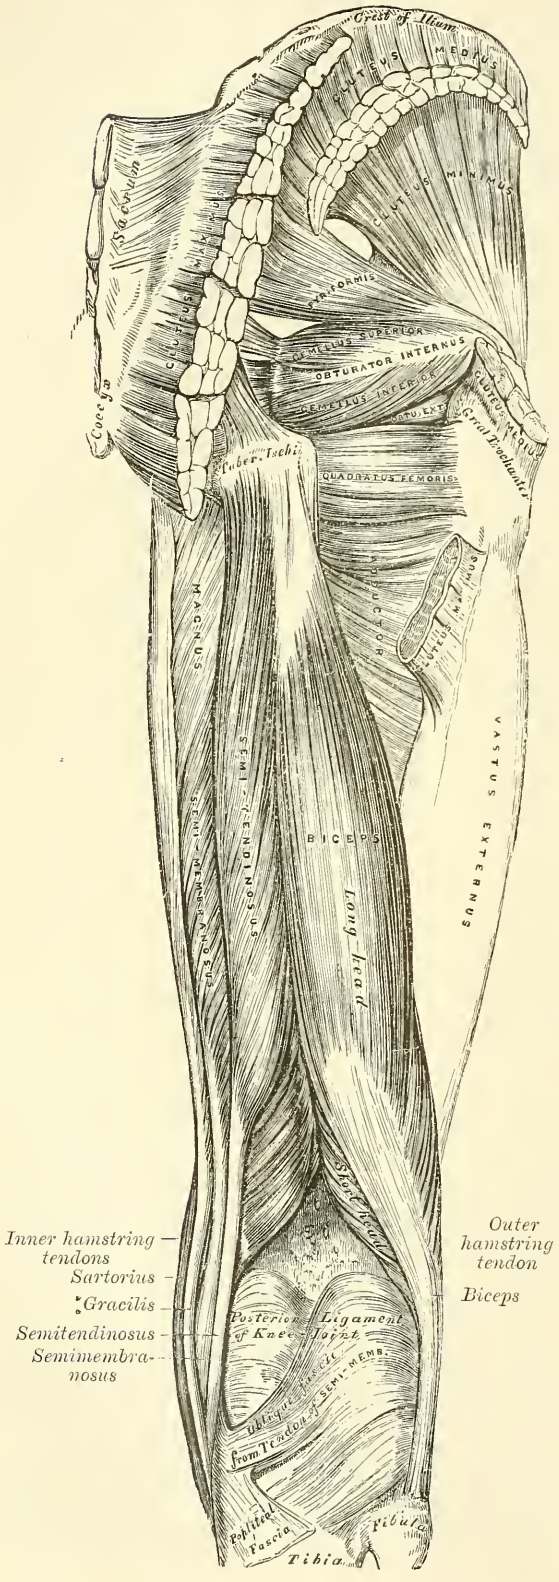
Fig. 366.—Dissection of lower extremity. Posterior view.



Dissection.—Now divide the Gluteus maximus near its origin by a vertical incision carried from its upper to its lower border; a cellular interval will be exposed, separating it from the Gluteus medius and External rotator muscles beneath. The upper portion of the muscle is to be altogether detached, and the lower portion turned outwards; the loose areolar tissue filling up the interspace between the trochanter major and tuberosity of the ischium being removed, the parts already enumerated as exposed by the removal of this muscle will be seen.

The **Gluteus medius** is a broad, thick, radiated muscle, situated on the outer surface of the pelvis. Its posterior third is covered by the Gluteus maximus; its anterior two-thirds by the fascia lata, which separates it from the integument. It arises from the outer surface of the ilium, between the superior and middle curved lines, and from the outer lip of that portion of the crest which is between them; it also arises from the dense fascia (Gluteal aponeurosis) covering its outer surface. The fibres converge to a strong flattened tendon, which is inserted into the oblique line which traverses the outer surface of the great trochanter. A synovial bursa separates the tendon of the muscle from the surface of the trochanter in front of its insertion.

Fig. 367.—Muscles of the hip and thigh.



Relations.— By its *superficial surface*, with the Gluteus maximus behind, the Tensor vaginæ femoris and deep fascia in front. By its *deep surface*, with the Gluteus minimus and the gluteal vessels and superior gluteal nerve. Its *anterior border* is blended with the Gluteus minimus. Its *posterior border* lies parallel with the Pyriformis, the gluteal vessels intervening.

This muscle should now be divided near its insertion and turned upwards, when the Gluteus minimus will be exposed.

The **Gluteus minimus**, the smallest of the three Glutei, is placed immediately beneath the preceding. It is fan-shaped, arising from the outer surface of the ilium, between the middle and inferior curved lines, and behind, from the margin of the great sacro-sciatic notch: the fibres converge to the deep surface of a radiated aponeurosis, which, terminating in a tendon, is inserted into an impression on the anterior border of the great trochanter. A synovial bursa is interposed between the tendon and the great trochanter.

Relations.—By its *superficial surface*, with the Gluteus medius, and the gluteal vessels and superior gluteal nerve. By its *deep surface*, with the ilium, the reflected tendon of the Rectus femoris, and capsular ligament of the hip-joint. Its *anterior margin* is blended with the Gluteus medius. Its *posterior margin* is in contact and sometimes joined with the tendon of the Pyriformis.

The **Pyriformis** is a flat muscle, pyramidal in shape, lying almost parallel with

the posterior margin of the Gluteus medius. It is situated partly within the pelvis at its posterior part, and partly at the back of the hip-joint. It arises from the front of the sacrum by three fleshy digitations, attached to the portions of bone between the first, second, third, and fourth anterior sacral foramina, and also from the grooves leading from the foramina: a few fibres also arise from the margin of the great sacro-sciatic foramen, and from the anterior surface of the great sacro-sciatic ligament. The muscle passes out of the pelvis through the great sacro-sciatic foramen, the upper part of which it fills, and is inserted by a rounded tendon into the upper border of the great trochanter, behind, but often blended with, the tendon of the Obturator internus and Gemelli muscles.

Relations.—By its *anterior surface, within the pelvis*, with the Rectum (especially on the left side), the sacral plexus of nerves, and the branches of the internal iliac vessels; *external to the pelvis*, with the os innominatum and capsular ligament of the hip-joint. By its *posterior surface, within the pelvis*, with the sacrum; and *external to it*, with the Gluteus maximus. By its *upper border*, with the Gluteus medius, from which it is separated by the gluteal vessels and superior gluteal nerve. By its *lower border*, with the Gemellus superior and Coccygeus; the sciatic vessels and nerves, the internal pudic vessels and nerve, and muscular branches from the sacral plexus, passing from the pelvis in the interval between the two muscles.

The **Obturator membrane** is a thin layer of interlacing fibres, which closes the obturator foramen. It is attached, externally, to the margin of the foramen; internally, to the posterior surface of the ischio-pubic ramus, internal to the inner margin of the foramen. It is occasionally incomplete, and presents at its upper and outer part a small canal, which is bounded below by a thickened band of fibres, for the passage of the obturator vessels and nerve. Each Obturator muscle is connected with this membrane.

Dissection.—The next muscle, as well as the origin of the Pyriformis, can only be seen when the pelvis is divided and the viscera removed.

The **Obturator internus**, like the preceding muscle, is situated partly within the cavity of the pelvis, and partly at the back of the hip-joint. It arises from the inner surface of the anterior and external wall of the pelvis, around the inner side of the obturator foramen, being attached to the descending ramus of the os pubis and the ascending ramus of the ischium, and at the side to the inner surface of the body of the ischium, between the margin of the obturator foramen in front, and the great sacro-sciatic notch behind, and to the inner surface of the ilium below the brim of the true pelvis. It also arises from the inner surface of the obturator membrane except at its lower part, from the tendinous arch which completes the canal for the passage of the obturator vessels and nerve and to a slight extent from the obturator layer of the pelvic fascia, which covers it. The fibres are directed backwards and downwards, and terminate in four or five tendinous bands, which are found on its deep surface; these bands are reflected at a right angle over the inner surface of the tuberosity of the ischium, which is grooved for their reception: the groove is covered with cartilage, and lined by a synovial bursa. The muscle leaves the pelvis by the lesser sacro-sciatic notch; and the tendinous bands unite into a single flattened tendon, which passes horizontally outwards, and, after receiving the attachment of the Gemelli, is inserted into the fore part of the inner surface of the great trochanter in front of the Obturator externus. A synovial bursa, narrow and elongated in form, is usually found between the tendon of this muscle and the capsular ligament of the hip: it occasionally communicates with the bursa between the tendon and the tuberosity of the ischium, the two forming a single sac.

In order to display the peculiar appearances presented by the tendon of this muscle, it must be divided near its insertion and reflected outwards.

Relations.—*Within the pelvis*, this muscle is in relation, by its *anterior surface*, with the obturator membrane and inner surface of the anterior wall of the pelvis; by its *posterior surface*, with the pelvic and obturator fasciæ, which separate it from the Levator ani; and it is crossed by the internal pudic vessels and nerve. This surface forms the outer boundary of the ischio-rectal fossa. *External to the pelvis*, it is covered by the great sciatic nerve and Gluteus maximus, and rests on the back part of the hip-joint.

The **Gemelli** are two small muscular fasciculi, accessories to the tendon of the Obturator internus, which is received into a groove between them. They are called *superior* and *inferior*.

The **Gemellus superior**, the smaller of the two, arises from the outer surface of the spine of the ischium, and passing horizontally outwards becomes blended with the upper part of the tendon of the Obturator internus, and is inserted with it into the inner surface of the great trochanter. This muscle is sometimes wanting.

Relations.—By its *superficial surface*, with the Gluteus maximus and the sciatic vessels and nerves. By its *deep surface*, with the capsule of the hip-joint. By its *upper border*, with the lower margin of the Pyriformis. By its *lower border*, with the tendon of the Obturator internus.

The **Gemellus inferior** arises from the upper part of the tuberosity of the ischium, where it forms the lower edge of the groove for the Obturator internus tendon, and, passing horizontally outwards, is blended with the lower part of the tendon of the Obturator internus, and inserted with it into the inner surface of the great trochanter.

Relations.—By its *superficial surface*, with the Gluteus maximus and the sciatic vessels and nerves. By its *deep surface*, with the capsular ligament of the hip-joint. By its *upper border*, with the tendon of the Obturator internus. By its *lower border*, with the tendon of the Obturator externus and Quadratus femoris.

The **Quadratus femoris** is a short, flat muscle, quadrilateral in shape (hence its name), situated between the Gemellus inferior and the upper margin of the Adductor magnus. It arises from the external lip of the tuberosity of the ischium, and, proceeding horizontally outwards, is inserted into the upper part of the linea quadrata, that is, the line which crosses the posterior intertrochanteric line. A synovial bursa is often found between the under surface of this muscle and the lesser trochanter, which it covers.

Relations.—By its *posterior surface*, with the Gluteus maximus and the sciatic vessels and nerves. By its *anterior surface*, with the tendon of the Obturator externus and trochanter minor, and with the capsule of the hip-joint. By its *upper border*, with the Gemellus inferior. Its *lower border* is separated from the Adductor magnus by the terminal branches of the internal circumflex vessels.

Dissection.—In order to expose the next muscle (the Obturator externus), it is necessary to remove the Psoas, Iliacus, Pectineus, and Adductor brevis and longus muscles from the front and inner side of the thigh; and the Gluteus maximus and Quadratus femoris from the back part. Its dissection should, consequently, be postponed until the muscles of the anterior and internal femoral regions have been examined.

The **Obturator externus** (fig. 368) is a flat, triangular muscle, which covers the outer surface of the anterior wall of the pelvis. It arises from the margin of bone immediately around the inner side of the obturator foramen, viz. from the body and ramus of the os pubis, and the ramus of the ischium; it also arises from the inner two-thirds of the outer surface of the obturator membrane, and from the tendinous arch which completes the canal for the passage of the obturator vessels and nerves. The fibres converging pass backwards, outwards and upwards, and terminate in a tendon which runs across the back part of the hip-joint, and is inserted into the digital fossa of the femur.

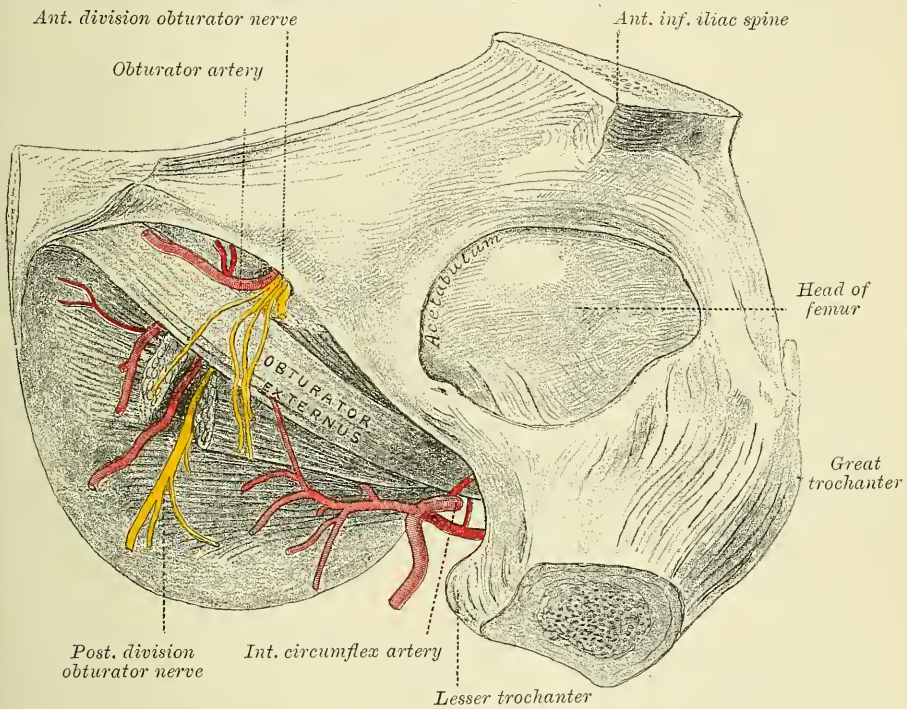
Relations.—By its *anterior surface*, with the Psoas, Iliacus, Pectineus,

Adductor magnus, and Adductor brevis; and more externally, with the neck of the femur and capsule of the hip-joint. The obturator artery and vein lie between this muscle and the obturator membrane; the superficial part of the obturator nerve lies above the muscle and the deep branch perforates it. By its *posterior surface*, with the obturator membrane and Quadratus femoris.

Nerves.—The Gluteus maximus is supplied by the fifth lumbar and first and second sacral nerves through the inferior gluteal nerve from the sacral plexus; the Gluteus medius and minimus, by the fourth and fifth lumbar and first sacral nerves through the superior gluteal; the Pyriformis is supplied by the second sacral nerve; the Gemellus inferior and Quadratus femoris by the last lumbar and first sacral nerve; the Gemellus superior and Obturator internus by the first and second sacral nerves, and the Obturator externus by the second, third, and fourth lumbar nerves through the Obturator.

Actions.—The Gluteus maximus, when it takes its fixed point from the pelvis,

Fig. 368.—Obturator externus muscle. (From a preparation in the Hunterian Museum, Royal College of Surgeons.)



extends the femur and brings the bent thigh into a line with the body. Taking its fixed point from below, it acts upon the pelvis, supporting it and the whole trunk upon the head of the femur, which is especially obvious in standing on one leg. Its most powerful action is to cause the body to regain the erect position after stooping, by drawing the pelvis backwards, being assisted in this action by the Biceps, Semitendinosus, and Semimembranosus. The Gluteus maximus is a tensor of the fascia lata, and by its connection with the ilio-tibial band it steadies the femur on the articular surface of the tibia during standing, when the extensor muscles are relaxed. The lower part of the muscle also acts as an adductor and external rotator of the limb. The Gluteus medius and minimus abduct the thigh, when the limb is extended, and are principally called into action in supporting the body on one limb, in conjunction with the Tensor vaginæ femoris. Their anterior fibres, by drawing the great trochanter forwards, rotate the thigh inwards,

in which action they are also assisted by the Tensor vaginæ femoris. The remaining muscles are powerful rotators of the thigh outwards. In the sitting posture, when the thigh is flexed upon the pelvis, their action as rotators ceases, and they become abductors, with the exception of the Obturator externus, which still rotates the femur outwards. When the femur is fixed, the Pyriformis and Obturator muscles serve to draw the pelvis forwards if it has been inclined backwards, and assist in steadying it upon the head of the femur.

4. *Posterior Femoral Region*

Biceps. Semitendinosus. Semimembranosus.

Dissection (fig. 366).—Make a vertical incision along the middle of the thigh, from the lower fold of the nates to about three inches below the back of the knee-joint, and there connect it with a transverse incision, carried from the inner to the outer side of the leg. Make a third incision transversely at the junction of the middle with the lower third of the thigh. The integument having been removed from the back of the knee, and the boundaries of the popliteal space examined, the removal of the integument from the remaining part of the thigh should be continued, when the fascia and muscles of this region will be exposed.

The **Biceps** (*Biceps flexor cruris*) is a large muscle, of considerable length, situated on the posterior and outer aspect of the thigh (fig. 367). It arises by two heads. One, the long head, arises from the lower and inner facet on the back part of the tuberosity of the ischium, by a tendon common to it and the Semitendinosus, and from the lower part of the great sacro-sciatic ligament. The femoral, or short head, arises from the outer lip of the linea aspera, between the Adductor magnus and Vastus externus, extending up almost as high as the insertion of the Gluteus maximus; from the outer prolongation of the linea aspera to within two inches of the outer condyle; and from the external intermuscular septum. The fibres of the long head form a fusiform belly, which, passing obliquely downwards and a little outwards, terminates in an aponeurosis which covers the posterior surface of the muscle, and receives the fibres of the short head: this aponeurosis becomes gradually contracted into a tendon, which is inserted into the outer side of the head of the fibula, and by a small slip into the lateral surface of the external tuberosity of the tibia. At its insertion the tendon divides into two portions, which embrace the long external lateral ligament of the knee-joint. From the posterior border of the tendon a thin expansion is given off to the fascia of the leg. The tendon of this muscle forms the outer hamstring.

Relations.—By its *superficial surface*, with the Gluteus maximus above, with the fascia lata and integument in the rest of its extent. By its *deep surface*, with the Semimembranosus, Adductor magnus, and Vastus externus, the great sciatic nerve, and, near its insertion, with the external head of the Gastrocnemius, Plantaris, the superior external articular artery, and the external popliteal nerve.

The **Semitendinosus**, remarkable for the great length of its tendon, is situated at the posterior and inner aspect of the thigh. It arises from the lower and inner facet on the tuberosity of the ischium, by a tendon common to it and the long head of the Biceps; it also arises from an aponeurosis which connects the adjacent surfaces of the two muscles to the extent of about three inches after their origin. It forms a fusiform muscle, which, passing downwards and inwards, terminates a little below the middle of the thigh in a long round tendon which lies along the inner side of the popliteal space, then curves around the inner tuberosity of the tibia, and is inserted into the upper part of the inner surface of the shaft of that bone, nearly as far forwards as its anterior border. At its insertion it gives off from its lower border a prolongation to the deep fascia of the leg. This tendon is surrounded by the tendon of the Sartorius, and lies

below that of the Gracilis, to which it is united. A tendinous intersection is usually observed about the middle of the muscle.

Relations.—By its *superficial surface*, with the Gluteus maximus and fascia lata. By its *deep surface*, with the Semimembranosus, Adductor magnus, inner head of the Gastrocnemius, and internal lateral ligament of the knee-joint.

The **Semimembranosus**, so called from a membranous expansion on its anterior and posterior surfaces, is situated at the back part and inner side of the thigh. It arises by a thick tendon from the upper and outer facet on the back part of the tuberosity of the ischium, above and to the outer side of the Biceps and Semitendinosus, and is inserted into the groove on the inner and back part of the inner tuberosity of the tibia, beneath the internal lateral ligament. The tendon of the muscle at its origin expands into an aponeurosis, which covers the upper part of its anterior surface: from this aponeurosis muscular fibres arise, and converge to another aponeurosis which covers the lower part of its posterior surface and contracts into the tendon of insertion. The tendon of the muscle at its insertion gives off two fibrous expansions; one of these, of considerable size, passes upwards and outwards to be inserted into the back part of the outer condyle of the femur, forming part of the posterior ligament of the knee-joint. The second is continued downwards to the fascia which covers the Popliteus muscle. The tendon also sends a few fibres to join the internal lateral ligament of the joint.

The tendons of the two preceding muscles, with that of the Gracilis, form the inner hamstring.

Relations.—By its *superficial surface*, with the Semitendinosus, Biceps, and fascia lata. By its *deep surface*, with the popliteal vessels, Adductor magnus, and inner head of the Gastrocnemius, from which it is separated by a synovial bursa. By its *inner border*, with the Gracilis. By its *outer border*, with the great sciatic nerve, and its internal popliteal branch.

Nerves.—The muscles of this region are supplied by the first, second, and third sacral nerves through the great sciatic nerve.

Actions.—The hamstring muscles flex the leg upon the thigh. When the knee is semi-flexed, the Biceps, in consequence of its oblique direction downwards and outwards, rotates the leg slightly outwards; and the Semitendinosus, and to a slight extent the Semimembranosus, rotate the leg inwards, assisting the Popliteus. Taking their fixed point from below, these muscles serve to support the pelvis upon the head of the femur, and to draw the trunk directly backwards, as in feats of strength, when the body is thrown backwards in the form of an arch. When the leg is extended on the thigh they limit the amount of flexion of the trunk on the lower limbs.

Surgical Anatomy.—The tendons of these muscles occasionally require subcutaneous division in some forms of spurious ankylosis of the knee-joint dependent upon permanent contraction and rigidity of the flexor muscles, or from stiffening of the ligamentous and other tissues surrounding the joint, the result of disease. This is effected by putting the tendon upon the stretch, and inserting a narrow, sharp-pointed knife between it and the skin: the cutting edge being then turned towards the tendon, it should be divided, taking care that the wound in the skin is not at the same time enlarged. The relation of the external popliteal nerve to the tendon of the Biceps must always be borne in mind in dividing this tendon.

III. Muscles and Fasciæ of the Leg

These may be divided into three groups: those on the anterior, those on the posterior, and those on the outer side of the leg.

5. *Anterior Tibio-fibular Region*

Tibialis anticus.	Extensor longus digitorum.
Extensor proprius hallucis.*	Peroneus tertius.

* There is no such word as 'Hallux, -cis.' It is the result of some ignorant blunder, copied until it has become established by usage; it has been thought better, therefore, to

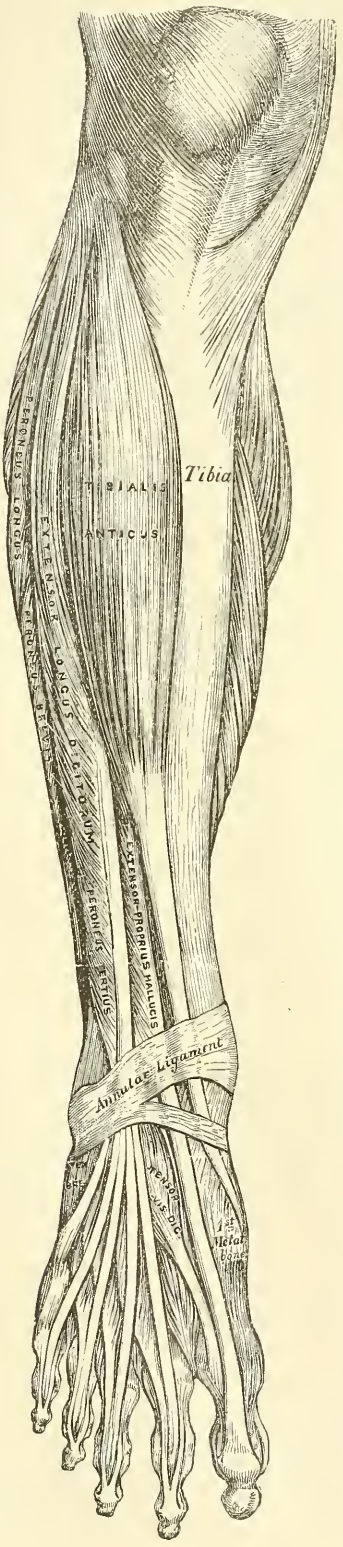


Fig. 369.—Muscles of the front of the leg.

Dissection (fig. 363).—The knee should be bent, a block placed beneath it, and the foot kept in an extended position; then make an incision through the integument in the middle line of the leg to the ankle, and continue it along the dorsum of the foot to the toes. Make a second incision transversely across the ankle, and a third in the same direction across the bases of the toes; remove the flaps of integument included between these incisions in order to examine the deep fascia of the leg.

The **Deep Fascia of the Leg** forms a complete investment to the muscles, but is not continued over the subcutaneous surfaces of the bones. It is continuous above with the fascia lata, receiving an expansion from the tendon of the Biceps on the outer side, and from the tendons of the Sartorius, Gracilis, and Semitendinosus on the inner side; in front, it blends with the periosteum covering the subcutaneous surface of the tibia, and with that covering the head and external malleolus of the fibula; below, it is continuous with the annular ligaments of the ankle. It is thick and dense in the upper and anterior part of the leg, and gives attachment, by its deep surface, to the Tibialis anticus and Extensor longus digitorum muscles: but thinner behind, where it covers the Gastrocnemius and Soleus muscles. Over the popliteal space it is much strengthened by transverse fibres, which stretch across from the inner to the outer hamstring muscles, and it is here perforated by the external saphenous vein. Its deep surface gives off, on the outer side of the leg, two strong intermuscular septa, which enclose the Peronei muscles, and separate them from the muscles on the anterior and posterior tibial regions and several smaller and more slender processes, which enclose the individual muscles in each region; at the same time a broad transverse intermuscular septum, called the *deep transverse fascia of the leg*, intervenes between the superficial and deep muscles in the posterior tibio-fibular region.

Now remove the fascia by dividing it in the same direction as the integument, excepting opposite the ankle, where it should be left entire. Commence

---

retain it. According to Lewis and Short the word is Allex, masculine; genitive, Allĭcis, the great toe, and the correct rendering would be Extensor proprius allicis. It is a rare word, and is sometimes spelt, but not so correctly, 'Hallex.' It is used by Plautus, in the 'Pœnulus' V. v. 31, of a little man, as we might say 'a hop-o'-my-thumb.' 'Tunc hic amator audes esse, *allex* viri' (To think of you daring to make up to her, you hop-o'-my-thumb!). The word 'alex,' sometimes spelt 'allex,' a fish sauce, is probably a different word altogether. It is used by Horace and Pliny.

the removal of the fascia from below, opposite the tendons, and detach it in the line of direction of the muscular fibres.

The **Tibialis anticus** is situated on the outer side of the tibia; it is thick and fleshy at its upper part, tendinous below. It arises from the outer tuberosity and upper two-thirds of the external surface of the shaft of the tibia; from the adjoining part of the interosseous membrane; from the deep surface of the fascia; and from the intermuscular septum between it and the Extensor longus digitorum: the fibres pass vertically downwards, and terminate in a tendon, which is apparent on the anterior surface of the muscle at the lower third of the leg. After passing through the innermost compartment of the anterior annular ligament, it is inserted into the inner and under surface of the internal cuneiform bone, and base of the metatarsal bone of the great toe.

Relations.—By its *anterior surface*, with the fascia, and with the annular ligament. By its *posterior surface*, with the interosseous membrane, tibia, ankle-joint, and inner side of the tarsus: this surface also overlaps the anterior tibial vessels and nerve in the upper part of the leg. By its *inner surface*, with the tibia. By its *outer surface*, with the Extensor longus digitorum, and Extensor proprius hallucis, and the anterior tibial vessels and nerve.

The **Extensor proprius hallucis** is a thin, elongated, and flattened muscle, situated between the Tibialis anticus and Extensor longus digitorum. It arises from the anterior surface of the fibula for about the middle two-fourths of its extent, its origin being internal to that of the Extensor longus digitorum; it also arises from the interosseous membrane to a similar extent. The fibres pass downwards, and terminate in a tendon, which occupies the anterior border of the muscle, passes through a distinct compartment in the horizontal portion of the annular ligament, crosses the anterior tibial vessels near the bend of the ankle, and is inserted into the base of the last phalanx of the great toe. Opposite the metatarso-phalangeal articulation, the tendon gives off a thin prolongation on each side, which covers the surface of the joint. It usually sends an expansion, from the inner side of the tendon, to be inserted into the base of the first phalanx.

Relations.—By its *anterior surface*, with the fascia, and the anterior annular ligament. By its *posterior surface*, with the interosseous membrane, fibula, tibia, ankle-joint, and Extensor brevis digitorum. By its *outer side*, with the Extensor longus digitorum above, the dorsalis pedis vessels and anterior tibial nerve below. By its *inner side*, with the Tibialis anticus and the anterior tibial vessels above. The muscle is external to the anterior tibial vessels in the upper part of the leg; but in the lower third its tendon crosses over them, so that it lies internal to them on the dorsum of the foot.

The **Extensor longus digitorum** is an elongated, flattened, penniform muscle, situated the most externally of all the muscles on the fore part of the leg. It arises from the outer tuberosity of the tibia; from the upper three-fourths of the anterior surface of the shaft of the fibula; from the interosseous membrane; from the deep surface of the fascia; and from the intermuscular septa between it and the Tibialis anticus on the inner, and the Peronei on the outer side. The tendon enters a canal in the annular ligament, with the Peroneus tertius, and divides into four slips, which run across the dorsum of the foot, and are inserted into the second and third phalanges of the four lesser toes. The mode in which the tendons are inserted is the following: the three inner tendons opposite the metatarso-phalangeal articulation are joined, on their outer side, by a tendon of the Extensor brevis digitorum. They all receive a fibrous expansion from the Interossei and Lumbricales, and then spread out into a broad aponeurosis, which covers the dorsal surface of the first phalanx: this aponeurosis, at the articulation of the first with the second phalanx, divides into three slips, a middle one, which is inserted into the base of the second phalanx; and two lateral slips, which, after uniting on the dorsal surface of the second phalanx, are continued onwards, to be inserted into the base of the third.

Relations.—By its *anterior surface*, with the fascia and the annular ligament. By its *posterior surface*, with the fibula, interosseous membrane, ankle-joint, and Extensor brevis digitorum. By its *inner side*, with the Tibialis anticus, Extensor proprius hallucis, and anterior tibial vessels and nerve. By its *outer side*, with the Peroneus longus and brevis.

The **Peroneus tertius** is a part of the Extensor longus digitorum, and might be described as its fifth tendon. The fibres belonging to this tendon arise from the lower fourth of the anterior surface of the fibula; from the lower part of the interosseous membrane; and from an intermuscular septum between it and the Peroneus brevis. The tendon, after passing through the same canal in the annular ligament as the Extensor longus digitorum, is inserted into the dorsal surface of the base of the metatarsal bone of the little toe, on its inner side. This muscle is sometimes wanting.

Nerves.—These muscles are supplied by the anterior tibial nerve.

Actions.—The Tibialis anticus and Peroneus tertius are the direct flexors of the tarsus upon the leg; the former muscle, from the obliquity in the direction of its tendon, raises the inner border of the foot; and the latter, acting with the Peroneus brevis and longus, draws the outer border of the foot upwards and the sole outwards. The extensor longus digitorum and Extensor proprius hallucis extend the phalanges of the toes, and, continuing their action, flex the tarsus upon the leg. Taking their fixed point from below, in the erect posture, all these muscles serve to fix the bones of the leg in the perpendicular position, and give increased strength to the ankle-joint.

6. *Posterior Tibio-fibular Region*

Dissection (fig. 366).—Make a vertical incision along the middle line of the back of the leg, from the lower part of the popliteal space to the heel, connecting it below by a transverse incision extending between the two malleoli; the flaps of integument being removed, the fascia and muscles should be examined.

The muscles in this region of the leg are subdivided into two layers—superficial and deep. The superficial layer constitutes a powerful muscular mass, forming the calf of the leg. Their large size is one of the most characteristic features of the muscular apparatus in man, and bears a direct connection with his ordinary attitude and mode of progression.

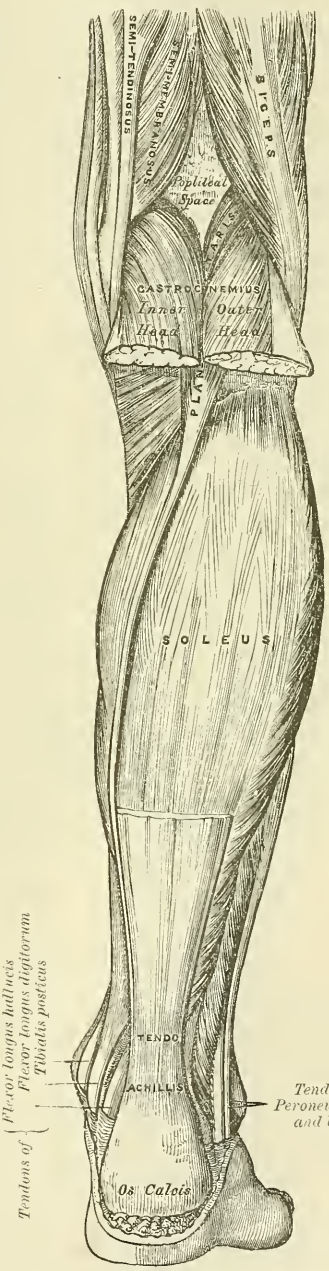
Superficial Layer

Gastrocnemius. Soleus. Plantaris.

The **Gastrocnemius** is the most superficial muscle, and forms the greater part of the calf. It arises by two heads, which are connected to the condyles of the femur by two strong flat tendons. The inner head, the larger, and a little the more posterior, arises from a depression at the upper and back part of the inner condyle. The outer head arises from the upper and back part of the external condyle, immediately above the origin of the Popliteus. Both heads, also, arise by a few tendinous and fleshy fibres from the ridges which are continued upwards from the condyles to the linea aspera. Each tendon spreads out into an aponeurosis, which covers the posterior surface of that portion of the muscle to which it belongs; that covering the inner head being longer and thicker than the outer. From the anterior surface of these tendinous expansions, muscular fibres are given off. The fibres in the median line, which correspond to the accessory portions of the muscle derived from the bifurcations of the linea aspera, unite at an angle upon a median tendinous raphé below: the remaining fibres converge to the posterior surface of an aponeurosis which covers the anterior surface of the muscle, and this, gradually contracting, unites with the tendon of the Soleus, and forms with it the tendo Achillis.

Relations.—By its *superficial surface*, with the fascia of the leg, which separates it from the external saphenous vein and nerve. By its *deep surface*, with the posterior ligament of the knee-joint, the Popliteus, Soleus, Plantaris, popliteal vessels, and internal popliteal nerve. The tendon of the inner head corresponds with the back part of the inner condyle, from which it is separated by a synovial bursa, which, in some cases, communicates with the cavity of the knee-joint. The tendon of the outer head contains a sesamoid fibro-cartilage (rarely osseous), where it plays over the corresponding outer condyle; and one is occasionally found in the tendon of the inner head.

FIG. 370.—Muscles of the back of the leg. Superficial layer.



The Gastrocnemius should be divided across, just below its origin, and turned downwards, in order to expose the next muscles.

The **Soleus** is a broad flat muscle situated immediately beneath the Gastrocnemius. It has received its name from its resemblance in shape to a sole-fish. It arises by tendinous fibres from the back part of the head of the fibula, and from the upper third of the posterior surface of its shaft; from the oblique line of the tibia, and from the middle third of its internal border; some fibres also arise from a tendinous arch placed between the tibial and fibular origins of the muscle, beneath which the popliteal vessels and internal popliteal nerve pass. The fibres pass backwards to an aponeurosis which covers the posterior surface of the muscle, and this gradually becoming thicker and narrower, joins with the tendon of the Gastrocnemius, and forms with it the tendo Achillis.

Relations.—By its *superficial surface*, with the Gastrocnemius and Plantaris. By its *deep surface*, with the Flexor longus digitorum, Flexor longus hallucis, Tibialis posticus, and posterior tibial vessels and nerve, from which it is separated by the transverse intermuscular septum or deep transverse fascia of the leg.

The **tendo Achillis**, the common tendon of the Gastrocnemius and Soleus,* is the thickest and strongest tendon in the body. It is about six inches in length, and commences about the middle of the leg, but receives fleshy fibres on its anterior surface, nearly to its lower

* These two muscles with a common tendon are by some anatomists classed together as one muscle, the *Triceps suræ*, the two heads of origin of the Gastrocnemius and the Soleus constituting the three heads of the Triceps, and the tendo Achillis the single tendon of insertion.

end. Gradually becoming contracted below, it is inserted into the lower part of the posterior surface of the os calcis, a synovial bursa being interposed between the tendon and the upper part of this surface. The tendon spreads out somewhat at its lower end, so that its narrowest part is usually about an inch and a half above its insertion. The tendon is covered by the fascia and the integument, and is separated from the deep muscles and vessels by a considerable interval filled up with areolar and adipose tissue. Along its outer side, but superficial to it, is the external saphenous vein.

The **Plantaris** is an extremely diminutive muscle, placed between the Gastrocnemius and Soleus, and remarkable for its long and delicate tendon. It arises from the lower part of the outer prolongation of the linea aspera, and from the posterior ligament of the knee-joint. It forms a small fusiform belly, about three or four inches in length, terminating in a long slender tendon which crosses obliquely between the two muscles of the calf, and, running along the inner border of the tendo Achillis, is inserted with it into the posterior part of the os calcis. This muscle is occasionally double, and is sometimes wanting. Occasionally, its tendon is lost in the internal annular ligament, or in the fascia of the leg.

Nerves.—These muscles are supplied by the internal popliteal nerve. The Soleus receives an additional branch from the posterior tibial.

Actions.—The muscles of the calf possess considerable power, and are constantly called into use in standing, walking, dancing, and leaping; hence the large size they usually present. In walking, these muscles draw powerfully upon the os calcis, raising the heel, and with it the entire body, from the ground; the body being thus supported on the raised foot, the opposite limb can be carried forwards. In standing, the Soleus, taking its fixed point from below steadies the leg upon the foot, and prevents the body from falling forwards, to which there is a constant tendency from the superincumbent weight. The Gastrocnemius, acting from below, serves to flex the femur upon the tibia assisted by the Popliteus. The Plantaris is the rudiment of a large muscle which exists in some of the lower animals, and which is continued over the os calcis to be inserted into the plantar fascia. In man it is an accessory to the Gastrocnemius, extending the ankle if the foot is free, or bending the knee if the foot is fixed. Possibly, acting from below, by its attachment to the posterior ligament of the knee-joint, it may pull that ligament backwards during flexion and so protect it from being compressed between the two articular surfaces.

Deep Layer (fig. 371)

Popliteus.	Flexor longus digitorum.
Flexor longus hallucis.	Tibialis posticus.

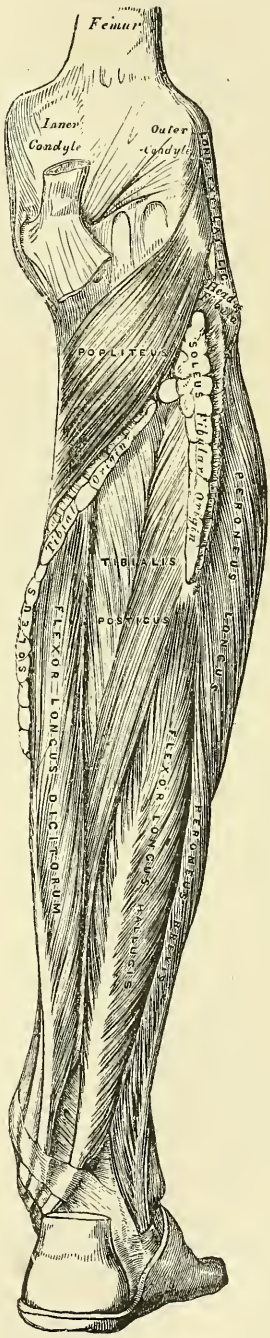
Dissection.—Detach the Soleus from its attachment to the fibula and tibia, and turn downwards, when the deep layer of muscles is exposed, covered by the deep transverse fascia of the leg.

The **Deep Transverse Fascia** of the leg is a broad, transverse, intermuscular septum, interposed between the superficial and deep muscles in the posterior tibio-fibular region. On either side it is connected to the margins of the tibia and fibula. Above, where it covers the Popliteus, it is thick and dense, and receives an expansion from the tendon of the Semimembranosus; it is thinner in the middle of the leg; but below, where it covers the tendons passing behind the malleoli, it is thickened. It is continued onwards in the interval between the ankle and the heel, where it covers the vessels, and is blended with the internal annular ligament.

This fascia should now be removed, commencing from below opposite the tendons, and detaching it from the muscles in the direction of their fibres.

The **Popliteus** is a thin, flat, triangular muscle, which forms part of the floor of the popliteal space. It arises by a strong tendon about an inch in length, from a deep depression on the outer side of the external condyle of the femur and from the posterior ligament of the knee-joint; and is inserted into the inner two-thirds of the triangular surface above the oblique line on the posterior surface of the shaft of the tibia, and into the tendinous expansion covering the surface of the muscle. The tendon of the muscle is covered by that of the Biceps and the external lateral ligament of the knee-joint; it grooves the outer border of the external semilunar fibro-cartilage, and is invested by the synovial membrane of the knee-joint.

Fig. 371.—Muscles of the back of the leg. Deep layer.



Relations.—By its *superficial surface*, with the fascia covering it, which separates it from the Gastrocnemius, Plantaris, popliteal vessels, and internal popliteal nerve. By its *deep surface*, with the superior tibio-fibular articulation and back of the tibia.

The **Flexor longus hallucis** is situated on the fibular side of the leg, and is the most superficial and largest of the three next muscles. It arises from the lower two-thirds of the posterior surface of the shaft of the fibula, with the exception of an inch at its lowest part; from the lower part of the interosseous membrane; from an intermuscular septum between it and the Peronei, externally; and from the fascia covering the Tibialis posticus internally. The fibres pass obliquely downwards and backwards, and terminate in a tendon which occupies nearly the whole length of the posterior surface of the muscle. This tendon passes through a groove on the posterior surface of the tibia; it then passes through another groove on the posterior surface of the astragalus, and along a third groove, beneath the sustentaculum tali of the os calcis, into the sole of the foot, where it runs forwards between the two heads of the Flexor brevis hallucis, and is inserted into the base of the last phalanx of the great toe. The grooves in the astragalus and os calcis, which contain the tendon of the muscle, are converted by tendinous fibres into distinct canals, lined by synovial membrane; and as the tendon crosses the sole of the foot, it is connected to the common flexor by a tendinous slip.

Relations.—By its *superficial surface*, with the Soleus and tendo Achillis, from which it is separated by the deep transverse fascia. By its *deep surface*, with the fibula, Tibialis posticus, the peroneal vessels, the lower part of the interosseous membrane, and the ankle-joint. By its *outer border*, with the Peronei. By its *inner border*, with the Tibialis posticus, and posterior tibial vessels and nerve.

The **Flexor longus digitorum** (*perforans*) is situated on the tibial side of the leg. At its origin it is thin and pointed, but gradually increases in size as it descends. It arises from the posterior surface of the shaft of the tibia immediately below the oblique line, to within three inches of its extremity, internal to the tibial origin of the Tibialis posticus; some fibres also arise from the fascia covering the Tibialis posticus. The fibres terminate in a tendon, which runs nearly the whole length of the posterior surface of the muscle. This tendon passes behind the internal malleolus, in a groove, common to it and the Tibialis posticus, but separated from the latter by a fibrous septum; each tendon being contained in a special sheath lined by a separate synovial membrane. It then passes obliquely forwards and outwards, crossing over the internal lateral ligament into the sole of the foot (fig. 373), where, crossing superficially to the tendon of the Flexor longus hallucis,* to which it is connected by a strong tendinous slip, it becomes expanded, is joined by the Flexor accessorius, and finally divides into four tendons, which are inserted into the bases of the last phalanges of the four lesser toes, each tendon passing through a fissure in the tendon of the Flexor brevis digitorum opposite the bases of the first phalanges.

Relations.—*In the leg*: by its *superficial surface*, with the posterior tibial vessels and nerve, and the deep transverse fascia, which separates it from the Soleus muscle; by its *deep surface*, with the tibia and Tibialis posticus. *In the foot*, it is covered by the Abductor hallucis and Flexor brevis digitorum, and crosses superficial to the Flexor longus hallucis.

The **Tibialis posticus** lies between the two preceding muscles, and is the most deeply seated of all the muscles in the leg. It commences above by two pointed processes, separated by an angular interval, through which the anterior tibial vessels pass forwards to the front of the leg. It arises from the whole of the posterior surface of the interosseous membrane, excepting its lowest part; from the outer portion of the posterior surface of the shaft of the tibia, between the commencement of the oblique line above and the junction of the middle and lower third of the shaft below; and from the upper two-thirds of the internal surface of the fibula; some fibres also arise from the deep transverse fascia, and from the intermuscular septa separating it from the adjacent muscles on each side. This muscle, in the lower fourth of the leg, passes in front of the Flexor longus digitorum, and terminates in a tendon, which passes through a groove behind the inner malleolus, with the tendon of that muscle, but enclosed in a separate sheath; it then passes through another sheath, over the internal lateral ligament into the foot, and then beneath the inferior calcaneo-navicular ligament, and is inserted into the tuberosity of the navicular and internal cuneiform bones. The tendon of this muscle contains a sesamoid fibro-cartilage, as it passes over the navicular bone, and gives off fibrous expansions, one of which passes backwards to the sustentaculum tali of the os calcis, others outwards to the middle and external cuneiform and cuboid, and some forwards to the bases of the second, third, and fourth metatarsal bones (fig. 374).

Relations.—By its *superficial surface*, with the Soleus, from which it is separated by the deep transverse fascia, the Flexor longus digitorum, the posterior tibial vessels and nerve, and the peroneal vessels. By its *deep surface*, with the interosseous ligament, the tibia, fibula, and ankle-joint.

Nerves.—The Popliteus is supplied by the internal popliteal nerve, the remaining muscles of this group by the posterior tibial nerve.

Actions.—The Popliteus assists in flexing the leg upon the thigh; when the leg is flexed, it will rotate the tibia inwards. It is especially called into action at the commencement of the act of bending the knee, inasmuch as it produces a slight inward rotation of the tibia, which is essential in the early stage of this movement. The Tibialis posticus is a direct extensor of the tarsus upon the leg; acting in conjunction with the Tibialis anticus, it turns the sole of the foot inwards,

* That is, in the order of dissection of the sole of the foot.

antagonising the Peroneus longus, which turns it outwards. The Flexor longus digitorum and Flexor longus hallucis are the direct flexors of the phalanges, and, continuing their action, extend the foot upon the leg; they assist the Gastrocnemius and Soleus in extending the foot, as in the act of walking, or in standing on tiptoe. In consequence of the oblique direction of the tendon of the long flexor, the toes would be drawn inwards, were it not for the Flexor accessorius muscle, which is inserted into the outer side of its tendon, and draws it to the middle line of the foot during its action. Taking their fixed point from the foot, these muscles serve to maintain the upright posture by steadying the tibia and fibula, perpendicularly, upon the ankle-joint. They also serve to raise these bones from the oblique position they assume in the stooping posture.

7. *Outer or Fibular Region*

Peroneus longus. Peroneus brevis.

Dissection.—The muscles are readily exposed, by removing the fascia covering their surface, from below upwards, in the line of direction of their fibres.

The **Peroneus longus** is situated at the upper part of the outer side of the leg, and is the more superficial of the two muscles. It arises from the head and upper two-thirds of the outer surface of the shaft of the fibula, from the deep surface of the fascia, and from the intermuscular septa, between it and the muscles on the front, and those on the back of the leg: occasionally also by a few fibres from the outer tuberosity of the tibia. Between its attachment to the head and to the shaft of the fibula there is a small interval of bone from which no muscular fibres arise; through this gap the external popliteal nerve passes beneath the muscle. It terminates in a long tendon, which passes behind the outer malleolus, in a groove common to it and the Peroneus brevis, the groove being converted into a canal by a fibrous band, and the tendons invested by a common synovial membrane; it is then reflected, obliquely forwards, across the outer side of the os calcis, being contained in a separate fibrous sheath, lined by a prolongation of the synovial membrane from that which lines the groove behind the malleolus. Having reached the outer side of the cuboid bone, it runs in a groove on the under surface of that bone, which is converted into a canal by the long calcaneo-cuboid ligament, and is lined by a synovial membrane: the tendon thus crosses obliquely the sole of the foot, and is inserted into the outer side of the base of the metatarsal bone of the great toe and the internal cuneiform bone. Occasionally it sends a slip to the base of the second metatarsal bone. The tendon changes its direction at two points: first, behind the external malleolus; secondly, on the outer side of the cuboid bone; in both of these situations the tendon is thickened, and, in the latter, a sesamoid fibro-cartilage, or sometimes a bone, is usually developed in its substance.

Relations.—By its *superficial surface*, with the fascia and integument; by its *deep surface*, with the fibula, external popliteal nerve, the Peroneus brevis, os calcis, and cuboid bone; by its *anterior border*, with an intermuscular septum, which intervenes between it and the Extensor longus digitorum; by its *posterior border*, with an intermuscular septum, which separates it from the Soleus above and the Flexor longus hallucis below.

The **Peroneus brevis** lies beneath the Peroneus longus, and is shorter and smaller than it. It arises from the lower two-thirds of the external surface of the shaft of the fibula, internal to the Peroneus longus; and from the intermuscular septa, separating it from the adjacent muscles on the front and back part of the leg. The fibres pass vertically downwards, and terminate in a tendon, which runs in front of that of the preceding muscle, through the same groove behind the external malleolus, being contained in the same fibrous sheath, and lubricated by the same synovial membrane. It then passes through a separate sheath on the outer side of the os calcis, above that for the tendon of the Peroneus longus,

and is finally inserted into the tuberosity at the base of the metatarsal bone of the little toe, on its outer side.

Relations.—By its *superficial surface*, with the Peroneus longus and the fascia of the leg and foot. By its *deep surface*, with the fibula and outer side of the os calcis.

Nerves.—The Peroneus longus and brevis are supplied by the musculo-cutaneous branch of the external popliteal nerve.

Actions.—The Peroneus longus and brevis extend the foot upon the leg, in conjunction with the Tibialis posticus, antagonising the Tibialis anticus and Peroneus tertius, which are flexors of the foot. The Peroneus longus also everts the sole of the foot; hence the extreme eversion occasionally observed in fracture of the lower end of the fibula, where that bone offers no resistance to the action of this muscle. Taking their fixed point below, the Peronei serve to steady the leg upon the foot. This is especially the case in standing upon one leg, when the tendency of the superincumbent weight is to throw the leg inwards: the Peroneus longus overcomes this tendency by drawing on the outer side of the leg, and thus maintains the perpendicular direction of the limb.

Surgical Anatomy.—The student should now consider the position of the tendons of the various muscles of the leg, their relation with the ankle-joint and surrounding blood-vessels, and especially their action upon the foot, as their rigidity and contraction give rise to one or other of the kinds of deformity known as *club foot*. The most simple and common deformity, and one that is rarely, if ever, congenital, is the *talipes equinus*, the heel being raised by rigidity and contraction of the Gastrocnemius muscle, and the patient walking upon the ball of the foot. In the *talipes varus*, the foot is forcibly adducted and the inner side of the sole raised, sometimes to a right angle with the ground, by the action of the Tibialis anticus and posticus. In the *talipes valgus*, the outer edge of the foot is raised by the Peronei muscles, and the patient walks on the inner ankle. In the *talipes calcaneus* the toes are raised by the Extensor muscles, the heel is depressed and the patient walks upon it. Other varieties of deformity are met with, as the *talipes equino-varus*, *equino-valgus*, and *calcaneo-valgus*, whose names sufficiently indicate their nature. Of these, the talipes equino-varus is the most common congenital form; the heel is raised by the tendo Achillis, the inner border of the foot drawn upwards by the Tibialis anticus, the anterior two-thirds twisted inwards by the Tibialis posticus, and the arch increased by the contraction of the plantar fascia, so that the patient walks on the middle of the outer border of the foot. Each of these deformities may sometimes be successfully relieved by division of the opposing tendons and fascia: by this means the foot regains its proper position, and the tendons heal by the organisation of lymph thrown out between the divided ends. The operation is easily performed by putting the contracted tendon upon the stretch, and dividing it by means of a narrow, sharp pointed knife inserted beneath it.

Rupture of a few of the fibres of the Gastrocnemius, or rupture of the Plantaris tendon not uncommonly occurs, especially in men somewhat advanced in life, from some sudden exertion, and frequently occurs during the game of lawn temis, and is hence known as 'lawn-tennis leg.' The accident is accompanied by a sudden pain, and produces a sensation as if the individual had been struck a violent blow on the part. The tendo Achillis is also sometimes ruptured. It is stated that John Hunter ruptured his tendo Achillis whilst dancing, at the age of forty.

IV. Muscles and Fasciæ of the Foot

The fibrous bands which bind down the tendons in front of and behind the ankle in their passage to the foot should now be examined; they are termed the *annular ligaments*, and are three in number—anterior, internal, and external.

The **anterior annular ligament** consists of a superior or vertical portion, which binds down the extensor tendons as they descend on the front of the tibia and fibula; and an inferior or horizontal portion, which retains them in connection with the tarsus, the two portions being connected by a thin intervening layer of fascia. The vertical portion is attached externally to the lower end of the fibula and internally to the tibia; above it is continuous with the fascia of the leg; it contains only one synovial sheath, for the tendon of the Tibialis anticus; the other tendons and the anterior tibial vessels and nerve passing beneath it, but without any distinct synovial sheath. The horizontal portion is

attached externally to the upper surface of the os calcis, in front of the depressior for the interosseous ligament; it passes upwards and inwards, as a double layer one lamina passing in front, and the other behind, the tendons of the Peroneus tertius and Extensor longus digitorum. At the inner border of the latter tendon these two layers join together, forming a sort of loop or sheath in which the tendons are enclosed, surrounded by a synovial membrane. From the inner extremity of this loop two bands are given off: one passes upwards and inwards, to be attached to the internal malleolus, passing over the Extensor proprius hallucis and vessels and nerves, but enclosing the Tibialis anticus and its synovial sheath by a splitting of its fibres. The other limb passes downwards and inwards to be attached to the inner border of the plantar fascia, and passes over both the tendon of the Extensor proprius hallucis and the Tibialis anticus and also the vessels and nerves. These two tendons are contained in separate synovial sheaths situated beneath the ligament. It will thus be seen that the horizontal portion of the ligament is like the letter Y, the foot of the letter being attached to the os calcis, and the two diverging arms to the tibia and plantar fascia respectively.

The **internal annular ligament** is a strong fibrous band, which extends from the inner malleolus above to the internal margin of the os calcis below, converting a series of grooves in this situation into canals, for the passage of the tendons of the Flexor muscles and vessels into the sole of the foot. It is continuous by its upper border with the deep fascia of the leg, and by its lower border with the plantar fascia and the fibres of origin of the Abductor hallucis muscle. The four canals which it forms transmit, from within outwards, first, the tendon of the Tibialis posticus; second, the tendon of the Flexor longus digitorum; third, the posterior tibial vessels and nerve, which run through a broad space beneath the ligament; lastly, in a canal formed partly by the astragalus, the tendon of the Flexor longus hallucis. The canals for the tendons are lined by separate synovial membranes.

The **external annular ligament** extends from the extremity of the outer malleolus to the outer surface of the os calcis: it binds down the tendons of the Peronei muscles in their passage beneath the outer ankle. The two tendons are enclosed in one synovial sac.

Dissection of the Sole of the Foot.—The foot should be placed on a high block with the sole uppermost, and firmly secured in that position. Carry an incision round the heel and along the inner and outer borders of the foot to the great and little toes. This incision should divide the integument and thick layer of granular fat beneath, until the fascia is visible; the skin and fat should then be removed from the fascia in a direction from behind forwards, as seen in fig. 366.

The **plantar fascia**, the densest of all the fibrous membranes, is of great strength, and consists of dense pearly-white glistening fibres, disposed, for the most part, longitudinally: it is divided into a central and two lateral portions.

The *central portion*, the thickest, is narrow behind and attached to the inner tubercle of the os calcis, behind the origin of the Flexor brevis digitorum; and becoming broader and thinner in front, divides near the heads of the metatarsal bones into five processes, one for each of the toes. Each of these processes divides opposite the metatarso-phalangeal articulation into two strata, superficial and deep. The superficial stratum is inserted into the skin of the transverse sulcus which divides the toes from the sole. The deeper stratum divides into two slips which embrace the sides of the flexor tendons of the toes, and blend with the sheaths of the tendons and laterally with the transverse metatarsal ligament, thus forming a series of arches through which the tendons of the short and long flexors pass to the toes. The intervals left between the five processes allow the digital vessels and nerves, and the tendons of the Lumbricales muscles, to become superficial. At the point of division of the fascia into processes and slips, numerous transverse fibres are superadded, which serve to increase the strength of the fascia at this part by binding the processes together, and

connecting them with the integument. The central portion of the plantar fascia is continuous with the lateral portions at each side, and sends upwards into the foot, at their point of junction, two strong vertical intermuscular septa, broader in front than behind, which separate the middle from the external and internal plantar group of muscles; from these again thinner transverse septa are derived, which separate the various layers of muscles in this region. The upper surface of this fascia gives attachment behind to the Flexor brevis digitorum muscle.

The *lateral portions* of the plantar fascia are thinner than the central piece, and cover the sides of the foot.

The *outer portion* covers the under surface of the Abductor minimi digiti; it is thick behind, thin in front, and extends from the outer tubercle of the os calcis, forwards, to the base of the fifth metatarsal bone, into the outer side of which it is attached; it is continuous internally with the middle portion of the plantar fascia, and externally with the dorsal fascia.

The *inner portion* is very thin, and covers the Abductor hallucis muscle; it is attached behind to the internal annular ligament, and is continuous around the side of the foot with the dorsal fascia, and externally with the middle portion of the plantar fascia.

8. *Dorsal Region*

Extensor brevis digitorum.

The **fascia** on the dorsum of the foot is a thin membranous layer, continuous above with the anterior margin of the annular ligament; it becomes gradually lost opposite the heads of the metatarsal bones, and on each side blends with the lateral portions of the plantar fascia; it forms a sheath for the tendons placed on the dorsum of the foot. On the removal of this fascia, the muscle and tendons of the dorsal region of the foot are exposed.

The **Extensor brevis digitorum** (fig. 369) is a broad thin muscle, which arises from the fore part of the upper and outer surfaces of the os calcis, in front of the groove for the Peroneus brevis; from the external calcaneo-astragaloid ligament; and from the horizontal portion of the anterior annular ligament. It passes obliquely across the dorsum of the foot, and terminates in four tendons. The innermost, which is the largest, is inserted into the dorsal surface of the base of the first phalanx of the great toe, crossing the Dorsalis pedis artery; the other three, into the outer sides of the long extensor tendons of the second, third, and fourth toes.

Relations.—By its *superficial surface*, with the fascia of the foot, the tendons of the Extensor longus digitorum and Peroneus tertius. By its *deep surface*, with the tarsal and metatarsal bones, and the Dorsal interossei muscles.

Nerves.—It is supplied by the anterior tibial nerve.

Actions.—The Extensor brevis digitorum is an accessory to the long Extensor, extending the phalanges of the four inner toes, but acting only on the first phalanx of the great toe. The obliquity of its direction counteracts the oblique movement given to the toes by the long Extensor, so that, both muscles acting together, the toes are evenly extended.

9. *Plantar Region*

The muscles in the plantar region of the foot may be divided into three groups, in a similar manner to those in the hand. Those of the internal plantar region are connected with the great toe, and correspond with those of the thumb; those of the external plantar region are connected with the little toe, and correspond with those of the little finger; and those of the middle plantar region are connected with the tendons intervening between the two former groups. But in order to facilitate the dissection of these muscles, it will be found more convenient to divide them into four layers, as they present themselves, in the order in which they are successively exposed.

First Layer

Abductor hallucis. Flexor brevis digitorum.
Abductor minimi digiti.

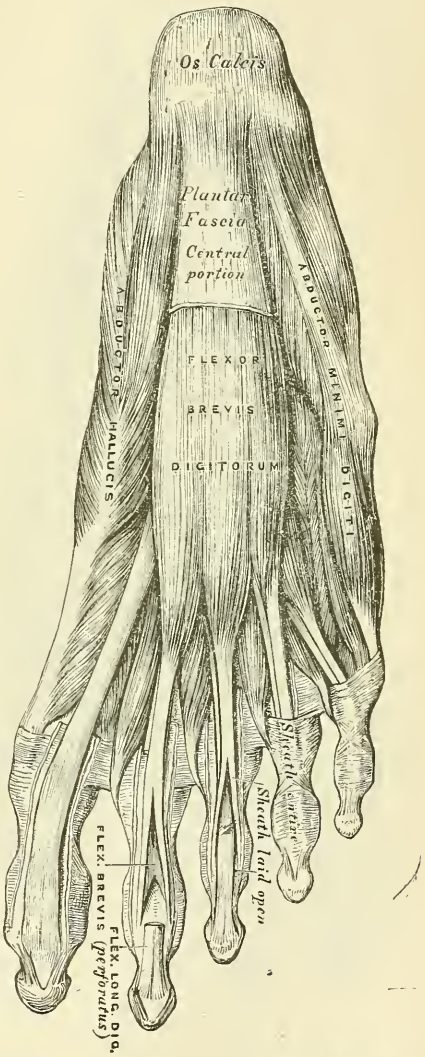
Dissection.—Remove the fascia on the inner and outer sides of the foot, commencing in front over the tendons, and proceeding backwards. The central portion should be divided transversely in the middle of the foot, and the two flaps dissected forwards and backwards.

The **Abductor hallucis** lies along the inner border of the foot. It arises from the inner tubercle on the under surface of the os calcis; from the internal annular ligament; from the plantar fascia; and from the intermuscular septum between it and the Flexor brevis digitorum. The fibres terminate in a tendon, which is inserted, together with the innermost tendon of the Flexor brevis hallucis, into the inner side of the base of the first phalanx of the great toe.

Relations.—By its *superficial surface*, with the plantar fascia. By its *deep surface*, with the Flexor brevis hallucis, the Flexor accessorius, and the tendons of the Flexor longus digitorum and Flexor longus hallucis, the Tibialis anticus and posticus, the plantar vessels and nerves, and the articulations of the tarsus.

The **Flexor brevis digitorum** (*perforatus*) lies in the middle of the sole of the foot, immediately beneath * the plantar fascia, with which it is firmly united. It arises by a narrow tendinous process, from the inner tubercle of the os calcis, from the central part of the plantar fascia, and from the intermuscular septa between it and the adjacent muscles. It passes forwards, and divides into four tendons. Opposite the bases of the first phalanges, each tendon divides into two slips, to allow of the passage of the corresponding tendon of the Flexor longus digitorum; the two portions of the tendon then unite and form a grooved channel for the reception of the accompanying long flexor tendon. Finally, they divide a second time, to be inserted into the sides of the second phalanges about their middle. The mode of division of the tendons of the Flexor brevis digitorum, and their insertion into the phalanges, is analogous to the Flexor sublimis digitorum in the hand.

FIG. 372.—Muscles of the sole of the foot. First layer.



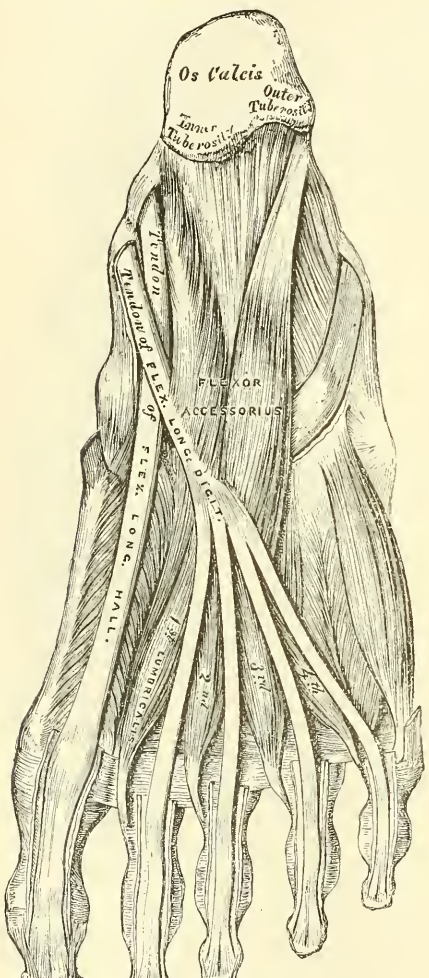
Relations.—By its *superficial surface*, with the plantar fascia. By its *deep surface*, with the Flexor accessorius, the Lumbricales, the tendons of the Flexor longus digitorum, and the external plantar vessels and nerve, from which it is separated by a thin layer of fascia. The *outer* and *inner borders* are separated

* That is, in the order of dissection of the sole of the foot.

from the adjacent muscles by means of vertical prolongations of the plantar fascia.

Fibrous sheaths of the flexor tendons.—These are not so well marked as in the fingers. The flexor tendons of the toes as they run along the phalanges are retained against the bones by a fibrous sheath, forming osseo-aponeurotic canals. These sheaths are formed by strong fibrous bands, which arch across the tendons, and are attached on each side to the margins of the phalanges. Opposite the middle of the proximal and second phalanges the sheath is very strong, and the fibres pass transversely; but opposite the joints it is much thinner, and the fibres pass obliquely. Each sheath is lined by a synovial membrane, which is reflected on the contained tendon.

Fig. 373.—Muscles of the sole of the foot. Second layer.



The **Abductor minimi digiti** lies along the outer border of the foot. It arises, by a very broad origin, from the outer tubercle of the os calcis, from the under surface of the os calcis in front of both tubercles, from the fore part of the inner tubercle, from the plantar fascia, and the intermuscular septum between it and the Flexor brevis digitorum. Its tendon, after gliding over a smooth facet on the under surface of the base of the fifth metatarsal bone, is inserted, with the short Flexor of the little toe, into the outer side of the base of the first phalanx of this toe.

Relations.—By its *superficial surface*, with the plantar fascia. By its *deep surface*, with the Flexor accessorius, the Flexor brevis minimi digiti, the long plantar ligament, and the tendon of the Peroneus longus. On its *inner side* are the external plantar vessels and nerve, and it is separated from the Flexor brevis digitorum by a vertical septum of fascia.

Dissection.—The muscles of the superficial layer should be divided at their origin, by inserting the knife beneath each, and cutting obliquely backwards, so as to detach them from the bone; they should then be drawn forwards, in order to expose the second layer, but not cut away at their insertion. The two layers are separated by a thin membrane, the *deep plantar fascia*, on the removal of which is seen the tendon of the Flexor longus digitorum, the Flexor accessorius, the tendon of the Flexor longus hallucis, and the Lumbricales. The long flexor tendons cross each other at an acute angle, the Flexor longus hallucis running along the inner side of the foot, on a plane superior to that of the Flexor longus digitorum, the direction of which is obliquely outwards.

Second Layer

Flexor accessorius. Lumbricales.

The **Flexor accessorius** arises by two heads: the inner or larger, which is muscular, being attached to the inner concave surface of the os calcis, and to the inferior calcaneo-navicular ligament; the outer head, flat and tendinous, to

the under surface of the os calcis, in front of its outer tubercle, and to the long plantar ligament: the two portions join at an acute angle, and are inserted into the outer margin and upper and under surfaces of the tendon of the Flexor longus digitorum, forming a kind of groove, in which the tendon is lodged.*

Relations.—By its *superficial surface*, with the muscles of the superficial layer, from which it is separated by the external plantar vessels and nerves. By its *deep surface*, with the os calcis, and long calcaneo-cuboid ligament.

The **Lumbricales** are four small muscles, accessory to the tendons of the Flexor longus digitorum: they arise from the tendons of the long flexor, as far back as their angle of division, each arising from two tendons, except the internal one. Each muscle terminates in a tendon, which passes forwards on the inner side of each of the lesser toes, and is inserted into the expansion of the long extensor tendon on the dorsum of the first phalanx of the corresponding toe.

Dissection.—The flexor tendons should be divided at the back part of the foot, and the Flexor accessorius at its origin, and drawn forwards, in order to expose the third layer.

FIG. 374.—Muscles of the sole of the foot. Third layer.

Third Layer

Flexor brevis hallucis.
Adductor obliquus hallucis.
Flexor brevis minimi digiti.
Adductor transversus hallucis.

The **Flexor brevis hallucis** arises, by a pointed tendinous process, from the inner part of the under surface of the cuboid bone, from the contiguous portion of the external cuneiform, and from the prolongation of the tendon of the Tibialis posticus, which is attached to that bone. The muscle divides, in front, into two portions, which are inserted into the inner and outer sides of the base of the first phalanx of the great toe, a sesamoid bone being developed in each tendon at its insertion. The inner portion of this muscle is blended with the Abductor hallucis previous to its insertion, the outer with the Adductor obliquus hallucis, and the tendon of the Flexor longus hallucis lies in a groove between them.

Relations.—By its *superficial surface*, with the Abductor hallucis, the tendon of the Flexor longus hallucis, and plantar fascia. By its *deep surface*, with the tendon of the Peroneus longus, and metatarsal bone of the great toe. By its *inner border*, with the Abductor hallucis. By its *outer border*, with the Adductor obliquus hallucis.

The **Adductor obliquus hallucis** is a large, thick, fleshy mass, passing obliquely across the foot, and occupying the hollow space between the four

* According to Turner, the fibres of the Flexor accessorius end in aponeurotic bands, which contribute slips to the second, third, and fourth digits.

inner metatarsal bones. It arises from the tarsal extremities of the second, third, and fourth metatarsal bones, and from the sheath of the tendon of the Peroneus longus, and is inserted, together with the outer portion of the Flexor brevis hallucis, into the outer side of the base of the first phalanx of the great toe.

The small muscles of the great toe, the Abductor, Flexor brevis, Adductor obliquus, and Adductor transversus, like the similar muscles of the thumb, give off fibrous expansions, at their insertions, to blend with the long Extensor tendon.

The **Flexor brevis minimi digiti** lies on the metatarsal bone of the little toe, and much resembles one of the Interossei. It arises from the base of the metatarsal bone of the little toe, and from the sheath of the Peroneus longus; its tendon is inserted into the base of the first phalanx of the little toe on its outer side. Occasionally some of the deeper fibres of the muscle are inserted into the outer part of the distal half of the fifth metatarsal bone; these are described by some as a distinct muscle, the Opponens minimi digiti.

Relations.—By its *superficial surface*, with the plantar fascia and tendon of the Abductor minimi digiti. By its *deep surface*, with the fifth metatarsal bone.

Fig. 375.—The Dorsal interossei. Left foot.

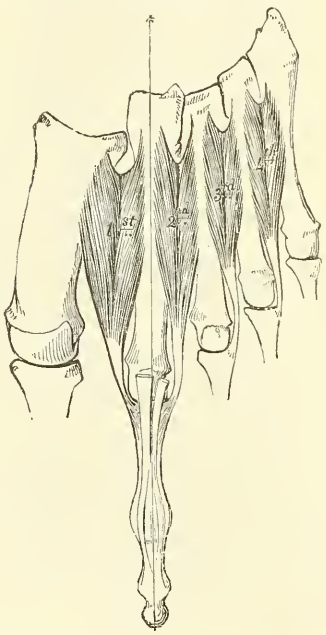


Fig. 376.—The Plantar interossei. Left foot.

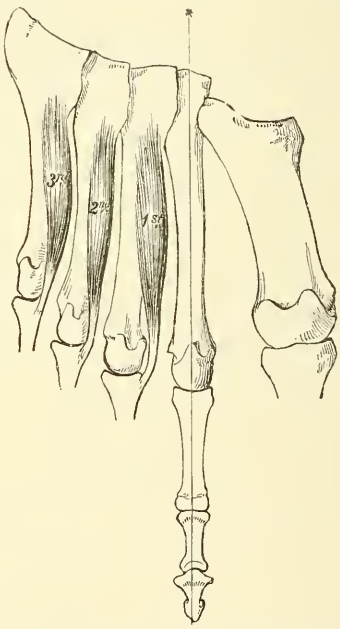


The **Adductor transversus hallucis** (*Transversus pedis*) is a narrow, flat, muscular fasciculus, stretched transversely across the heads of the metatarsal bones, between them and the flexor tendons. It arises from the inferior metatarsophalangeal ligaments of the three outer toes, sometimes only from the third and fourth, and from the transverse ligament of the metatarsus; and is inserted into the outer side of the first phalanx of the great toe; its fibres being blended with the tendon of insertion of the Adductor obliquus hallucis.

Relations.—By its *superficial surface*, with the tendons of the long and short Flexors and Lumbricales. By its *deep surface*, with the Interossei.

Fourth Layer

The Interossei.

The **Interossei muscles** in the foot are similar to those in the hand, with this exception, that they are grouped around the middle line of the *second* toe, instead

of the middle line of the *third* finger, as in the hand. They are seven in number, and consist of two groups, dorsal and plantar.

The **Dorsal interossei**, four in number, are situated between the metatarsal bones. They are bipenniform muscles, arising by two heads from the adjacent sides of the metatarsal bones between which they are placed; their tendons are inserted into the bases of the first phalanges, and into the aponeurosis of the common extensor tendon. In the angular interval left between the heads of each muscle at its posterior extremity the perforating arteries pass to the dorsum of the foot; except in the First interosseous muscle, where the interval allows the passage of the communicating branch of the dorsalis pedis artery. The First dorsal interosseous muscle is inserted into the inner side of the second toe; the other three are inserted into the outer sides of the second, third, and fourth toes.

The **Plantar interossei**, three in number, lie beneath, rather than between, the metatarsal bones. They are single muscles, and are each connected with but one metatarsal bone. They arise from the base and inner sides of the shaft of the third, fourth, and fifth metatarsal bones, and are inserted into the inner sides of the bases of the first phalanges of the same toes, and into the aponeurosis of the common extensor tendon.

Nerves.—The Flexor brevis digitorum, the Flexor brevis and Abductor hallucis, and the inner Lumbrical* are supplied by the internal plantar nerve. All the other muscles in the sole of the foot by the external plantar. The First and Second dorsal interossei muscles receive extra filaments from the ganglionic enlargement of the anterior tibial nerve on the dorsum of the foot.

Actions.—All the muscles of the foot act upon the toes, and for purposes of description as regards their action may be grouped as Abductors, Adductors, Flexors or Extensors. The *Abductors* are the Dorsal interossei, the Abductor hallucis, and the Abductor minimi digiti. The Dorsal interossei are abductors from an imaginary line passing through the axis of the second toe, so that the first muscle draws the second toe inwards, towards the great toe; the second muscle draws the same toe outwards; the third draws the third toe, and the fourth draws the fourth toe in the same direction. Like the interossei in the hand, they also assist in flexing the proximal phalanx and extending the two terminal phalanges. The Abductor hallucis abducts the great toe from the others, and also flexes the proximal phalanx of this toe. And in the same way the action of the Abductor minimi digiti is twofold, as an abductor of this toe from the others, and also as a flexor of the proximal phalanx. The *Adductors* are the Plantar interossei, the Adductor obliquus hallucis, and the Adductor transversus hallucis. The plantar interosseous muscles adduct the third, fourth, and fifth toes, towards the imaginary line passing through the second toe, and by means of their insertion into the aponeurosis of the extensor tendon they assist in flexing the proximal phalanx and extending the two terminal phalanges. The Adductor obliquus hallucis is chiefly concerned in adducting the great toe towards the second one, but also assists in flexing this toe. The Adductor transversus hallucis approximates all the toes and thus increases the curve of the transverse arch of the metatarsus. The *Flexors* are the Flexor brevis digitorum, the Flexor accessorius, the Flexor brevis hallucis, the Flexor brevis minimi digiti, and the Lumbricales. The Flexor brevis digitorum flexes the second phalanges upon the first, and, continuing its action, flexes the first phalanges also, and brings the toes together. The Flexor accessorius assists the long flexor of the toes and converts the oblique pull of the tendons of that muscle into a direct backward pull upon the toes. The Flexor brevis minimi

* Formerly the two inner Lumbricales were described as being supplied by the internal plantar nerve. Brook, however (*Journal of Anatomy*, vol. xxi. p. 575), in ten dissections found that in nine of them only the inner Lumbrical obtained its nerve supply from this source. In the tenth instance both the first and second Lumbricales were supplied by both external and internal plantar.

digiti flexes the little toe and draws its metatarsal bone downwards and inwards. The Lumbricales, like the corresponding muscles in the hand, assist in flexing the proximal phalanx, and by their insertion into the long extensor tendon aid that muscle in straightening the two terminal phalanges. The only muscle in the *Extensor* group is the Extensor brevis digitorum. It extends the first phalanx of the great toe and assists the long extensor in extending the next three toes, and at the same time gives to the toes an outward direction when they are extended.

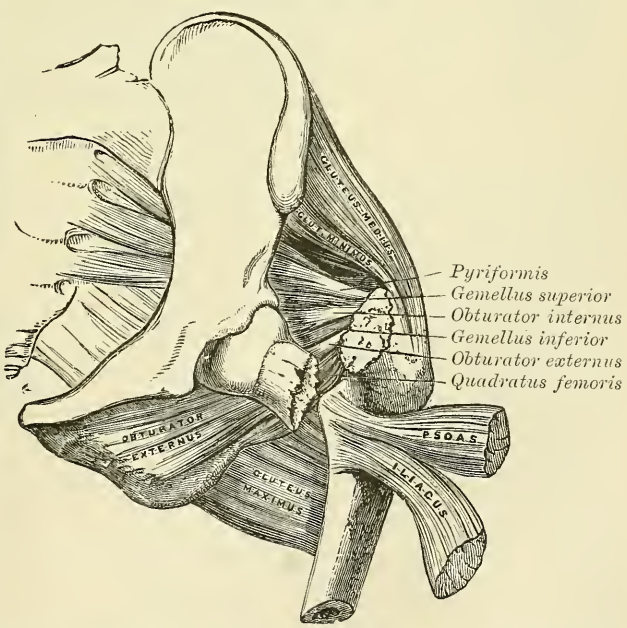
Surface Form.—Of the muscles of the thigh, those of the iliac region have no influence on surface form, while those of the anterior femoral region, being to a great extent superficial, largely contribute to the surface form of this part of the body. The *Tensor vaginæ femoris* produces a broad elevation immediately below the anterior portion of the crest of the ilium and behind the anterior superior spinous process. From its lower border, a longitudinal groove, corresponding to the ilio-tibial band, may be seen running down the outer side of the thigh to the outer side of the knee-joint. The *Sartorius* muscle, when it is brought into action by flexing the leg on the thigh, and the thigh on the pelvis, and rotating the thigh outwards, presents a well-marked surface form. At its upper part, where it constitutes the outer boundary of Scarpa's triangle, it forms a prominent oblique ridge, which becomes changed into a flattened plane below, and this gradually merges in a general fulness on the inner side of the knee-joint. When the Sartorius is not in action, a depression exists between the Extensor quadriceps and the Adductor muscles, running obliquely downwards and inwards from the apex of Scarpa's triangle to the inner side of the knee, which corresponds to this muscle. In the depressed angle formed by the divergence of the Sartorius and Tensor vaginæ femoris muscles, just below the anterior superior spinous process of the ilium, the *Rectus femoris* muscle appears, and, below this, determines to a great extent the convex form of the front of the thigh. In a well-developed subject, the borders of the muscle, when in action, are clearly to be defined. The *Vastus externus* forms a long flattened plane on the outer side of the thigh, traversed by the longitudinal groove formed by the ilio-tibial band. The *Vastus internus*, on the inner side of the lower half of the thigh, gives rise to a considerable prominence, which increases towards the knee and terminates somewhat abruptly in this situation with a full, curved outline. The *Crureus* and *Subcrureus* are completely hidden, and do not directly influence surface form. The *Adductor muscles*, constituting the internal femoral group, are not to be individually distinguished from each other, with the exception of the upper tendon of the Adductor longus and the lower tendon of the Adductor magnus. The upper tendon of the *Adductor longus*, when the muscle is in action, stands out as a prominent ridge, which runs obliquely downwards and outwards from the neighbourhood of the pubic spine, and forms the inner boundary of a flattened triangular space on the upper part of the front of the thigh, known as Scarpa's triangle. The lower tendon of the *Adductor magnus* can be distinctly felt as a short ridge extending down to the Adductor tubercle on the internal condyle, between the Sartorius and Vastus internus. The Adductor group of muscles fills in the triangular space at the upper part of the thigh, formed between the oblique femur and the pelvic wall, and to them is due the contour of the inner border of the thigh, the *Gracilis* largely contributing to the smoothness of the outline. These muscles are not marked off on the surface from those of the posterior femoral region by any intermuscular marking; but on the outer side of the thigh these latter muscles are defined from the Vastus externus by a distinct marking, corresponding to the external intermuscular septum. The *Gluteus maximus* and a part of the *Gluteus medius* are the only muscles of the buttock which influence surface form. The other part of the Gluteus medius, the Gluteus minimus, and the External rotators are completely hidden. The *Gluteus maximus* forms the full rounded outline of the buttock; it is more prominent behind, compressed in front, and terminates at its tendinous insertion in a depression immediately behind the great trochanter. Its lower border does not correspond to the gluteal fold, but is much more oblique, being marked by a line drawn from the side of the coccyx to the junction of the upper with the lower two-thirds of the thigh on the outer side. From beneath the fold of this muscle, the *Hamstring muscles* appear, at first narrow and not well marked, but as they descend, becoming more prominent and widened out, and eventually dividing into two well-marked ridges, which form the upper boundaries of the popliteal space, being formed by the tendons of the inner and outer Hamstring muscles respectively. In the upper part of the thigh these muscles are not to be individually distinguished from each other, but lower down, the separation between the Semitendinosus and Semimembranosus is denoted by a slight intermuscular marking. The external hamstring tendon formed by the *Biceps* is seen as a thick cord running down to the head of the fibula. The inner hamstring tendons comprise the Semitendinosus, the Semimembranosus, and the Gracilis. The *Semitendinosus* is the most internal of these, and can be felt, in certain positions of the limb, as a sharp cord; the *Semimembranosus* is thick, and the *Gracilis* is situated a little further forwards than the other two. All the muscles on the front of the leg appear to a certain extent somewhere on the surface, but the form of this region is mainly dependent upon the Tibialis anticus and the Extensor longus digitorum. The *Tibialis anticus* is well marked, and presents a fusiform

enlargement at the outer side of the tibia, and projects beyond the crest of the shin bone. From the muscular mass, its tendon may be traced downward, standing out boldly, when the muscle is in action, on the front of the tibia and ankle-joint, and coursing down to its insertion along the inner border of the foot. A well-marked groove separates this muscle externally from the *Extensor longus digitorum*, which fills up the rest of the space between the upper part of the shaft of the tibia and fibula. It does not present so bold an outline as the Tibialis anticus, and its tendon below, diverging from the tendon of the Tibialis anticus, forms a sort of plane, in which may be seen the tendon of the Extensor proprius hallucis. A groove on the outer side of the Extensor longus digitorum, seen most plainly when the muscle is in action, separates from it a slight eminence corresponding to the *Peroneus tertius*. The fleshy fibres of the *Peroneus longus* are strongly marked at the upper part of the outer side of the leg, especially when the muscle is in action. It forms a bold swelling, separated by furrows from the Extensor longus digitorum in front and the Soleus behind. Below, the fleshy fibres terminate abruptly in a tendon which overlaps the more flattened form of the *Peroneus brevis*. At the External malleolus the tendon of the Peroneus brevis is more marked than that of the Peroneus longus. On the dorsum of the foot the tendons of the Extensor muscles, emerging from beneath the anterior annular ligament, spread out and can be distinguished in the following order: the most internal and largest is the Tibialis anticus, then the Extensor proprius hallucis; next comes the Extensor longus digitorum, dividing into four tendons to the four outer toes; and lastly, most externally, is the Peroneus tertius. The flattened form of the dorsum of the foot is relieved by the rounded outline of the fleshy belly of the *Extensor brevis digitorum*, which forms a soft fulness on the outer side of the tarsus in front of the external malleolus, and by the Dorsal interossei, which bulge between the metatarsal bones. At the back of the knee is the popliteal space, bounded above by the tendons of the Hamstring muscles; below, by the two heads of the Gastrocnemius. Below this space is the prominent fleshy mass of the calf of the leg, produced by the *Gastrocnemius* and *Soleus*. When these muscles are in action, as in standing on tiptoe, the borders of the Gastrocnemius are well defined, presenting two curved lines, which converge to the tendon of insertion. Of these borders, the inner is more prominent than the outer. The fleshy mass of the calf terminates somewhat abruptly below in the tendo Achillis, which stands out prominently on the lower part of the back of the leg. It presents a somewhat tapering form in the upper three-fourths of its extent, but widens out slightly below. When the muscles of the calf are in action, the lateral portions of the *Soleus* may be seen, forming curved eminences, of which the outer is the longer, on either side of the Gastrocnemius. Behind the inner border of the lower part of the shaft of the tibia, a well-marked ridge, produced by the tendon of the Tibialis posticus, is visible when this muscle is in a state of contraction.

On the sole of the foot the superficial layer of muscles influences surface form; the *Abductor minimi digiti* most markedly. This muscle forms a narrow rounded elevation along the outer border of the foot, while the *Abductor hallucis* does the same, though to a less extent, on the inner side. The *Flexor brevis digitorum*, bound down by the plantar fascia, is not very apparent; it produces a flattened form, covered by the thickened skin of the sole, which is here thrown into numerous wrinkles.

Surgical Anatomy.—The student should now consider the effects produced by the action of the various muscles in fractures of the bones of the lower extremity. The more common forms of fracture are selected for illustration and description.

FIG. 377.—Fracture of the neck of the femur within the capsular ligament.



In fracture of the *neck of the femur internal to the capsular ligament* (fig. 377), the characteristic marks are slight shortening of the limb, and eversion of the foot, neither of

which symptoms occurs, however, in some cases until some time after the injury. The eversion is caused by the weight of the limb rotating it outwards. The shortening is produced by the action of the Glutei, and by the Rectus femoris in front, and the Biceps Semitendinosus, and Semimembranosus behind.

FIG. 378.—Fracture of the femur below the trochanters.

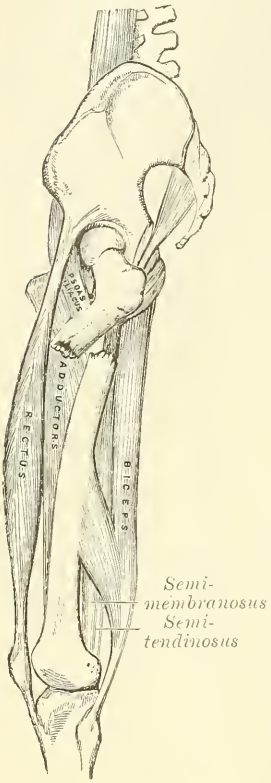


FIG. 379.—Fracture of the femur above the condyles.

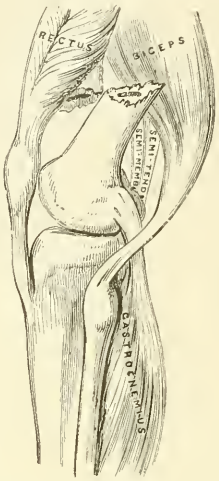

FIG. 380.—Fracture of the patella.

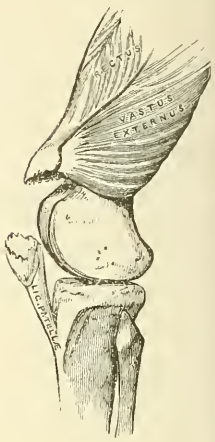
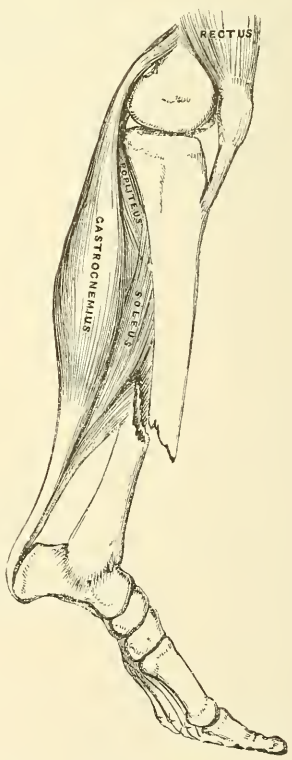


In fracture of the *femur just below the trochanters* (fig. 378), the upper fragment, the portion chiefly displaced, is tilted forwards almost at right angles with the pelvis, by the combined action of the Psoas and Iliacus; and, at the same time, everted and drawn outwards by the external rotator and Gluteimuscles, causing a marked prominence at the upper and outer side of the thigh, and much pain from the bruising and laceration of the muscles. The limb is shortened, in consequence of the lower fragment being drawn upwards by the Rectus in front, and the Biceps, Semimembranosus, and Semitendinosus behind; and is, at the same time, everted. This fracture may be reduced in two different methods: either by direct relaxation of all the opposing muscles, to effect which the limb should be put up in such a manner that the thigh is flexed on the pelvis and the leg on the thigh; or by overcoming the contraction of the muscles, by continued extension, which may be effected by means of the long splint.

FIG. 381.—Oblique fracture of the shaft of the tibia.



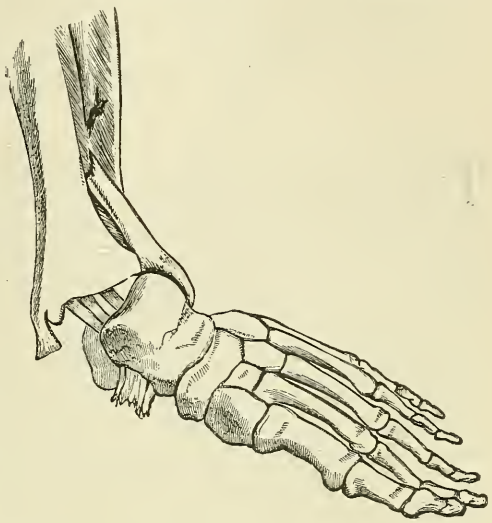
Oblique fracture of the femur *immediately above the condyles* (fig. 379) is a formidable injury, and attended with considerable displacement. On examination of the limb, the lower fragment may be felt deep in the popliteal space, being drawn backwards by the Gastrocnemius and Plantaris muscles; and upwards by the Hamstring and Rectus muscles. The pointed end of the upper fragment is drawn inwards by the Pectineus and Adductor muscles, and tilted forwards by the Psoas and Iliacus, piercing the Rectus muscle, and occasionally the integument. Relaxation of these muscles, and direct approximation of the broken fragments, are effected by placing the limb on a double inclined plane. The greatest care is requisite in keeping the pointed extremity

of the upper fragment in proper position; otherwise, after union of the fracture, the power of extension of the limb is partially destroyed, from the Rectus muscle being held down by the fractured end of the bone, and from the patella, when elevated, being drawn upwards against the projecting fragment.

In fracture of the *patella* (fig. 380) the fragments are separated by the effusion which takes place into the joint, and possibly by the action of the Quadriceps extensor; the extent of separation of the two fragments depending upon the degree of laceration of the ligamentous structures around the bone.

In oblique fracture of the *shaft of the tibia* (fig. 381), if the fracture has taken place obliquely from above, downwards and forwards, the fragments ride over one another, the lower fragments being drawn backwards and upwards by the powerful action of the muscles of the calf; the pointed extremity of the upper fragment projects forwards immediately beneath the integument, often protruding through it, and rendering the fracture a compound one. If the direction of the fracture is the reverse of that shown in the figure, the pointed extremity of the lower fragment projects forwards, riding upon the lower end of the upper one. By bending the knee, which relaxes the opposing muscles, and making extension from the ankle and counter-extension at the knee, the fragments may be brought into apposition. It is often necessary, however, in compound fracture, to remove a portion of the projecting bone with the saw before complete adaptation can be effected.

FIG. 382.—Fracture of the fibula, with dislocation of the foot outwards—'Pott's Fracture.'



Fracture of the *fibula with dislocation of the foot outwards* (fig. 382), commonly known as 'Pott's Fracture,' is one of the most frequent injuries of the ankle-joint. The fibula is fractured about three inches above the ankle: in addition to this the internal malleolus is broken off, or the deltoid ligament torn through, and the end of the tibia displaced from the corresponding surface of the astragalus. The foot is markedly everted, and the sharp edge of the root of the inner malleolus presses strongly against the skin; at the same time, the heel is drawn up by the muscles of the calf. This injury may be at once reduced by flexing the leg at right angles with the thigh, which relaxes all the opposing muscles, and by making extension from the ankle and counter-extension at the knee.

OF THE ARTERIES

THE Arteries are cylindrical tubular vessels, which serve to convey blood from both ventricles of the heart to every part of the body. These vessels were named arteries (*ἀήρ, air* ; *τηρεῖν, to contain*) from the belief entertained by the ancients that they contained air. To Galen is due the honour of refuting this opinion ; he showed that these vessels, though for the most part empty after death, contain blood in the living body.

The pulmonary artery, which arises from the right ventricle of the heart, carries venous blood directly into the lungs, whence it is returned by the pulmonary veins into the left auricle. This constitutes the lesser or pulmonic circulation. The great artery which arises from the left ventricle, the *aorta*, conveys arterial blood to the body generally ; whence it is brought back to the right side of the heart by means of the veins. This constitutes the greater or systemic circulation.

The distribution of the systemic arteries is like a highly ramified tree, the common trunk of which, formed by the aorta, commences at the left ventricle of the heart, the smallest ramifications corresponding to the circumference of the body and the contained organs. The arteries are found in nearly every part of the body, with the exception of the hairs, nails, epidermis, cartilages, and cornea ; and the larger trunks usually occupy the most protected situations, running, in the limbs, along the flexor side, where they are less exposed to injury.

There is considerable variation in the mode of division of the arteries : occasionally a short trunk subdivides into several branches at the same point, as we observe in the cœliac and thyroid axes ; or the vessel may give off several branches in succession, and still continue as the main trunk, as is seen in the arteries of the limbs ; but the usual division is dichotomous, as, for instance, the aorta dividing into the two common iliacs ; and the common carotid into the external and internal.

The branches of arteries arise at very variable angles ; some, as the superior intercostal arteries from the aorta, arise at an obtuse angle ; others, as the lumbar arteries, at a right angle ; or, as the spermatic, at an acute angle. An artery from which a branch is given off is smaller in size, but retains a uniform diameter until a second branch is derived from it. A branch of an artery is smaller than the trunk from which it arises ; but if an artery divides into two branches, the combined area of the two vessels is, in nearly every instance, somewhat greater than that of the trunk ; and the combined area of all the arterial branches greatly exceeds the area of the aorta ; so that the arteries collectively may be regarded as a cone, the apex of which corresponds to the aorta, the base to the capillary system.

The arteries, in their distribution, communicate freely with one another, forming what is called an *anastomosis* (*ἀνά, between* ; *στόμα, mouth*), or inosculation : and this communication is very free between the large as well as between the smaller branches. The anastomosis between trunks of equal size is found
