where great freedom and activity of the circulation are requisite, as in the brain; here the two vertebral arteries unite to form the basilar, and the two internal carotid arteries are connected by a short communicating trunk; it is also found in the abdomen, the intestinal arteries having very free anastomoses between their larger branches. In the limbs, the anastomoses are most frequent and of largest size around the joints; the branches of an artery above freely inosculating with branches from the vessels below. These anastomoses are of considerable interest to the surgeon, as it is by their enlargement that a *collateral circulation* is established after the application of a ligature to an artery for the cure of aneurism. The smaller branches of arteries anastomose more frequently than the larger; and between the smallest twigs these inosculations become so numerous as to constitute a close network that pervades nearly every tissue of the body.

Throughout the body generally the larger arterial branches pursue a perfectly straight course; but in certain situations they are tortuous; thus, the facial artery in its course over the face, and the arteries of the lips, are extremely tortuous in their course, to accommodate themselves to the movements of the parts. The uterine arteries are also tortuous, to accommodate themselves to the increase of size which the organ undergoes during pregnancy. Again, the internal carotid and vertebral arteries, previous to their entering the cavity of the skull, describe a series of curves, which are evidently intended to diminish the velocity of the current of blood, by increasing the extent of surface over which it moves, and adding to the amount of impediment which is produced by friction.

The arteries are dense in structure, of considerable strength, highly elastic, and, when divided, they preserve, although empty, their cylindrical form.

The minute structure of these vessels has been described in the chapter on General Anatomy.

In the description of the arteries, we shall first consider the efferent trunk of the pulmonic circulation, the pulmonary artery; and then the efferent trunk of the systemic circulation, the aorta, and its branches.

Pulmonary Artery (fig. 383)

The **pulmonary artery** conveys the venous blood from the right side of the heart to the lungs. It is a short, wide vessel, about two inches in length and 1⅕ inch (30 mm.) in diameter, arising from the left side of the base (conus arteriosus) of the right ventricle, in front of the aorta. It extends obliquely upwards and backwards, passing at first in front of and then to the left of the ascending aorta, as far as the under surface of the arch, where it divides, about on a level with the intervertebral substance between the fifth and sixth dorsal vertebræ, into two branches of nearly equal size, the *right* and *left pulmonary arteries*.

Relations.—The whole of this vessel is contained, together with the ascending aorta, in the pericardium. It is enclosed with the aorta in a single tube of the serous pericardium, which is continued upwards upon them from the base of the heart and connects them together. The fibrous layer of the pericardium becomes gradually lost upon the external coat of its two branches. In front, the pulmonary artery is separated from the anterior extremity of the second intercostal space by the pleura and left lung, in addition to the pericardium; it rests at first upon the ascending aorta, and higher up lies in front of the left auricle on a plane posterior to the ascending aorta. On each side of its origin is the appendix of the corresponding auricle and a coronary artery.

The **right pulmonary artery**, longer and larger than the left, runs horizontally outwards, behind the ascending aorta and superior vena cava, to the root of the

right lung, where it divides into two branches, of which the lower, which is the smaller, supplies the lower lobe; the upper supplies the upper lobe, giving a branch to the middle lobe.

The **left pulmonary artery**, shorter and somewhat smaller than the right, passes horizontally in front of the descending aorta and left bronchus to the root of the left lung, where it divides into two branches for the two lobes.

The root of the left pulmonary artery is connected to the under surface of the arch of the aorta by a short fibrous cord, the remains of a vessel peculiar to fœtal life, the *ductus arteriosus*.

The terminal branches of the pulmonary artery will be described with the anatomy of the lung.

The Aorta

The **aorta** (*ἀορτή, arteria magna*) is the main trunk of a series of vessels which convey the oxygenated blood to every part of the body for its nutrition. This

Fig. 383.—The arch of the aorta and its branches.

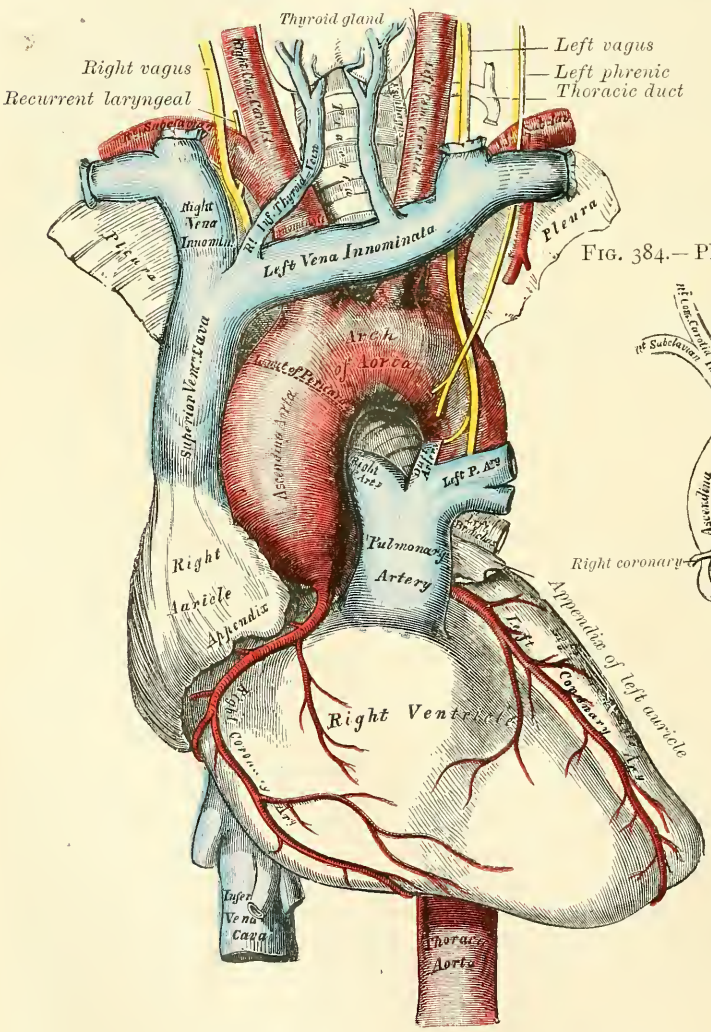

Fig. 384.— Plan of the branches.

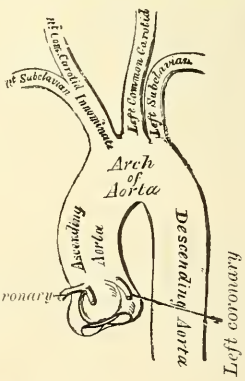

vessel commences at the upper part of the left ventricle, where it is about $1\frac{1}{8}$ inch in diameter, and after ascending for a short distance, arches backwards, and to

the left side, over the root of the left lung, then descends within the thorax on the left side of the vertebral column, passes through the aortic opening in the Diaphragm, and entering the abdominal cavity, terminates, considerably diminished in size (about $\frac{7}{10}$ of an inch in diameter), opposite the fourth lumbar vertebra, where it divides into the right and left common iliac arteries. Hence its division into the *ascending aorta*, the *arch* of the aorta, and the *descending aorta*, which last is again divided into *thoracic aorta*, and *abdominal aorta*, from the position of these parts.

Ascending Aorta

The **ascending aorta** is about two inches in length. It commences at the upper part of the base of the left ventricle, on a level with the lower border of the third costal cartilage behind the left half of the sternum; it passes obliquely upwards, forwards, and to the right in the direction of the heart's axis, as high as the upper border of the second right costal cartilage, describing a slight curve in its course, and being situated, when distended, about a quarter of an inch behind the posterior surface of the sternum. A little above its commencement it is somewhat enlarged, and presents three small dilatations called the *sinuses of the aorta* (sinuses of Valsalva), opposite to which are attached the three semilunar valves, which serve the purpose of preventing any regurgitation of blood into the cavity of the ventricle. These valves are placed one in front and two behind. A section of the aorta opposite this part has a somewhat triangular figure; but below the attachment of the valves it is circular. This portion of the aorta is contained in the cavity of the pericardium, and, together with the pulmonary artery, is invested in a tube of serous membrane, continued on to them from the surface of the heart.

Relations.—The ascending aorta is covered at its commencement by the trunk of the pulmonary artery and the right auricular appendix, and, higher up, is separated from the sternum by the pericardium, the right pleura, and anterior margin of right lung, some loose areolar tissue, and the remains of the thymus gland; *behind*, it rests upon the root of the right lung and left auricle. On the *right side*, it is in relation with the superior vena cava and right auricle; on the *left side*, with the pulmonary artery.

Branches.—The only branches of the ascending aorta are the coronary arteries. They supply the heart, and are two in number, right and left, arising

near the commencement of the aorta immediately above the free margin of the semilunar valves.

The **Right Coronary Artery**, about the size of a crow's quill, arises from the aorta immediately above the free margin of the anterior semilunar valve. It passes forwards between the pulmonary artery and the right auricular appendix, then runs obliquely to the right side, in the groove between the right auricle and ventricle, and curving around the right border of the heart, runs along its posterior surface as far as the posterior interventricular groove, where it divides into two branches, one of which continues onwards in the groove between the left auricle and ventricle, and anastomoses with the left coronary; the other descends along the posterior interventricular furrow, supplying branches to both ventricles and to the septum, and anastomosing at the apex of the heart with the descending branches of the left coronary.

This vessel sends a large branch along the thin margin of the right ventricle to the apex, and numerous small branches to the right auricle and ventricle, and the commencement of the pulmonary artery.

The **Left Coronary**, larger than the former, arises immediately above the free edge of the left anterior semilunar valve, a little higher than the right; it passes forwards between the pulmonary artery and the left auricular appendix, and divides into two branches. Of these, one passes transversely outwards in the left auriculo-ventricular groove, and winds around the left border of the heart to its posterior surface, where it anastomoses with the transverse branch of the right coronary; the other descends along the anterior interventricular groove to the apex of the heart, where it anastomoses with the descending branches of the right coronary. The left coronary supplies the left auricle and its appendix, both ventricles, and numerous small branches to the pulmonary artery, and commencement of the aorta.*

Peculiarities.—These vessels occasionally arise by a common trunk, or their number may be increased to three; the additional branch being of small size. More rarely, there are two additional branches.

Arch of the Aorta

The **arch**, or **transverse aorta**, commences at the upper border of the second chondro-sternal articulation of the right side, and passes from right to left, and from before backwards, to the left side of the lower border of the fourth dorsal vertebra behind. Its upper border is usually about an inch below the upper margin of the sternum.

Relations.—Its *anterior surface* is covered by the pleuræ and lungs and the remains of the thymus gland, and crossed towards the left side by the left pneumogastric and phrenic nerves, and superior cardiac branches of the left sympathetic, and by the left superior intercostal vein. Its *posterior surface* lies on the trachea, just above its bifurcation, on the great, or deep, cardiac plexus, the œsophagus, thoracic duct, and left recurrent laryngeal nerve. Its *upper border* is in relation with the left innominate vein; and from its upper part are given off the innominate, left common carotid, and left subclavian arteries. Its *lower border* is in relation with the bifurcation of the pulmonary artery, the remains of the ductus arteriosus, which is connected with the left division of that vessel, and the superficial cardiac plexus; the left recurrent laryngeal nerve winds round it from before backwards, whilst the left bronchus passes below it.

* According to Dr. Samuel West, there is a very free and complete anastomosis between the two coronary arteries (*Lancet*, June 2, 1883, p. 945). This, however, is not the view generally held by anatomists, for, with the exception of the anastomosis mentioned above in the auriculo-ventricular and interventricular grooves, it is believed that the two arteries only communicate by very small vessels in the substance of the heart.

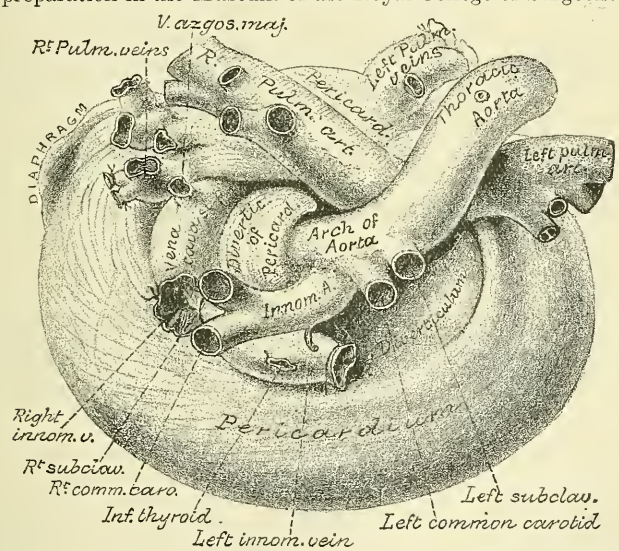
Peculiarities.—The height to which the aorta rises in the chest is usually about an inch below the upper border of the sternum; but it may ascend nearly to the top of that bone. Occasionally it is found an inch and a half, more rarely two or even three inches below this point.

FIG. 385.—Relation of great vessels at base of heart, seen from above. (From a preparation in the Museum of the Royal College of Surgeons.)



In Direction.—Sometimes the aorta arches over the root of the right instead of the left lung, as in birds, and passes down on the right side of the spine. In such cases all the viscera of the thoracic and abdominal cavities are transposed. Less frequently, the aorta, after arching over the root of the right lung, is directed to its usual position on the left side of the spine, this peculiarity not being accompanied by any transposition of the viscera.

In Conformation.—The aorta occasionally divides, as in some quadrupeds, into an ascending and a descending trunk, the former of which is directed vertically upwards, and subdivides into three branches, to supply the head and upper extremities. Sometimes the aorta subdivides soon after its origin into two branches, which soon reunite. In one of these cases the œsophagus and trachea were found to pass through the interval left by their division; this is the normal condition of the vessel in the reptilia.

Surgical Anatomy.—Of all the vessels of the arterial system, the aorta, and more especially its arch, is most frequently the seat of disease; hence it is important to consider some of the consequences that may ensue from aneurism of this part.

It will be remembered that the ascending aorta is contained in the pericardium, just behind the sternum, being crossed at its commencement by the pulmonary artery and

right auricular appendix, and having the root of the right lung behind, the vena cava on the right side, and the pulmonary artery and left auricle on the left side.

Aneurism of the ascending aorta, in the situation of the aortic sinuses, in the great majority of cases, affects the anterior sinus; this is mainly owing to the fact that the regurgitation of blood upon the sinuses takes place chiefly on the anterior aspect of the vessel. As the aneurismal sac enlarges, it may compress any or all of the structures in immediate proximity with it, but chiefly projects towards the right anterior side; and, consequently, interferes mainly with those structures that have a corresponding relation with the vessel. In the majority of cases, it bursts into the cavity of the pericardium, the patient suddenly drops down dead, and, upon a post-mortem examination, the pericardial sac is found full of blood; or it may compress the right auricle, or the pulmonary artery, and adjoining part of the right ventricle, and open into one or the other of these parts, or it may press upon the superior vena cava.

Aneurism of the ascending aorta, originating above the sinuses, most frequently implicates the right anterior wall of the vessel; this is probably mainly owing to the blood being impelled against this part. The direction of the aneurism is also chiefly towards the right of the median line. If it attains a large size and projects forwards, it may absorb the sternum and the cartilages of the ribs, usually on the right side, and appear as a pulsating tumour on the front of the chest, just below the manubrium; or it may burst into the pericardium, or may compress, or open into the right lung, the trachea, bronchi, or œsophagus.

Regarding the transverse aorta, the student is reminded that the vessel lies on the trachea, the œsophagus, and thoracic duct; that the recurrent laryngeal nerve winds around it; and that from its upper part are given off three large trunks, which supply the head, neck, and upper extremities. Now, an aneurismal tumour taking origin from the posterior part of the vessel, its most usual site, may press upon the trachea, impede the breathing, or produce cough, hæmoptysis, or stridulous breathing, or it may ultimately burst into that tube, producing fatal hæmorrhage. Again, its pressure on the laryngeal nerves may give rise to symptoms which so accurately resemble those of laryngitis, that the operation of tracheotomy has in some cases been resorted to, from the supposition that disease existed in the larynx; or it may press upon the thoracic duct and destroy life by inanition; or it may involve the œsophagus, producing dysphagia; or may burst into the œsophagus, when fatal hæmorrhage will occur. Again, the innominate artery, or the subclavian, or left carotid, may be so obstructed by clots as to produce a weakness, or even a disappearance, of the pulse in one or the other wrist, or in the left temporal artery; or the tumour may present itself at or above the manubrium, generally either in the median line, or to the right of the sternum, and may simulate an aneurism of one of the arteries of the neck.

Branches (figs. 383, 384).—The branches given off from the arch of the aorta are three in number: the innominate artery, the left common carotid, and the left subclavian.

Peculiarities. Position of the Branches.—The branches, instead of arising from the highest part of the arch (their usual position), may be moved more to the right, arising from the commencement of the transverse or upper part of the ascending portion; or the distance from one another at their origin may be increased or diminished, the most frequent change in this respect being the approximation of the left carotid towards the innominate artery.

The Number of the primary branches may be reduced to a single vessel, or more commonly two: the left carotid arising from the innominate artery; or (more rarely), the carotid and subclavian arteries of the left side arising from a left innominate artery. But the number may be increased to four, from the right carotid and subclavian arteries arising directly from the aorta, the innominate being absent. In most of these latter cases the right subclavian has been found to arise from the left end of the arch; in other cases it was the second or third branch given off instead of the first. Another common form in which there are four primary branches is that in which the left vertebral artery arises from the arch of the aorta between the left carotid and subclavian arteries. Lastly, the number of trunks from the arch may be increased to five or six; in these instances, the external and internal carotids arise separately from the arch, the common carotid being absent on one or both sides. In some cases, where six branches have been found, it has been due to a separate origin of the vertebral on both sides.

Number usual, Arrangement different.—When the aorta arches over to the right side, the three branches have an arrangement the reverse of what is usual, the innominate supplying the left side, and the carotid and subclavian (which arise separately) the right side. In other cases, where the aorta takes its usual course, the two carotids may be joined in a common trunk, and the subclavians arise separately from the arch, the right subclavian generally arising from the left end of the arch.*

* The anomalies of the aorta and its branches are minutely described by Krause in Henle's *Anatomy* (Brunswick, 1868), vol. iii. p. 203 *et seq.*

Innominate Artery

The **innominate artery** (**brachio-cephalic**) is the largest branch given off from the arch of the aorta. It arises, on a level with the upper border of the second right costal cartilage, from the commencement of the arch of the aorta in front of the left carotid, and, ascending obliquely to the upper border of the right sterno-clavicular articulation, divides into the right common carotid and right subclavian arteries. This vessel varies from an inch and a half to two inches in length.

Relations.—*In front*, it is separated from the first bone of the sternum by the Sterno-hyoid and Sterno-thyroid muscles, the remains of the thymus gland, the left innominate and right inferior thyroid veins which cross its root, and sometimes the inferior cervical cardiac branch of the right pneumogastric. *Behind*, it lies upon the trachea, which it crosses obliquely. On the *right side* is the right innominate vein, right pneumogastric nerve, and the pleura; and on the *left side*, the remains of the thymus gland, the origin of the left carotid artery, the left inferior thyroid vein, and the trachea.

Branches.—The innominate usually gives off no branches; but occasionally a small branch, the *thyroidea ima*, is given off from this vessel. It also sometimes gives off a *thymic* or *bronchial branch*. The **Thyroidea ima** ascends in front of the trachea to the lower part of the thyroid body, which it supplies. It varies greatly in size, and appears to compensate for deficiency or absence of one of the other thyroid vessels. It occasionally is found to arise from the right common carotid or from the aorta, the subclavian or internal mammary artery.

Peculiarities in point of Division.—When the bifurcation of the innominate artery varies from the point above mentioned, it sometimes ascends a considerable distance above the sternal end of the clavicle; less frequently it divides below it. In the former class of cases, its length may exceed two inches; and, in the latter, be reduced to an inch or less. These are points of considerable interest for the surgeon to remember in connection with the operation of tying this vessel.

Position.—When the aorta arches over to the right side, the innominate is directed to the left side of the neck instead of the right.

Collateral Circulation.—Allan Burns demonstrated, on the dead subject, the possibility of the establishment of the collateral circulation after ligature of the innominate artery, by tying and dividing that artery, after which, he says, 'Even coarse injection, impelled into the aorta, passing freely by the anastomosing branches into the arteries of the right arm, filling them and all the vessels of the head completely.' (*Surgical Anatomy of the Head and Neck*, p. 62.) The branches by which this circulation would be carried on are very numerous; thus, all the communications across the middle line between the branches of the carotid arteries of opposite sides would be available for the supply of blood to the right side of the head and neck; while the anastomosis between the superior intercostal of the subclavian and the first aortic intercostal (see *infra* on the collateral circulation after obliteration of the thoracic aorta) would bring the blood, by a free and direct

course, into the right subclavian: the numerous connections, also, between the intercostal arteries and the branches of the axillary and internal mammary arteries would, doubtless, assist in the supply of blood to the right arm, while the epigastric, from the external iliac, would, by means of its anastomosis with the internal mammary, compensate for any deficiency in the vascularity of the wall of the chest.

Surgical Anatomy.—Although the operation of tying the innominate artery has been performed by several surgeons, for aneurism of the right subclavian extending inwards as far as the Scalenus, in only two instances has the patient survived.* Mott's patient, however, on whom the operation was first performed, lived nearly four weeks, and Graefe's more than two months. The main obstacles to the operation are, as the student will perceive from his dissection of this vessel, the deep situation of the artery behind and beneath the sternum, and the number of important structures which surround it in every part.

In order to apply a ligature to this vessel, the patient is to be placed upon his back with the thorax slightly raised, the head bent a little backwards, and the shoulder on the side of the aneurism strongly depressed, so as to draw out the artery from behind the sternum into the neck. An incision three or more inches long is then made along the anterior border of the Sterno-mastoid muscle, terminating at the sternal end of the clavicle. From this point, a second incision is carried about the same length along the upper border of the clavicle. The skin is then dissected back, and the Platysma divided on a director: the sternal end of the Sterno-mastoid is now brought into view, and a director being passed beneath it, and close to its under surface, so as to avoid any small vessels, it is to be divided; in like manner the clavicular origin is to be divided throughout the whole or greater part of its attachment. By pressing aside any loose cellular tissue or vessels that may now appear, the Sterno-hyoid and Sterno-thyroid muscles will be exposed, and must be divided, a director being previously passed beneath them. The inferior thyroid veins may come into view, and must be carefully drawn either upwards or downwards, by means of a blunt hook, or tied with double ligatures and divided. After tearing through a strong fibro-cellular lamina, the right carotid is brought into view, and being traced downwards, the arteria innominata is arrived at. The left innominate vein should now be depressed: the right innominate vein, the internal jugular vein, and the pneumogastric nerve drawn to the right side; and a curved aneurism needle may then be passed around the vessel, close to its surface, and in a direction from below upwards and inwards; care being taken to avoid the right pleural sac, the trachea, and cardiac nerves. The ligature should be applied to the artery as high as possible, in order to allow room between it and the aorta for the formation of the coagulum. The importance of avoiding the thyroid plexus of veins during the primary steps of the operation, and the pleural sac whilst including the vessel in the ligature, should be most carefully borne in mind. The most frequent cause of death after operation is secondary hæmorrhage, which has occurred in almost every case. Other causes are pleurisy, pericarditis, and suppurative cellulitis.

ARTERIES OF THE HEAD AND NECK

The artery which supplies the head and neck is the Common Carotid, which ascends in the neck and divides into two branches: the External Carotid, which supplies the superficial parts of the head and face and the greater part of the neck, and the Internal Carotid, which supplies to a great extent the part within the cranial cavity.

Common Carotid Arteries

The **common carotid arteries**, although occupying a nearly similar position in the neck, differ in position, and, consequently, in their relations at their origin. The right carotid arises from the innominate artery, behind the right sterno-clavicular articulation; the left from the highest part of the arch of the aorta. The left carotid is, consequently, longer, and at its origin is contained within the thorax. The course and relation of that portion of the left carotid which intervenes between the arch of the aorta and the left sterno-clavicular articulation, will first be described (see fig. 383).

The *left carotid within the thorax* ascends obliquely outwards from the arch of the aorta to the root of the neck. *In front*, it is separated from the first piece of

* In one of these, the operation was performed by Dr. Smyth of New Orleans. See the New Sydenham Society's *Biennial Retrospect* for 1865-6, p. 346. In the other, the operation was performed by Dr. Mitchell Banks, in the Liverpool Infirmary. The case is recorded by Mr. Jacobson in *Operations of Surgery*, p. 536.

the sternum by the Sterno-hyoid and Sterno-thyroid muscles, the left innominate vein, and the remains of the thymus gland; *behind*, it lies on the trachea, œsophagus, and thoracic duct. *Internally*, it is in relation with the innominate artery, inferior thyroid veins and remains of Thymus gland; *externally*, with the left pneumogastric nerve, left pleura, and lung. The left subclavian artery is posterior and external to it.

In the neck, the two common carotids resemble each other so closely, that one description will apply to both. Each vessel passes obliquely upwards, from behind the sterno-clavicular articulation, to a level with the upper border of the thyroid cartilage, opposite the fourth cervical vertebra, where it divides into the external and internal carotid; these names being derived from the distribution of the arteries to the external parts of the head and face, and to the internal parts of the cranium and orbit respectively.

At the lower part of the neck the two common carotid arteries are separated from each other by a very small interval, which contains the trachea; but at the upper part, the thyroid body, the larynx and pharynx project forwards between the two vessels, and give the appearance of their being placed further back in that situation. The common carotid artery is contained in a sheath, derived from the deep cervical fascia, which also encloses the internal jugular vein and pneumogastric nerve, the vein lying on the outer side of the artery, and the nerve between the artery and vein, on a plane posterior to both. On opening the sheath, these three structures are seen to be separated from one another, each being enclosed in a separate fibrous investment.

Relations.—At the lower part of the neck the common carotid artery is very deeply seated, being covered by the integument, superficial fascia, Platysma, and deep cervical fascia, the Sterno-mastoid, Sterno-hyoid, and Sterno-thyroid muscles, and by the Omo-hyoid, opposite the cricoid cartilage; but in the upper part of its course, near its termination, it is more superficial, being covered merely by the integument, the superficial fascia, Platysma, deep cervical fascia, and inner margin of the Sterno-mastoid, and is contained in a triangular space, bounded behind by the Sterno-mastoid, above by the posterior belly of the Digastric, and below by the anterior belly of the Omo-hyoid. This part of the artery is crossed obliquely, from within outwards, by the sterno-mastoid artery; it is crossed also by one, or sometimes two superior thyroid veins, which terminate in the internal jugular; and descending on its sheath in front is seen the descendens hypoglossi nerve, this filament being joined by one or two branches from the cervical nerves, which cross the vessel from without inwards. Sometimes the descendens hypoglossi is

contained within the sheath. The middle thyroid vein crosses the artery about its middle, and the anterior jugular vein below. *Behind*, the artery lies in front of the cervical portion of the spine, resting first on the Longus colli muscle, then on the Rectus capitis anticus major, from which it is separated by the sympathetic nerve. The recurrent laryngeal nerve and inferior thyroid artery cross behind the vessel at its lower part. *Internally*, it is in relation with the trachea and thyroid gland, the inferior thyroid artery and recurrent laryngeal nerve being interposed:

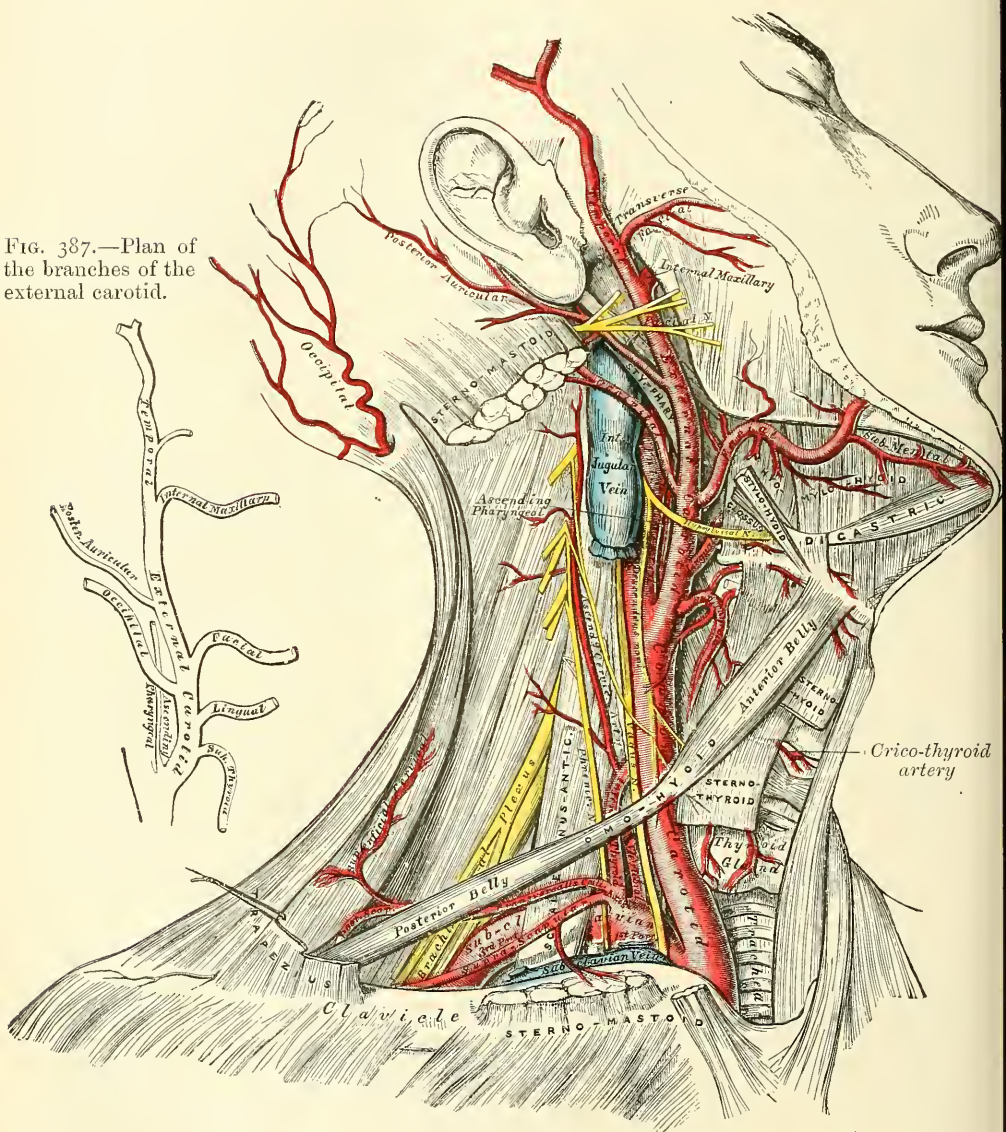

FIG. 387.—Plan of the branches of the external carotid.

higher up, with the larynx and pharynx. On its *outer side* are placed the internal jugular vein and pneumogastric nerve.

At the lower part of the neck, the internal jugular vein on the right side diverges from the artery, but on the left side it approaches it, and often crosses its lower part. This is an important fact to bear in mind during the performance of any operation on the lower part of the left common carotid artery.

Peculiarities as to Origin.—The *right common carotid* may arise above or below its usual point, the upper border of the sterno-clavicular articulation. This variation occurs in one out of about eight cases and a half, and the origin is more frequently above than below the usual point: or the artery may arise as a separate branch from the arch of the aorta, or in conjunction with the left carotid. The *left common carotid* varies more frequently in its origin than the right. In the majority of abnormal cases it arises with the innominate artery, or, if the innominate artery is absent, the two carotids arise usually by a single trunk. The left carotid is occasionally the first branch given off from the arch of the aorta. It rarely joins with the left subclavian, except in cases of transposition of the arch.

Peculiarities as to point of Division.—The most important peculiarities of this vessel, in a surgical point of view, relate to its place of division in the neck. In the majority of abnormal cases, this occurs higher than usual, the artery dividing into two branches opposite the hyoid bone, or even higher; more rarely, it occurs below its usual place opposite the middle of the larynx, or the lower border of the cricoid cartilage; and one case is related by Morgagni, where the common carotid, only an inch and a half in length, divided at the root of the neck. Very rarely, the common carotid ascends in the neck without any subdivision, the internal carotid being wanting; and in a few cases the common carotid has been found to be absent, the external and internal carotids arising directly from the arch of the aorta. This peculiarity existed on both sides in some instances, on one side in others.

Occasional Branches.—The common carotid usually gives off no branch previous to its bifurcation; but it occasionally gives origin to the superior thyroid, or its laryngeal branch, the inferior thyroid, or, more rarely, the vertebral artery.

Surface Marking.—The carotid arteries are overlapped throughout their entire extent by the anterior border of the Sterno-mastoid muscle, but their course does not correspond to the border of the muscle, which passes in a somewhat curved direction from the mastoid process to the sterno-clavicular joint. The course of the artery is indicated more exactly by a line drawn from the sternal end of the clavicle below, to a point midway between the angle of the jaw and the mastoid process above. That portion of the line below the level of the upper border of the thyroid cartilage would represent the course of the vessel.

Surgical Anatomy.—The operation of tying the common carotid artery may be necessary in a case of wound of that vessel or its branches, in aneurism, or in a case of pulsating tumour of the orbit or skull. If the wound involves the trunk of the common carotid, it will be necessary to tie the artery above and below the wounded part. But in cases of aneurism, or where one of the branches of the common carotid is wounded in an inaccessible situation, it may be judged necessary to tie the trunk. In such cases, the whole of the artery is accessible, and any part may be tied, except close to either end. When the case is such as to allow of a choice being made, the lower part of the carotid should never be selected as the spot upon which to place a ligature, for not only is the artery in this situation placed very deeply in the neck, but it is covered by three layers of muscles, and, on the left side, the internal jugular vein, in the great majority of cases, passes obliquely in front of it. Neither should the upper end be selected, for here the superior thyroid vein and its tributaries would give rise to very considerable difficulty in the application of a ligature. The point most favourable for the operation is that part of the vessel which is at the level of the cricoid cartilage. It occasionally happens that the carotid artery bifurcates below its usual position: if the artery be exposed at its point of bifurcation,

both divisions of the vessel should be tied near their origin, in preference to tying the trunk of the artery near its termination; and if, in consequence of the entire absence of the common carotid, or from its early division, two arteries, the external and internal carotids, are met with, the ligature should be placed on that vessel which is found on compression to be connected with the disease.

In this operation, the direction of the vessel and the inner margin of the Sterno-mastoid are the chief guides to its performance. The patient should be placed on his back with the head thrown back and turned slightly to the opposite side: an incision is to be made, three inches long, in the direction of the anterior border of the Sterno-mastoid, so that the centre corresponds to the level of the cricoid cartilage: after dividing the integument, superficial fascia, and Platysma, the deep fascia must be cut through on a director, so as to avoid wounding numerous small veins that are usually found beneath. The head may now be brought forwards so as to relax the parts somewhat, and the margins of the wound held asunder by retractors. The descendens hypoglossi nerve may now be exposed, and must be avoided, and the sheath of the vessel having been raised by forceps, is to be opened to a small extent over the artery at its inner side. The internal jugular vein may present itself alternately distended and relaxed; this should be compressed, both above and below, and drawn outwards, in order to facilitate the operation. The aneurism needle is passed from the outside, care being taken to keep the needle in close contact with the artery, and thus avoid the risk of injuring the internal jugular vein, or including the vagus nerve. Before the ligature is tied, it should be ascertained that nothing but the artery is included in it.

Ligature of the Common Carotid at the Lower Part of the Neck.—This operation is sometimes required in cases of aneurism of the upper part of the carotid, especially if the sac is of large size. It is best performed by dividing the sternal origin of the Sterno-mastoid muscle, but may be done in some cases, if the aneurism is not of very large size, by an incision along the anterior border of the Sterno-mastoid, extending down to the sterno-clavicular articulation, and by then retracting the muscle. The easiest and best plan, however, is to make an incision two or three inches long down the lower part of the anterior border of the Sterno-mastoid muscle to the sterno-clavicular joint, and a second incision, starting from the termination of the first, along the upper border of the clavicle for about two inches. This incision is made through the superficial and deep fascia, and the sternal origin of the muscle exposed. This is to be divided on a director and turned up, with the superficial structures, as a triangular flap. Some loose connective tissue is to be divided or torn through, and the outer border of the Sterno-hyoid muscle exposed. In doing this, care must be taken not to wound the anterior jugular vein, which crosses the muscle to reach the external jugular or subclavian vein. The Sterno-hyoid, and with it the Sterno-thyroid, are to be drawn inwards by means of a retractor, and the sheath of the vessel is exposed. This must be opened with great care on its inner or tracheal side, so as to avoid the internal jugular vein. This is especially necessary on the left side, where the artery is commonly overlapped by the vein. On the right side there is usually an interval between the artery and the vein, and not the same risk of wounding the latter.

The common carotid artery, being a long vessel without any branches, is particularly suitable for the performance of Brasdor's operation for the cure of an aneurism of the lower part of the vessel. Brasdor's procedure consists in ligaturing the artery on the distal side of the aneurism, and in the case of the common carotid there are no branches given off from the vessel between the aneurism and the site of the ligature, hence the flow of blood through the sac of the aneurism is diminished and cure takes place in the usual way, by the deposit of laminated fibrin.

Collateral Circulation.—After ligature of the common carotid, the collateral circulation can be perfectly established, by the free communication which exists between the carotid arteries of opposite sides, both without and within the cranium, and by enlargement of the branches of the subclavian artery on the side corresponding to that on which the vessel has been tied—the chief communication outside the skull taking place between the superior and inferior thyroid arteries, and the profunda cervicis and arteria princeps cervicis of the occipital; the vertebral taking the place of the internal carotid within the cranium.

Sir A. Cooper had an opportunity of dissecting, thirteen years after the operation, the case in which he first successfully tied the common carotid (the second case in which he performed the operation).* The injection, however, does not seem to have been a successful one. It showed merely that the arteries at the base of the brain (circle of Willis) were much enlarged on the side of the tied artery, and that the anastomosis between the branches of the external carotid on the affected side and those of the same artery on the sound side was free, so that the external carotid was pervious throughout.

* *Guy's Hospital Reports*, i. 56.

External Carotid Artery

The **external carotid artery** (fig. 386) commences opposite the upper border of the thyroid cartilage, and, taking a slightly curved course, passes upwards and forwards, and then inclines backwards to the space between the neck of the condyle of the lower jaw and the external meatus, where it divides into the temporal and internal maxillary arteries. It rapidly diminishes in size in its course up the neck, owing to the number and large size of the branches given off from it. In the child, it is somewhat smaller than the internal carotid; but in the adult, the two vessels are of nearly equal size. At its commencement, this artery is more superficial, and placed nearer the middle line than the internal carotid, and is contained in the triangular space bounded by the Sterno-mastoid behind, the Omo-hyoid below, and the posterior belly of the Digastric and Stylo-hyoid above.

Relations.—It is covered by the skin, superficial fascia, Platysma, deep fascia, and anterior margin of the Sterno-mastoid, crossed by the hypoglossal nerve, and by the lingual and facial veins; it is afterwards crossed by the Digastric and Stylo-hyoid muscles, and higher up passes deeply into the substance of the parotid gland, where it lies beneath the facial nerve and the junction of the temporal and internal maxillary veins. *Internally* is the hyoid bone, wall of the pharynx, the superior laryngeal nerve, and the ramus of the jaw, from which it is separated by a portion of the parotid gland. *Externally*, in the lower part of its course, is the internal carotid artery. *Behind* it, near its origin, is the superior laryngeal nerve; and higher up, it is separated from the internal carotid by the Stylo-glossus and Stylo-pharyngeus muscles, the glosso-pharyngeal nerve, and part of the parotid gland.

Plan of the Relations of the External Carotid

In front.

Skin, superficial fascia.
Platysma and deep fascia.
Anterior border of Sterno-mastoid.
Hypoglossal nerve.

Internal carotid artery.

Behind.

Superior laryngeal nerve.
Stylo-glossus.
Stylo-pharyngeus.
Glosso-pharyngeal nerve.
Parotid gland.

Surface Marking.—The position of the external carotid artery may be marked out with sufficient accuracy by a line drawn from the front of the meatus of the external ear to the side of the cricoid cartilage, slightly arching the line forwards.

Surgical Anatomy.—The application of a ligature to the external carotid may be required in cases of wounds of this vessel, or of its branches when these cannot be tied, and in some cases of pulsating tumours of the scalp or face. The operation has not received the attention which it deserves, owing to the fear which surgeons have entertained of secondary hæmorrhage, on account of the number of branches given off from the vessel. This fear, however, has been shown by Mr. Cripps not to be well founded.* To tie this

* *Med.-Chir. Trans.* lxi. 229.

vessel near its origin, below the point where it is crossed by the Digastric, an incision about three inches in length should be made along the margin of the Sterno-mastoid, from the angle of the jaw to the upper border of the thyroid cartilage. The ligature should be applied between the lingual and superior thyroid branches. To tie the vessel above the Digastric, between it and the parotid gland, an incision should be made, from the lobe of the ear to the great cornu of the os hyoides dividing successively the skin, Platysma, and fascia. By drawing the Sterno-mastoid outwards, and the posterior belly of the Digastric and Stylo-hyoid muscles downwards, and separating them from the parotid gland, the vessel will be exposed, and a ligature may be applied to it. The circulation is at once re-established by the free communication between most of the large branches of the artery (facial, lingual, superior thyroid, occipital) and the corresponding arteries of the opposite side, and by the anastomosis of its branches with those of the internal carotid, and of the occipital with branches of the subclavian, etc.

Branches.—The external carotid artery gives off eight branches, which, for convenience of description, may be divided into four sets. (See fig. 387, Plan of the Branches.)

Anterior.	*Posterior.*	*Ascending.*	*Terminal.*
Superior Thyroid.	Occipital.	Ascending Pharyngeal.	Superficial Temporal.
Lingual.	Posterior Auricular.		Internal Maxillary.
Facial.			

The student is here reminded that many variations are met with in the number, origin, and course of these branches in different subjects; but the above arrangement is that which is found in the great majority of cases.

The **Superior Thyroid Artery** (figs. 386 and 391) is the first branch given off from the external carotid, being derived from that vessel just below the great cornu of the hyoid bone. At its commencement, it is quite superficial, being covered by the integument, fascia, and Platysma, and is contained in the triangular space bounded by the Sterno-mastoid, Digastric, and Omo-hyoid muscles. After running upwards and inwards for a short distance, it curves downwards and forwards, in an arched and tortuous manner, to the upper part of the thyroid gland, passing beneath the Omo-hyoid, Sterno-hyoid, and Sterno-thyroid muscles and supplying them. It distributes numerous branches to the upper part of the gland, anastomosing with its fellow of the opposite side, and with the inferior thyroid arteries. The branches supplying the gland are generally three in number: one, the largest, supplies principally the anterior surface of the gland; it courses along the inner border of the lobe as far as the upper border of the isthmus, and then passes in the substance of the isthmus to the middle line of the neck, where it anastomoses with the corresponding artery of the opposite side: a second branch courses along the external border of the lobe and supplies this portion of the gland, and the third passes to the posterior surface, the upper part of which it supplies. Besides the arteries distributed to the muscles by which it is covered and the substance of the gland, the branches of the superior thyroid are the following:—

Hyoid.	Superior Laryngeal.
Superficial descending branch (Sterno-mastoid).	Crico-thyroid.

The **hyoid (infra-hyoid)** is a small branch which runs along the lower border of the os hyoides beneath the Thyro-hyoid muscle; after supplying the muscles connected to that bone, it forms an arch, by anastomosing with the vessels of the opposite side.

The **superficial descending branch** runs downwards and outwards across the sheath of the common carotid artery, and supplies the Sterno-mastoid and neighbouring muscles and integument. There is also often a distinct branch from the external carotid distributed to the Sterno-mastoid muscle.

The **superior laryngeal**, larger than either of the preceding, accompanies the superior laryngeal nerve, beneath the Thyro-hyoid muscle; it pierces the thyro-hyoid membrane, and supplies the muscles, mucous membrane, and glands of the larynx, anastomosing with the branch from the opposite side.

The **crico-thyroid** is a small branch which runs transversely across the crico-thyroid membrane, communicating with the artery of the opposite side.

Surgical Anatomy.—The superior thyroid, or some of its branches, is often divided in cases of cut throat, giving rise to considerable hæmorrhage. In such cases, the artery should be secured, the wound being enlarged for that purpose, if necessary. The operation may be easily performed, the position of the artery being very superficial, and the only structures of importance covering it being a few small veins. The operation of tying the superior thyroid artery, in bronchocele, has been performed in numerous instances with partial or temporary success. When, however, the collateral circulation between this vessel and the artery of the opposite side, and the inferior thyroid, is completely re-established, the tumour usually regains its former size.

The position of the superficial descending branch is of importance in connection with the operation of ligature of the common carotid artery. It crosses and lies on the sheath of this vessel and may chance to be wounded in opening the sheath. The position of the crico-thyroid branch should be remembered, as it may prove the source of troublesome hæmorrhage during the operation of laryngotomy.

The **Lingual Artery** (fig. 391) arises from the external carotid between the superior thyroid and facial; it first runs obliquely upwards and inwards to the great cornu of the hyoid bone; it then curves downwards and forwards, forming a loop which is crossed by the hypoglossal nerve, and passing beneath the Digastric and Stylo-hyoid muscles, it runs horizontally forwards, beneath the Hyo-glossus, and finally, ascending perpendicularly to the tongue, turns forwards on its under surface as far as the tip, under the name of the *ranine artery*.

Relations.—Its first, or oblique, portion is superficial, being contained in the same triangular space as the superior thyroid artery, resting upon the Middle constrictor of the pharynx, and covered by the Platysma, and fascia of the neck. Its second, or curved, portion also lies upon the Middle constrictor, being covered at first by the tendon of the Digastric and the Stylo-hyoid muscle, and afterwards by the Hyo-glossus, the latter muscle separating it from the hypoglossal nerve. Its third, or horizontal, portion lies between the Hyo-glossus and Genio-hyo-glossus muscles. The fourth, or terminal, part, under the name of the *ranine*, runs along the under surface of the tongue to its tip: here it is very superficial, being covered only by the mucous membrane, and rests on the Lingualis, on the outer side of the Genio-hyo-glossus. The hypoglossal nerve crosses the lingual artery, and then becomes separated from it, in the second part of its course, by the Hyo-glossus muscle.

The branches of the lingual artery are, the

Hyoid.	Sublingual.
Dorsalis Linguæ.	Ranine.

The **hyoid branch** (**supra-hyoid**) runs along the upper border of the hyoid bone, supplying the muscles attached to it and anastomosing with its fellow of the opposite side.

The **dorsalis linguæ** (fig. 391) arises from the lingual artery beneath the Hyo-glossus muscle (which, in the figure, has been partly cut away, to show the vessel); it ascends to the dorsum of the tongue, and supplies the mucous membrane, the tonsil, soft palate, and epiglottis; anastomosing with its fellow from the opposite side.

The **sublingual**, which may be described as a branch of bifurcation of the lingual artery, arises at the anterior margin of the Hyo-glossus muscle, and runs forward between the Genio-hyo-glossus and the sublingual gland. It supplies the substance of the gland, giving branches to the Mylo-hyoid and neighbouring muscles, the mucous membrane of the mouth and gums. One branch runs behind the alveolar process of the lower jaw in the substance of the gum to anastomose with a similar artery from the other side.

The **ranine** may be regarded as the other branch of bifurcation, or, as is more usual, as the continuation of the lingual artery; it runs along the under surface of the tongue, resting on the Inferior lingualis, and covered by the mucous

membrane of the mouth; it lies on the outer side of the Genio-hyo-glossus, accompanied by the lingual nerve. On arriving at the tip of the tongue, it has been said to anastomose with the artery of the opposite side; but this is denied by Hyrtl. These vessels in the mouth are placed one on each side of the frænum.

Surgical Anatomy.—The lingual artery may be divided near its origin in cases of cut throat, a complication that not unfrequently happens in this class of wounds; or severe hæmorrhage which cannot be restrained by ordinary means, may ensue from a wound, or deep ulcer, of the tongue. In the former case, the primary wound may be enlarged if necessary, and the bleeding vessel secured. In the latter case, it has been suggested that the lingual artery should be tied near its origin. Ligature of the lingual artery is also occasionally practised, as a palliative measure, in cases of cancer of the tongue, in order to check the progress of the disease by starving the growth, and it is sometimes tied, as a preliminary measure to removal of the tongue. The operation is a difficult one, on account of the depth of the artery, the number of important parts by which it is surrounded, the loose and yielding nature of the parts upon which it is supported, and its occasional irregularity of origin. An incision is to be made in a curved direction from a finger's breadth external to the symphysis of the jaw downwards to the cornu of the hyoid bone, and then upwards to near the angle of the jaw. Care must be taken not to carry this incision too far backwards, for fear of endangering the facial vein. In the first incision the skin, superficial fascia, and Platysma will be divided, and the deep fascia exposed. This is then to be incised and the submaxillary gland exposed and pulled upwards by retractors. A triangular space is now exposed, bounded internally by the posterior border of the Mylo-hyoid muscle; below and externally, by the tendon of the Digastric; and above, by the hypoglossal nerve. The floor of the space is formed by the Hyo-glossus muscle, beneath which the artery lies. The fibres of this muscle are now to be cut through horizontally, and the vessel exposed, care being taken, while near the vessel, not to open the pharynx.

Troublesome hæmorrhage may occur in the division of the frænum in children, if the ranine artery, which lies on each side of it, is wounded. The student should remember that the operation is always to be performed with a pair of blunt-pointed scissors, and the mucous membrane only is to be divided by a very superficial cut, which cannot endanger any vessel. The scissors, also, should be directed away from the tongue. Any further liberation of the tongue which may be necessary can be effected by tearing.

The **Facial Artery** (fig. 388) arises a little above the lingual, and passes obliquely upwards, beneath the Digastric and Stylo-hyoid muscles; it then runs forwards under cover of the body of the lower jaw, lodged in a groove on the posterior surface of the submaxillary gland; this may be called the cervical part of the artery. It then curves upwards over the body of the jaw at the anterior inferior angle of the Masseter muscle; passes forwards and upwards across the cheek to the angle of the mouth, then upwards along the side of the nose, and terminates at the inner canthus of the eye, under the name of the *angular artery*. This vessel, both in the neck and on the face, is remarkably tortuous: in the former situation, to accommodate itself to the movements of the pharynx in deglutition; and in the latter, to the movements of the jaw, and the lips and cheeks.

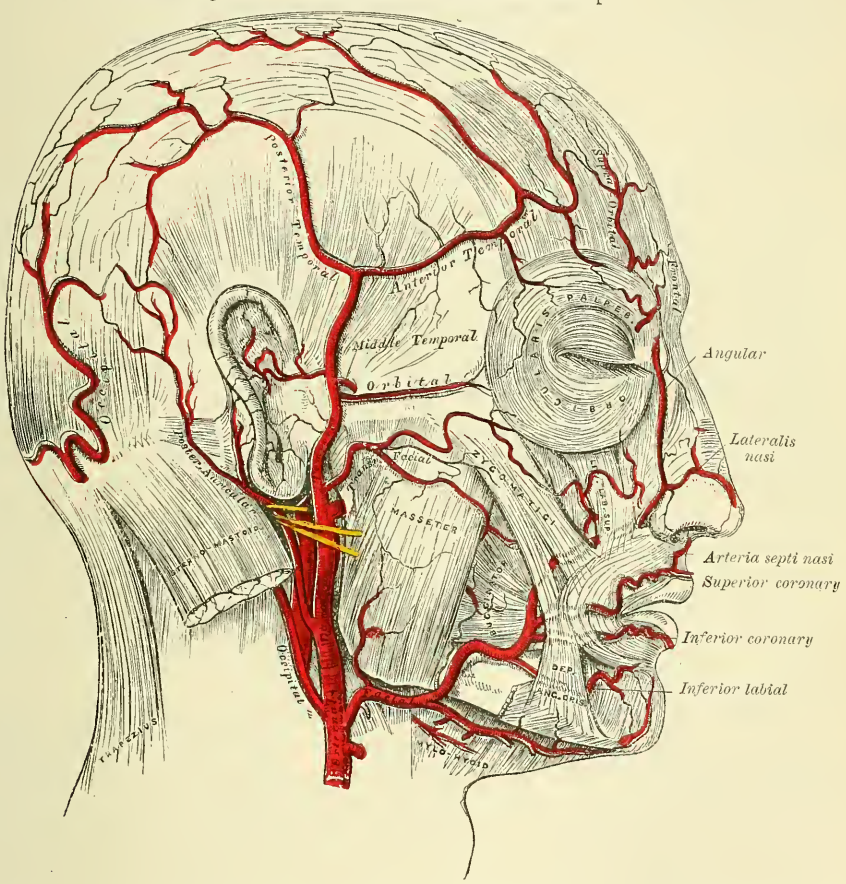
Relations—*In the neck*, its origin is superficial, being covered by the integument, Platysma, and fascia; it then passes beneath the Digastric and Stylo-hyoid muscles, and the submaxillary gland. *On the face*, where it passes over the body of the lower jaw, it is comparatively superficial, lying immediately beneath the Platysma. In this situation its pulsation may be distinctly felt, and compression of the vessel effectually made against the bone for a time. In its course over the face, it is covered by the integument, the fat of the cheek, and, near the angle of the mouth, by the Platysma, Risorius, and Zygomatici muscles. It rests on the Buccinator, the Levator anguli oris, and the Levator labii superioris (sometimes piercing or else passing under this last muscle). It is accompanied by the facial vein throughout its entire course; the vein is not tortuous like the artery, and, on the face, is separated from that vessel by a considerable interval, lying to its outer side. The branches of the facial nerve cross the artery, and the infra-orbital nerve lies beneath it.

The branches of this vessel may be divided into two sets: those given off below the jaw (cervical), and those on the face (facial).

Cervical Branches.	*Facial Branches.*
Inferior or Ascending Palatine.	Muscular.
Tonsillar.	Inferior Labial.
Submaxillary.	Inferior Coronary.
Submental.	Superior Coronary.
Muscular.	Lateralis Nasi.
	Angular.

The **inferior** or **ascending palatine** (fig. 391) passes up between the Stylo-glossus and Stylo-pharyngeus to the outer side of the pharynx, along which it is continued between the Superior constrictor and the Internal pterygoid to near the base of the skull. It supplies the neighbouring muscles, the tonsil, and

FIG. 388.—The arteries of the face and scalp.*



Eustachian tube, and divides, near the Levator palati, into two branches: one follows the course of the Levator palati, and, winding over the upper border of the Superior constrictor, supplies the soft palate and the palatine glands, anastomosing with its fellow of the opposite side and with the posterior palatine branch of the internal maxillary artery; the other pierces the Superior constrictor and supplies the tonsil, anastomosing with the tonsillar artery.

The **tonsillar branch** (fig. 391) passes up between the Internal Pterygoid and Stylo-glossus, and then ascends along the side of the pharynx, perforating the Superior constrictor, to ramify in the substance of the tonsil and root of the tongue.

* The muscular tissue of the lips must be supposed to have been cut away, in order to show the course of the coronary arteries.

The **submaxillary** consist of three or four large branches, which supply the submaxillary gland, some being prolonged to the neighbouring muscles, lymphatic glands, and integument.

The **submental**, the largest of the cervical branches, is given off from the facial artery just as that vessel quits the submaxillary gland: it runs forwards upon the Mylo-hyoid muscle, just below the body of the jaw, and beneath the Digastric; after supplying the surrounding muscles, and anastomosing with the sublingual artery by branches which perforate the Mylo-hyoid muscle, it arrives at the symphysis of the chin, where it turns over the border of the jaw and divides into a superficial and a deep branch; the former passes between the integument and Depressor labii inferioris, supplies both, and anastomoses with the inferior labial. The deep branch passes between the latter muscle and the bone, supplies the lip, and anastomoses with the inferior labial and mental arteries.

The **muscular branches** are distributed to the Internal pterygoid and Stylo-hyoid in the neck, and to the Masseter and Buccinator on the face.

The **inferior labial** passes beneath the Depressor anguli oris, to supply the muscles and integument of the lower lip, anastomosing with the inferior coronary and submental branches of the facial, and with the mental branch of the inferior dental artery.

The **inferior coronary** is derived from the facial artery, near the angle of the mouth; it passes upwards and inwards beneath the Depressor anguli oris, and, penetrating the Orbicularis oris muscle, runs in a tortuous course along the edge of the lower lip between this muscle and the mucous membrane, inosculating with the artery of the opposite side. This artery supplies the labial glands, the mucous membrane, and muscles of the lower lip; and anastomoses with the inferior labial and the mental branch of the inferior dental artery.

The **superior coronary** is larger and more tortuous in its course than the preceding. It follows the same course along the edge of the upper lip, lying between the mucous membrane and the Orbicularis oris, and anastomoses with the artery of the opposite side. It supplies the textures of the upper lip, and gives off in its course two or three vessels which ascend to the nose. One, named the *inferior artery of the septum*, ramifies on the septum of the nares as far as the point of the nose; another, the *artery of the ala*, supplies the ala of the nose.

The **lateralis nasi** is derived from the facial, as that vessel is ascending along the side of the nose; it supplies the ala and dorsum of the nose, anastomosing with its fellow, the nasal branch of the ophthalmic, the inferior artery of the septum, the artery of the ala, and the infra-orbital.

The **angular artery** is the termination of the trunk of the facial; it ascends to the inner angle of the orbit, embedded in the fibres of the Levator labii superioris alæque nasi, and accompanied by a large vein, the *angular*; it distributes some branches on the cheek which anastomose with the infra-orbital, and, after supplying the lachrymal sac and Orbicularis palpebrarum muscle, terminates by anastomosing with the nasal branch of the ophthalmic artery.

The anastomoses of the facial artery are very numerous, not only with the vessel of the opposite side, but, in the neck, with the sublingual branch of the lingual; with the ascending pharyngeal; with the posterior palatine, a branch of the internal maxillary, by its inferior or ascending palatine and tonsillar branches; on the face, with the mental branch of the inferior dental as it emerges from the mental foramen; with the transverse facial, a branch of the temporal; with the infra-orbital, a branch of the internal maxillary; and with the nasal branch of the ophthalmic.

Peculiarities.—The facial artery not unfrequently arises by a common trunk with the lingual. This vessel is also subject to some variations in its size, and in the extent to which it supplies the face. It occasionally terminates as the submental, and not unfrequently supplies the face only as high as the angle of the mouth or nose. The deficiency is then supplied by enlargement of one of the neighbouring arteries.

Surgical Anatomy.—The passage of the facial artery over the body of the jaw would appear to afford a favourable position for the application of pressure in cases of hæmorrhage from the lips, the result either of an accidental wound or during an operation; but its application is useless, except for a very short time, on account of the free communication of this vessel with its fellow, and with numerous branches from different sources. In a wound involving the lip, it is better to seize the part between the fingers, and evert it, when the bleeding vessel may be at once secured with pressure-forceps. In order to prevent hæmorrhage in cases of removal of diseased growths from the part, the lip should be compressed on each side between the fingers and thumb, or by a pair of specially devised clamp-forceps, whilst the surgeon excises the diseased part. In order to stop hæmorrhage where the lip has been divided in an operation, it is necessary, in uniting the edges of the wound, to pass the sutures through the cut edges, almost as deep as its mucous surface; by these means, not only are the cut surfaces more neatly and securely adapted to each other, but the possibility of hæmorrhage is prevented by including in the suture the divided artery. If the suture is, on the contrary, passed through merely the cutaneous portion of the wound, hæmorrhage occurs into the cavity of the mouth. The student should, lastly, observe the relation of the angular artery to the lachrymal sac, and it will be seen that, as the vessel passes up along the inner margin of the orbit, it ascends on its nasal side. In operating for fistula lachrymalis, the sac should always be opened on its outer side, in order that this vessel may be avoided.

The **Occipital Artery** (fig. 388) arises from the posterior part of the external carotid, opposite the facial, near the lower margin of the Digastric muscle. At its origin, it is covered by the posterior belly of the Digastric and Stylo-hyoid muscles, and the hypoglossal nerve winds around it from behind forwards; higher up, it passes across the internal carotid artery, the internal jugular vein, and the pneumogastric and spinal accessory nerves; it then ascends to the interval between the transverse process of the atlas and the mastoid process of the temporal bone, and passes horizontally backwards, grooving the surface of the latter bone, being covered by the Sterno-mastoid, Splenius, Trachelo-mastoid, and Digastric muscles, and resting upon the Rectus lateralis, the Superior oblique, and Complexus muscles; it then changes its course and passes vertically upwards, pierces the fascia which connects the cranial attachment of the Trapezius with the Sterno-mastoid, and ascends in a tortuous course over the occiput, as high as the vertex, where it divides into numerous branches. It is accompanied in the latter part of its course by the great occipital and a cutaneous filament from the suboccipital nerve.

The branches given off from this vessel are,—

Muscular.	Auricular.
Sterno-mastoid.	Meningeal.

Arteria Princeps Cervicis.

The **muscular branches** supply the Digastric, Stylo-hyoid, Splenius, and Trachelo-mastoid muscles.

The **sterno-mastoid** is a large and constant branch, generally arising from the artery close to its commencement. It first passes upwards and backwards, and then turns downwards over the hypoglossal nerve, and enters the substance of the muscle, frequently in company with the spinal accessory nerve.

The **auricular branch** supplies the back part of the concha. It frequently gives off a branch, which enters the skull through the mastoid foramen and supplies the dura mater, the diploë, and the mastoid cells.

The **meningeal branch** ascends with the internal jugular vein, and enters the skull through the foramen lacerum posterius, to supply the dura mater in the posterior fossa.

The **arteria princeps cervicis** (fig. 391) is a large branch which descends along the back part of the neck, and divides into a superficial and deep portion. The former runs beneath the Splenius, giving off branches which perforate that muscle to supply the Trapezius, anastomosing with the superficial cervical artery, a branch of the transversalis colli: the latter passes beneath the Complexus, between it and the Semispinalis colli, and anastomoses with branches from the vertebral and with the deep cervical artery, a branch of the superior intercostal.

The anastomosis between these vessels serves mainly to establish the collateral circulation after ligature of the carotid or subclavian artery.

The cranial branches of the occipital artery are distributed upon the occiput: they are very tortuous, and lie between the integument and Occipito-frontalis, anastomosing with the artery of the opposite side, the posterior auricular and temporal arteries. They supply the back part of the Occipito-frontalis muscle, the integument, and pericranium.

The **Posterior Auricular Artery** (fig. 388) is a small vessel which arises from the external carotid, above the Digastric and Stylo-hyoid muscles, opposite the apex of the styloid process. It ascends, under cover of the parotid gland, to the groove between the cartilage of the ear and the mastoid process, immediately above which it divides into its two terminal branches, the auricular and mastoid. Just before arriving at the mastoid process, this artery is crossed by the portio dura, and has beneath it the spinal accessory nerve.

Besides several small branches to the Digastric, Stylo-hyoid, and Sterno-mastoid muscles, and to the parotid gland, this vessel gives off three branches:—

Stylo-mastoid. Auricular. Mastoid.

The **stylo-mastoid branch** enters the stylo-mastoid foramen, and supplies the tympanum, mastoid cells, and semicircular canals. In the young subject a branch from this vessel forms, with the tympanic branch from the internal maxillary, a vascular circle, which surrounds the auditory meatus, and from which delicate vessels ramify on the membrana tympani. It anastomoses with the petrosal branch of the middle meningeal artery by a twig, which enters the hiatus Fallopii.

The **auricular branch**, one of the terminal branches, ascends behind the ear, beneath the Retrahens aurem muscle, and is distributed to the back part of the cartilage of the ear, upon which it ramifies minutely, some branches curving round the margin of the fibro-cartilage, others perforating it, to supply its anterior surface. It anastomoses with the posterior branch of the superficial temporal and also with its anterior auricular branches.

The **mastoid branch** passes backwards, over the Sterno-mastoid muscle, to the scalp above and behind the ear. It supplies the posterior belly of the Occipito-frontalis muscle and the scalp in this situation. It anastomoses with the occipital artery.

The **Ascending Pharyngeal Artery** (fig. 391), the smallest branch of the external carotid, is a long, slender vessel, deeply seated in the neck, beneath the other branches of the external carotid and the Stylo-pharyngeus muscle. It arises from the back part of the external carotid, near the commencement of that vessel, and ascends vertically between the internal carotid and the side of the pharynx, to the under surface of the base of the skull, lying on the Rectus capitis anticus major. Its branches may be subdivided into four sets:—

Prevertebral. Pharyngeal. Tympanic. Meningeal.

The **prevertebral branches** are numerous small vessels, which supply the Recti capitis antici and Longus colli muscles, the sympathetic, hypoglossal, and pneumogastric nerves, and the lymphatic glands of the neck, anastomosing with the ascending cervical artery.

The **pharyngeal branches** are three or four in number. Two of these descend to supply the middle and inferior Constrictors and the Stylo-pharyngeus, ramifying in their substance and in the mucous membrane lining them. The largest of the pharyngeal branches passes inwards, running upon the Superior constrictor, and sends ramifications to the soft palate and tonsil, which take the place of the ascending palatine branch of the facial artery, when that vessel is of small size. A twig from this branch supplies the Eustachian tube.

The **tympanic branch** is a small artery which passes through a minute foramen in the petrous portion of the temporal bone, in company with the tympanic

branch of the Glosso-pharyngeal nerve to supply the inner wall of the tympanum and anastomose with the other tympanic arteries.

The **meningeal branches** consist of several small vessels, which pass through foramina in the base of the skull, to supply the dura mater. One, the posterior meningeal, enters the cranium through the foramen lacerum posterius; a second passes through the foramen lacerum medium; and occasionally a third through the anterior condyloid foramen. They are all distributed to the dura mater.

Surgical Anatomy.—The ascending pharyngeal artery has been wounded from the throat; as in the case in which the stem of a tobacco-pipe was driven into the vessel, causing fatal hæmorrhage.

The **Superficial Temporal Artery** (fig. 388), the smaller of the two terminal branches of the external carotid, appears, from its direction, to be the continuation of that vessel. It commences in the substance of the parotid gland, in the interspace between the neck of the condyle of the lower jaw and the external auditory meatus, crosses over the posterior root of the zygoma, passes beneath the Attrahens aurem muscle, lying on the temporal fascia, and divides, about two inches above the zygomatic arch, into two branches, an anterior and a posterior.

The **anterior temporal** inclines forwards over the forehead, supplying the muscles, integument, and pericranium in this region, and anastomoses with the supra-orbital and frontal arteries.

The **posterior temporal**, larger than the anterior, curves upwards and backwards along the side of the head, lying superficial to the temporal fascia, and inosculates with its fellow of the opposite side, and with the posterior auricular and occipital arteries.

The superficial temporal artery, as it crosses the zygoma, is covered by the Attrahens aurem muscle, and by a dense fascia given off from the parotid gland: it is crossed by the temporo-facial division of the facial nerve and one or two veins, and is accompanied by the auriculo-temporal nerve, which lies behind it. Besides some twigs to the parotid gland, the articulation of the jaw, and the Masseter muscle, its branches are, the

Transverse Facial. Middle Temporal.
Anterior Auricular.

The **transverse facial** is given off from the temporal before that vessel quits the parotid gland; running forwards through its substance, it passes transversely across the face, between Stenson's duct and the lower border of the zygoma, and divides on the side of the face into numerous branches, which supply the parotid gland, the Masseter muscle, and the integument, anastomosing with the facial, masseteric, and infra-orbital arteries. This vessel rests on the Masseter, and is accompanied by one or two branches of the facial nerve. It is sometimes a branch of the external carotid.

The **middle temporal artery** arises immediately above the zygomatic arch, and, perforating the temporal fascia, supplies the Temporal muscle, anastomosing with the deep temporal branches of the internal maxillary. It occasionally gives off an orbital branch, which runs along the upper border of the zygoma, between the two layers of the temporal fascia, to the outer angle of the orbit. This branch supplies the Orbicularis palpebrarum, and anastomoses with the lachrymal and palpebral branches of the ophthalmic artery.

The **anterior auricular branches** are distributed to the anterior portion of the pinna, the lobule, and part of the external meatus, anastomosing with branches of the posterior auricular.

Surgical Anatomy.—It occasionally happens that the surgeon is called upon to perform the operation of arteriotomy upon this vessel in cases of inflammation of the eye or brain. If the student will consider the relations of the trunk of this vessel, as it crosses the zygomatic arch, with the surrounding structures, he will observe that it is covered by a thick and dense fascia, crossed by one of the main divisions of the facial nerve and one

or two veins, and accompanied by the auriculo-temporal nerve. Bleeding should not be performed in this situation, as much difficulty may arise from the dense fascia over the vessel preventing a free flow of blood, and considerable pressure is requisite afterwards to arrest the hæmorrhage. Again, a varicose aneurism may be formed by the accidental opening of one of the veins in front of the artery; or severe neuralgic pain may arise from the operation implicating one of the nervous filaments in the neighbourhood. The anterior branch, on the contrary, is subcutaneous, is a large vessel, and is readily compressed; it should consequently always be selected for the operation.

The **Internal Maxillary** (fig. 389), the larger of the two terminal branches of the external carotid, arises from that vessel opposite the neck of the condyle of the lower jaw, and is at first embedded in the substance of the parotid gland; it passes

Fig. 389.—The internal maxillary artery, and its branches.

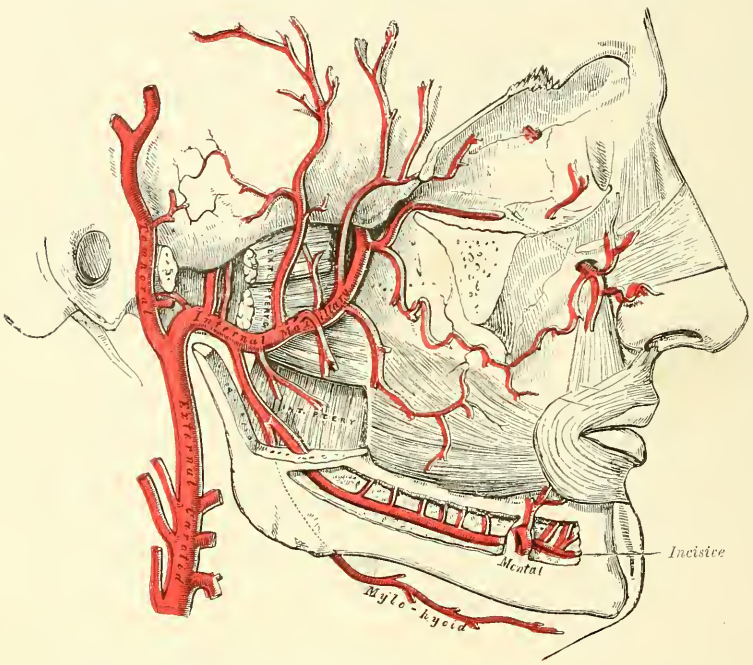


Fig. 390.—Plan of the branches.

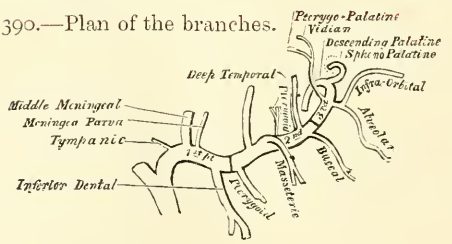

inwards between the ramus of the jaw and the internal lateral ligaments, and then upon the outer surface of the External pterygoid muscle to the spheno-maxillary fossa to supply the deep structures of the face. For convenience of description, it is divided into three portions: a maxillary, a pterygoid, and a spheno-maxillary.

In the first part of its course (*maxillary portion*), the artery passes horizontally forwards and inwards, between the ramus of the jaw and the internal lateral ligament. The artery here lies parallel to and a little below the auriculo-temporal nerve; it crosses the inferior dental nerve, and lies along the lower border of the External pterygoid muscle.

In the second part of its course (*pterygoid portion*), it runs obliquely forwards and upwards upon the outer surface of the External pterygoid muscle, being

covered by the ramus of the lower jaw, and lower part of the Temporal muscle; or it may pass on the inner surface of the External pterygoid muscle to reach the interval between its two heads, between which it passes to reach the spheno-maxillary fossa.

In the third part of its course (*spheno-maxillary portion*), it approaches the superior maxillary bone, and enters the spheno-maxillary fossa in the interval between the two heads of the External pterygoid, where it lies in relation with Meckel's ganglion, and gives off its terminal branches.

The branches of this vessel may be divided into three groups, corresponding with its three divisions.

Branches of the First or Maxillary Portion (fig. 390)

Tympanic (anterior).
Deep Auricular.
Middle Meningeal.
Small Meningeal.
Inferior Dental.

The **tympanic branch** passes upwards behind the articulation of the lower jaw, enters the tympanum through the Glaserian fissure, and ramifies upon the membrana tympani, forming a vascular circle around the membrane with the stylo-mastoid artery, and anastomosing with the Vidian and the tympanic branch from the internal carotid.

The **deep auricular branch** often arises in common with the preceding. It passes upwards in the substance of the parotid gland, behind the temporo-maxillary articulation, pierces the cartilaginous or bony wall of the external auditory meatus, and supplies its cuticular lining and the outer surface of the membrana tympani.

The **middle meningeal** is the largest of the branches which supply the dura mater. It arises from the internal maxillary, between the internal lateral ligament and the neck of the jaw, and passes vertically upwards between the two roots of the auriculo-temporal nerve to the foramen spinosum of the sphenoid bone. On entering the cranium, it divides into two branches, anterior and posterior. The *anterior branch*, the larger, crosses the great ala of the sphenoid, and reaches the groove, or canal, in the anterior inferior angle of the parietal bone: it then divides into branches which spread out between the dura mater and internal surface of the cranium, some passing upwards over the parietal bone as far as the vertex, and others backwards to the occipital bone. The *posterior branch* crosses the squamous portion of the temporal, and on the inner surface of the parietal bone divides into branches which supply the posterior part of the dura mater and cranium. The branches of this vessel are distributed partly to the dura mater, but chiefly to the bones; they anastomose with the arteries of the opposite side, and with the anterior and posterior meningeal.

The middle meningeal on entering the cranium gives off the following collateral branches: 1. Numerous small vessels to the Gasserian ganglion, and to the dura mater in this situation. 2. A branch (*petrosal branch*), which enters the hiatus Fallopii, supplies the facial nerve, and anastomoses with the stylo-mastoid branch of the posterior auricular artery. 3. Orbital branches, which pass through the sphenoidal fissure, or through separate canals in the great wing of the sphenoid to anastomose with the lachrymal or other branches of the ophthalmic artery. 4. Temporal branches, which pass through foramina in the great wing of the sphenoid, and anastomose in the temporal fossa with the deep temporal arteries.

Surgical Anatomy.—The middle meningeal is an artery of considerable surgical importance, as it may be injured in fractures of the temporal region of the skull, and the injury may be followed by considerable hæmorrhage between the bone and dura mater, which may cause compression of the brain, and require the operation of trephining for its relief. This artery crosses the anterior inferior angle of the parietal bone at a point $1\frac{1}{2}$ inch behind the external angular process of the frontal bone, and $1\frac{3}{4}$ inch above the

zygoma. From this point the anterior branch passes upwards and slightly backwards to the sagittal suture, lying about ½ inch to ¾ inch behind the coronal suture. The posterior branch passes upwards and backwards over the squamous portion of the temporal bone. In order to expose the artery as it lies in the canal in the parietal bone, a semilunar incision, with its convexity upwards, should be made, commencing an inch behind the external angular process, and carried backwards for 2 inches. The structures cut through are: (1) skin; (2) superficial fascia, with branches of the superficial temporal vessels and nerves; (3) the fascia continued down from the aponeurosis of the Occipito-frontalis; (4) the two layers of the temporal fascia; (5) the temporal muscle; (6) the deep temporal vessels; (7) the pericranium; and (8) the bone.

The **small meningeal** is sometimes derived from the preceding. It enters the skull through the foramen ovale, and supplies the Gasserian ganglion and dura mater. Before entering the cranium it gives off a branch to the nasal fossæ, soft palate, and tonsil.

The **inferior dental** descends with the dental nerve to the foramen on the inner side of the ramus of the jaw. It runs along the dental canal in the substance of the bone, accompanied by the nerve, and opposite the first bicuspid tooth divides into two branches, incisor and mental; the *former* is continued forwards beneath the incisor teeth as far as the symphysis, where it anastomoses with the artery of the opposite side; the *mental* branch escapes with the nerve at the mental foramen, supplies the structures composing the chin, and anastomoses with the submental, inferior labial, and inferior coronary arteries. Near its origin the inferior dental artery gives off a *lingual* branch, which descends with the lingual (gustatory) nerve and supplies the mucous membrane of the mouth. As the inferior dental artery enters the foramen, it gives off a *mylo-hyoid* branch, which runs in the mylo-hyoid groove, and ramifies on the under surface of the Mylo-hyoid muscle. The dental and incisor arteries during their course through the substance of the bone give off a few twigs which are lost in the cancellous tissue, and a series of branches which correspond in number to the roots of the teeth: these enter the minute apertures at the extremities of the fangs, and supply the pulp of the teeth.

Branches of the Second or Pterygoid Portion

Deep Temporal.	Masseteric.
Pterygoid.	Buccal.

These branches are distributed, as their names imply, to the muscles in the maxillary region.

The **deep temporal branches**, two in number, anterior and posterior, each occupy that part of the temporal fossa indicated by its name. Ascending between the Temporal muscle and pericranium, they supply that muscle, and anastomose with the middle temporal artery; the anterior branch communicating with the lachrymal through small branches which perforate the malar bone and great wing of the sphenoid.

The **pterygoid branches**, irregular in their number and origin, supply the Pterygoid muscles.

The **masseteric** is a small branch which passes outwards, above the sigmoid notch of the lower jaw, to the deep surface of the Masseter. It supplies that muscle, and anastomoses with the masseteric branches of the facial and with the transverse facial artery.

The **buccal** is a small branch which runs obliquely forwards, between the Internal pterygoid and the ramus of the jaw, to the outer surface of the Buccinator, to which it is distributed, anastomosing with branches of the facial artery.

Branches of the Third or Spheno-maxillary Portion

Alveolar.	Vidian.
Infra-orbital.	Pterygo-palatine.
Posterior or Descending Palatine.	Naso- or Spheno-palatine.

The **alveolar** or **posterior dental branch** is given off from the internal maxillary, frequently by a common branch with the infra-orbital, just as the trunk of the vessel is passing into the spheno-maxillary fossa. Descending upon the tuberosity of the superior maxillary bone, it divides into numerous branches, some of which enter the posterior dental canals, to supply the molar and bicuspid teeth and the lining of the antrum, and others are continued forwards on the alveolar process to supply the gums.

The **infra-orbital** appears, from its direction, to be the continuation of the trunk of the internal maxillary. It often arises from that vessel by a common trunk with the preceding branch, and runs along the infra-orbital canal with the superior maxillary nerve, emerging upon the face at the infra-orbital foramen, beneath the Levator labii superioris. Whilst contained in the canal, it gives off branches which ascend into the orbit, and supply the Inferior rectus and Inferior oblique muscles and the lachrymal gland. Other branches (*anterior dental*) descend through canals in the bone, to supply the mucous membrane of the antrum, and the front teeth of the upper jaw. On the face, some branches pass upwards to the inner angle of the orbit and the lachrymal sac, anastomosing with the angular branch of the facial artery; other branches pass inwards towards the nose, anastomosing with the nasal branch of the ophthalmic; and other branches descend beneath the Levator labii superioris, and anastomose with the transverse facial and buccal arteries.

The four remaining branches arise from that portion of the internal maxillary which is contained in the spheno-maxillary fossa.

The **descending palatine** passes down the posterior palatine canal with the anterior palatine branch of Meckel's ganglion, and, emerging from the posterior palatine foramen, runs forwards in a groove on the inner side of the alveolar border of the hard palate to the anterior palatine canal, where the terminal branch of the artery passes upwards through the foramen of Stenson to anastomose with the naso-palatine artery. Its branches are distributed to the gums, the mucous membrane of the hard palate, and the palatine glands. Whilst it is contained in the palatine canal, it gives off branches, which descend in the accessory palatine canals to supply the soft palate and tonsil, anastomosing with the ascending palatine artery.

Surgical Anatomy.—The position of the descending palatine artery on the hard palate should be borne in mind in performing an operation for the closure of a cleft in the hard palate, as it is in danger of being wounded, and may give rise to formidable hæmorrhage. In one case, in which it was wounded, it was necessary to plug the posterior palatine canal in order to arrest the bleeding.

The **Vidian branch** passes backwards along the Vidian canal with the Vidian nerve. It is distributed to the upper part of the pharynx and Eustachian tube, sending a small branch into the tympanum, which anastomoses with the anterior tympanic.

The **pterygo-palatine** is also a very small branch, which passes backwards through the pterygo-palatine canal with the pharyngeal nerve, and is distributed to the upper part of the pharynx and Eustachian tube.

The **spheno-palatine** passes through the spheno-palatine foramen into the cavity of the nose, at the back part of the superior meatus, and divides into two branches: one internal, the *naso-palatine* or *superior artery of the septum*, passes obliquely downwards and forwards along the septum nasi, supplies the mucous membrane, and anastomoses in front with the terminal branch of the descending palatine. The external branches, two or three in number, supply the mucous membrane covering the lateral wall of the nose, the antrum, and the ethmoid and sphenoid cells.

The Triangles of the Neck

The student having considered the relative anatomy of the large arteries of the neck and their branches, and the relations they bear to the veins and nerves,

should now examine these structures collectively, as they present themselves in certain regions of the neck, in each of which important operations are constantly being performed.

The side of the neck presents a somewhat quadrilateral outline, limited, above, by the lower border of the body of the jaw, and an imaginary line extending from the angle of the jaw to the mastoid process; below, by the prominent upper border of the clavicle; in front, by the median line of the neck; behind, by the anterior margin of the Trapezius muscle. This space is subdivided into two large triangles by the Sterno-mastoid muscle, which passes obliquely across the neck, from the sternum and clavicle below, to the mastoid process above. The triangular space in front of this muscle is called the *anterior triangle*; and that behind it, the *posterior triangle*.

Anterior Triangle of the Neck

The **anterior triangle** is bounded, in front, by a line extending from the chin to the sternum; behind, by the anterior margin of the Sterno-mastoid; its base, directed upwards, is formed by the lower border of the body of the jaw, and a line extending from the angle of the jaw to the mastoid process; its apex is below, at the sternum. This space is subdivided into three smaller triangles by the Digastric muscle above, and the anterior belly of the Omo-hyoid below. These smaller triangles are named, from below upwards, the inferior carotid, the superior carotid, and the submaxillary triangle.

The **Inferior Carotid Triangle** is bounded, in front, by the median line of the neck; behind, by the anterior margin of the Sterno-mastoid; above, by the anterior belly of the Omo-hyoid; and is covered by the integument, superficial fascia, Platysma, and deep fascia; ramifying between which are some of the descending branches of the superficial cervical plexus. Beneath these superficial structures are the Sterno-hyoid and Sterno-thyroid muscles, which, together with the anterior margin of the Sterno-mastoid, conceal the lower part of the common carotid artery.*

This vessel is enclosed within its sheath, together with the internal jugular vein and pneumogastric nerve; the vein lying on the outer side of the artery on the right side of the neck, but overlapping it, or passing directly across it on the left side; the nerve lying between the artery and vein, on a plane posterior to both. In front of the sheath are a few filaments descending from the loop of communication between the descendens and communicans hypoglossi; behind the sheath are seen the inferior thyroid artery, the recurrent laryngeal nerve, and the sympathetic nerve; and on its inner side, the trachea, the thyroid gland—much more prominent in the female than in the male—and the lower part of the larynx. By cutting into the upper part of this space, and slightly displacing the Sterno-mastoid muscle, the common carotid artery may be tied below the Omo-hyoid muscle.

The floor of the inferior carotid triangle is formed by the Longus colli muscle below, and by the Scalenus anticus above (see fig. 321, page 423), between which muscles the vertebral artery and vein will be found passing into the foramen in the sixth transverse process; a small portion of the origin of the Rectus capitis anticus major may also be seen in the floor of the space.

The **Superior Carotid Triangle** is bounded, behind, by the Sterno-mastoid; below, by the anterior belly of the Omo-hyoid; and above, by the posterior belly of the Digastric muscle. It is covered by the integument, superficial fascia, Platysma, and deep fascia; ramifying between which are branches of the facial

* Therefore the common carotid artery and internal jugular vein are not, strictly speaking, contained in this triangle, since they are covered by the Sterno-mastoid muscle; that is to say, lie behind the anterior border of that muscle, which forms the posterior border of the triangle. But as they lie very close to the structures which are really contained in the triangle, and whose position it is essential to remember in operating on this part of the artery, it has seemed expedient to study the relations of all these parts together.

nerve and superficial cervical plexus. Its floor is formed by parts of the Thyro-hyoid, Hyo-glossus, and the Inferior and Middle constrictor muscles of the pharynx. This space contains the upper part of the common carotid artery, which bifurcates opposite the upper border of the thyroid cartilage into the external and internal carotid. These vessels are occasionally somewhat concealed from view by the anterior margin of the Sterno-mastoid muscle, which overlaps them. The external and internal carotids lie side by side, the external being the more anterior of the two. The following branches of the external carotid are also met with in this space: the superior thyroid, running forwards and downwards; the lingual, directly forwards; the facial, forwards and upwards; the occipital, backwards; and the ascending pharyngeal directly upwards on the inner side of the internal carotid. The veins met with are: the internal jugular, which lies on the outer side of the common and internal carotid arteries; and veins corresponding to the above-mentioned branches of the external carotid—viz. the superior thyroid, the lingual, facial, ascending pharyngeal, and sometimes the occipital—all of which accompany their corresponding arteries, and terminate in the internal jugular. The nerves in this space are the following: In front of the sheath of the common carotid is the descendens hypoglossi. The hypoglossal nerve crosses both the internal and external carotid above, curving round the occipital artery at its origin. Within the sheath, between the artery and vein, and behind both, is the pneumogastric nerve; behind the sheath, the sympathetic. On the outer side of the vessels, the spinal accessory nerve runs for a short distance before it pierces the Sterno-mastoid muscle; and on the inner side of the external carotid, just below the hyoid bone, may be seen the superior laryngeal nerve; and, still more inferiorly, the external laryngeal nerve. The upper part of the larynx and lower part of the pharynx are also found in the front part of this space.

The **Submaxillary Triangle** corresponds to the part of the neck immediately beneath the body of the jaw. It is bounded, above, by the lower border of the body of the jaw, and a line drawn from its angle to the mastoid process; below, by the posterior belly of the Digastric and Stylo-hyoid muscles; in front, by the middle line of the neck. It is covered by the integument, superficial fascia, Platysma, and deep fascia; ramifying between which are branches of the facial and ascending filaments of the superficial cervical nerves. Its floor is formed by the anterior belly of the Digastric, the Mylo-hyoid, and Hyo-glossus muscles. This space contains, in front, the submaxillary gland, imbedded in the substance of which are the facial artery and vein, and their glandular branches; beneath this gland, on the surface of the Mylo-hyoid muscle, are the submental artery and the mylo-hyoid artery and nerve. The back part of this space is separated from the front part by the stylo-maxillary ligament; it contains the external carotid artery, ascending deeply in the substance of the parotid gland; this vessel here lies in front of, and superficial to, the internal carotid, being crossed by the facial nerve, and gives off in its course the posterior auricular, temporal, and internal maxillary branches: more deeply are the internal carotid, the internal jugular vein, and the pneumogastric nerve, separated from the external carotid by the Stylo-glossus and Stylo-pharyngeus muscles, and the glosso-pharyngeal nerve.*

Posterior Triangle of the Neck

The **posterior triangle** is bounded, in front, by the Sterno-mastoid muscle; behind, by the anterior margin of the Trapezius; its base corresponds to the upper border of the clavicle; its apex, to the occiput. The space is crossed, about

* The same remark will apply to this triangle as was made about the inferior carotid triangle. The structures enumerated as contained in the back part of the space lie, strictly speaking, beneath the muscles which form the posterior boundary of the triangle; but as it is very important to bear in mind their close relation to the parotid gland and its boundaries (on account of the frequency of surgical operations on this gland), all these parts are spoken of together.

an inch above the clavicle, by the posterior belly of the Omo-hyoid, which divides it unequally into two, an upper or occipital, and a lower or subclavian, triangle.

The **Occipital**, the larger of the two posterior triangles, is bounded, in front, by the Sterno-mastoid; behind, by the Trapezius; below, by the Omo-hyoid. Its floor is formed from above downwards by the Splenius, Levator anguli scapulæ, and the Middle and Posterior scaleni muscles. It is covered by the integument, the Platysma below, the superficial and deep fasciæ, and by the spinal accessory nerve which is directed obliquely across the space from the Sterno-mastoid, which it pierces, to the under surface of the Trapezius; below, the descending branches of the cervical plexus and the transversalis colli artery and vein cross the space. A chain of lymphatic glands is also found running along the posterior border of the Sterno-mastoid, from the mastoid process to the root of the neck.

The **Subclavian**, the smaller of the two posterior triangles, is bounded, above, by the posterior belly of the Omo-hyoid; below, by the clavicle; its base, directed forwards, being formed by the Sterno-mastoid. The size of the subclavian triangle varies according to the extent of attachment of the clavicular portion of the Sterno-mastoid and Trapezius muscles, and also according to the height at which the Omo-hyoid crosses the neck above the clavicle. Its height also varies much, according to the position of the arm, being much diminished by raising the limb, on account of the ascent of the clavicle, and increased by drawing the arm downwards, when that bone is depressed. This space is covered by the integument, superficial and deep fasciæ; and crossed by the descending branches of the cervical plexus. Just above the level of the clavicle, the third portion of the subclavian artery curves outwards and downwards from the outer margin of the Scalenus anticus, across the first rib, to the axilla. Sometimes this vessel rises as high as an inch and a half above the clavicle, or to any point intermediate between this and its usual level. Occasionally, it passes in front of the Scalenus anticus, or pierces the fibres of that muscle. The subclavian vein lies behind the clavicle, and is usually not seen in this space; but it occasionally rises as high up as the artery, and has even been seen to pass with that vessel behind the Scalenus anticus. The brachial plexus of nerves lies above the artery, and in close contact with it. Passing transversely across the clavicular margin of the space, are the suprascapular vessels; and traversing its upper angle in the same direction, the transversalis colli artery and vein. The external jugular vein runs vertically downwards behind the posterior border of the Sterno-mastoid, to terminate in the subclavian vein; it receives the transverse cervical and suprascapular veins, which occasionally form a plexus in front of the artery, and a small vein which crosses the clavicle from the cephalic. The small nerve to the Subclavius muscle also crosses this triangle about its middle. A lymphatic gland is also found in the space. Its floor is formed by the first rib with the first digitation of the Serratus magnus.

Internal Carotid Artery

The **internal carotid artery** supplies the anterior part of the brain, the eye and its appendages, and sends branches to the forehead and nose. Its size, in the adult, is equal to that of the external carotid, though, in the child, it is larger than that vessel. It is remarkable for the number of curvatures that it presents in different parts of its course. In its cervical portion it occasionally presents one or two flexures near the base of the skull, whilst through the rest of its extent it describes a double curvature which resembles the italic letter *s* placed horizontally. These curvatures most probably diminish the velocity of the current of blood, by increasing the extent of surface over which it moves, and adding to the amount of impediment produced from friction.

In considering the course and relations of this vessel, it may be conveniently divided into four portions: a cervical, petrous, cavernous, and cerebral.

Cervical Portion.—This portion of the internal carotid commences at the bifurcation of the common carotid, opposite the upper border of the thyroid cartilage, and runs perpendicularly upwards, in front of the transverse processes of the three upper cervical vertebræ, to the carotid canal in the petrous portion of the temporal bone. It is superficial at its commencement, being contained in the superior carotid triangle, and lying on the same level as the external carotid, but behind that artery, overlapped by the Sterno-mastoid, and covered by the deep fascia, Platysma, and integument: it then passes beneath the parotid gland, being crossed by the hypoglossal nerve, the Digastric and Stylo-hyoid muscles, and the occipital and posterior auricular arteries. Higher up, it is separated from the external carotid by the Stylo-glossus and Stylo-pharyngeus muscles, the glosso-pharyngeal nerve, and pharyngeal branch of the pneumogastric. It is in relation, *behind*, with the Rectus capitis anticus major, the superior cervical ganglion of the sympathetic, and superior laryngeal nerve; *externally*, with the internal jugular vein and pneumogastric nerve, the nerve lying on a plane posterior to the artery; *internally*, with the pharynx, tonsil, the superior laryngeal nerve, and ascending pharyngeal artery.

Plan of the Relations of the Internal Carotid Artery in the Neck

Tonsil.

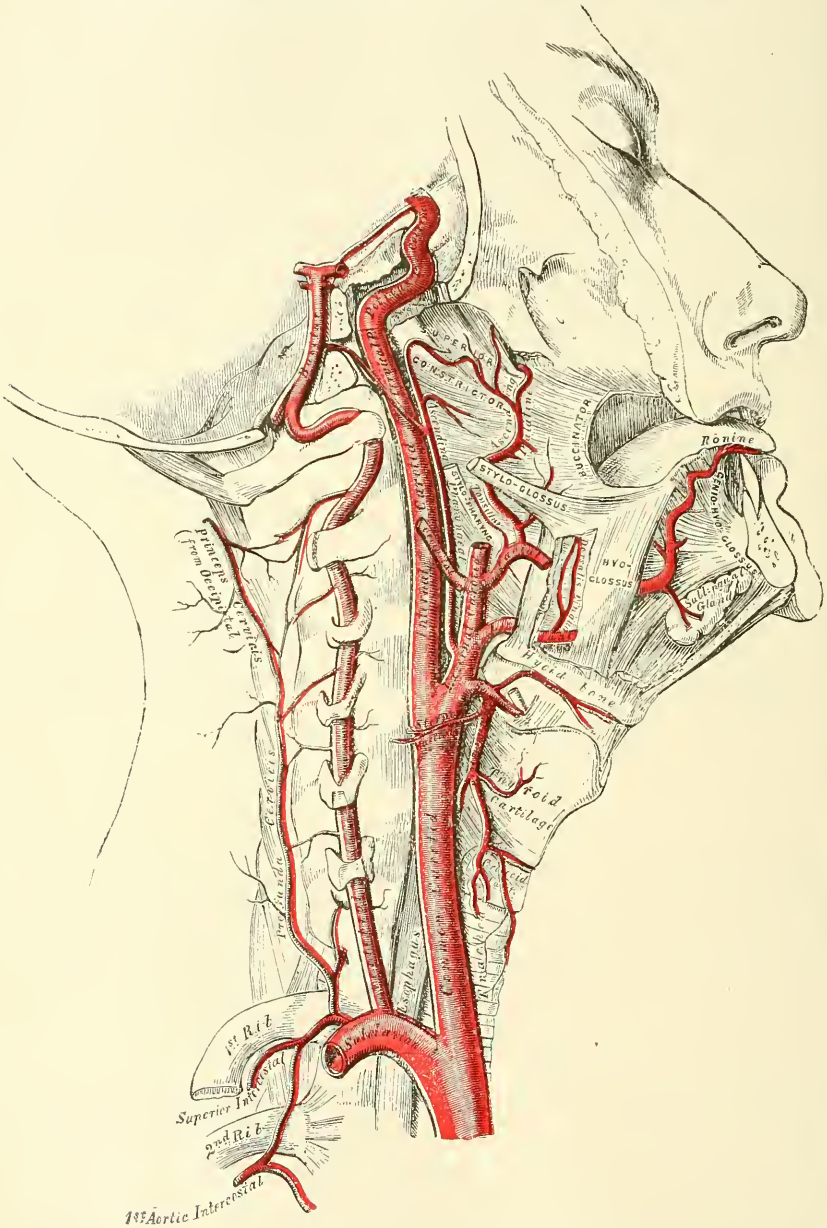
Behind.
Rectus capitis anticus major.
Sympathetic.
Superior laryngeal nerve.

Petrous Portion.—When the internal carotid artery enters the canal in the petrous portion of the temporal bone, it first ascends a short distance, then curves forwards and inwards, and again ascends as it leaves the canal to enter the cavity of the skull between the lingula and petrosal process. In this canal, the artery lies at first in front of the cochlea and tympanum; from the latter cavity it is separated by a thin, bony lamella, which is cribriform in the young subject, and often absorbed in old age. Farther forwards it is separated from the Gasserian ganglion by a thin plate of bone, which is sometimes perforated and forms the floor of the fossa for the ganglion and the roof of the horizontal portion of the canal. The artery is separated from the bony wall of the carotid canal by a prolongation of dura mater, and is surrounded by filaments of the carotid plexus and a number of small veins.

Cavernous Portion.—The internal carotid artery, in this part of its course, is situated between the layers of the dura mater forming the cavernous sinus, but covered by the lining membrane of the sinus. It at first ascends to the posterior clinoid process, then passes forwards by the side of the body of the sphenoid bone, and again curves upwards on the inner side of the anterior clinoid process, and perforates the dura mater forming the roof of the sinus. In this part of its course it is surrounded by filaments of the sympathetic nerve, and has in relation with it externally the sixth nerve.

Cerebral Portion.—Having perforated the dura mater, on the inner side of the anterior clinoid process, the internal carotid passes between the second and third cranial nerves to the anterior perforated spot at the inner extremity of the fissure of Sylvius, where it gives off its terminal or cerebral branches. This portion of the artery has the optic nerve on its inner side, and the third nerve externally.

Fig. 391.—The internal carotid and vertebral arteries. Right side.



Peculiarities.—The length of the internal carotid varies according to the length of the neck, and also according to the point of bifurcation of the common carotid. Its origin sometimes takes place from the arch of the aorta; in such rare instances, this vessel has been found to be placed nearer the middle line of the neck than the external carotid, as far upwards as the larynx, when the latter vessel crossed the internal carotid. The course of the vessel, instead of being straight, may be very tortuous. A few instances are recorded in which this vessel was altogether absent: in one of these the common carotid passed up the neck, and gave off the usual branches of the external carotid: the cranial portion of the

internal carotid being replaced by two branches of the internal maxillary, which entered the skull through the foramen rotundum and ovale, and joined to form a single vessel.

Surgical Anatomy.—The cervical part of the internal carotid is very rarely wounded. Mr. Cripps, in an interesting paper in the 'Medico-Chirurgical Transactions,' compares the rareness of a wound of the internal carotid with one of the external carotid or its branches. It is, however, sometimes injured by a stab or gunshot wound in the neck, or even occasionally by a stab from within the mouth, as when a person receives a thrust from the end of a parasol, or falls down with a tobacco-pipe in his mouth. The relation of the internal carotid with the tonsil should be especially remembered, as instances have occurred in which the artery has been wounded during the operation of scarifying the tonsil, and fatal hæmorrhage has supervened. The indications for ligature are wounds, when the vessel should be exposed by a careful dissection and tied above and below the bleeding-point; and aneurism, which if non-traumatic may be treated by ligature of the common carotid; but if traumatic in origin, by exposing the sac and tying the vessel above and below. The incision for ligature of the cervical portion of the internal carotid should be made along the anterior border of the Sterno-mastoid, from the angle of the jaw to the upper border of the thyroid cartilage. The superficial structures being divided, and the Sterno-mastoid defined and drawn outwards, the cellular tissue must be carefully separated and the posterior belly of the Digastric and hypoglossal nerve sought for as guides to the vessel. When the artery is found, the external carotid should be drawn inwards and the Digastric muscle upwards, and the aneurism needle passed from without inwards.

Branches.—The branches given off from the internal carotid are :—

From the Petrous portion	Tympanic (internal or deep).
From the Cavernous portion	Arteriæ Receptaculi. Anterior Meningeal. Ophthalmic.
From the Cerebral portion	Anterior Cerebral. Middle Cerebral. Posterior Communicating. Anterior Choroid.

The cervical portion of the internal carotid gives off no branches.

The **tympanic** is a small branch which enters the cavity of the tympanum, through a minute foramen in the carotid canal, and anastomoses with the tympanic branch of the internal maxillary, and with the stylo-mastoid artery.

The **arteriæ receptaculi** are numerous small vessels, derived from the internal carotid in the cavernous sinus; they supply the pituitary body, the Gasserian ganglion, and the walls of the cavernous and inferior petrosal sinuses. Some of these branches anastomose with branches of the middle meningeal.

The **anterior meningeal** is a small branch which passes over the lesser wing of the sphenoid to supply the dura mater of the anterior fossa; it anastomoses with the meningeal branch from the posterior ethmoidal artery.

The **Ophthalmic Artery** arises from the internal carotid, just as that vessel is emerging from the cavernous sinus, on the inner side of the anterior clinoid process, and enters the orbit through the optic foramen, below and on the outer side of the optic nerve. It then passes over the nerve to the inner wall of the orbit, and thence horizontally forwards, beneath the lower border of the Superior oblique muscle to a point behind the internal angular process of the frontal bone, where it divides into two terminal branches, the *frontal* and *nasal*.

The branches of this vessel may be divided into an *orbital group*, which are distributed to the orbit and surrounding parts; and an *ocular group*, which supply the muscles and globe of the eye.

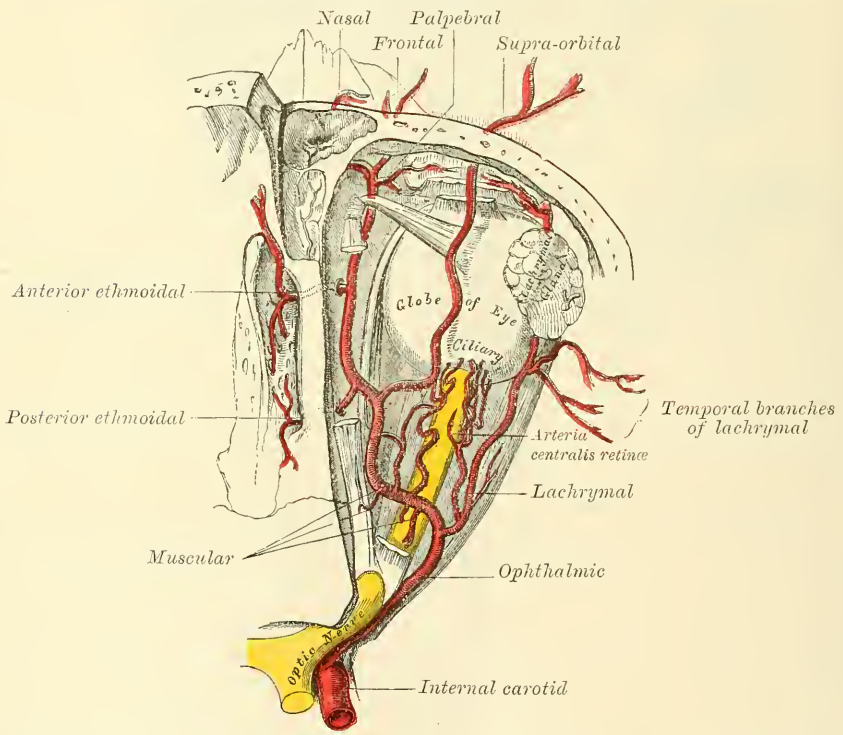
Orbital Group.	*Ocular Group.*
Lachrymal.	Muscular.
Supra-orbital.	Anterior Ciliary.
Posterior Ethmoidal.	Short Ciliary.
Anterior Ethmoidal.	Long Ciliary.
Internal Palpebral.	Arteria Centralis Retinæ.
Frontal.	
Nasal.	

The *lachrymal* is the first, and one of the largest branches derived from the ophthalmic, arising close to the optic foramen: not unfrequently it is given off from the artery before it enters the orbit. It accompanies the lachrymal nerve along the upper border of the External rectus muscle, and is distributed to the lachrymal gland. Its terminal branches, escaping from the gland, are distributed to the eyelids and conjunctiva: of those supplying the eyelids, two are of considerable size and are named the *external palpebral*; they run inwards in the upper and lower lids respectively and anastomose with the internal palpebral arteries, forming an arterial circle in this situation. The lachrymal artery gives off one or two *malar branches*, one of which passes through a foramen in the malar bone, to reach the temporal fossa, and anastomoses with the deep temporal arteries; the other appears on the cheek, and anastomoses with the transverse facial. A branch is also sent backwards, through the sphenoidal fissure, to the dura mater, which anastomoses with a branch of the middle meningeal artery.

Peculiarities.—The lachrymal artery is sometimes derived from one of the anterior branches of the middle meningeal artery.

The *supra-orbital artery* arises from the ophthalmic as that vessel is crossing over the optic nerve. Ascending so as to rise above all the muscles of the orbit,

FIG. 392.—The ophthalmic artery and its branches, the roof of the orbit having been removed.

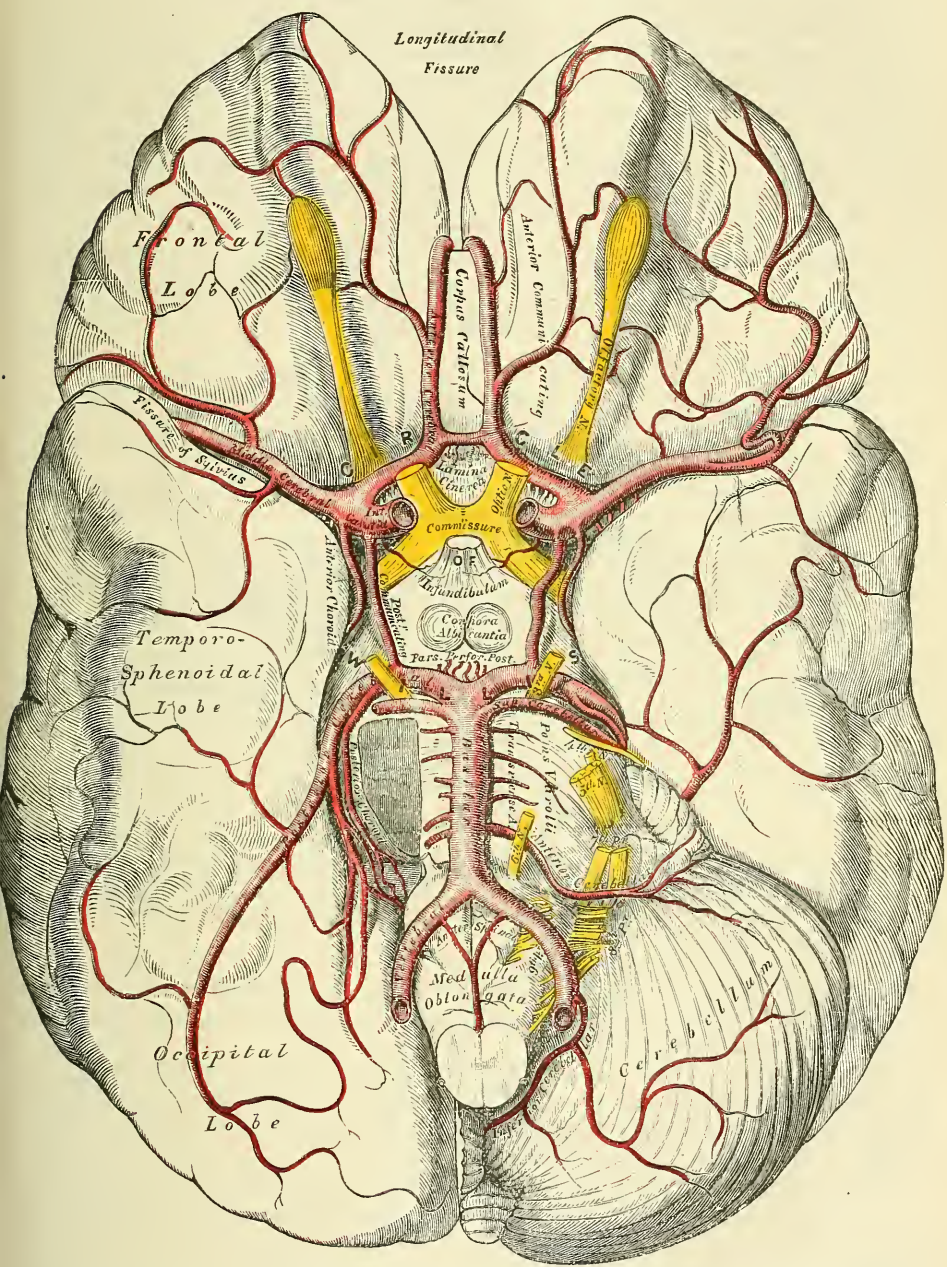


it passes forwards, with the supra-orbital nerve, between the periosteum and Levator palpebræ; and, passing through the supra-orbital foramen, divides into a superficial and deep branch, which supply the integument, the muscles, and the pericranium of the forehead, anastomosing with the frontal, the anterior branch of the temporal, and the artery of the opposite side. This artery in the orbit supplies the Superior rectus and the Levator palpebræ, and sends a branch inwards, across the pulley of the Superior oblique muscle, to supply the parts at the inner canthus. At the supra-orbital foramen it frequently transmits a branch to the diploë.

The *ethmoidal branches* are two in number: posterior and anterior. The

former, which is the smaller, passes through the posterior ethmoidal foramen, supplies the posterior ethmoidal cells, and, entering the cranium, gives off a meningeal branch, which supplies the adjacent dura mater; and nasal branches which descend into the nose through apertures in the cribriform plate, anasto-

Fig. 393.—The arteries of the base of the brain. The right half of the cerebellum and pons have been removed.



N.B.—It will be noticed that in the illustration the two anterior cerebral arteries have been drawn at a considerable distance from each other; this makes the anterior communicating artery appear very much longer than it really is.

mosing with branches of the spheno-palatine. The anterior ethmoidal artery accompanies the nasal nerve through the anterior ethmoidal foramen, supplies

the anterior ethmoidal cells and frontal sinuses, and, entering the cranium, gives off a meningeal branch, which supplies the adjacent dura mater; and nasal branches, which descend into the nose, through the slit by the side of the crista galli; and running along the groove on the under surface of the nasal bone supplies the skin of the nose.

The *palpebral arteries*, two in number, superior and inferior, arise from the ophthalmic, opposite the pulley of the Superior oblique muscle; they leave the orbit to encircle the eyelids near their free margin, forming a superior and an inferior arch, which lie between the Orbicularis muscle and tarsal plates; the superior palpebral inosculating, at the outer angle of the orbit, with the orbital branch of the temporal artery, and with the upper of the two external palpebral branches from the lachrymal artery: the inferior palpebral inosculating, at the outer angle of the orbit, with the lower of the two external palpebral branches from the lachrymal and with the transverse facial artery, and, at the inner side

of the lid, with a branch from the angular artery. From this last anastomosis a branch passes to the nasal duct, ramifying in its mucous membrane, as far as the inferior meatus.

The *frontal artery*, one of the terminal branches of the ophthalmic, passes from the orbit at its inner angle, and, ascending on the forehead, supplies the integument, muscles, and pericranium, anastomosing with the supra-orbital artery, and with the artery of the opposite side.

The *nasal artery*, the other terminal branch of the ophthalmic, emerges from the orbit above the tendo oculi, and, after giving a branch to the upper part of the lachrymal sac, divides into two branches, one of which crosses the root of the nose, the *transverse nasal*, and anastomoses with the angular artery; the other, the *dorsalis nasi*, runs along the dorsum of the nose, supplies its outer surface, and anastomoses with the artery of the opposite side, and with the lateral nasal branch of the facial.

The *ciliary arteries* are divisible into three groups, the short, long, and anterior. The *short ciliary arteries*, from six to twelve in number, arise from the

ophthalmic, or some of its branches; they surround the optic nerve as they pass forwards to the posterior part of the eyeball, pierce the sclerotic coat around the entrance of the nerve, and supply the choroid coat and ciliary processes. The *long ciliary arteries*, two in number, also pierce the posterior part of the sclerotic, and run forwards, along each side of the eyeball, between the sclerotic and choroid, to the ciliary muscle, where they divide into two branches; these form an arterial circle around the circumference of the iris, from which numerous radiating branches pass forwards, in its substance, to its free margin, where they form a second arterial circle around its pupillary margin. The *anterior ciliary arteries* are derived from the muscular branches; they pass to the front of the eyeball in company with the tendons of the recti muscles, form a vascular zone beneath the conjunctiva and then pierce the sclerotic a short distance from the cornea and terminate in the great arterial circle of the iris.

The *arteria centralis retinæ* is one of the smallest branches of the ophthalmic artery. It arises from the ophthalmic as that vessel is about to cross over the optic nerve; it pierces the optic nerve obliquely, and runs forward in the centre of its substance, and enters the globe of the eye through the porus opticus. Its mode of distribution will be described in the account of the anatomy of the eye.

The *muscular branches*, two in number, superior and inferior, supply the muscles of the eyeball. The superior, the smaller, often wanting, supplies the Levator palpebræ, Superior rectus, and Superior oblique. The inferior, more constant in its existence, passes forwards, between the optic nerve and Inferior rectus, and is distributed to the External, Internal, and Inferior recti, and Inferior oblique. This vessel gives off most of the anterior ciliary arteries.

The **anterior cerebral** arises from the internal carotid, at the inner extremity of the fissure of Sylvius. It passes forwards and inwards across the anterior perforated space, between the first and second cranial nerves, to the commencement of the great longitudinal fissure. Here it comes into close relationship with the artery of the opposite side, and the two vessels are connected together by a short anastomosing trunk, about two lines in length, the *anterior communicating* artery. From this point, the two vessels run side by side in the longitudinal fissure, curve round the anterior border of the corpus callosum, and turning backwards continue along its upper surface to its posterior part, where they terminate by anastomosing with the posterior cerebral arteries. In their course they give off the following branches:—

Antero-median Ganglionic.	Middle and Internal Frontal.
Anterior and Internal Frontal.	Posterior and Internal Frontal.

The *antero-median ganglionic* is a group of small arteries which arise at the commencement of the anterior cerebral artery; they pierce the anterior perforated space and lamina cinerea, and supply the head of the caudate nucleus.

The *anterior* and *internal frontal branches* supply the two inferior frontal convolutions. The *middle* and *internal frontal branches* supply the corpus callosum, the convolution of the corpus callosum, the inner surface of the first frontal convolution, and the upper part of the ascending frontal convolution. The *posterior* and *internal frontal branches* supply the lobus quadratus.

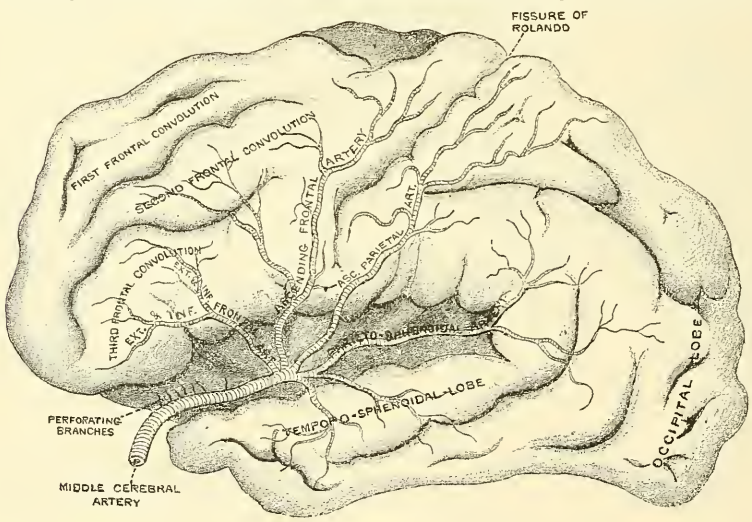
The *anterior communicating artery* is a short branch about two lines in length, but of moderate size, connecting together the two anterior cerebral arteries across the longitudinal fissure. Sometimes this vessel is wanting, the two arteries joining together to form a single trunk, which afterwards divides. Or the vessel may be wholly, or partially, divided into two; frequently, it is longer and smaller than usual. It gives off some of the antero-median ganglionic group of vessels, which are, however, principally derived from the anterior cerebral.

The **middle cerebral artery** (fig. 395), the largest branch of the internal carotid, passes obliquely outwards along the fissure of Sylvius, and, opposite the island of Reil, divides into its terminal branches. The branches of the middle cerebral artery are :—

Antero-lateral Ganglionic. Ascending Frontal.
External and Inferior Frontal. Ascending Parietal.
Parieto-sphenoidal.

The *antero-lateral ganglionic branches* are a group of small arteries which arise at the commencement of the middle cerebral artery ; they pierce the anterior perforated space and supply the greater part of the caudate nucleus, the lenticular nucleus, the internal capsule, and a part of the optic thalamus. One artery of this group, distributed to the lenticular nucleus, is of larger size than the rest, and is of special importance, as being the artery in the brain most frequently ruptured ; it has been termed by Charcot, the '*artery of cerebral hæmorrhage.*' The *external* and *inferior frontal* supplies the third or inferior frontal convolution (Broca's convolution). The *ascending frontal* supplies the ascending frontal convolution. The *ascending parietal* supplies the ascending parietal convolution. The *parieto-sphenoidal* supplies the superior temporo-sphenoidal convolution and the angular gyrus.

Fig. 395.—The distribution of the middle cerebral artery. (After Charcot.)



The **posterior communicating artery** arises from the back part of the internal carotid, runs directly backwards, and anastomoses with the posterior cerebral, a branch of the basilar. This artery varies considerably in size, being sometimes small, and occasionally so large that the posterior cerebral may be considered as arising from the internal carotid rather than from the basilar. It is frequently larger on one side than on the other side. From the posterior half of this vessel are given off a number of small branches, the *postero-median ganglionic branches*, which, with similar vessels from the posterior cerebral, pierce the posterior perforated space and supply the internal surfaces of the optic thalami and the walls of the third ventricle.

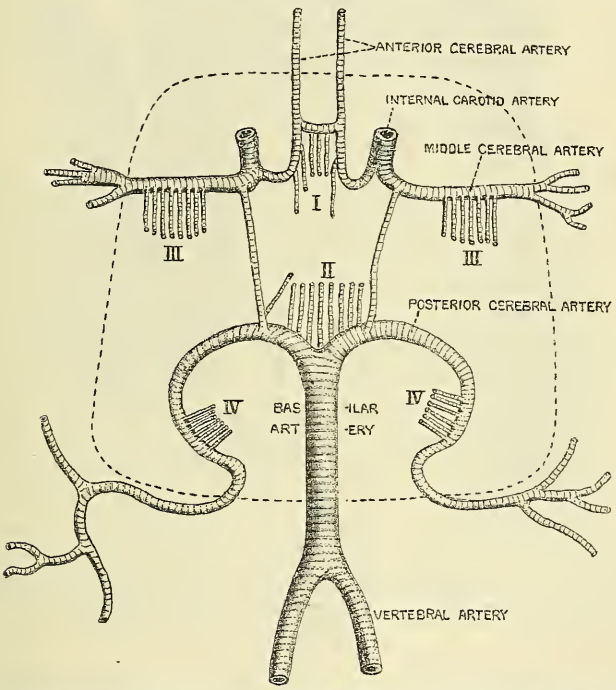
The **anterior choroid** is a small but constant branch, which arises from the back part of the internal carotid, near the posterior communicating artery. Passing backwards and outwards between the temporal lobe and the crus cerebri, it enters the descending horn of the lateral ventricle through the transverse fissure and ends in the choroid plexus. It is distributed to the hippocampus major, corpus fimbriatum, velum interpositum, and choroid plexus.

THE BLOOD VESSELS OF THE BRAIN

Recent investigations have tended to show that the mode of distribution of the vessels of the brain has an important bearing upon a considerable number of the anatomical lesions of which this part of the nervous system may be the seat; it therefore becomes important to consider a little more in detail the way in which the cerebral vessels are distributed.

The cerebral arteries are derived from the internal carotid and the vertebral, which at the base of the brain form a remarkable anastomosis known as the *circle of Willis*. It is formed in front by the anterior cerebral arteries, branches of the internal carotid, which are connected together by the anterior communicating; behind by the two posterior cerebrals, branches of the basilar which are connected on each side with the internal carotid by the posterior communicating (fig. 393, p. 579). The parts of the brain included within this arterial circle are the lamina cinerea, the commissure of the optic nerves, the infundibulum, the tuber cinereum, the corpora albicantia, and the posterior perforated space.

Fig. 396.—Diagram of the arterial circulation at the base of the brain. (After Charcot.)



I. Antero-median group of ganglionic branches. II. Postero-median group. III. Right and left antero-lateral group. IV. Right and left postero-lateral group. The dotted line shows the limit of the ganglionic circle.

From the circle of Willis arise the three trunks which together supply each cerebral hemisphere. From its anterior part proceed the two anterior cerebrals; from its antero-lateral part the middle cerebral, and from its posterior part the posterior cerebrals. Each of these principal arteries gives origin to two very different systems of secondary vessels. One of these systems has been named the *central ganglionic system*, and the vessels belonging to it supply the central ganglia of the brain; the other has been named the *cortical arterial system*, and its vessels ramify in the pia mater and supply the cortex and subjacent medullary matter. These two systems, though they have a common origin, do not communicate at any point of their peripheral distribution, and are entirely independent of each other. Though some of the arteries of the cortical system

approach, at their terminations, the regions supplied by the central ganglionic system, no communication between the two sets of vessels takes place, and there is between the parts supplied by the two systems a borderland of diminished nutritive activity, where, it is said, softening is especially liable to occur in the brains of old people.

The central ganglionic system.—All the vessels belonging to this system are given off from the circle of Willis, or from the vessels immediately after their origin from it. So that if a circle is drawn at a distance of about an inch from the circle of Willis, it will include the origin of all the arteries belonging to this system (fig. 396). The vessels of this system form six principal groups: (I) The *antero-median group*, derived from the anterior cerebrals and anterior communicating; (II) the *postero-median group*, from the posterior cerebrals and posterior communicating; (III) the right and left *antero-lateral group* from the middle cerebrals; and (IV) the right and left *postero-lateral group* from the posterior cerebrals, after they have wound round the crura cerebri. The vessels

belonging to this system are larger than those of the cortical system, and are what Cohnheim has termed 'terminal' arteries—that is to say, vessels which from their origin to their termination neither supply nor receive any anastomotic branch, so that, by one of the small vessels, only a limited area of the central ganglia can be injected, and the injection cannot be driven beyond the area of the part supplied by the particular vessel which is the subject of the experiment.

The cortical arterial system.—The vessels forming this system are the terminal branches of the anterior, middle, and posterior cerebral arteries, described above. These vessels divide and ramify in the substance of the pia mater, and give off nutrient arteries which penetrate the cortex perpendicularly. These nutrient vessels are divisible into two classes, the long and short. The *long*, or, as they are sometimes called, the *medullary arteries* pass through the grey matter to penetrate the centrum ovale to the depth of about an inch and a

half, without intercommunicating otherwise than by very fine capillaries, and thus constitute so many independent small systems. The *short vessels* are confined to the cortex, where they form with the long vessels a compact network in the middle zone of the grey matter, the outer and inner zones being sparingly supplied with blood (fig. 397). The vessels of the cortical arterial system are not so strictly 'terminal' as those of the central ganglionic system, but they approach this type very closely, so that injection of one area from the vessel of another area, though it may be possible, is frequently very difficult, and is only effected through vessels of small calibre. As a result of this, obstruction of one of the main branches, or its divisions, may have the effect of producing softening in a very limited area of the cortex.*

ARTERIES OF THE UPPER EXTREMITY

The artery which supplies the upper extremity continues as a single trunk from its commencement down to the elbow; but different portions of it have received different names, according to the region through which it passes. That part of the vessel which extends from its origin to the outer border of the first rib, is termed the subclavian; beyond this point to the lower border of the axilla, it is termed the axillary; and from the lower margin of the axillary space to the bend of the elbow, it is termed brachial; here, the single trunk terminates by dividing into two branches, the radial and ulnar, an arrangement precisely similar to what occurs in the lower limb.

Subclavian Arteries (fig. 398)

The **subclavian artery** on the right side arises from the innominate artery opposite the right sterno-clavicular articulation; on the left side it arises from the arch of the aorta. It follows, therefore, that these two vessels must, in the first part of their course, differ in their length, their direction, and their relation with neighbouring parts.

In order to facilitate the description of these vessels, more especially from a surgical point of view, each subclavian artery has been divided into three parts. The first portion, on the right side, passes upwards and outwards from the origin of the vessel to the inner border of the Scalenus anticus. On the left side it ascends nearly vertically, to gain the inner border of that muscle. The second part passes outwards, behind the Scalenus anticus; and the third part passes from the outer margin of that muscle, beneath the clavicle, to the outer border of the first rib, where it becomes the axillary artery. The first portion of these two vessels differs so much in its course, and in its relation with neighbouring parts, that it will be described separately. The second and third parts are alike on the two sides.

First Part of the Right Subclavian Artery (figs. 383, 386, 398)

The **right subclavian artery** arises from the arteria innominata, opposite the upper part of the right sterno-clavicular articulation, and passes upwards and outwards to the inner margin of the Scalenus anticus muscle. In this part of its course it ascends a little above the clavicle, the extent to which it does so varying in different cases. It is covered, *in front*, by the integument, superficial fascia, Platysma, deep fascia, the clavicular origin of the Sterno-mastoid, the Sterno-hyoid, and Sterno-thyroid muscles, and another layer of the deep fascia. It is crossed by the internal jugular and vertebral veins, and by the pneumo-gastric, the cardiac branches of the sympathetic, and the phrenic nerve. *Beneath*, the artery is invested by the pleura; and *behind*, it is separated by a cellular

* The student who desires further information on this subject is referred to Charcot's *Localisation of Cerebral and Spinal Diseases*, p. 42 *et seq.*, whence the facts above given have been principally derived.

interval from the Longus colli, the neck of the first rib, and the cord of the sympathetic nerve; the recurrent laryngeal nerve winds round the lower and back part of the vessel. The subclavian vein lies below the subclavian artery, immediately behind the clavicle.

First Part of the Left Subclavian Artery (fig. 383)

The **left subclavian artery** arises from the end of the arch of the aorta, opposite the fourth dorsal vertebra, and ascends nearly vertically to the inner margin of the Scalenus anticus muscle. This part of the vessel is, therefore, longer than the right, situated more deeply in the cavity of the chest, and directed nearly vertically upwards instead of arching outwards like the vessel of the opposite side.

It is in relation, *in front*, with the pleura, the left lung, the pneumogastric, cardiac, and phrenic nerves, which lie parallel with it, the left carotid artery, left internal jugular and vertebral veins, and the commencement of the left innominate vein, and is covered by the Sterno-thyroid, Sterno-hyoid, and Sterno-mastoid muscles; it has the left carotid in front of, but not in contact with it; *behind*, it is in relation with the œsophagus, thoracic duct, inferior cervical ganglion of the sympathetic, Longus colli, and vertebral column. To its *inner side* are the œsophagus, trachea, and thoracic duct; to its *outer side*, the pleura.

Second and Third Parts of the Subclavian Artery (fig. 386)

The **Second Portion of the Subclavian Artery** lies behind the Scalenus anticus muscle; it is very short, and forms the highest part of the arch described by that vessel.

Relations.—It is covered, *in front*, by the skin, superficial fascia, Platysma, deep cervical fascia, Sterno-mastoid, and by the phrenic nerve, which is separated from the artery by the Scalenus anticus muscle. *Behind*, it is in relation with the pleura and the Middle scalenus. *Above*, with the brachial plexus of nerves. *Below*, with the pleura. The subclavian vein lies below and in front of the artery, separated from it by the Scalenus anticus.

The **Third Portion of the Subclavian Artery** passes downwards and outwards from the outer margin of the Scalenus anticus to the outer border of the first rib, where it becomes the axillary artery. This portion of the vessel is the most superficial, and is contained in a triangular space, the base of which is formed in front by the Sterno-mastoid, and the two sides by the Omo-hyoid above and the clavicle below.

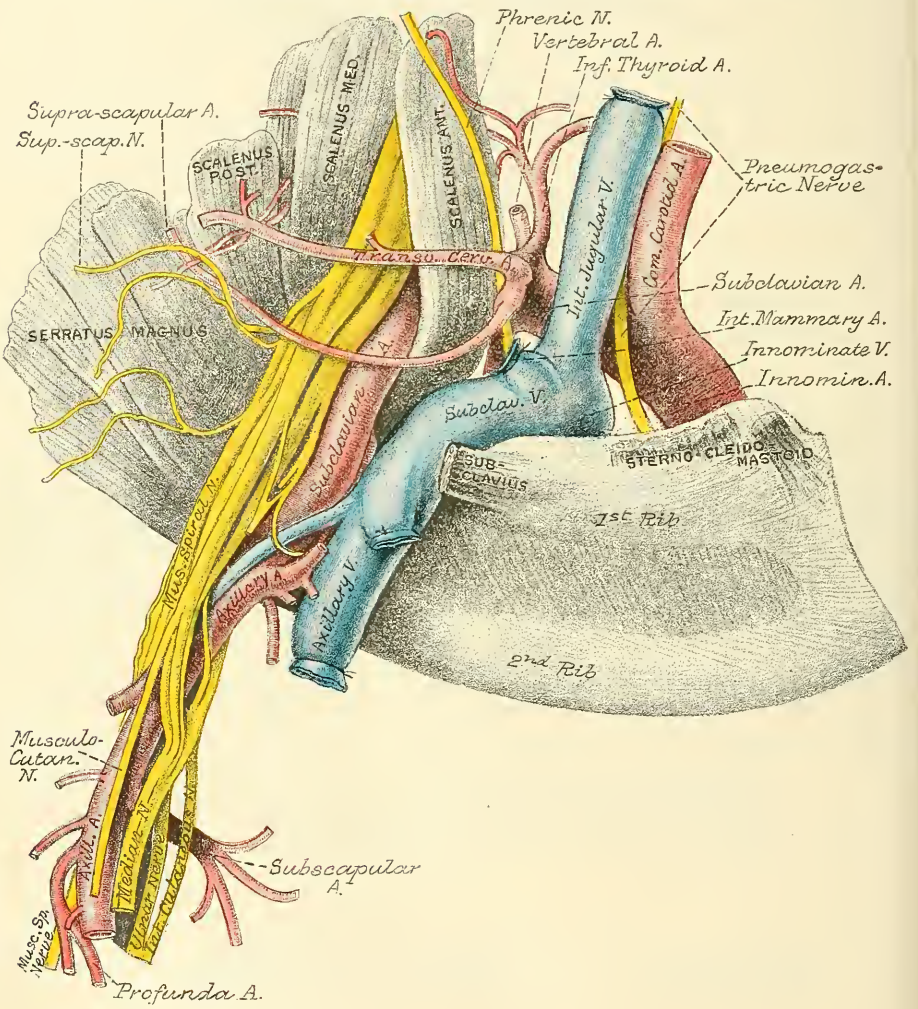
Lower cord of brachial plexus.

Relations.—It is covered, *in front*, by the skin, the superficial fascia, the Platysma, deep cervical fascia; by the clavicle, the Subclavius muscle, and the suprascapular artery and vein, and the transverse cervical vein; the clavicular descending branches of the cervical plexus and the nerve to the Subclavius muscle pass vertically downwards in front of the artery. The external jugular

vein crosses it at its inner side, and receives the suprascapular and transverse cervical veins, which occasionally form a plexus in front of it. The subclavian vein is below the artery, lying close behind the clavicle. *Behind*, it lies on the Middle Scalenus muscle and the lowest cord of the brachial plexus, formed by the union of the last cervical and first dorsal nerves. *Above* it, and to its outer side, is the brachial plexus, and Omo-hyoid muscle. *Below*, it rests on the upper surface of the first rib.

Peculiarities.—The subclavian arteries vary in their origin, their course, and the height to which they rise in the neck.

FIG. 398.—The subclavian artery, showing its relations. (From a preparation in the Museum of the Royal College of Surgeons.)



The origin of the right subclavian from the innominate takes place, in some cases, above the sterno-clavicular articulation; and occasionally, but less frequently, in the cavity of the thorax, below that joint. Or the artery may arise as a separate trunk from the arch of the aorta. In such cases it may be either the first, second, third, or even the last branch derived from that vessel; in the majority of cases, it is the first or last, rarely the second or third. When it is the first branch, it occupies the ordinary position of the innominate artery; when the second or third, it gains its usual position by passing behind the right carotid; and when the last branch, it arises from the left extremity of the arch, at its upper or back part, and passes obliquely towards the right side, usually behind the œsophagus and right carotid, sometimes between the œsophagus and trachea, to the upper border of the first rib, whence it follows its ordinary course. In very rare instances, this

vessel arises from the thoracic aorta, as low down as the fourth dorsal vertebra. Occasionally, it perforates the anterior Scalenus; more rarely it passes in front of that muscle. Sometimes the subclavian vein passes with the artery behind the Scalenus. The artery sometimes ascends as high as an inch and a half above the clavicle, or any intermediate point between this and the upper border of the bone, the right subclavian usually ascending higher than the left.

The left subclavian is occasionally joined at its origin with the left carotid.

Surface Marking.—The course of the subclavian artery in the neck may be mapped out, by describing a curve, with its convexity upwards at the base of the posterior triangle. The inner end of this curve corresponds to the sterno-clavicular joint, the outer end to the centre of the lower border of the clavicle. The curve is to be drawn with such an amount of convexity that its mid-point reaches half an inch above the upper border of the clavicle. The left subclavian artery is more deeply placed than the right in the first part of its course, and, as a rule, does not reach quite as high a level in the neck. It should be borne in mind that the posterior border of the Sterno-mastoid muscle corresponds to the outer border of the Scalenus anticus, so that the third portion of the artery, that part most accessible for operation, lies immediately external to the posterior border of the Sterno-mastoid.

Surgical Anatomy.—The relations of the subclavian arteries of the two sides having been examined, the student should direct his attention to a consideration of the best position in which compression of the vessel may be effected, or in what situation a ligature may be best applied in cases of aneurism or wound.

Compression of the subclavian artery is required in cases of operations about the shoulder, in the axilla, or at the upper part of the arm; and the student will observe that there is only one situation in which it can be effectually applied, viz. where the artery passes across the upper surface of the first rib. In order to compress the vessel in this situation, the shoulder should be depressed, and the surgeon grasping the side of the neck should press with his thumb in the angle formed by the posterior border of the Sterno-mastoid with the upper border of the clavicle, downwards, backwards, and inwards against the rib; if from any cause the shoulder cannot be sufficiently depressed, pressure may be made from before backwards, so as to compress the artery against the Middle scalenus and transverse process of the seventh cervical vertebra. In appropriate cases, a preliminary incision may be made through the cervical fascia, and the finger may be pressed down directly upon the artery.

Ligature of the subclavian artery may be required in cases of wounds, or of aneurism in the axilla, or in cases of aneurism on the cardiac side of the point of ligature; and the third part of the artery is that which is most favourable for an operation, on account of its being comparatively superficial, and most remote from the origin of the large branches. In those cases where the clavicle is not displaced, this operation may be performed with comparative facility; but where the clavicle is pushed up by a large aneurismal tumour in the axilla, the artery is placed at a great depth from the surface, which materially increases the difficulty of the operation. Under these circumstances, it becomes a matter of importance to consider the height to which this vessel reaches above the bone. In ordinary cases, its arch is about half an inch above the clavicle, occasionally as high as an inch and a half, and sometimes so low as to be on a level with its upper border. If the clavicle is displaced, these variations will necessarily make the operation more or less difficult, according as the vessel is more or less accessible.

The chief points in the operation of tying the third portion of the subclavian artery are as follows: the patient being placed on a table in the supine position, with the head drawn over to the opposite side, and the shoulder depressed as much as possible, the integument should be drawn downwards over the clavicle, and an incision made through it, upon that bone, from the anterior border of the Trapezius to the posterior border of the Sterno-mastoid, to which may be added a short vertical incision meeting the preceding in its centre. The object in drawing the skin downwards is to avoid any risk of wounding the external jugular vein, for as it perforates the deep fascia above the clavicle, it cannot be drawn downwards with the skin. The soft parts should now be allowed to glide up, and the cervical fascia divided upon a director, and if the interval between the Trapezius and Sterno-mastoid muscles be insufficient for the performance of the operation, a portion of one or both may be divided. The external jugular vein will now be seen towards the inner side of the wound: this and the suprascapular and transverse cervical veins which terminate in it should be held aside. If the external jugular vein is at all in the way and exposed to injury, it should be tied in two places and divided. The suprascapular artery should be avoided, and the Omo-hyoid muscle held aside if necessary. In the space beneath this muscle, careful search must be made for the vessel; a deep layer of fascia and some connective tissue having been divided carefully, the outer margin of the Scalenus anticus muscle must be felt for, and the finger being guided by it to the first rib, the pulsation of the subclavian artery will be felt as it passes over the rib. The sheath of the vessels having been opened, the aneurism needle may then be passed around the artery from above downwards and inwards so as to avoid including any of the branches of the brachial plexus. If the clavicle is so raised by the tumour that the application of the ligature cannot be effected in this situation, the artery may be tied above the first rib, or

even behind the Scalenus anticus muscle; the difficulties of the operation in such a case will be materially increased, on account of the greater depth of the artery, and the alteration in position of the surrounding parts.

The second part of the subclavian artery, from being that portion which rises highest in the neck, has been considered favourable for the application of the ligature, when it is difficult to tie the artery in the third part of its course. There are, however, many objections to the operation in this situation. It is necessary to divide the Scalenus anticus muscle, upon which lies the phrenic nerve, and at the inner side of which is situated the internal jugular vein; and a wound of either of these structures might lead to the most dangerous consequences. Again, the artery is in contact, below, with the pleura, which must also be avoided; and, lastly, the proximity of so many of its large branches arising internal to this point must be a still further objection to the operation. In cases, however, where the sac of an axillary aneurism encroaches on the neck, it may be necessary to divide the outer half or two-thirds of the Scalenus anticus muscle, so as to place the ligature on the vessel at a greater distance from the sac. The operation is performed exactly in the same way as ligature of the third portion, until the Scalenus anticus is exposed, when it is to be divided on a director (never to a greater extent than its outer two-thirds), and it immediately retracts. The operation is therefore merely an extension of ligature of the third portion of the vessel.

In those cases of aneurism of the axillary or subclavian artery which encroach upon the outer portion of the Scalenus muscle to such an extent that a ligature cannot be applied in that situation, it may be deemed advisable, as a last resource, to tie the first portion of the subclavian artery. On the left side, this operation is almost impracticable; the great depth of the artery from the surface, its intimate relation with the pleura, and its close proximity to the thoracic duct and to so many important veins and nerves, present a series of difficulties which it is next to impossible to overcome.* On the right side, the operation is practicable, and has been performed, though never with success. The main objection to the operation in this situation is the smallness of the interval which usually exists between the commencement of the vessel and the origin of the nearest branch. The operation may be performed in the following manner:—The patient being placed on the table in the supine position, with the neck extended, an incision should be made along the upper border of the inner part of the clavicle, and a second along the inner border of the Sterno-mastoid, meeting the former at an angle. The sternal attachment of the Sterno-mastoid must now be divided on a director, and turned outwards; a few small arteries and veins, and occasionally the anterior jugular, must be avoided, or, if necessary, ligatured in two places and divided, and the Sterno-hyoid and Sterno-thyroid muscles divided in the same manner as the preceding muscle. After tearing through the deep fascia with the finger-nail, the internal jugular vein will be seen crossing the subclavian artery; this should be pressed aside, and the artery secured by passing the needle from below upwards, by which the pleura is more effectually avoided. The exact position of the vagus, the recurrent laryngeal, the phrenic and sympathetic nerves should be remembered, and the ligature should be applied near the origin of the vertebral, in order to afford as much room as possible for the formation of a coagulum between the ligature and the origin of the vessel. It should be remembered, that the right subclavian artery is occasionally deeply placed in the first part of its course, when it arises from the left side of the aortic arch, and passes in such cases behind the œsophagus, or between it and the trachea.

Collateral Circulation.—After ligature of the third part of the subclavian artery, the collateral circulation is mainly established by three sets of vessels, thus described in a dissection:—

'1. A posterior set, consisting of the suprascapular and posterior scapular branches of the subclavian, anastomosing with the median branch from the subscapular from the axillary.

'2. An internal set produced by the connection of the internal mammary on the one hand, with the superior and long thoracic arteries, and the branches from the subscapular on the other.

'3. A middle or axillary set, which consisted of a number of small vessels derived from branches of the subclavian, above; and, passing through the axilla, terminated either in the main trunk, or some of the branches of the axillary below. This last set presented most conspicuously the peculiar character of newly-formed or, rather, dilated arteries, being excessively tortuous, and forming a complete plexus.

'The chief agent in the restoration of the axillary artery below the tumour was the subscapular artery, which communicated most freely with the internal mammary, suprascapular, and posterior scapular branches of the subclavian, from all of which it received so great an influx of blood as to dilate it to three times its natural size.' †

* The operation was, however, performed in New York by Dr. J. K. Rodgers, and the case is related in *A System of Surgery*, edited by T. Holmes, 2nd ed. vol. iii. pp. 620, &c.

† *Guy's Hospital Reports*, vol. i. 1836. Case of axillary aneurism, in which Mr. Aston Key had tied the subclavian artery on the outer edge of the Scalenus muscle, twelve years previously.

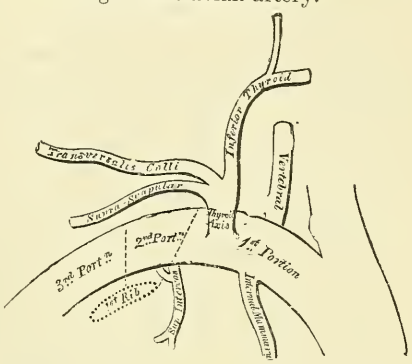
When a ligature is applied to the first part of the subclavian artery, the collateral circulation is carried on by: 1, the anastomosis between the superior and inferior thyroid; 2, the anastomosis of the two vertebrals; 3, the anastomosis of the internal mammary with the deep epigastric and the aortic intercostals; 4, the superior intercostal anastomosing with the aortic intercostals; 5, the profunda cervicis anastomosing with the princeps cervicis: 6. the scapular branches of the thyroid axis anastomosing with the branches of the axillary; and 7, the thoracic branches of the axillary anastomosing with the aortic intercostals.

Branches.—The branches given off from the subclavian artery are:—

Vertebral.	Thyroid axis.
Internal mammary.	Superior intercostal.

On the left side all four branches generally arise from the first portion of the vessel; but on the right side, the superior intercostal usually arises from the second portion of the vessel. On both sides of the body, the first three branches arise close together at the inner margin of the Scalenus anticus; in the majority of cases, a free interval of half an inch to an inch existing between the commencement of the artery and the origin of the nearest branch; in a smaller number of cases, an interval of more than an inch exists, never exceeding an inch and three-quarters. In a very few instances, the interval had been found to be less than half an inch. The vertebral artery arises from the upper part of the artery, slightly behind the middle line; the internal mammary from the lower part of the artery; the thyroid axis from in front, and the superior intercostal from behind.

Fig. 399.—Plan of the branches of the right subclavian artery.



The **Vertebral Artery** (fig. 391) is generally the first and largest branch of the subclavian; it arises from the upper and back part of the first portion of the vessel, and, passing upwards, enters the foramen in the transverse process of the sixth cervical vertebra,* and ascends through the foramina in the transverse processes of all the vertebræ above this. Above the upper border of the axis, it inclines outwards and upwards to the foramen in the transverse process of the atlas, through which it passes; it then winds backwards behind its articular process, runs in a deep groove on the upper surface of the posterior arch of this bone, and, passing beneath the posterior occipito-atlantal ligament, pierces the dura mater and arachnoid, and enters the skull through the foramen magnum. It then passes forwards and upwards, and inclining to the middle line to the front of the medulla oblongata, it unites with the vessel of the opposite side at the lower border of the pons Varolii to form the *basilar artery*.

Relations.—At its origin, it is situated behind the internal jugular and vertebral veins, and is crossed by the inferior thyroid artery: it lies between the Longus colli and Scalenus anticus muscles, having the thoracic duct in front of it on the left side. It rests on the transverse process of the seventh cervical vertebra and the sympathetic nerve. Within the foramina formed by the transverse processes of the vertebræ, it is accompanied by a plexus of nerves from the inferior cervical ganglion of the sympathetic, and is surrounded by a dense plexus of veins which unite to form the vertebral vein at the lower part of the neck. It is situated in front of the cervical nerves, as they issue from the intervertebral foramina. Whilst winding round the articular process of the atlas, it

* The vertebral artery sometimes enters the foramen in the transverse process of the fifth vertebra. Dr. Smyth, who tied this artery in the living subject, found it, in one of his dissections, passing into the foramen in the seventh vertebra.

is contained in a triangular space (*suboccipital triangle*) formed by the Rectus capitis posticus major, the Superior and the Inferior oblique muscles; and at this point is covered by the Complexus muscle. The suboccipital nerve here lies between the artery and the bone. Within the skull, as it winds round the medulla oblongata, it is placed between the hypoglossal nerve and the anterior root of the suboccipital nerve, beneath the first digitation of the ligamentum denticulatum, and finally lies between the dura mater and arachnoid covering the basilar process of the occipital bone and the anterior surface of the medulla oblongata.

The branches given off from this vessel may be divided into two sets—those given off in the neck, and those within the cranium.

Cervical Branches.	*Cranial Branches.*
Lateral Spinal.	Posterior Meningeal.
Muscular.	Anterior Spinal.
	Posterior Spinal.
	Posterior Inferior Cerebellar.

The **lateral spinal branches** enter the spinal canal through the intervertebral foramina, and divide into two branches. Of these, one passes along the roots of the nerves to supply the spinal cord and its membranes, anastomosing with the other arteries of the spinal cord; the other divides into an ascending and a descending branch, which unite with similar branches from the artery above and below, so that two lateral anastomotic chains are formed on the posterior surface of the bodies of the vertebræ, near the attachment of the pedicles. From these anastomotic chains branches are given off, to supply the periosteum and the bodies of the vertebræ, and to communicate with similar branches from the opposite side; from these latter small branches are given off which join similar branches above and below, so that a central anastomotic chain is formed on the posterior surface of the bodies of the vertebræ.

Muscular branches are given off to the deep muscles of the neck, where the vertebral artery curves round the articular process of the atlas. They anastomose with the occipital, and with the ascending and deep cervical arteries.

The **posterior meningeal** are one or two small branches given off from the vertebral opposite the foramen magnum. They ramify between the bone and dura mater in the cerebellar fossæ, and supply the falx cerebelli.

The **anterior spinal** is a small branch, though larger than the posterior spinal which arises near the termination of the vertebral, and, descending in front of the medulla oblongata, unites with its fellow of the opposite side at about the level of the foramen magnum. One of these vessels is usually of much larger size than the other, but occasionally they are about equal in size. The single trunk, thus formed, descends on the front of the spinal cord, and is reinforced by a succession of small branches which enter the spinal canal through the intervertebral foramina; these branches are derived from the vertebral and ascending cervical of the inferior thyroid in the neck; from the intercostal in the dorsal region; and from the lumbar, ilio-lumbar, and lateral sacral arteries in the lower part of the spine. They unite, by means of ascending and descending branches, to form a single anterior median artery, which extends as far as the lower part of the spinal cord. This vessel is placed in the pia mater along the anterior median fissure; it supplies that membrane, and the substance of the cord, and sends off branches at its lower part to be distributed to the cauda equina, and ends on the central fibrous prolongation of the cord.

The **posterior spinal** arises from the vertebral, at the side of the medulla oblongata; passing backwards to the posterior aspect of the spinal cord, it descends on each side, lying behind the posterior roots of the spinal nerves; and is reinforced by a succession of small branches, which enter the spinal canal through the intervertebral foramina, and by which it is continued to the lower part of the cord, and to the cauda equina. Branches from these vessels form a

free anastomosis round the posterior roots of the spinal nerves, and communicate, by means of very tortuous transverse branches, with the vessel of the opposite side. At its commencement it gives off an ascending branch, which terminates at the side of the fourth ventricle.

The **posterior inferior cerebellar artery** (fig. 393), the largest branch of the vertebral, winds backwards round the upper part of the medulla oblongata, passing between the origin of the pneumogastric and spinal accessory nerves, over the restiform body to the under surface of the cerebellum, where it divides into two branches: an internal one, which is continued backwards to the notch between the two hemispheres of the cerebellum; and an external one, which supplies the under surface of the cerebellum, as far as its outer border, where it anastomoses with the anterior inferior cerebellar and the superior cerebellar branches of the basilar artery. Branches from this artery supply the choroid plexus of the fourth ventricle.

Surgical Anatomy.—The vertebral artery has been tied in several instances: 1, for wounds or traumatic aneurism; 2, after ligature of the innominate, either at the same time to prevent hæmorrhage, or later on to arrest bleeding where it has occurred at the seat of ligature; and 3, in epilepsy. In these latter cases the treatment has been recommended by Dr. Alexander, of Liverpool, in the hope that by diminishing the supply of blood to the posterior part of the brain and the spinal cord, a diminution or cessation of the epileptic fits would result. The operation of ligature of the vertebral is performed by making an incision along the posterior border of the Sterno-mastoid muscle, just above the clavicle. The muscle is pulled to the inner side and the anterior tubercle of the transverse process of the sixth cervical vertebra sought for. A deep layer of fascia being now divided, the interval between the Scalenus anticus and the Longus colli, just below their attachment to the tubercle, is defined, and the artery and vein found in the interspace. The vein is to be drawn to the outer side, and the aneurism needle passed from without inwards. Drs. Ramskill and Bright have pointed out that severe pain at the back of the head may be symptomatic of disease of the vertebral artery just before it enters the skull. This is explained by the close connection of the artery with the suboccipital nerve in the groove on the posterior arch of the atlas. Disease of the same artery has been also said to affect speech, from pressure on the hypoglossal, where it is in relation with the vessel, leading to paralysis of the muscles of the tongue.

The **Basilar Artery** (fig. 393), so named from its position at the base of the skull, is a single trunk formed by the junction of the two vertebral arteries; it extends from the posterior to the anterior border of the pons Varolii, lying in its median groove, under cover of the arachnoid. It ends by dividing into two branches, the *posterior cerebral arteries*. Its branches are, on each side, the following:—

Transverse.	Superior Cerebellar.
Anterior Inferior Cerebellar.	Posterior Cerebral.

The **transverse branches** supply the pons Varolii and adjacent parts of the brain; one branch, the *internal auditory*, accompanies the auditory nerve into the internal auditory meatus.

The **anterior inferior cerebellar artery** passes backwards across the crus cerebelli, to be distributed to the anterior border of the under surface of the cerebellum, anastomosing with the posterior inferior cerebellar branch of the vertebral.

The **superior cerebellar arteries** arise near the termination of the basilar. They pass outwards, immediately behind the third nerve, which separates them from the posterior cerebral, wind round the crus cerebri, close to the fourth nerve, and arriving at the upper surface of the cerebellum, divide into branches which ramify in the pia mater and, reaching the circumference of the cerebellum, anastomose with the branches of the inferior cerebellar arteries. Several branches are given to the pineal gland, the valve of Vieussens, and the velum interpositum.

The **posterior cerebral arteries**, the two terminal branches of the basilar, are larger than the preceding, from which they are separated near their origin by the third nerves. Passing outwards, parallel to the superior cerebellar artery

and receiving the posterior communicating, they wind round the crura cerebri, and pass to the under surface of the occipital lobes of the cerebrum, and break up into branches for the supply of the temporo-sphenoidal and occipital lobes. The branches of the posterior cerebral artery are :—

Postero-median Ganglionic.	Postero-lateral Ganglionic.
Posterior Choroid.	Three Terminal.

The *postero-median ganglionic branches* (fig. 396) are a group of small arteries which arise at the commencement of the posterior cerebral artery; these, with similar branches from the posterior communicating, pierce the posterior perforated space, and supply the internal surfaces of the optic thalami and the walls of the third ventricle. The *posterior choroid* enters the interior of the brain beneath the posterior border of the corpus callosum, and supplies the velum interpositum and the choroid plexus. The *postero-lateral ganglionic branches* are a group of small arteries which arise from the posterior cerebral artery, after it has turned round the crus cerebri; they supply a considerable portion of the optic thalamus. The *terminal branches* are distributed as follows: the first to the uncinate gyrus; the second to the temporo-sphenoidal lobe; and the third to the cuneus or the occipital lobule.

Circle of Willis.—The remarkable anastomosis which exists between the branches of the internal carotid and vertebral arteries at the base of the brain constitutes the *circle of Willis*. It is formed, in front, by the anterior cerebral arteries, branches of the internal carotid, which are connected together by the anterior communicating; behind, by the two posterior cerebrals, branches of the basilar, which are connected on each side with the internal carotid by the posterior communicating arteries (fig. 393). It is by this anastomosis that the cerebral circulation is equalised, and provision made for effectually carrying it on if one or more of the branches are obliterated. The parts of the brain included within this arterial circle are: the lamina cinerea, the commissure of the optic nerves, the infundibulum, the tuber cinereum, the corpora albicantia, and the posterior perforated space.

The **Thyroid Axis** (fig. 386) is a short thick trunk, which arises from the fore part of the first portion of the subclavian artery, close to the inner border of the Scalenus anticus muscle, and divides, almost immediately after its origin, into three branches, the *inferior thyroid*, *suprascapular*, and *transversalis colli*.

The **Inferior Thyroid Artery** passes upwards, in front of the vertebral artery, recurrent laryngeal nerve and Longus colli muscle; then turns inwards behind the sheath of the common carotid artery and internal jugular vein, and also behind the sympathetic nerve, the middle cervical ganglion resting upon the vessel, and reaching the lower border of the lateral lobe of the thyroid gland it divides into two branches, which supply the posterior and under part of the organ, and anastomose in its substance with the superior thyroid, and with the corresponding artery of the opposite side. Its branches are, the

Inferior Laryngeal.	Œsophageal.
Tracheal.	Ascending Cervical.
Muscular.	

The **inferior laryngeal branch** ascends upon the trachea to the back part of the larynx, in company with the recurrent laryngeal nerve, and supplies the muscles and mucous membrane of this part, anastomosing with the branch from the opposite side, and with the laryngeal branch from the superior thyroid artery.

The **tracheal branches** are distributed upon the trachea, anastomosing below with the bronchial arteries.

The **œsophageal branches** are distributed to the œsophagus, and anastomose with the œsophageal branches of the aorta.

The **ascending cervical** is a small branch which arises from the inferior

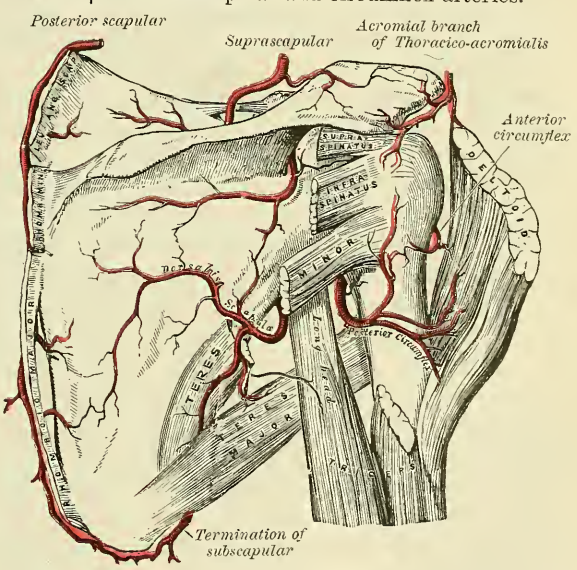
thyroid, just where that vessel is passing behind the common carotid artery, and runs up on the anterior tubercles of the transverse processes of the cervical vertebræ in the interval between the Scalenus anticus and Rectus capitis anticus major. It gives branches to the muscles of the neck, which anastomose with branches of the vertebral, and sends one or two branches into the spinal canal through the intervertebral foramina to be distributed to the spinal cord and its membranes, and to the bodies of the vertebræ in the same manner as the lateral spinal branches from the vertebral. It anastomoses with the ascending pharyngeal and occipital arteries.

The **muscular branches** supply the depressors of the hyoid bone, the Longus colli, the Scalenus anticus, and the Inferior constrictor of the pharynx.

Surgical Anatomy.—This artery is sometimes tied, in conjunction with the superior thyroid, in cases of bronchocele. An incision is made along the anterior border of the Sterno-mastoid down to the clavicle. After the deep fascia has been divided, the Sterno-mastoid and carotid vessels are drawn outwards, and the carotid (Chassaignac's) tubercle sought for. The vessel will be found just below this tubercle, between the carotid sheath on the outer side and the trachea and œsophagus on the inner side. In passing the ligature, great care must be exercised to avoid including the recurrent laryngeal nerve, which is occasionally found crossing in *front* of the vessel.

The **Suprascapular Artery** (**transversalis humeri**), smaller than the transversalis colli, passes obliquely from within outwards, across the root of the neck. It at first lies on the lower part of the Scalenus anticus, being covered by the Sterno-mastoid; it then crosses the subclavian artery and runs outwards, behind and parallel with the clavicle and Subclavius muscle, and beneath the posterior belly of the Omo-hyoid, to the superior border of the scapula, where it passes over the transverse ligament of the scapula, to the supraspinous fossa. In this situation it lies close to the bone, and ramifies between it and the Supraspinatus muscle, to which it is mainly distributed, giving off a communicating branch, which crosses the neck of the scapula, to reach the infraspinous fossa, where it anastomoses with the dorsal branch of the subscapular artery. Besides distributing branches to the Sterno-mastoid, Subclavius, and neighbouring muscles, it gives off a *supra-sternal branch*, which crosses over the sternal end of the clavicle to the skin of the upper part of the chest; and a *supra-acromial branch*, which, piercing the Trapezius muscle, supplies the cutaneous surface of the acromion, anastomosing with the acromial thoracic artery. As the artery passes over the transverse ligament of the scapula, a branch descends into the subscapular fossa, ramifies beneath that muscle, and anastomoses with the posterior and subscapular arteries. It also sends branches to the acromio-clavicular joint and the shoulder-joint, and a nutrient artery to the clavicle.

Fig. 400.—The scapular and circumflex arteries.



The **Transversalis Colli** passes transversely outwards, across the upper part of the subclavian triangle, to the anterior margin of the Trapezius muscle, beneath which it divides into two branches, the *superficial cervical* and the

posterior scapular. In its passage across the neck, it crosses in front of the Scaleni muscles and the brachial plexus, between the divisions of which it sometimes passes, and is covered by the Platysma, Sterno-mastoid, Omo-hyoid, and Trapezius muscles.

The **superficial cervical** ascends beneath the anterior margin of the Trapezius, distributing branches to it, and to the neighbouring muscles and glands in the neck, and anastomoses with the superficial branch of the arteria princeps cervicis.

The **posterior scapular** passes beneath the Levator anguli scapulæ to the superior angle of the scapula. It now descends along the posterior border of that bone as far as the inferior angle, where it anastomoses with the subscapular branch of the axillary. In its course it is covered by the Rhomboid muscles, supplying them and the Latissimus dorsi and Trapezius, and anastomosing with the suprascapular and subscapular arteries, and with the posterior branches of some of the intercostal arteries.

Peculiarities.—The *superficial cervical* frequently arises as a separate branch from the thyroid axis; and the posterior scapular, from the third, more rarely from the second, part of the subclavian.

The **Internal Mammary** (fig. 401) arises from the under surface of the first portion of the subclavian artery, opposite the thyroid axis. It descends behind the costal cartilage of the first rib to the inner surface of the anterior wall of the chest, resting against the costal cartilages about half an inch from the margin of the sternum; and, at the interval between the sixth and seventh cartilages, divides into two branches, the *musculo-phrenic* and *superior epigastric*.

Relations.—At its origin it is covered by the internal jugular and subclavian veins, and crossed by the phrenic nerve. In the upper part of the thorax, it lies against the costal cartilages and Internal intercostal muscles in front, and is covered by the pleura behind. At the lower part of the thorax, the Triangularis sterni separates the artery from the pleura. It has two venæ comites, which unite into a single vein before joining the innominate vein of its own side.

The branches of the internal mammary are—

Comes Nervi Phrenici (Superior Phrenic).	Anterior Intercostal.
Mediastinal.	Perforating.
Pericardiac.	Musculo-phrenic.
Sternal.	Superior Epigastric.

The **comes nervi phrenici** (**superior phrenic**) is a long slender branch, which accompanies the phrenic nerve, between the pleura and pericardium, to the Diaphragm, to which it is distributed; anastomosing with the other phrenic arteries from the internal mammary, and abdominal aorta.

The **mediastinal branches** are small vessels, which are distributed to the areolar tissue and lymphatic glands in the anterior mediastinum, and the remains of the thymus gland.

The **pericardiac branches** supply the upper part of the anterior surface of the pericardium, the lower part receiving branches from the musculo-phrenic artery.

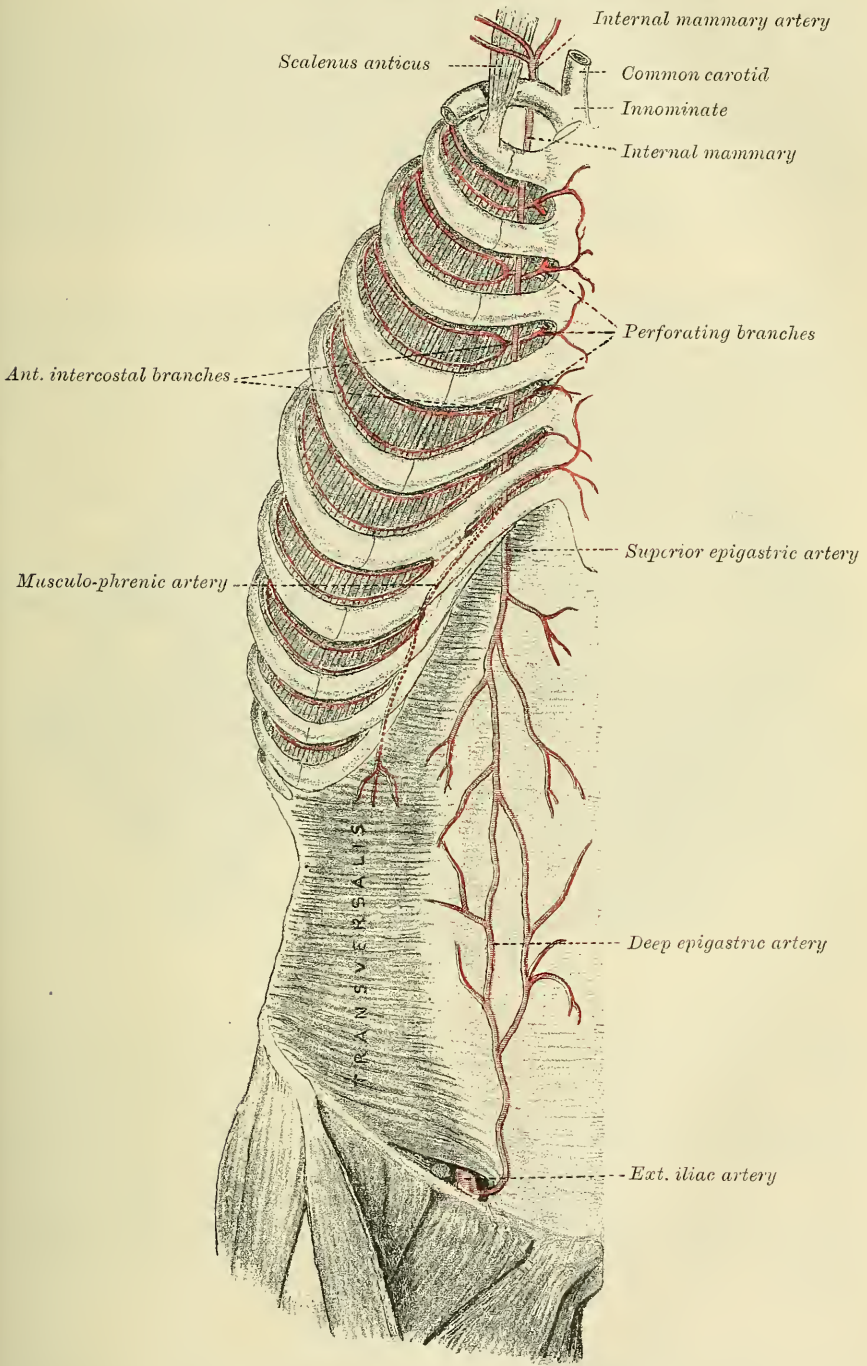
The **sternal branches** are distributed to the Triangularis sterni, and to the posterior surface of the sternum.

The mediastinal, pericardiac, and sternal branches, together with some twigs from the comes nervi phrenici, anastomose with branches from the intercostal and bronchial arteries, and form a minute plexus beneath the pleura which has been named by Turner the *subpleural mediastinal plexus*.

The **anterior intercostal arteries** supply the five or six upper intercostal spaces. The branch corresponding to each space soon divides into two; or the two branches may come off separately from the parent trunk. These small vessels pass outwards in the intercostal spaces, one lying near the lower margin of the rib above, and the other near the upper margin of the rib below, and anastomose

with the intercostal arteries from the aorta. They are at first situated between the pleura and the Internal intercostal muscles, and then between the Internal and External intercostal muscles. They supply the Intercostal muscles and, by

Fig. 401.—The internal mammary artery and its branches.



branches which perforate the External intercostal muscle, the Pectoral muscles and the mammary gland.

The **perforating arteries** correspond to the five or six upper intercostal spaces.

They arise from the internal mammary, pass forwards through the intercostal spaces, and, curving outwards, supply the Pectoralis major, and the integument. Those which correspond to the second, third, and fourth spaces are distributed to the mammary gland. In females, during lactation, these branches are of large size.

The **musculo-phrenic artery** is directed obliquely downwards and outwards, behind the cartilages of the false ribs, perforating the Diaphragm at the eighth or ninth rib, and terminating, considerably reduced in size, opposite the last intercostal space. It gives off anterior intercostal arteries to each of the intercostal spaces across which it passes; these diminish in size as the spaces decrease in length, and are distributed in a manner precisely similar to the anterior intercostals from the internal mammary. The musculo-phrenic also gives branches to the lower part of the pericardium, and others which run backwards to the Diaphragm, and downwards to the abdominal muscles.

The **superior epigastric** continues in the original direction of the internal mammary; it descends through the cellular interval between the costal and sternal attachments of the Diaphragm, and enters the sheath of the Rectus abdominis muscle, at first lying behind the muscle, and then perforating it and supplying it, and anastomosing with the deep epigastric artery from the external iliac. Some vessels perforate the sheath of the Rectus, and supply the muscles of the abdomen and the integument, and a small branch, which passes inwards upon the side of the ensiform appendix, anastomoses in front of that cartilage with the artery of the opposite side.

Surgical Anatomy.—The course of the internal mammary artery may be defined by drawing a line across the six upper intercostal spaces, half an inch from and parallel with the sternum. The position of the vessel must be remembered, as it is liable to be wounded in stabs of the chest-wall. It is most easily reached by a transverse incision in the second intercostal space.

The **Superior Intercostal** (fig. 391) arises from the upper and back part of the subclavian artery, behind the Anterior scalenus on the right side, and to the inner side of the muscle on the left side. Passing backwards, it gives off the *deep cervical branch*, and then descends behind the pleura in front of the necks of the first two ribs, and inosculates with the first aortic intercostal. In the first intercostal space, it gives off a branch which is distributed in a manner similar to the distribution of the aortic intercostals. The branch for the second intercostal space usually joins with one from the aortic intercostals. Each intercostal gives off a branch to the posterior spinal muscles, and a small one which passes through the corresponding intervertebral foramen to the spinal cord and its membranes.

The *deep cervical branch* (*profunda cervicis*) arises, in most cases, from the superior intercostal, and is analogous to the posterior branch of an aortic intercostal artery: occasionally it arises as a separate branch from the subclavian artery. Passing backwards, between the transverse process of the seventh cervical vertebra and the first rib, it runs up the back part of the neck, between the Complexus and Semispinalis colli muscles, as high as the axis, supplying these and adjacent muscles, and anastomosing with the deep branch of the arteria princeps cervicis of the occipital, and with branches which pass outwards from the vertebral. It gives off a special branch which enters the spinal canal through the intervertebral foramen between the seventh cervical and first dorsal vertebra.

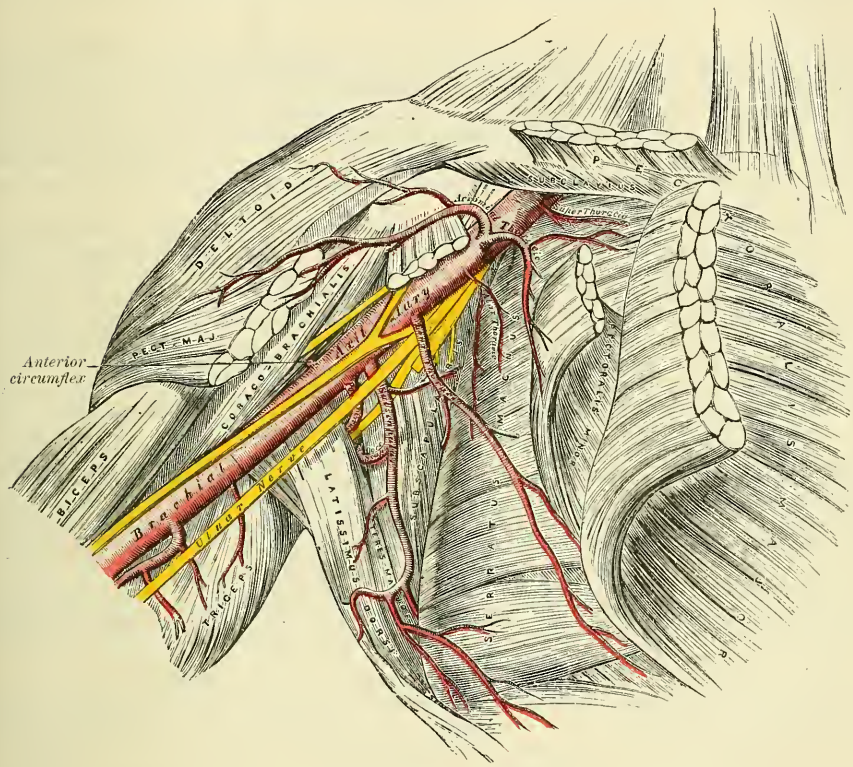
Anatomy of the Axilla

The **Axilla** is a pyramidal space, situated between the upper and lateral part of the chest and the inner side of the arm.

Boundaries.—Its *apex*, which is directed upwards towards the root of the neck, corresponds to the interval between the first rib, the upper edge of

the scapula, and the clavicle, through which the axillary vessels and nerves pass. The *base*, directed downwards, is formed by the integument, and a thick layer of fascia, extending between the lower border of the Pectoralis major in front, and the lower border of the Latissimus dorsi behind; it is broad internally, at the chest, but narrow and pointed externally, at the arm. The *anterior boundary* is formed by the Pectoralis major and minor muscles, the former covering the whole of the anterior wall of the axilla, the latter covering only its central part. The *posterior boundary*, which extends somewhat lower than the anterior, is formed by the Subscapularis above, the Teres major and Latissimus dorsi below. On the *inner side* are the first four ribs with their corresponding Intercostal muscles, and part of the Serratus magnus. On the *outer side*, where the anterior and posterior boundaries con-

Fig. 402.—The axillary artery and its branches.



verge, the space is narrow, and bounded by the humerus, the Coraco-brachialis and Biceps muscles.

Contents.—This space contains the axillary vessels, and brachial plexus of nerves, with their branches; some branches of the intercostal nerves, and a large number of lymphatic glands, all connected together by a quantity of fat and loose areolar tissue.

Their Position.—The axillary artery and vein, with the brachial plexus of nerves, extend obliquely along the outer boundary of the axillary space, from its apex to its base, and are placed much nearer the anterior than the posterior wall, the vein lying to the inner or thoracic side of the artery, and partially concealing it. At the fore part of the axillary space, in contact with the Pectoral muscles, are the thoracic branches of the axillary artery, and along the anterior margin of the axilla the long thoracic artery extends to the side of the chest. At the back part, in contact with the lower margin of the Subscapularis muscle, are the subscapular vessels and nerves; winding around the lower border of this

muscle is the dorsalis scapulæ artery and veins; and towards the outer extremity of the muscle, the posterior circumflex vessels and the circumflex nerve are seen curving backwards to the shoulder.

Along the inner or thoracic side no vessel of any importance exists, the upper part of the space being crossed merely by a few small branches from the superior thoracic artery. There are some important nerves, however, in this situation, viz. the posterior thoracic or external respiratory nerve, descending on the surface of the Serratus magnus, to which it is distributed; and perforating the upper and anterior part of this wall, the intercosto-humeral nerve or nerves, passing across the axilla to the inner side of the arm.

The cavity of the axilla is filled by a quantity of loose areolar tissue, and a large number of small arteries and veins, all of which are, however, of inconsiderable size, and numerous lymphatic glands: these are from ten to twelve in number, and situated chiefly on the thoracic side, and lower and back part of this space.

Surgical Anatomy.—The axilla is a space of considerable surgical importance. It transmits the large vessels and nerves to the upper extremity, and these may be the seat of injury or disease: it contains numerous lymphatic glands which may require removal when diseased; in it is a quantity of loose connective and adipose tissue which may be readily infiltrated with blood or inflammatory exudation, and it may be the seat of rapidly growing tumours. Moreover, it is covered at its base by thin skin, largely supplied with sebaceous and sweat glands, which is frequently the seat of small cutaneous abscesses and boils, and of eruptions due to irritation.

In suppuration in the axilla, the arrangement of the fasciæ plays a very important part in the direction which the pus takes. As described on page 470, the costo-coracoid membrane, after covering in the space between the clavicle and the upper border of the Pectoralis minor, splits to enclose this muscle, and, reblending at its lower border, becomes incorporated with the fascia covering the Pectoralis major muscle at the anterior fold of the axilla. This is known as the clavi-pectoral fascia. Suppuration may take place either superficial to or beneath this layer of fascia; that is, either between the Pectorals or below the Pectoralis minor: in the former case, it would point either at the anterior border of the axillary fold, or in the groove between the Deltoid and the Pectoralis major; in the latter, the pus would have a tendency to surround the vessels and nerves, and ascend into the neck, that being the direction in which there is least resistance. Its progress towards the skin is prevented by the axillary fascia; its progress backwards, by the Serratus magnus; forwards, by the clavi-pectoral fascia; inwards, by the wall of the thorax; and outwards, by the upper limb. The pus in these cases, after extending into the neck, has been known to spread through the superior opening of the thorax into the mediastinum.

In opening an axillary abscess, the knife should be entered in the floor of the axilla, midway between the anterior and posterior margins and near the thoracic side of the space. It is well to use a director and dressing forceps, after an incision has been made through the skin and fascia, in the manner directed by the late Mr. Hilton.

The student should attentively consider the relation of the vessels and nerves in the several parts of the axilla; for it not unfrequently happens that the surgeon is called upon to extirpate diseased glands, or to remove a tumour from this situation. In performing such an operation, it will be necessary to proceed with much caution in the direction of the outer wall and apex of the space, as here the axillary vessels will be in danger of being wounded. Towards the posterior wall, it will be necessary to avoid the subscapular, dorsalis scapulæ, and posterior circumflex vessel. Along the anterior wall, it will be necessary to avoid the thoracic branches. It is only along the inner or thoracic wall, and in the centre of the axillary cavity, that there are no vessels of any importance; a fortunate circumstance, for it is in this situation more especially that tumours requiring removal are usually situated.

The Axillary Artery

The **Axillary Artery**, the continuation of the subclavian, commences at the outer border of the first rib, and terminates at the lower border of the tendon of the Teres major muscle, where it takes the name of brachial. Its direction varies with the position of the limb: when the arm lies by the side of the chest, the vessel forms a gentle curve, the convexity being upwards and outwards; when it is directed at right angles with the trunk, the vessel is nearly straight; and when it is elevated still higher, the artery describes a curve, the concavity of which is directed upwards. At its commencement the artery is very deeply

situated, but near its termination is superficial, being covered only by the skin and fascia. The description of the relations of this vessel is facilitated by its division into three portions: the first portion being that above the Pectoralis minor; the second portion, behind; and the third below, that muscle.

The **first portion of the axillary artery** is in relation, *in front*, with the clavicular portion of the Pectoralis major, the costo-coracoid membrane, the external anterior thoracic nerve, and the acromio-thoracic and cephalic veins; *behind*, with the first intercostal space, the corresponding Intercostal muscle, the second and a portion of the third serration of the Serratus magnus, and the posterior thoracic and internal anterior thoracic nerves; on its *outer side*, with the brachial plexus, from which it is separated by a little cellular interval; on its *inner*, or thoracic side, with the axillary vein.

Relations of the First Portion of the Axillary Artery

Pectoralis major.
Costo-coracoid membrane.
External anterior thoracic nerve.
Acromio-thoracic and Cephalic veins.

Outer side.
Brachial plexus.

Inner side.
Axillary vein.

Behind.
First intercostal space, and Intercostal muscle.
Second and third serrations of Serratus magnus.
Posterior thoracic and internal anterior thoracic nerves.

The **second portion of the axillary artery** lies behind the Pectoralis minor. It is covered, *in front*, by the Pectoralis major and minor muscles; *behind*, it is separated from the Subscapularis by a cellular interval; on the *inner side* is the axillary vein, separated from the artery by the inner cord of the plexus and the internal anterior thoracic nerve. The brachial plexus of nerves surrounds the artery, and separates it from direct contact with the vein and adjacent muscles.

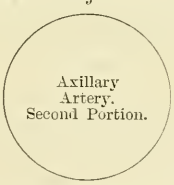
Outer side.
Outer cord of plexus.



Inner side.
Axillary vein.
Inner cord of plexus.
Internal anterior thoracic nerve.

Behind.
Subscapularis.
Posterior cord of plexus.

The **third portion of the axillary artery** lies below the Pectoralis minor. It is in relation, *in front*, with the lower part of the Pectoralis major above, being covered only by the integument and fascia below, where it is crossed by the inner head of the median nerve; *behind*, with the lower part of the Subscapularis, and the tendons of the Latissimus dorsi and Teres major; on its *outer side*, with the

Coraco-brachialis; on its *inner*, or thoracic side, with the axillary vein. The nerves of the brachial plexus bear the following relation to the artery in this part of its course: on the *outer side* is the median nerve, and the musculo-cutaneous for a short distance; on the *inner side*, the ulnar, the internal, and lesser internal cutaneous nerves; and *behind*, the musculo-spiral and circumflex, the latter extending only to the lower border of the Subscapularis muscle.

Musculo-spiral, and circumflex nerves.

Peculiarities.—The axillary artery, in about one case out of every ten, gives off a large branch, which forms either one of the arteries of the forearm, or a large muscular trunk. In the first set of cases, this artery is most frequently the radial (1 in 33), sometimes the ulnar (1 in 72), and, very rarely, the interosseous (1 in 506). In the second set of cases, the trunk has been found to give origin to the subscapular, circumflex, and profunda arteries of the arm. Sometimes, only one of the circumflex, or one of the profunda arteries, arose from the trunk. In these cases the brachial plexus surrounded the trunk of the branches, and not the main vessel.

Surface Marking.—The course of the axillary artery may be marked out by raising the arm to a right angle and drawing a line from the middle of the clavicle to the point where the tendon of the Pectoralis major crosses the prominence caused by the Coraco-brachialis as it emerges from under cover of the anterior fold of the axilla. The third portion of the artery can be felt pulsating beneath the skin and fascia, at the junction of the anterior with the middle third of the space between the anterior and posterior folds of the axilla, close to the inner border of the Coraco-brachialis.

Surgical Anatomy.—The student, having carefully examined the relations of the axillary artery in its various parts, should now consider in what situation compression of this vessel may be most easily effected, and the best position for the application of a ligature to it when necessary.

Compression of the vessel may be required in the removal of tumours, or in amputation of the upper part of the arm; and the only situation in which this can be effectually made is in the lower part of its course; by pressing on it in this situation from within outwards against the humerus, the circulation may be effectually arrested.

The axillary artery is perhaps more frequently lacerated than any other artery in the body, with the exception of the popliteal, by violent movements of the upper extremity, especially in those cases where its coats are diseased. It has occasionally been ruptured in attempts to reduce old dislocations of the shoulder-joint. This lesion is most likely to occur during the preliminary breaking down of adhesions, in consequence of the artery having contracted adhesions to the capsule of the joint. Aneurism of the axillary artery is of frequent occurrence: a large percentage of the cases being traumatic in their origin, due to the violence to which it is exposed in the varied, extensive, and often violent movement of the limb.

The *application of a ligature to the axillary artery* may be required in cases of aneurism of the upper part of the brachial, or as a distal operation for aneurism of the subclavian; and there are only two situations in which it can be secured, viz. in the first and in the third parts of its course; for the axillary artery at its central part is so deeply seated, and, at the same time, so closely surrounded with large nervous trunks, that the application of a ligature to it in that situation would be almost impracticable.

In the *third part* of its course the operation is most simple, and may be performed in the following manner:—The patient being placed on a bed, and the arm separated from the side, with the hand supinated, an incision is made through the integument forming the floor of the axilla, about two inches in length, a little nearer to the anterior than the

posterior fold of the axilla. After carefully dissecting through the areolar tissue and fascia, the median nerve and axillary vein are exposed; the former having been displaced to the outer, and the latter to the inner side of the arm, the elbow being at the same time bent, so as to relax the structures and facilitate their separation, the ligature may be passed round the artery from the ulnar to the radial side. This portion of the artery is occasionally crossed by a muscular slip derived from the Latissimus dorsi, which may mislead the surgeon during an operation. The occasional existence of this muscular fasciculus was spoken of in the description of the muscles. It may easily be recognised by the transverse direction of its fibres.

The *first portion* of the axillary artery may be tied in cases of aneurism encroaching so far upwards that a ligature cannot be applied in the lower part of its course. Notwithstanding that this operation has been performed in some few cases, and with success, its performance is attended with much difficulty and danger. The student will remark that, in this situation, it would be necessary to divide a thick muscle, and, after incising the costo-coracoid membrane, the artery would be exposed at the bottom of a more or less deep space, with the cephalic and axillary veins in such relation with it as must render the application of a ligature to this part of the vessel particularly hazardous. Under such circumstances it is an easier, and, at the same time, more advisable operation, to tie the subclavian artery in the third part of its course.

The vessel can be best secured by a curved incision with the convexity downwards from a point half an inch external to the Sterno-clavicular joint to a point half an inch internal to the coracoid process. The limb is to be well abducted and the head inclined to the opposite side, and the incision carried through the superficial structures, care being taken of the cephalic vein at the outer angle of the incision. The clavicular origin of the Pectoralis major is then divided in the whole extent of the wound. The arm is now to be brought to the side, and the upper edge of the Pectoralis minor defined and drawn downwards. The costo-coracoid membrane is to be carefully divided on a director, close to the coracoid process, and the axillary sheath exposed; this is to be opened with especial care on account of the vein overlapping the artery. The needle should be passed from below, so as to avoid wounding the vein.

In a case of wound of the vessel, the general practice of cutting down upon, and tying it above and below the wounded point, should be adopted in all cases.

Collateral Circulation after Ligature of the Axillary Artery.—If the artery be tied above the origin of the acromial thoracic, the collateral circulation will be carried on by the same branches as after the ligature of the subclavian; if at a lower point, between the acromial thoracic and subscapular arteries, the latter vessel, by its free anastomoses with the other scapular arteries, branches of the subclavian, will become the chief agent in carrying on the circulation, to which the long thoracic, if it be below the ligature, will materially contribute, by its anastomoses with the intercostal and internal mammary arteries. If the point included in the ligature be below the origin of the subscapular artery, it will most probably also be below the origins of the two circumflex arteries. The chief agents in restoring the circulation will then be the subscapular and the two circumflex arteries anastomosing with the superior profunda from the brachial, which will be afterwards referred to as performing the same office after ligature of the brachial. The cases in which the operation has been performed are few in number, and no published account of dissection of the collateral circulation appears to exist.

The branches of the axillary artery are—

From first part { Superior Thoracic. / Acromial Thoracic. } *From second part* { Long Thoracic. / Alar Thoracic. }

From third part { Subscapular. / Anterior Circumflex. / Posterior Circumflex. }

The **superior thoracic** is a small artery, which arises from the axillary separately, or by a common trunk with the acromial thoracic. Running forwards and inwards along the upper border of the Pectoralis minor, it passes between it and the Pectoralis major to the side of the chest. It supplies these muscles, and the parietes of the thorax, anastomosing with the internal mammary and intercostal arteries.

The **acromial thoracic** is a short trunk, which arises from the fore part of the axillary artery. Projecting forwards to the upper border of the Pectoralis minor, it divides into three sets of branches—*thoracic*, *acromial*, and *descending*. The *thoracic branches*, two or three in number, are distributed to the Serratus magnus and Pectoral muscles, anastomosing with the intercostal branches of the internal mammary. The *acromial branches* are directed outwards towards the acromion, supplying the Deltoid muscle, and anastomosing, on the surface of the acromion, with the suprascapular, and posterior circumflex arteries. The

descending branch passes in the space between the Pectoralis major and Deltoid, in the same groove as the cephalic vein, and supplies both muscles. The artery also gives off a very small branch, the *clavicular*, which passes upwards to the Subclavius muscle.

The **long thoracic** passes downwards and inwards along the lower border of the Pectoralis minor to the side of the chest, supplying the Serratus magnus, the Pectoral muscles, and mammary gland, and sending branches across the axilla to the axillary glands and Subscapularis; it anastomoses with the internal mammary and intercostal arteries.

The **alar thoracic** is a small branch, which supplies the glands and areolar tissue of the axilla. Its place is frequently supplied by branches from some of the other thoracic arteries.

The **subscapular**, the largest branch of the axillary artery, arises opposite the lower border of the Subscapularis muscle, and passes downwards and backwards along its lower margin to the inferior angle of the scapula, where it anastomoses with the long thoracic and intercostal arteries and with the posterior scapular, a branch of the transversalis colli, from the thyroid axis of the subclavian. About an inch and a half from its origin it gives off a large branch, the *dorsalis scapulæ*, and terminates by supplying branches to the muscles in the neighbourhood.

The *dorsalis scapulæ* is given off from the subscapular about an inch and a half from its origin, and is generally larger than the continuation of the vessel. It curves round the axillary border of the scapula, leaving the axilla through the space between the Teres minor above, the Teres major below, and the long head of the Triceps externally (fig. 400), and enters the infraspinous fossa, where it anastomoses with the posterior scapular and suprascapular arteries. In its course it gives off two sets of branches: one enters the subscapular fossa beneath the Subscapularis, which it supplies, anastomosing with the posterior scapular and suprascapular arteries; the other is continued along the axillary border of the scapula, between the Teres major and minor, and, at the dorsal surface of the inferior angle of the bone, anastomoses with the posterior scapular. In addition to these, small branches are distributed to the back part of the Deltoid muscle and the long head of the Triceps, anastomosing with an ascending branch of the superior profunda of the brachial.

The **circumflex arteries** wind round the neck of the humerus. The *posterior circumflex* (fig. 400), the larger of the two, arises from the back part of the axillary opposite the lower border of the Subscapularis muscle, and, passing backwards with the circumflex veins and nerve through the quadrangular space bounded by the Teres major and minor, the scapular head of the Triceps and the humerus, winds round the neck of that bone and is distributed to the Deltoid muscle and shoulder-joint, anastomosing with the anterior circumflex, and acromial thoracic arteries, and with the superior profunda branch of the brachial artery. The *anterior circumflex* (figs. 400, 402), considerably smaller than the preceding, arises just below that vessel, from the outer side of the axillary artery. It passes horizontally outwards, beneath the Coraco-brachialis and short head of the Biceps, lying upon the fore part of the neck of the humerus, and, on reaching the bicipital groove, gives off an ascending branch which passes upwards along the groove to supply the head of the bone and the shoulder-joint. The trunk of the vessel is then continued outwards beneath the Deltoid, which it supplies, and anastomoses with the posterior circumflex artery.

Brachial Artery (fig. 403)

The **Brachial Artery** commences at the lower margin of the tendon of the Teres major, and, passing down the inner and anterior aspect of the arm, terminates about half an inch below the bend of the elbow, where it divides into the *radial* and *ulnar* arteries. At first the brachial artery lies internal to the humerus; but as it passes down the arm it gradually gets in front of the bone, and at the bend of the elbow it lies midway between the two condyles.

Relations.—This artery is superficial throughout its entire extent, being covered, *in front*, by the integument, the superficial and deep fascia; the bicipital fascia separates it opposite the elbow from the median basilic vein; the median nerve crosses it at its middle. *Behind*, it is separated from the inner side of the humerus above, by the long and inner heads of the Triceps, the musculo-spiral nerve and superior profunda artery intervening; and from the front of the bone below, by the insertion of the Coraco-brachialis muscle, and by the Brachialis anticus. By its *outer side*, it is in relation with the commencement of the median nerve, and the Coraco-brachialis and Biceps muscles, which slightly overlap the artery. By its *inner side*, its upper half is in relation with the internal cutaneous and ulnar nerves, its lower half with the median nerve. The basilic vein lies on the inner side of the artery, but is separated from it in the lower part of the arm by the deep fascia. It is accompanied by two venæ comites, which lie in close contact with the artery, being connected together at intervals by short transverse communicating branches.

Anatomy of the Bend of the Elbow

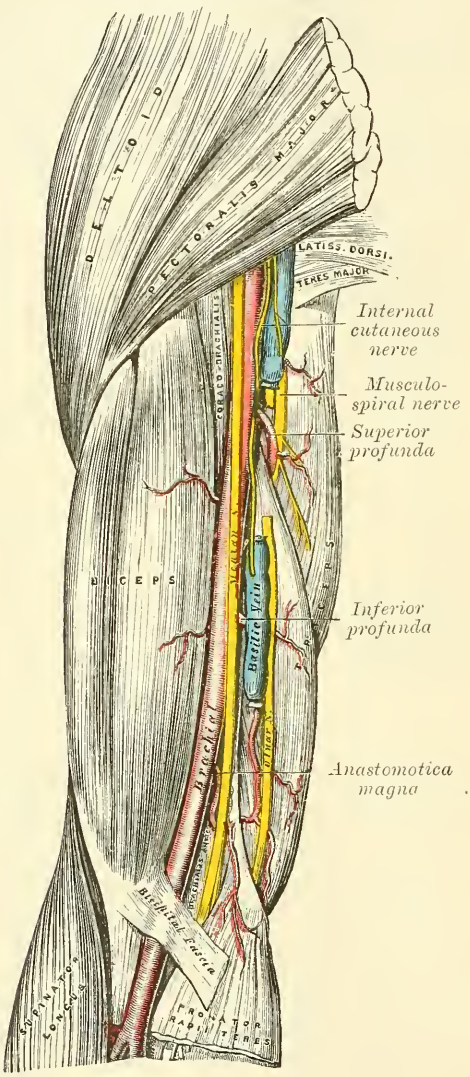
At the bend of the elbow the brachial artery sinks deeply into a triangular interval, the base of which is directed upwards towards the humerus, and the sides of which are bounded, externally, by the Supinator longus; internally, by the Pronator radii teres; its floor is formed by the Brachialis anticus and Supinator brevis. This space contains the brachial artery, with its accompanying veins; the radial and ulnar arteries; the median and musculo-spiral nerves; and the tendon of the Biceps. The brachial artery occupies the middle line of this space, and divides opposite the neck of the radius into the radial and ulnar arteries; it is covered, *in front*, by the integument, the superficial fascia, and the median basilic vein, the vein being separated from direct contact with the artery by the bicipital fascia. *Behind*, it lies on the Brachialis anticus, which separates it from the elbow-joint. The median nerve lies on the inner side of the artery, close to it above; but separated from it below by the coronoid origin of the Pronator radii teres. The tendon of the Biceps lies to the outer side of the space, and the musculo-spiral nerve still more externally, lying upon the Supinator brevis, and partly concealed by the Supinator longus.

Peculiarities of the Brachial Artery as regards its Course.—The brachial artery, accompanied by the median nerve, may leave the inner border of the Biceps, and descend towards the inner condyle of the humerus, where it usually curves round a prominence of bone, to which it is connected by a fibrous band; it then inclines outwards, beneath or through the substance of the Pronator radii teres muscle, to the bend of the elbow. The variation bears considerable analogy with the normal condition of the artery in some of the carnivora: it has been referred to, above, in the description of the humerus (page 234).

As regards its Division.—Occasionally, the artery is divided for a short distance at its upper part into two trunks, which are united above and below. A similar peculiarity occurs in the main vessel of the lower limb.

The point of bifurcation may be above or below the usual point, the former condition being by far the more frequent. Out of 481 examinations recorded by Mr. Quain, some made on the right, and some on the left side of the body, in 386 the artery bifurcated in its normal position. In one case only was the place of division lower than usual, being two or three inches below the elbow-joint. 'In 94 cases out of 481, or about one in 5⅛, there were two arteries instead of one in some part, or in the whole of the arm.'

Fig. 403.—The brachial artery.



There appears, however, to be no correspondence between the arteries of the two arms, with respect to their irregular division; for in sixty-one bodies it occurred on one side only in forty-three; on both sides, in different positions, in thirteen; on both sides, in the same position, in five.

The point of bifurcation takes place at different parts of the arm, being most frequent in the upper part, less so in the lower part, and least so in the middle, the most usual point for the application of a ligature; under any of these circumstances, two large arteries would be found in the arm instead of one. The most frequent (in three out of four) of these peculiarities is the high division of the radial. That artery often arises from the inner side of the brachial, and runs parallel with the main trunk to the elbow, where it crosses it, lying beneath the fascia; or it may perforate the fascia, and pass over the artery immediately beneath the integument.

The ulnar sometimes arises from the brachial high up, and then occasionally leaves that vessel at the lower part of the arm, and descends towards the inner condyle. In the forearm it generally lies beneath the deep fascia, superficial to the flexor muscles; occasionally between the integument and deep fascia, and very rarely beneath the flexor muscles.

The interosseous artery sometimes arises from the upper part of the brachial or axillary: as it passes down the arm, it lies behind the main trunk, and at the bend of the elbow regains its usual position.

In some cases of high division of the radial, the remaining trunk (ulnar-interosseous) occasionally passes, together with the median nerve, along the inner margin of the arm to the inner condyle, and then passing from within outwards, beneath or through the Pronator radii teres, regains its usual position at the bend of the elbow.

Occasionally, the two arteries representing the brachial are connected at the bend of the elbow by a short transverse branch, and are even sometimes reunited.

Sometimes, long slender vessels, *vasa aberrantia*, connect the brachial or axillary arteries with one of the arteries of the forearm, or a branch from them. These vessels usually join the radial.

*Varieties in Muscular Relations.**—The brachial artery is occasionally concealed, in some part of its course, by muscular or tendinous slips derived from the Coraco-brachialis, Biceps, Brachialis anticus, and Pronator radii teres muscles.

* See Struthers's *Anatomical and Physiological Observations*

Surface Marking.—The direction of the brachial artery is marked by a line drawn along the inner edge of the Biceps from the insertion of the Teres major muscle to the point midway between the condyles of the humerus.

Surgical Anatomy.—Compression of the brachial artery is required in cases of amputation and some other operations in the arm and forearm; and it will be observed that it may be effected in almost any part of the course of the artery. If pressure is made in the upper part of the limb, it should be directed from within outwards; and if in the lower part, from before backwards, as the artery lies on the inner side of the humerus above, and in front of it below. The most favourable situation is about the middle of the arm, where it lies on the tendon of the Coraco-brachialis on the inner flat side of the humerus.

The application of a ligature to the brachial artery may be required in cases of wound of the vessel, and in some cases of wound of the palmar arch. It is also sometimes necessary in cases of aneurism of the brachial, the radial, ulnar, or interosseous arteries. The artery may be secured in any part of its course. The chief guides in determining its position are the surface-markings produced by the inner margin of the Coraco-brachialis and Biceps, the known course of the vessel, and its pulsation, which should be carefully felt for before any operation is performed, as the vessel occasionally deviates from its usual position in the arm. In whatever situation the operation is performed, great care is necessary, on account of the extreme thinness of the parts covering the artery, and the intimate connection which the vessel has throughout its whole course with important nerves and veins. Sometimes a thin layer of muscular fibre is met with concealing the artery; if such is the case, it must be cut across in order to expose the vessel.

In the upper third of the arm the artery may be exposed in the following manner:—The patient being placed supine upon a table, the affected limb should be raised from the side, and the hand supinated. An incision about two inches in length should be made on the inner side of the Coraco-brachialis muscle, and the subjacent fascia cautiously divided, so as to avoid wounding the internal cutaneous nerve or basilic vein, which sometimes runs on the surface of the artery as high as the axilla. The fascia having been divided, it should be remembered that the ulnar and internal cutaneous nerves lie on the inner side of the artery, the median on the outer side, the latter nerve being occasionally superficial to the artery in this situation, and that the venæ comites are also in relation with the vessel, one on either side. These being carefully separated, the aneurism needle should be passed round the artery from the inner to the outer side.

If two arteries are present in the arm, in consequence of a high division, they are usually placed side by side; and if they are exposed in an operation, the surgeon should endeavour to ascertain, by alternately pressing on each vessel, which of the two communicates with the wound or aneurism, when a ligature may be applied accordingly; or if pulsation or hæmorrhage ceases only when both vessels are compressed, both vessels may be tied, as it may be concluded that the two communicate above the seat of disease, or are reunited.

It should also be remembered that two arteries may be present in the arm in a case of high division, and that one of these may be found along the inner intermuscular septum, in a line towards the inner condyle of the humerus; or in the usual position of the brachial, but deeply placed beneath the common trunk; a knowledge of these facts will suggest the precautions necessary in every case, and indicate the measures to be adopted when anomalies are met with.

In the middle of the arm the brachial artery may be exposed by making an incision along the inner margin of the Biceps muscle. The forearm being bent so as to relax the muscle, it should be drawn slightly aside, and, the fascia being carefully divided, the median nerve will be exposed lying upon the artery (sometimes beneath); this being drawn inwards and the muscle outwards, the artery should be separated from its accompanying veins and secured. In this situation the inferior profunda may be mistaken for the main trunk, especially if enlarged, from the collateral circulation having become established; this may be avoided by directing the incision externally towards the Biceps, rather than inwards or backwards towards the Triceps.

The lower part of the brachial artery is of interest in a surgical point of view, on account of the relation which it bears to the veins most commonly opened in venesection. Of these vessels, the median basilic is the largest and most prominent, and, consequently, the one usually selected for the operation. It should be remembered, that this vein runs parallel with the brachial artery, from which it is separated by the bicipital fascia, and that care should be taken, in opening the vein, not to carry the incision too deeply, so as to endanger the artery.

Collateral Circulation.—After the application of a ligature to the brachial artery in the upper third of the arm, the circulation is carried on by branches from the circumflex and subscapular arteries, anastomosing with ascending branches from the superior profunda. If the brachial is tied *below* the origin of the profunda arteries, the circulation is maintained by the branches of the profundæ, anastomosing with the recurrent radial, ulnar, and interosseous arteries. In two cases described by Mr. South,* in which the brachial

* Chelius's *Surgery*, vol. ii. p. 254. See also White's engraving, referred to by Mr. South, of the anastomosing branches after ligature of the brachial, in White's *Cases in Surgery*. Porta also gives a case (with drawings) of the circulation after ligature of both brachial and radial.—*Alterazioni Patologiche delle Arterie.*

artery had been tied some time previously: in one 'a long portion of the artery had been obliterated, and sets of vessels are descending on either side from above the obliteration, to be received into others which ascend in a similar manner from below it. In the other the obliteration is less extensive, and a single curved artery about as big as a crow-quill passes from the upper to the lower open part of the artery.'

The branches of the brachial artery are, the

Superior Profunda.	Inferior Profunda.
Nutrient.	Anastomotica Magna.

Muscular.

The **superior profunda** arises from the inner and back part of the brachial, just below the lower border of the Teres major, and passes backwards to the interval between the outer and inner heads of the Triceps muscle, accompanied by the musculo-spiral nerve; it winds round the back part of the shaft of the humerus in the spiral groove, between the Triceps and the bone, to the outer side of the humerus, just above the external condyle, where it divides into two terminal branches. One of these pierces the external intermuscular septum, and descends to the space between the Brachialis anticus and Supinator longus, where it anastomoses with the recurrent branch of the radial artery; while the other, the *posterior articular*, descends along the back of the external intermuscular septum to the back of the elbow-joint, where it anastomoses with the posterior interosseous recurrent, and across the back of the humerus with the posterior ulnar recurrent, the anastomotica magna, and inferior profunda (fig. 406). The superior profunda supplies the Triceps muscle and gives off a nutrient artery which enters the bone at the upper end of the musculo-spiral groove. Near its commencement it sends off a branch which passes upwards between the external and long heads of the Triceps muscle to anastomose with the posterior circumflex artery; and, while in the groove, a small branch which accompanies a branch of the musculo-spiral nerve through the substance of the Triceps muscle and ends in the Anconeus below the outer condyle of the humerus.

The **nutrient artery** of the shaft of the humerus arises from the brachial, about the middle of the arm. Passing downwards, it enters the nutrient canal of that bone, near the insertion of the Coraco-brachialis muscle.

The **inferior profunda**, of small size, arises from the brachial, a little below the middle of the arm; piercing the internal intermuscular septum, it descends on the surface of the inner head of the Triceps muscle, to the space between the inner condyle and olecranon, accompanied by the ulnar nerve, and terminates by anastomosing with the posterior ulnar recurrent and anastomotica magna. It also supplies a branch to the front of the internal condyle, which anastomoses with the anterior ulnar recurrent.

The **anastomotica magna** arises from the brachial, about two inches above the elbow-joint. It passes transversely inwards upon the Brachialis anticus, and piercing the internal intermuscular septum, winds round the back part of the humerus between the Triceps and the bone, forming an arch above the olecranon fossa, by its junction with the posterior articular branch of the superior profunda. As this vessel lies on the Brachialis anticus, branches ascend to join the inferior profunda; and others descend in front of the inner condyle, to anastomose with the anterior ulnar recurrent. Behind the internal condyle an offset is given off which anastomoses with the inferior profunda and posterior ulnar recurrent arteries and supplies the Triceps.

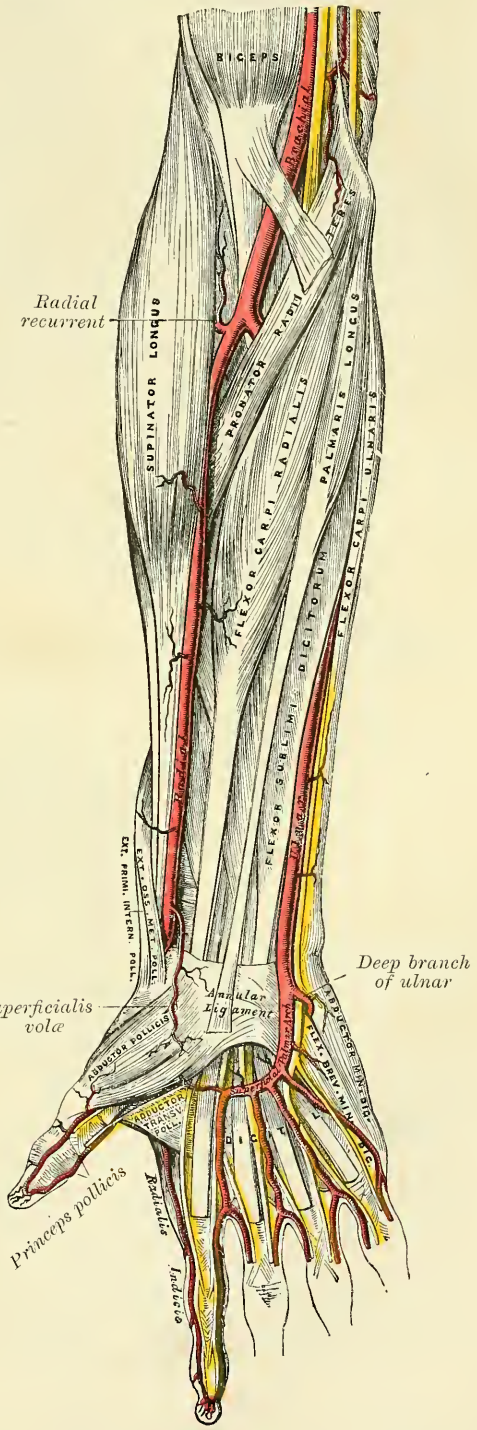
The **muscular** are three or four large branches, which are distributed to the muscles in the course of the artery. They supply the Coraco-brachialis, Biceps, and Brachialis anticus muscles.

The Anastomosis around the Elbow-joint (fig. 406).—The vessels engaged in this anastomosis may be conveniently divided into those situated *in front* and *behind* the internal and external condyles. The branches anastomosing *in front*

of the internal condyle are:—The anastomotica magna, the anterior ulnar recurrent, and the anterior terminal branch of the inferior profunda. Those *behind* the internal condyle are:—The anastomotica magna, the posterior ulnar recurrent, and the posterior terminal branch of the inferior profunda. The branches anastomosing *in front* of the external condyle are:—The radial recurrent and one of the terminal branches of the superior profunda. Those *behind* the external condyle (perhaps more properly described as being situated between the external condyle and the olecranon) are:—The anastomotica magna, the interosseous recurrent, and one of the terminal branches of the superior profunda. There is also a large arch of anastomosis above the olecranon, formed by the interosseous recurrent joining with the anastomotica magna and posterior ulnar recurrent (fig. 406).

From this description it will be observed that the anastomotica magna is the vessel most engaged, the only part of the anastomosis in which it is not employed being that *in front* of the external condyle.

Fig. 404.—The radial and ulnar arteries.



Radial Artery (fig. 404)

The **Radial Artery** appears, from its direction, to be the continuation of the brachial, but, in size, it is smaller than the ulnar. It commences at the bifurcation of the brachial, just below the bend of the elbow, and passes along the radial side of the forearm to the wrist; it then winds backwards, round the outer side of the carpus, beneath the extensor tendons of the thumb to the upper end of the space between the metacarpal bones of the thumb and index finger, and, finally, passes forwards between the two heads of the First dorsal interosseous muscle, into the palm of the hand, where it crosses the metacarpal bones to the ulnar border of the hand, to form the deep palmar arch. At its termination, it inosculates with the deep branch of the ulnar artery. The

relations of this vessel may thus be conveniently divided into three parts, viz. in the forearm, at the back of the wrist, and in the hand.

Relations.—*In the forearm*, this vessel extends from opposite the neck of the radius, to the fore part of the styloid process, being placed to the inner side of the shaft of the bone above, and in front of it below. It is overlapped in the upper part of its course by the fleshy belly of the Supinator longus muscle; throughout the rest of its course it is superficial, being covered by the integument, the superficial and deep fasciæ. In its course downwards, it lies upon the tendon of the Biceps, the Supinator brevis, the Pronator radii teres, the radial origin of the Flexor sublimis digitorum, the Flexor longus pollicis, the Pronator quadratus, and the lower extremity of the radius. In the upper third of its course, it lies between the Supinator longus and the Pronator radii teres; in its lower two-thirds, between the tendons of the Supinator longus and the Flexor carpi radialis. The radial nerve lies along the outer side of the artery in the middle third of its course; and some filaments of the musculo-cutaneous nerve, after piercing the deep fascia, run along the lower part of the artery as it winds round the wrist. The vessel is accompanied by venæ comites throughout its whole course.

At the wrist, as it winds round the outer side of the carpus, from the styloid process to the first interosseous space, it lies upon the external lateral ligament, and then upon the scaphoid bone and trapezium, being covered by the extensor tendons of the thumb, subcutaneous veins, some filaments of the radial nerve, and the integument. It is accompanied by two veins, and a filament of the musculo-cutaneous nerve.

In the hand, it passes from the upper end of the first interosseous space, between the heads of the Abductor indicis or First dorsal interosseous muscle, transversely across the palm, to the base of the metacarpal bone of the little finger, where it inosculates with the communicating branch from the ulnar artery, forming the *deep palmar arch*. It lies upon the carpal extremities of the metacarpal bones and the Interossei muscles, being covered by the Adductor obliquus pollicis, the flexor tendons of the fingers, the Lumbricales, the Opponens and Flexor brevis minimi digiti. Alongside of it is the deep branch of the ulnar nerve, but running in the opposite direction, that is to say, from within outwards.

Peculiarities.—The origin of the radial artery, according to Quain, is, in nearly one case in eight, higher than usual; more frequently arising from the axillary or upper part of the brachial, than from the lower part of this vessel. The variations in the position of this vessel in the arm, and at the bend of the elbow, have been already mentioned. In the forearm it deviates less frequently from its position than the ulnar. It has been found

lying over the fascia instead of beneath it. It has also been observed on the surface of the Supinator longus, instead of under its inner border; and in turning round the wrist, it has been seen lying over, instead of beneath, the extensor tendons.

Surface Marking.—The position of the radial artery in the forearm is represented by a line drawn from the outer border of the tendon of the Biceps in the centre of the hollow in front of the elbow-joint with a straight course to the inner side of the fore part of the styloid process of the radius.

Surgical Anatomy.—The radial artery is much exposed to injury in its lower third, and is frequently wounded by the hand being driven through a pane of glass, by the slipping of a knife or chisel held in the other hand, and such-like accidents. The injury is often followed by a traumatic aneurism, for which the old operation of laying open the sac and securing the vessel above and below is required.

The operation of tying the radial artery is required in cases of wounds either of its trunk, or of some of its branches, or for aneurism: and it will be observed, that the vessel may be exposed in any part of its course through the forearm without the division of any muscular fibres. The operation in the middle or inferior third of the forearm is easily performed; but in the upper third, near the elbow, it is attended with some difficulty, from the greater depth of the vessel, and from its being overlapped by the Supinator longus muscle.

To tie the artery in the upper third, an incision three inches in length should be made through the integument, in a line drawn from the centre of the bend of the elbow to the front of the styloid process of the radius, avoiding the branches of the median vein; the fascia of the arm being divided, and the Supinator longus drawn a little outwards, the artery will be exposed. The venæ comites should be carefully separated from the vessel, and the ligature passed from the radial to the ulnar side.

In the middle third of the forearm the artery may be exposed by making an incision of similar length on the inner margin of the Supinator longus. In this situation, the radial nerve lies in close relation with the outer side of the artery, and should, as well as the veins, be carefully avoided.

In the lower third, the artery is easily secured by dividing the integument and fascia in the interval between the tendons of the Supinator longus and Flexor carpi radialis muscles.

The branches of the radial artery may be divided into three groups, corresponding with the three regions in which the vessel is situated.

In the forearm.	*Wrist.*	*Hand.*
Radial Recurrent.	Posterior Carpal.	Princeps Pollicis.
Muscular.	Metacarpal.	Radialis Indicis.
Anterior Carpal.	Dorsales Pollicis.	Perforating.
Superficialis Volæ.	Dorsalis Indicis.	Interosseous.
		Palmar Recurrent.

The **radial recurrent** is given off immediately below the elbow. It ascends between the branches of the musculo-spiral nerve lying on the Supinator brevis, and then between the Supinator longus and Brachialis anticus, supplying these muscles and the elbow-joint, and anastomosing with one of the terminal branches of the superior profunda.

The **muscular branches** are distributed to the muscles on the radial side of the forearm.

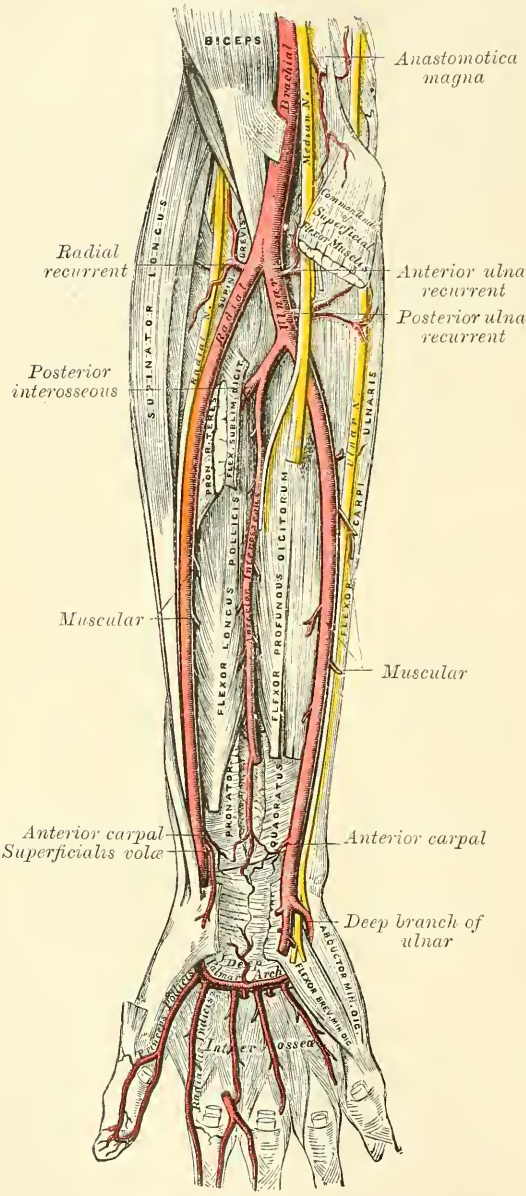
The **anterior carpal** is a small vessel which arises from the radial artery near the lower border of the Pronator quadratus, and, running inwards in front of the radius, anastomoses with the anterior carpal branch of the ulnar artery. In this way an arterial anastomosis, *anterior carpal arch*, is formed in front of the wrist: it is joined by branches from the anterior interosseous above, and by recurrent branches from the deep carpal arch below, and gives off branches which descend to supply the articulations of the wrist and carpus.

The **superficialis volæ** arises from the radial artery, just where this vessel is about to wind round the wrist. Running forwards, it passes between the muscles of the thumb, which it supplies, and sometimes anastomoses with the palmar portion of the ulnar artery, completing the superficial palmar arch. This vessel varies considerably in size: usually it is very small, and terminates in the muscles of the thumb; sometimes it is as large as the continuation of the radial.

The **posterior carpal** is a small vessel which arises from the radial artery

beneath the extensor tendons of the thumb; crossing the carpus transversely to the inner border of the hand, it anastomoses with the posterior carpal branch of the ulnar, forming the *posterior carpal arch*, which is joined by the termination of the posterior interosseous artery. From this arch are given off descending branches, the *dorsal interosseous arteries* for the third and fourth interosseous spaces, which run forwards on the Third and Fourth dorsal interossei muscles and divide into dorsal digital branches which supply the adjacent sides of the middle, ring, and little fingers respectively, communicating with the digital arteries of the superficial palmar arch. At their origin they anastomose with the perforating branches from the deep palmar arch.

Fig. 405.—Ulnar and radial arteries. Deep view.



The **metacarpal (first dorsal interosseous branch)** arises beneath the extensor tendons of the thumb, sometimes with the posterior carpal artery; running forwards on the Second dorsal interosseous muscle, it communicates, behind, with the corresponding perforating branch of the deep palmar arch; and, in front, it divides into two *dorsal digital branches*, which supply the adjoining sides of the index and middle fingers, inosculating with the digital branch of the superficial palmar arch.

The **dorsales pollicis** are two small vessels which run along the sides of the dorsal aspect of the thumb. They arise separately, or occasionally by a common trunk, near the base of the first metacarpal bone.

The **dorsalis indicis**, also a small branch, runs along the radial side of the back of the index finger, sending a few branches to the Abductor indicis.

The **princeps pollicis** arises from the radial just as it turns inwards to the deep part of the hand; it descends between the Abductor indicis and Adductor obliquus pollicis, then between the Adductor transversus pollicis and Adductor obliquus pollicis, along the ulnar side of the metacarpal bone of the thumb, to the base of the first phalanx where it divides into two branches, which run along the sides of the palmar aspect of the thumb, and form an arch on the under surface of the last phalanx, from which branches are distributed to the integument and pulp of the thumb.

The **radialis indicis** arises close to the preceding, descends between the Abductor indicis and Adductor transversus pollicis, and runs along the radial side of the index finger to its extremity, where it anastomoses with the collateral digital artery from the superficial palmar arch. At the lower border of the Adductor transversus pollicis, this vessel anastomoses with the princeps pollicis, and gives a communicating branch to the superficial palmar arch.

The **perforating arteries**, three in number, pass backwards between the heads of the last three Dorsal interossei muscles, to inosculate with the dorsal interosseous arteries.

The **palmar interosseous**, three or four in number, are branches of the deep palmar arch; they run forwards upon the Interossei muscles, and anastomose at the clefts of the fingers with the digital branches of the superficial arch.

The **palmar recurrent branches** arise from the concavity of the deep palmar arch. They pass upwards in front of the wrist, supplying the carpal articulations and anastomosing with the anterior carpal arch.

Ulnar Artery

The **Ulnar Artery**, the larger of the two terminal branches of the brachial, commences a little below the bend of the elbow, and crosses obliquely the inner side of the forearm, to the commencement of its lower half; it then runs along its ulnar border to the wrist, crosses the annular ligament on the radial side of the pisiform bone, and immediately beyond this bone divides into two branches, which enter into the formation of the superficial and deep palmar arches.

Relations in the Forearm.—In its *upper half*, it is deeply seated, being covered by all the superficial flexor muscles, excepting the Flexor carpi ulnaris; it is crossed by the median nerve, which lies to its inner side for about an inch, and it lies upon the Brachialis anticus and Flexor profundus digitorum muscles. In the *lower half* of the forearm, it lies upon the Flexor profundus, being covered by the integument, the superficial and deep fasciæ, and is placed between the Flexor carpi ulnaris and Flexor sublimis digitorum muscles. It is accompanied by two venæ comites; the ulnar nerve lies on its inner side for the lower two-thirds of its extent, and a small branch from the nerve descends on the lower part of the vessel to the palm of the hand.

At the wrist (fig. 404) the ulnar artery is covered by the integument and fascia, and lies upon the anterior annular ligament. On its inner side is the pisiform bone. The ulnar nerve lies at the inner side, and somewhat behind the artery.

Peculiarities.—The ulnar artery has been found to vary in its origin nearly in the proportion of one in thirteen cases, in one case arising lower than usual, about two or three inches below the elbow, and in all other cases much higher, the brachial being a more frequent source of origin than the axillary.

Variations in the position of this vessel are more frequent than in the radial. When its origin is normal, the course of the vessel is rarely changed. When it arises high up, it is almost invariably superficial to the flexor muscles in the forearm, lying commonly beneath the fascia, more rarely between the fascia and integument. In a few cases, its position was subcutaneous in the upper part of the forearm, subaponeurotic in the lower part.

Surface Marking.—On account of the curved direction of the ulnar artery, the line on the surface of the body which indicates its course is somewhat complicated. First, draw a line from the front of the internal condyle of the humerus to the radial side of the pisiform bone; the lower two-thirds of this line represents the course of the middle and lower third of the ulnar artery. Secondly, draw a line from the centre of the hollow in front of the elbow-joint to the junction of the upper and middle third of the first line; this represents the course of the upper third of the artery.

Surgical Anatomy.—The application of a ligature to this vessel is required in cases of wound of the artery, or of its branches, or in consequence of aneurism. In the upper half of the forearm, the artery is deeply seated beneath the superficial flexor muscles, and the application of a ligature in this situation is attended with some difficulty. An incision is to be made in the course of a line drawn from the front of the internal condyle of the humerus to the outer side of the pisiform bone, so that the centre of the incision is three fingers' breadth below the internal condyle. The skin and superficial fascia having been divided, and the deep fascia exposed, the white line which separates the Flexor carpi ulnaris from the other flexor muscles is to be sought for, and the fascia incised in this line. The Flexor carpi ulnaris is now to be carefully separated from the other muscles, when the ulnar nerve will be exposed and must be drawn aside. Some little distance below the nerve, the artery will be found accompanied by its venæ comites, and may be ligatured by passing the needle from within outwards. In the middle and lower third of the forearm, this vessel may be easily secured by making an incision on the radial side of the tendon of the Flexor carpi ulnaris: the deep fascia being divided, and the Flexor carpi ulnaris and its companion muscle, the Flexor sublimis, being separated from each other, the vessel will be exposed, accompanied by its venæ comites, the ulnar nerve lying on its inner side. The veins being separated from the artery, the ligature should be passed from the ulnar to the radial side, taking care to avoid the ulnar nerve.

The branches of the ulnar artery may be arranged in the following groups:—

- *Forearm.*
  - Anterior Ulnar Recurrent.
  - Posterior Ulnar Recurrent.
  - Interosseous
    - Anterior Interosseous.
    - Posterior Interosseous.
  - Muscular.
- *Wrist.*
  - Anterior Carpal.
  - Posterior Carpal.
- *Hand.*
  - Deep Palmar or Communicating.
  - Superficial Palmar Arch.

The **anterior ulnar recurrent** (fig. 405) arises immediately below the elbow-joint, passes upwards and inwards between the Brachialis anticus and Pronator radii teres, supplies those muscles, and, in front of the inner condyle, anastomoses with the anastomotica magna and inferior profunda.

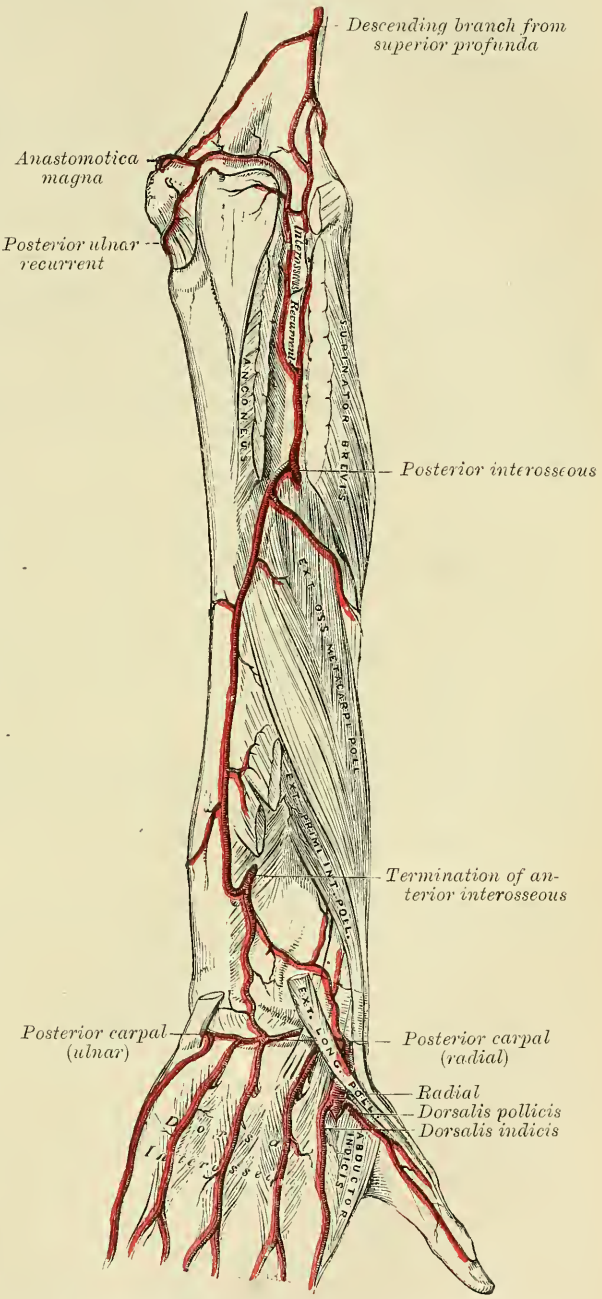
The **posterior ulnar recurrent** is much larger, and arises somewhat lower than the preceding. It passes backwards and inwards, beneath the Flexor sublimis, and ascends behind the inner condyle of the humerus. In the interval between this process and the olecranon, it lies beneath the Flexor carpi ulnaris, ascending between the heads of that muscle, in relation with the ulnar nerve; it supplies the neighbouring muscles and joint, and anastomoses with the inferior profunda, anastomotica magna, and interosseous recurrent arteries (fig. 406).

The **interosseous artery** (fig. 405) is a short trunk about an inch in length, and of considerable size, which arises immediately below the tuberosity of the radius, and, passing backwards to the upper border of the interosseous membrane, divides into two branches, the *anterior* and *posterior interosseous*.

The **anterior interosseous** passes down the forearm on the anterior surface of the interosseous membrane, to which it is connected by a thin aponeurotic arch. It is accompanied by the interosseous branch of the median nerve, and overlapped by the contiguous margins of the Flexor profundus digitorum and Flexor

longus pollicis muscles, giving off in this situation muscular branches, and the nutrient arteries of the radius and ulna. At the upper border of the Pronator quadratus, a branch descends beneath the muscle, to anastomose in front of the carpus with the anterior carpal arch. The continuation of the artery passes behind the Pronator quadratus, and, piercing the interosseous membrane, gets to the back of the forearm, and anastomoses with the posterior interosseous artery (fig. 406). It then descends to the back of the wrist to join the posterior carpal arch. The anterior interosseous gives off a long, slender branch, the *median artery*, which accompanies the median nerve, and gives offsets to its substance. This artery is sometimes much enlarged. It also gives off nutrient branches to the radius and ulna about the middle of the forearm.

Fig. 406.—Arteries of the back of the forearm and hand.



The **posterior interosseous artery** passes backwards through the interval between the oblique ligament and the upper border of the interosseous membrane. It appears between the contiguous borders of the Supinator brevis and the Extensor ossis metacarpi pollicis, and runs down the back part of the forearm, between the superficial and deep layer of muscles, to both of which it distributes branches. At the lower part of the forearm it anastomoses with the termination of the anterior interosseous artery. Then, continuing its course over the head of the ulna, it joins the posterior carpal branch of the ulnar artery. This artery gives off, near its origin, the *interosseous recurrent branch*.

The **interosseous recurrent artery** is a large vessel which ascends to the interval between the external condyle and olecranon, on or through the fibres of the Supinator brevis, but beneath the Anconeus, anastomosing with a branch

from the superior profunda, and with the posterior ulnar recurrent and anastomotica magna.

The **muscular branches** are distributed to the muscles along the ulnar side of the forearm.

The **anterior carpal** is a small vessel which crosses the front of the carpus beneath the tendons of the Flexor profundus, and inosculates with a corresponding branch of the radial artery.

The **posterior carpal** arises immediately above the pisiform bone, and winds backwards beneath the tendon of the Flexor carpi ulnaris; it passes across the dorsal surface of the carpus beneath the extensor tendons, anastomosing with a corresponding branch of the radial artery, and forming the *posterior carpal arch.* Immediately after its origin, it gives off a small branch, which runs along the ulnar side of the metacarpal bone of the little finger, forming one of the *metacarpal arteries*, and supplies the ulnar side of the dorsal surface of the little finger.

The **branch to the deep palmar arch** or **communicating branch** (fig. 405) passes deeply inwards between the Abductor minimi digiti and Flexor brevis minimi digiti, near their origins; it anastomoses with the termination of the radial artery, completing the deep palmar arch.

The **branch to the superficial palmar arch** appears to be the direct continuation of the ulnar artery in the hand; it forms the greater part of the superficial palmar arch.

The Superficial Palmar Arch

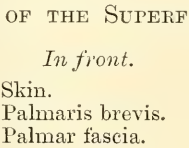
The **Superficial Palmar arch** is formed by the ulnar artery in the hand, and is completed on the outer side by this vessel anastomosing with a branch from the radialis indicis, though sometimes the arch is completed by the ulnar anastomosing with the superficialis volæ branch of the radial artery. The arch passes across the palm, describing a curve, with its convexity forwards, to the space between the ball of the thumb and the index finger, where the above mentioned anastomosis takes place.

Relations.—The superficial palmar arch is covered by the skin, the Palmaris brevis, and the palmar fascia. It lies upon the annular ligament, origin of the muscles of the little finger, the tendons of the superficial flexor of the fingers, and the divisions of the median and ulnar nerves.

Plan of Relations of the Superficial Palmar Arch

In front.

Skin.
Palmaris brevis.
Palmar fascia.



Behind.

Annular ligament.
Origin of muscles of little finger.
Superficial flexor tendons.
Divisions of median and ulnar nerves.

The branches of the superficial palmar arch are the digital.

The **digital branches** (fig. 404), four in number, are given off from the convexity of the superficial palmar arch. They supply the ulnar side of the little

finger, and the adjoining sides of the little, ring, middle, and index fingers; the radial side of the index finger and thumb being supplied from the radial artery. The digital arteries at first lie superficial to the flexor tendons, but as they pass forwards with the digital nerves to the clefts between the fingers, they lie between them, and are there joined by the interosseous branches from the deep palmar arch. The digital arteries on the sides of the fingers lie beneath the digital nerves; and, about the middle of the last phalanx, the two branches for each finger form an arch, from the convexity of which branches pass to supply the pulp of the finger.

Surface Marking.—The superficial palmar arch is represented by a curved line, starting from the outer side of the pisiform bone, and carried downwards as far as the middle third of the palm, and then curved outwards on a level with the upper end of the cleft between the thumb and index finger.

The deep palmar arch is situated about half an inch nearer to the carpus.

Surgical Anatomy.—Wounds of the palmar arches are of special interest, and are always difficult to deal with. When the wound in the superficial tissues is extensive, it may be possible to secure the bleeding ends of the vessel; but when there is a small punctured wound, as from a penknife or piece of glass, pressure systematically applied is probably the best course of treatment, as there is difficulty in reaching the wounded vessel without damaging important structures. At the same time it must be admitted that pressure applied to the palm of the hand, to arrest hæmorrhage from a wound of one of the palmar arches, especially the deep arch, is apt to be followed by sloughing, owing to the rigidity of the parts and the facility with which a considerable amount of pressure can be applied. In wounds of the deep palmar arch, a ligature may be applied to the bleeding points, from the dorsum of the hand, by resection of the upper part of the third metacarpal bone. It is useless in these cases to ligature one of the arteries of the forearm alone, and indeed simultaneous ligature of both radial and ulnar arteries above the wrist is often unsuccessful, on account of the anastomosis carried on by the carpal arches. Therefore, upon the failure of pressure to arrest hæmorrhage, it is expedient to apply a ligature to the brachial artery.

ARTERIES OF THE TRUNK

The Descending Aorta

The **Descending Aorta** is divided into two portions, the *thoracic* and *abdominal*, in correspondence with the two great cavities of the trunk in which it is situated.

The Thoracic Aorta

The **Thoracic Aorta** commences at the lower border of the fourth dorsal vertebra, on the left side, and terminates at the aortic opening in the Diaphragm, in front of the lower border of the last dorsal vertebra. At its commencement, it is situated on the left side of the spine; it approaches the median line as it descends; and, at its termination, lies directly in front of the column. The direction of this vessel being influenced by the spine, upon which it rests, it describes a curve which is concave forwards in the dorsal region. As the branches given off from it are small, the diminution in the size of the vessel is inconsiderable. It is contained in the back part of the posterior mediastinum.

Relations.—It is in relation, *in front*, from above downwards, with the left pulmonary artery, the left bronchus, the pericardium, and the œsophagus; *behind*, with the vertebral column, and the vena azygos minor; on the *right side*, with the vena azygos major, and thoracic duct; on the *left side*, with the left pleura and lung. The œsophagus, with its accompanying nerves, lies on the right side of the aorta *above*; but at the lower part of the thorax it gets in front of the aorta, and close to the Diaphragm is situated to its left side.

The aorta is occasionally found to be obliterated at a particular spot, viz. at the junction of the arch with the thoracic aorta, just below the ductus arteriosus. Whether this is the result of disease, or of congenital malformation, is immaterial to our present purpose; it affords an interesting opportunity of observing the resources of the collateral circulation. The course of the anastomosing vessels, by which the blood is brought from the upper to the lower part of the artery, will be found well described in an account of two cases in the *Pathological Transactions*, vols. viii. and x. In the former (p. 162), Mr. Sydney Jones thus sums up the detailed description of the anastomosing vessels:—'The principal communications by which the circulation was carried on, were—Firstly, the internal mammary, anastomosing with the intercostal arteries, with the phrenic of the abdominal aorta by means of the musculo-phrenic and comes nervi phrenici, and largely with the deep epigastric. Secondly, the superior intercostal, anastomosing anteriorly by means of a large branch with the first aortic intercostal, and posteriorly with the posterior branch of the same artery. Thirdly, the inferior thyroid, by means of a branch about the size of an ordinary radial, formed a communication with the first aortic intercostal. Fourthly, the transversalis colli, by means of very large communications with the posterior branches of the intercostals. Fifthly, the branches (of the subclavian and axillary) going to the side of the chest were large, and anastomosed freely with the lateral branches of the intercostals.' In the second case also (vol. x. p. 97), Mr. Wood describes the anastomoses in a somewhat similar manner, adding the remark, that 'the blood which was brought into the aorta through the anastomoses of the intercostal arteries appeared to be expended principally in supplying the abdomen and pelvis; while the supply to the lower extremities had passed through the internal mammary and epigastrics.'

Surgical Anatomy.—The student should now consider the effects likely to be produced by aneurism of the thoracic aorta, a disease of common occurrence. When we consider the great depth of the vessel from the surface, and the number of important structures which surround it on every side, it may easily be conceived what a variety of obscure symptoms may arise from disease of this part of the arterial system, and how they may be liable to be mistaken for those of other affections. Aneurism of the thoracic aorta most usually extends backwards, along the left side of the spine, producing absorption of the bodies of the vertebræ, with curvature of the spine; whilst the irritation or pressure on the cord will give rise to pain, either in the chest, back, or loins, with radiating pain in the left upper intercostal spaces, from pressure on the intercostal nerves; at the same time the tumour may project backwards on each side of the spine, beneath the integument, as a pulsating swelling, simulating abscess connected with diseased bone; or it may displace the œsophagus, and compress the lung on one or the other side. If the tumour extend forward, it may press upon and displace the heart, giving rise to palpitation and other symptoms of disease of that organ; or it may displace, or even compress, the œsophagus, causing pain and difficulty of swallowing, as in stricture of that tube; and ultimately even open into it by ulceration, producing fatal hæmorrhage. If the disease extends to the right side, it may press upon the thoracic duct; or it may burst into the pleural cavity, or into the trachea or lung; and lastly, it may open into the posterior mediastinum.

Branches of the Thoracic Aorta

Pericardiac.
Bronchial.
Œsophageal.
Posterior Mediastinal.
Intercostal.

The **pericardiac** are a few small vessels, irregular in their origin, distributed to the pericardium.

The **bronchial arteries** are the nutrient vessels of the lungs, and vary in number, size, and origin. That of the right side arises from the first aortic intercostal, or by a common trunk with the left bronchial, from the front of the thoracic aorta. Those of the left side, usually two in number, arise from the thoracic aorta, one a little lower than the other. Each vessel is directed to the back part of the corresponding bronchus along which it runs, dividing and subdividing upon the bronchial tubes, supplying them, the cellular tissue of the lungs, the bronchial glands, and the œsophagus.

The **œsophageal arteries**, usually four or five in number, arise from the front of the aorta, and pass obliquely downwards to the œsophagus, forming a chain of anastomoses along that tube, anastomosing with the œsophageal branches of the inferior thyroid arteries above, and with ascending branches from the phrenic and gastric arteries below.

The **posterior mediastinal arteries** are numerous small vessels which supply the glands and loose areolar tissue in the mediastinum.

The **Intercostal arteries** arise from the back of the aorta. They are usually ten in number on each side, the two superior intercostal spaces being supplied by the superior intercostal, a branch of the subclavian. The second space usually receives a considerable branch from the first aortic intercostal, which joins with the branch from the superior intercostal of the subclavian. The lowest or tenth intercostal branch from the aorta runs along the lower border of the last rib, and is named the *subcostal artery*. The right intercostals are longer than the left, on account of the position of the aorta on the left side of the spine: they pass outwards, across the bodies of the vertebræ, to the intercostal spaces, being covered by the pleura, the œsophagus, thoracic duct, sympathetic nerve, and the vena azygos major; the left passing outwards are crossed by the sympathetic; the upper two are also crossed by the superior intercostal vein, the lower by the vena azygos minor. In each intercostal space the artery passes outwards, at first lying upon the External intercostal muscle, covered in front by the pleura and a thin fascia. It then passes between the two layers of Intercostal muscles, and having ascended obliquely to the lower border of the rib above it is continued forwards in the groove on its lower border and anastomoses with the anterior intercostal branches of the internal mammary. The first aortic intercostal anastomoses with the superior intercostal, and the last three pass between the abdominal muscles, inosculating with the epigastric in front, and with the phrenic and lumbar arteries. Each intercostal artery is accompanied by a vein and nerve, the former being above, and the latter below, except in the upper intercostal spaces, where the nerve is at first above the artery. The arteries are protected from pressure during the action of the Intercostal muscles, by fibrous arches thrown across, and attached by each extremity to the bone. The lower intercostal arteries are continued anteriorly from the intercostal spaces into the abdominal wall, except the last, the *subcostal*, which lies throughout its whole course in the abdominal wall, since it is placed below the last rib. They pass behind the costal cartilages between the Internal oblique and Transversalis muscle to the sheath of the Rectus, where they anastomose with the internal mammary and the deep epigastric arteries. Behind, the subcostal artery anastomoses with the first lumbar artery.

Each intercostal artery gives off the following branches:—

Posterior or dorsal branch. Spinal.
Collateral intercostal.

The *posterior or dorsal branch* of each intercostal artery passes backwards to the inner side of the anterior costo-transverse ligament, and divides into an external and internal branch, which are distributed to the muscles and integument of the back.

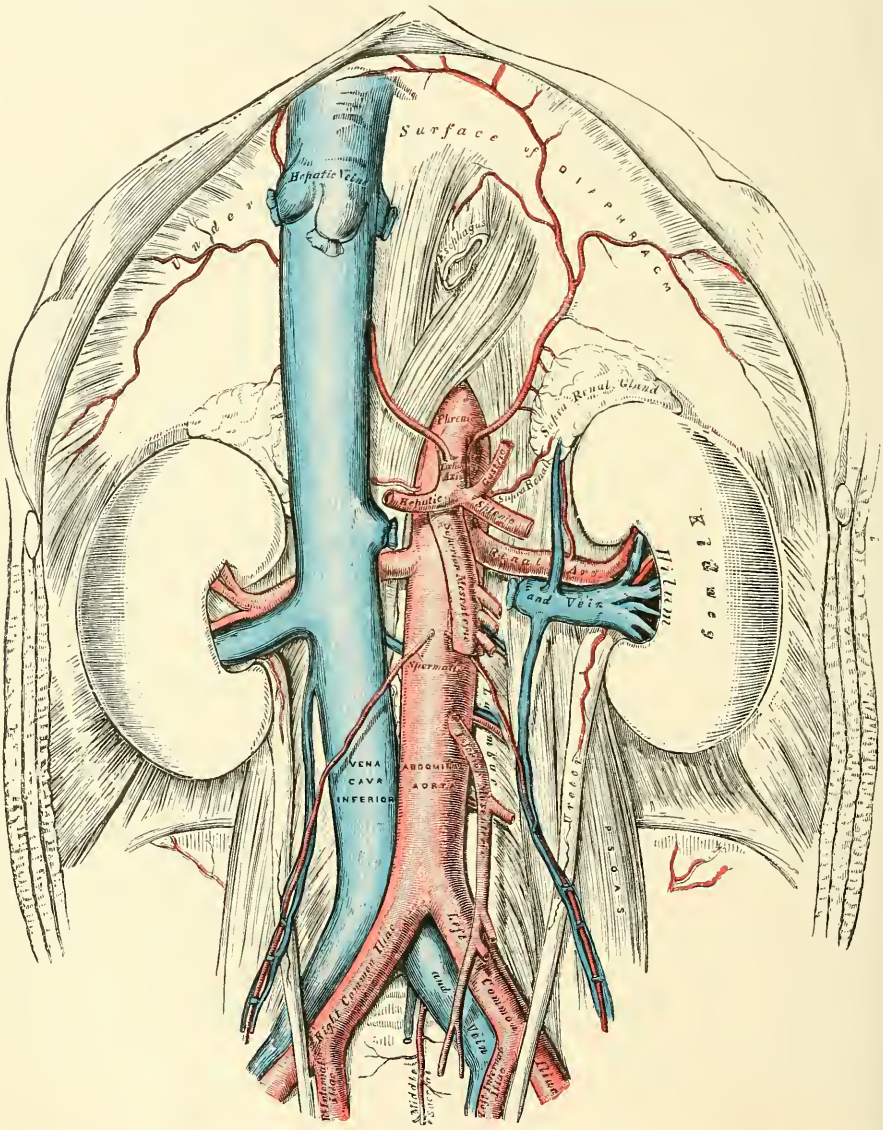
The *spinal branch*, which enters the spinal canal through the intervertebral foramen, is distributed to the spinal cord and its membranes, and to the bodies

of the vertebræ in the same manner as the lateral spinal branches from the vertebral.

The *collateral intercostal branch* comes off from the intercostal artery near the angle of the rib, and descends to the upper border of the rib below, along which it courses to anastomose with the anterior intercostal branch of the internal mammary.

Surgical Anatomy.—The position of the intercostal vessels should be borne in mind in performing the operation of paracentesis thoracis. The puncture should never be made

Fig. 407.—The abdominal aorta and its branches.



nearer the middle line than the angle of the rib, as the artery crosses the space internal to this point. In the lateral portion of the chest, where the puncture is usually made, the artery lies at the upper part of the intercostal space, and therefore the puncture should be made just above the upper border of the rib forming the lower boundary of the space.

The Abdominal Aorta (fig. 407)

The **Abdominal Aorta** commences at the aortic opening of the Diaphragm, in front of the lower border of the body of the last dorsal vertebra, and, descending

a little to the left side of the vertebral column, terminates on the body of the fourth lumbar vertebra, commonly a little to the left of the middle line,* where it divides into the two common iliac arteries. It diminishes rapidly in size, in consequence of the many large branches which it gives off. As it lies upon the bodies of the vertebræ, the curve which it describes is convex forwards, the greatest convexity corresponding to the third lumbar vertebra, which is a little above and to the left side of the umbilicus.

Relations.—It is covered, *in front*, by the lesser omentum and stomach, behind which are the branches of the cœliac axis, and the solar plexus: below these, by the splenic vein, the pancreas, the left renal vein, the transverse portion of the duodenum, the mesentery, and aortic plexus. *Behind*, it is separated from the lumbar vertebræ by the left lumbar veins, the receptaculum chyli, and thoracic duct. On the *right side* it is in relation with the inferior vena cava (the right crus of the Diaphragm being interposed above), the vena azygos major, thoracic duct, and right semilunar ganglion; on the *left side*, with the sympathetic nerve, and left semilunar ganglion.

Surface Marking.—In order to map out the abdominal aorta on the surface of the abdomen, a line must be drawn from the middle line of the body, on a level with the distal extremity of the seventh costal cartilage, downwards and slightly to the left, so that it just skirts the umbilicus, to a zone drawn round the body opposite the highest point of the crest of the ilium. This point is generally half an inch below and to the left of the umbilicus, but as the position of this structure varies with the obesity of the individual, it is not a reliable landmark as to the situation of the bifurcation of the aorta.

Surgical Anatomy.—Aneurisms of the abdominal aorta near the cœliac axis communicate in nearly equal proportion with the anterior and posterior parts of the artery.

When an aneurismal sac is connected with the back part of the abdominal aorta, it usually produces absorption of the bodies of the vertebræ, and forms a pulsating tumour, that presents itself in the left hypochondriac or epigastric regions, and is accompanied by symptoms of disturbance in the alimentary canal. Pain is invariably present, and is usually of two kinds—a fixed and constant pain in the back, caused by the tumour pressing on or displacing the branches of the solar plexus and splanchnic nerves; and a sharp lancinating pain, radiating along those branches of the lumbar nerves which are pressed on by the tumour; hence the pain in the loins, the testes, the hypogastrium, and in the lower limb (usually of the left side). This form of aneurism usually bursts into the peritoneal cavity, or behind the peritoneum, in the left hypochondriac region; or it may form a large aneurismal sac, extending down as low as Poupart's ligament;

* Lord Lister, having accurately examined 30 bodies in order to ascertain the exact point of termination of this vessel, found it 'either absolutely, or almost absolutely, mesial in 15, while in 13 it deviated more or less to the left, and in 2 was slightly to the right.'—*System of Surgery*, edited by T. Holmes, 2nd ed. vol. v. p. 652.

hæmorrhage in these cases being generally very extensive, but slowly produced, and not rapidly fatal.

When an aneurismal sac is connected with the front of the aorta near the cœliac axis, it forms a pulsating tumour in the left hypochondriac or epigastric regions, usually attended with symptoms of disturbance of the alimentary canal, as sickness, dyspepsia, or constipation, and accompanied by pain, which is constant, but not nearly always fixed, in the loins, epigastrium, or some part of the abdomen; the radiating pain being rare, as the lumbar nerves are seldom implicated. This form of aneurism may burst into the peritoneal cavity, or behind the peritoneum, between the layers of the mesentery, or, more rarely, into the duodenum; it rarely extends backwards so as to affect the spine.

The abdominal aorta has been tied several times, and although none of the patients permanently recovered, still, as one of them lived as long as ten days, the possibility of the re-establishment of the circulation may be considered to be proved. In the lower animals this artery has been often successfully tied. The vessel may be reached in several ways. In the original operation, performed by Sir A. Cooper, an incision was made in the linea alba, the peritoneum opened in front, the finger carried down amongst the intestines, towards the spine, the peritoneum again opened behind, by scratching through the mesentery, and the vessel thus reached. Or either of the operations, described below, for securing the common iliac artery, may, by extending the dissection a sufficient distance upwards, be made use of to expose the aorta. The chief difficulty in the dead subject consists in isolating the artery, in consequence of its great depth; but in the living subject, the embarrassment resulting from the proximity of the aneurismal tumour, and the great probability of disease in the vessel itself, add to the dangers and difficulties of this formidable operation so greatly, that it is very doubtful whether it ought ever to be performed.

The collateral circulation would be carried on by the anastomosis between the internal mammary and the deep epigastric; by the free communication between the superior and inferior mesenterics, if the ligature were placed above the latter vessel; or by the anastomosis between the inferior mesenteric and the internal pudic, when (as is more common) the point of ligature is below the origin of the inferior mesenteric; and possibly by the anastomoses of the lumbar arteries with the branches of the internal iliac.

The circulation through the abdominal aorta may be commanded, in thin persons, by firm pressure with the fingers. A tourniquet has been invented for this purpose, which is sometimes used in amputation at the hip-joint and some other operations.

Branches of the Abdominal Aorta

Phrenic.	Renal.
Cœliac axis. { Gastric.	Spermatic in male.
Cœliac axis. { Hepatic.	Ovarian in female.
Cœliac axis. { Splenic.	Inferior Mesenteric.
Superior Mesenteric.	Lumbar.
Suprarenal.	Sacra Media.

The branches may be divided into two sets: 1. Those supplying the viscera. 2. Those distributed to the walls of the abdomen.

Superior Mesenteric.	Phrenic.
Inferior Mesenteric.	Lumbar.
Suprarenal.	Sacra Media.

Cœliac Axis (fig. 408)

To expose this artery, raise the liver, draw down the stomach, and then tear through the layers of the lesser omentum.

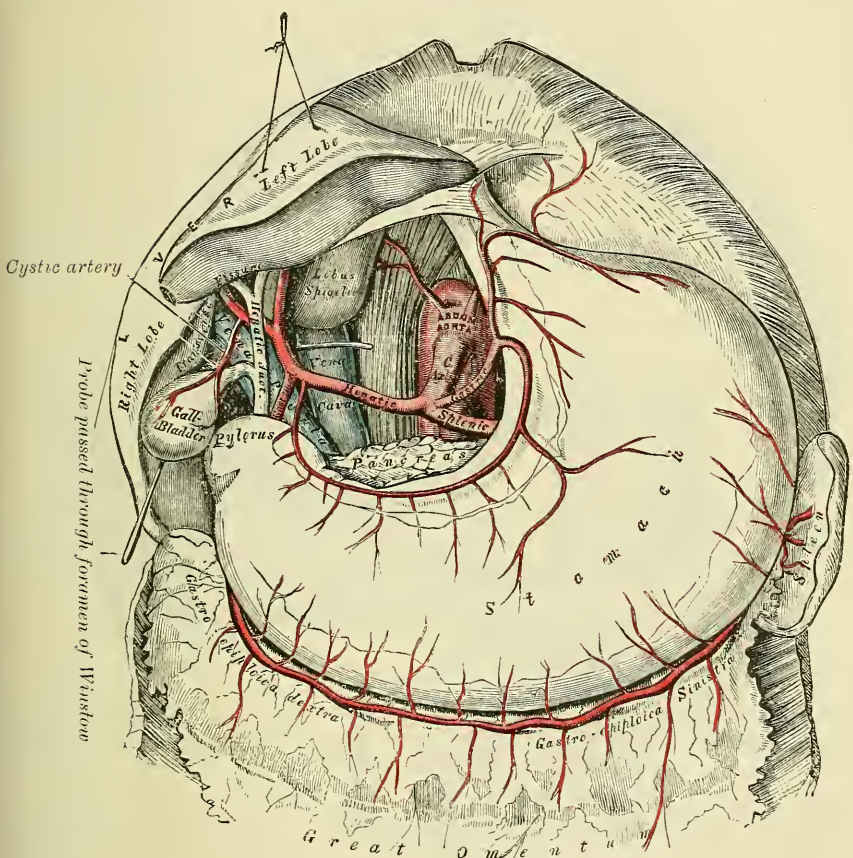
The **Cœliac Axis** is a short thick trunk, about half an inch in length, which arises from the aorta, close to the margin of the opening in the Diaphragm, and passing nearly horizontally forwards (in the erect posture), divides into three large branches, the *gastric, hepatic,* and *splenic,* occasionally giving off one of the phrenic arteries.

Relations.—It is covered by the lesser omentum. On the *right side,* it is in

relation with the right semilunar ganglion, and the lobus Spigelii; on the *left side* with the left semilunar ganglion and cardiac end of the stomach. *Below*, it rests upon the upper border of the pancreas.

The **Gastric** or **Coronary Artery**, the smallest of the three branches of the cœliac axis, passes upwards and to the left side, to the cardiac orifice of the stomach, distributing branches to the œsophagus, which anastomose with the aortic œsophageal arteries; others supply the cardiac end of the stomach, inosculating with branches of the splenic artery: it then passes from left to right, along the lesser curvature of the stomach to the pylorus, lying in its course between the layers of the lesser omentum, and giving branches to both surfaces of the organ: at its termination it anastomoses with the pyloric branch of the hepatic.

Fig. 408.—The cœliac axis and its branches, the liver having been raised, and the lesser omentum removed.



The **Hepatic Artery** in the adult is intermediate in size between the gastric and splenic; in the fœtus, it is the largest of the three branches of the cœliac axis. It is first directed forwards and to the right, to the upper margin of the pyloric end of the stomach, forming the lower boundary of the foramen of Winslow. It then passes upwards between the layers of the lesser omentum, and in front of the foramen of Winslow, to the transverse fissure of the liver, where it divides into two branches, right and left, which supply the corresponding lobes of that organ, accompanying the ramifications of the vena portæ and hepatic duct. The hepatic artery, in its course along the right border of the lesser omentum, is in relation with the ductus communis choledochus and portal veins, the duct lying to the right of the artery, and the vena portæ behind.

Its branches are, the

Pyloric.

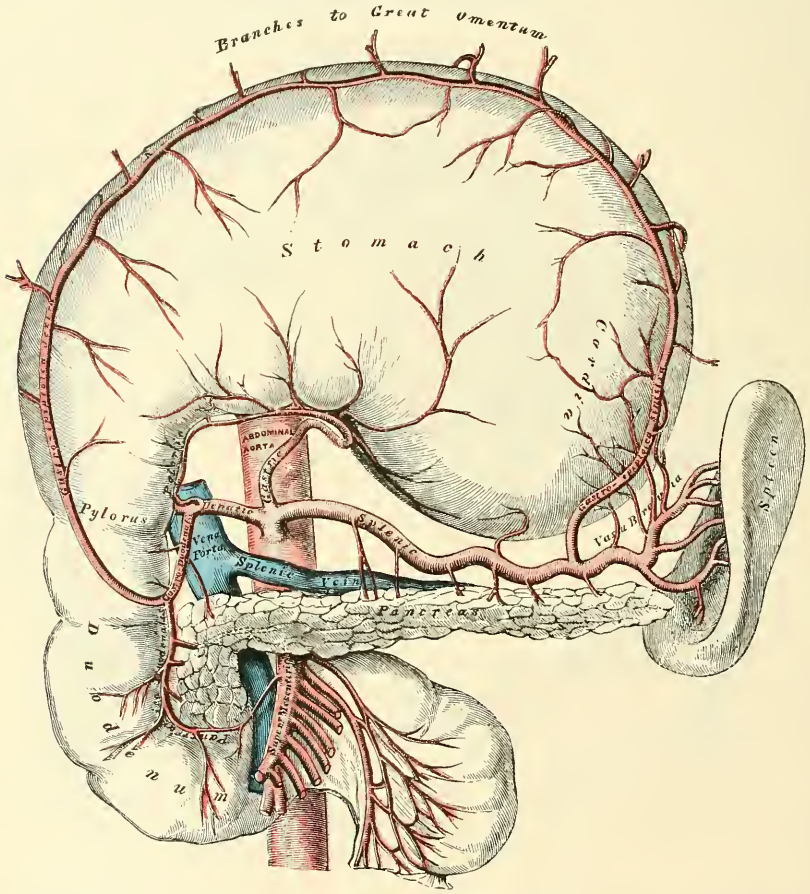
Gastro-duodenalis { Gastro-epiploica Dextra. / Pancreatico-duodenalis superior.

Cystic.

The **pyloric branch** arises from the hepatic, above the pylorus, descends to the pyloric end of the stomach, and passes from right to left along its lesser curvature, supplying it with branches, and inosculating with the gastric artery.

The **gastro-duodenalis** (fig. 409) is a short but large branch, which descends, near the pylorus, behind the first portion of the duodenum, and divides at the

Fig. 409.—The cœliac axis and its branches, the stomach having been raised and the transverse meso-colon removed.



lower border of this viscus into two branches, the *gastro-epiploica dextra* and the *pancreatico-duodenalis superior*. Previous to its division, it gives off two or three small inferior pyloric branches to the pyloric end of the stomach and pancreas.

The **gastro-epiploica dextra** runs from right to left along the greater curvature of the stomach, between the layers of the great omentum, anastomosing about the middle of the lower border of the stomach with the gastro-epiploica sinistra from the splenic artery. This vessel gives off numerous branches, some of which ascend to supply both surfaces of the stomach, whilst others descend to supply the great omentum.

The **pancreatico-duodenalis superior** descends between the contiguous margins

of the duodenum and pancreas. It supplies both these organs, and anastomoses with the inferior pancreatico-duodenal branch of the superior mesenteric artery, and with the pancreatic branches of the splenic.

The **cystic artery** (fig. 408), usually a branch of the right hepatic, passes upwards and forwards along the neck of the gall-bladder, and divides into two branches, one of which ramifies on its free surface, the other between it and the substance of the liver.

The **Splenic Artery**, in the adult, is the largest of the three branches of the cœliac axis, and is remarkable for the extreme tortuosity of its course. It passes horizontally to the left side along the upper border of the pancreas, accompanied by the splenic vein, which lies below it; and, on arriving near the spleen, divides into branches, some of which enter the hilum of that organ to be distributed to its structure, whilst others are distributed to the great end of the stomach. Its branches are, the

Pancreaticæ Parvæ.	Gastric (Vasa Brevia).
Pancreatica Magna.	Gastro-epiploica Sinistra.

The **pancreatic** are numerous small branches derived from the splenic as it runs behind the upper border of the pancreas, supplying its middle and left parts. One of these, larger than the rest, is given off from the splenic near the left extremity of the pancreas; it runs from left to right near the posterior surface of the gland, following the course of the pancreatic duct, and is called the **pancreatica magna**. These vessels anastomose with the pancreatic branches of the pancreatico-duodenal arteries, derived from the hepatic on the one hand and superior mesenteric on the other.

The **gastric (vasa brevia)** consist of from five to seven small branches, which arise either from the termination of the splenic artery, or from its terminal branches; and, passing from left to right, between the layers of the gastro-splenic omentum, are distributed to the great curvature of the stomach; anastomosing with branches of the gastric and gastro-epiploica sinistra arteries.

The **gastro-epiploica sinistra**, the largest branch of the splenic, runs from left to right along the great curvature of the stomach, between the layers of the great omentum, and anastomoses with the gastro-epiploica dextra. In its course it distributes several branches to the stomach, which ascend upon both surfaces; others descend to supply the omentum.

Superior Mesenteric Artery (fig. 410)

In order to expose this vessel, raise the great omentum and transverse colon, draw down the small intestines, and cut through the peritoneum where the transverse mesocolon and mesentery join: the artery will then be exposed, just as it issues from beneath the lower border of the pancreas.

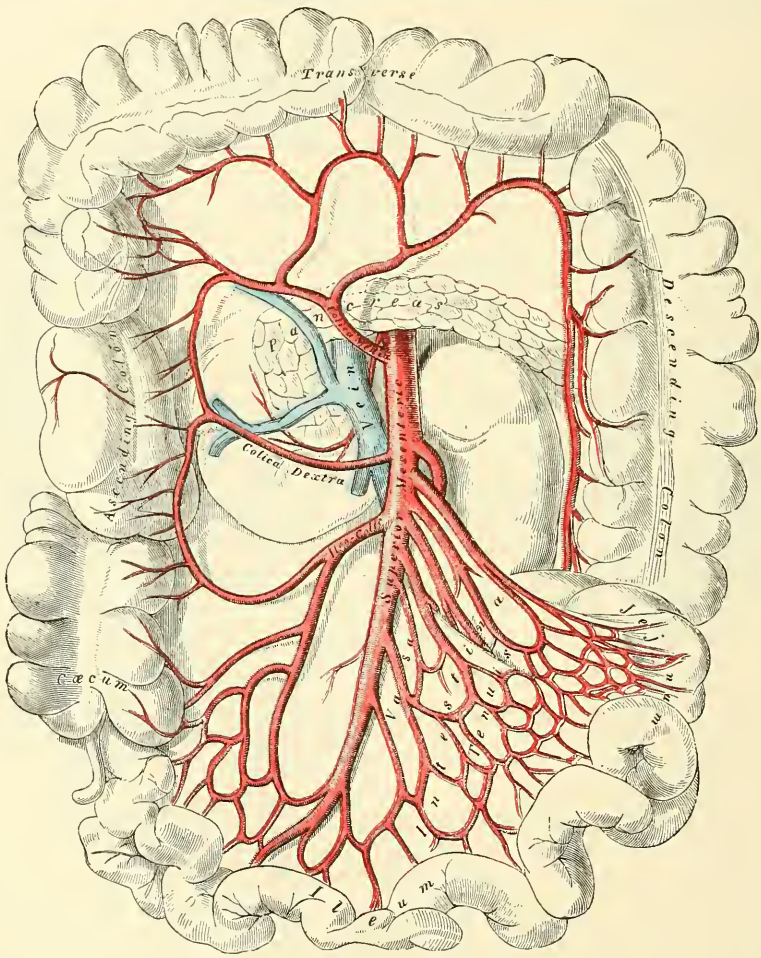
The **Superior Mesenteric Artery** supplies the whole length of the small intestine, except the first part of the duodenum; it also supplies the cæcum, ascending and transverse colon; it is a vessel of large size, arising from the fore part of the aorta, about a quarter of an inch below the cœliac axis; being covered at its origin by the splenic vein and pancreas. It passes forwards, between the pancreas and transverse portion of the duodenum, crosses in front of this portion of the intestine, and descends between the layers of the mesentery to the right iliac fossa, where it terminates, considerably diminished in size. In its course it forms an arch, the convexity of which is directed forwards and downwards to the left side, the concavity backwards and upwards to the right. It is accompanied by the superior mesenteric vein, and is surrounded by the superior mesenteric plexus of nerves. Its branches are, the

Inferior Pancreatico-duodenal.	Ileo-colic.
Vasa Intestini Tenuis.	Colica Dextra.
Colica Media.	

The **Inferior pancreatico-duodenal** is given off from the superior mesenteric behind the pancreas. It courses to the right between the head of the pancreas and duodenum, and then ascends to anastomose with the superior pancreatico-duodenal artery. It distributes branches to the head of the pancreas and to the transverse and descending portions of the duodenum.

The **vasa intestini tenuis** arise from the convex side of the superior mesenteric artery. They are usually from twelve to fifteen in number, and are distributed to the jejunum and ileum. They run parallel with one another between the layers of the mesentery; each vessel dividing into two branches, which unite with a similar branch on each side, forming a series of arches, the convexities of which are directed towards the intestine. From this first set of arches branches arise,

Fig. 410.—The superior mesenteric artery and its branches.



which again unite with similar branches from either side, and thus a second series of arches is formed; and from these latter, a third, and a fourth, or even fifth series of arches is constituted, diminishing in size the nearer they approach the intestine. From the terminal arches numerous small straight vessels arise which encircle the intestine, upon which they are distributed, ramifying between its coats. Throughout their course small branches are given off to the glands and other structures between the layers of the mesentery.

The **ileo-colic artery** is the lowest branch given off from the concavity of the superior mesenteric artery. It descends between the layers of the mesentery to

the right iliac fossa, where it divides into two branches. Of these, the inferior division inosculates with the lowest branches of the vasa intestini tenuis, from the convexity of which branches proceed to supply the termination of the ileum, the cæcum and appendix cæci, and the ileo-cæcal valve. The superior division inosculates with the colica dextra, and supplies the commencement of the colon.

The **colica dextra** arises from about the middle of the concavity of the superior mesenteric artery, and, passing behind the peritoneum to the middle of the ascending colon, divides into two branches: a descending branch, which inosculates with the ileo-colic; and an ascending branch, which anastomoses with the colica media. These branches form arches, from the convexity of which vessels are distributed to the ascending colon. The branches of this vessel are covered with peritoneum only on their anterior aspect.

The **colica media** arises from the upper part of the concavity of the superior mesenteric, and, passing forwards between the layers of the transverse meso-colon, divides into two branches: the one on the right side inosculating with the colica dextra; that on the left side with the colica sinistra, a branch of the inferior mesenteric. From the arches formed by their inosculation, branches are distributed to the transverse colon. The branches of this vessel lie between two layers of peritoneum.

Inferior Mesenteric Artery (fig. 411)

In order to expose this vessel, draw the small intestines and mesentery over to the right side of the abdomen, raise the transverse colon towards the thorax, and divide the peritoneum covering the left side of the aorta.

The **Inferior Mesenteric Artery** supplies the descending and sigmoid flexure of the colon, and the greater part of the rectum. It is smaller than the superior mesenteric; and arises from the left side of the aorta, between one and two inches above its division into the common iliacs. It passes downwards to the left iliac fossa, and then descends, between the layers of the meso-rectum, into the pelvis, under the name of the *superior hæmorrhoidal artery*. It lies at first in close relation with the left side of the aorta, and then passes as the superior hæmorrhoidal in front of the left common iliac artery. Its branches are, the

Colica Sinistra. Sigmoid.
Superior Hæmorrhoidal.

The **colica sinistra** passes behind the peritoneum, in front of the left kidney, to reach the descending colon, and divides into two branches: an ascending branch, which inosculates with the colica media; and a descending branch, which anastomoses with the sigmoid artery. From the arches formed by these inosculations, branches are distributed to the descending colon.

The **sigmoid artery** runs obliquely downwards across the Psoas muscle to the sigmoid flexure of the colon, and divides into branches which supply that part of the intestine; anastomosing above, with the colica sinistra; and below, with the superior hæmorrhoidal artery. This vessel is sometimes replaced by three or four small branches.

The **superior hæmorrhoidal artery**, the continuation of the inferior mesenteric, descends into the pelvis between the layers of the meso-rectum, crossing, in its course, the ureter and left common iliac vessels. It divides into two branches, which descend one on each side of the rectum, and about five inches from the anus break up into several small branches, which pierce the muscular coat of the bowel and run downwards, as straight vessels, placed at regular intervals from each other in the wall of the gut between its muscular and mucous coat, to the level of the internal sphincter; here they form a series of loops around the lower end of the rectum, and communicate with the middle hæmorrhoidal arteries, branches of the internal iliac, and with the inferior hæmorrhoidal branches of the internal pudic.

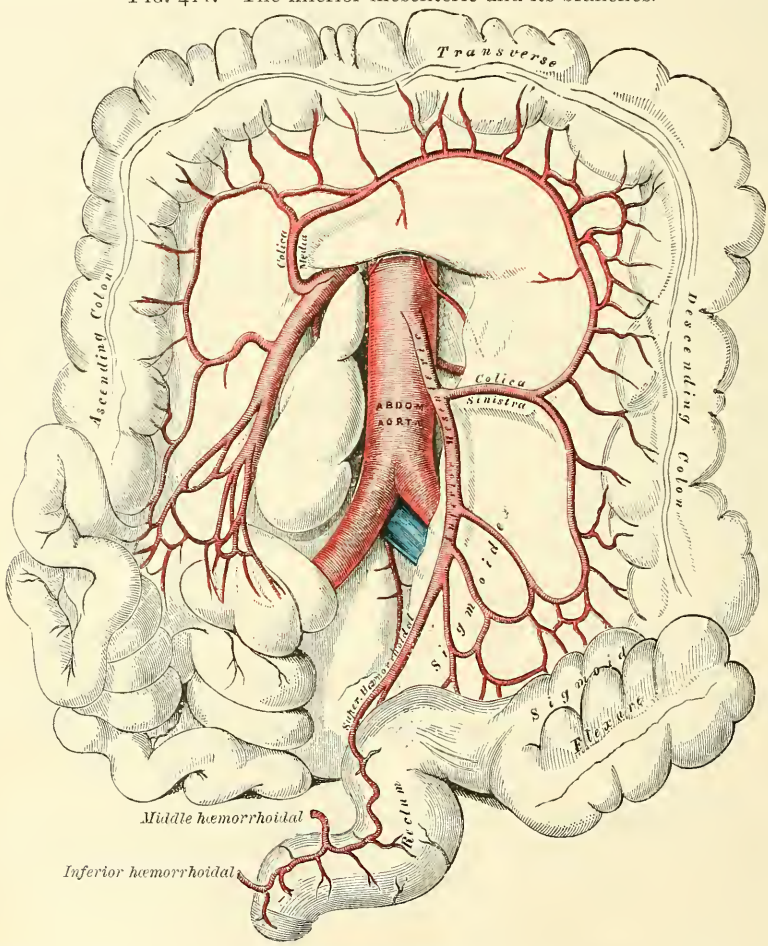
Suprarenal Arteries (fig. 407)

The **Suprarenal Arteries** are two small vessels which arise, one on each side of the aorta, opposite the superior mesenteric artery. They pass obliquely upwards and outwards, over the crura of the Diaphragm, to the under surface of the suprarenal capsules, to which they are distributed, anastomosing with capsular branches from the phrenic and renal arteries. In the adult these arteries are of small size; in the fœtus they are as large as the renal arteries.

Renal Arteries (fig. 407)

The **Renal Arteries** are two large trunks, which arise from the sides of the aorta, immediately below the superior mesenteric artery. Each is directed

Fig. 411.—The inferior mesenteric and its branches.



outwards, across the crus of the Diaphragm, so as to form nearly a right angle with the aorta. The right is longer than the left, on account of the position of the aorta; it passes behind the inferior vena cava. The left is somewhat higher than the right. Previously to entering the kidney, each artery divides into four or five branches which are distributed to its substance. At the hilum, these branches lie between the renal vein and ureter, the vein being in front, the ureter behind. Each vessel gives off some small branches to the suprarenal capsule, the ureter, and the surrounding cellular tissue and muscles. Frequently there is a second renal artery, which is given off from the abdominal aorta at a lower level and supplies the lower portion of the kidney. It is termed the *inferior renal artery*.

Spermatic Arteries

The **Spermatic Arteries** are distributed to the testes. They are two slender vessels, of considerable length, which arise from the front of the aorta, a little below the renal arteries. Each artery passes obliquely outwards and downwards, behind the peritoneum, resting on the Psoas muscle, the right spermatic lying in front of the inferior vena cava, the left behind the sigmoid flexure of the colon. It then crosses obliquely over the ureter and the lower part of the external iliac artery to reach the internal abdominal ring, through which it passes, and accompanies the other constituents of the spermatic cord along the inguinal canal to the scrotum, where it becomes tortuous, and divides into several branches, two or three of which accompany the vas deferens, and supply the epididymis, anastomosing with the artery of the vas deferens; others pierce the back part of the tunica albuginea, and supply the substance of the testis.

The **Ovarian Arteries** (fig. 413) are the corresponding arteries in the female to the spermatic in the male. They supply the ovaries, are shorter than the spermatic, and do not pass out of the abdominal cavity. The origin and course of the first part of the artery are the same as the spermatic in the male, but on arriving at the margin of the pelvis the ovarian artery passes inwards, between the two layers of the broad ligament of the uterus, to be distributed to the ovary. One or two small branches supply the Fallopian tube; another passes on to the side of the uterus, and anastomoses with the uterine arteries. Other offsets are continued along the round ligament, through the inguinal canal, to the integument of the labium and groin.

At an early period of fœtal life, when the testes or ovaries lie by the side of the spine, below the kidneys, the spermatic or ovarian arteries are short; but as these organs descend from the abdomen into the scrotum or pelvis, the arteries become gradually lengthened.

Phrenic Arteries

The **Phrenic Arteries** are two small vessels, which present much variety in their origin. They may arise separately from the front of the aorta, immediately above the cœliac axis, or by a common trunk, which may spring either from the aorta or from the cœliac axis. Sometimes one is derived from the aorta, and the other from one of the renal arteries. In only one out of thirty-six cases examined did these arteries arise as two separate vessels from the aorta. They diverge from one another across the crura of the Diaphragm, and then pass obliquely upwards and outwards upon its under surface. The left phrenic passes behind the œsophagus, and runs forwards on the left side of the œsophageal opening. The right phrenic passes behind the inferior vena cava, and ascends along the right side of the aperture for transmitting that vein. Near the back part of the central tendon each vessel divides into two branches. The internal branch runs forwards to the front of the thorax, supplying the Diaphragm, and anastomosing with its fellow of the opposite side, and with the musculo-phrenic and comes nervi phrenici, branches of the internal mammary. The external branch passes towards the side of the thorax, and inosculates with the intercostal arteries. The internal branch of the right phrenic gives off a few vessels to the inferior vena cava; and the left one some branches to the œsophagus. Each vessel also sends capsular branches to the suprarenal capsule of its own side. The spleen on the left side, and the liver on the right, also receive a few branches from these vessels.

Lumbar Arteries

The **Lumbar Arteries** are analogous to the intercostal. They are usually four in number on each side, and arise from the back part of the aorta, nearly at right

angles with that vessel. They pass outwards and backwards, around the sides of the bodies of the lumbar vertebræ, behind the sympathetic nerve and the Psoas magnus muscle; those on the right side being covered by the inferior vena cava, and the two upper ones on each side by the crura of the Diaphragm. In the interval between the transverse processes of the vertebræ each artery divides into a *dorsal* and an *abdominal branch*.

The *dorsal branch* gives off, immediately after its origin, a *spinal branch*, which enters the spinal canal; it then continues its course backwards, between the transverse processes, and is distributed to the muscles and integument of the back, anastomosing with the similar branches of the adjacent lumbar arteries, and with the posterior branches of the intercostal arteries. The *spinal branch* enters the spinal canal through the intervertebral foramen, to be distributed to the spinal cord and its membranes and to the bodies of the vertebræ in the same manner as the lateral spinal branches from the vertebral (see page 592).

The *abdominal branches* pass outwards, having a variable relation to the Quadratus lumborum muscle. Most frequently the first branch passes in front of the muscle and the others behind it; sometimes the order is reversed and the lowest branch passes in front of the muscle. At the outer border of the Quadratus they are continued between the abdominal muscles, anastomose with branches of the epigastric and internal mammary *in front*, the intercostals *above*, and those of the ilio-lumbar and circumflex iliac *below*.

Middle Sacral Artery

The **Middle Sacral Artery** is a small vessel, which arises from the back part of the aorta, just at its bifurcation. It descends upon the last lumbar vertebra, and along the middle line of the front of the sacrum, to the upper part of the coccyx, where it anastomoses with the lateral sacral arteries, and terminates in a minute branch, which runs down to the situation of the body immediately to be described as 'Luschka's gland.' From it, branches arise which run through the meso-rectum, to supply the posterior surface of the rectum. Other branches are given off on each side, which anastomose with the lateral sacral arteries, and send off small offsets, which enter the anterior sacral foramina.

The artery is the representative of the caudal prolongation of the aorta of animals, and its lateral branches correspond to the intercostal and lumbar arteries in the dorsal and lumbar regions.

Coccygeal Gland, or Luschka's Gland.—Lying near the tip of the coccyx in a small tendinous interval formed by the union of the Levator ani muscle of each side, and just above the coccygeal attachment of the Sphincter ani, is a small conglobate body, about as large as a lentil or a pea, first described by Luschka,* and named by him the *coccygeal gland*. Its most obvious connections are with the arteries of the part.

Structure.—It consists of a congeries of small arteries, with little aneurismal dilatations, derived from the middle sacral, and freely communicating with each other. These vessels are enclosed in one or more layers of polyhedral granular cells, and the whole structure is invested in a capsule of connective tissue which sends in trabeculæ, dividing the interior into a number of spaces in which the vessels and cells are contained. Nerves pass into this little body from the sympathetic, but their mode of termination is unknown. Macalister believes the glomerulus of vessels 'consists of the condensed and convoluted metameric dorsal arteries of the caudal segments embedded in tissue which is possibly a small persisting fragment of the neurenteric canal.'

Common Iliac Arteries

The abdominal aorta divides into the two **common iliac arteries.** The bifurcation usually takes place on the left side of the body of the fourth lumbar vertebra. The common iliac arteries are about two inches in length; diverging from the termination of the aorta, they pass downwards and outwards to the margin of the pelvis, and divide opposite the intervertebral substance, between the last lumbar vertebra, and the sacrum, into two branches, the *external* and *internal iliac arteries:* the former supplying the lower extremity; the latter, the viscera and parietes of the pelvis.

The **right common iliac** is somewhat larger than the left, and passes more obliquely across the body of the last lumbar vertebra. In front of it are the peritoneum, the small intestines, branches of the sympathetic nerve, and, at its point of division, the ureter. *Behind*, it is separated from the fourth and fifth lumbar vertebræ, with the intervening intervertebral disc, by the two common iliac veins. On its *outer side*, it is in relation with the inferior vena cava, and the right common iliac vein, above; and the Psoas magnus muscle below.

The **left common iliac** is in relation, in front, with the peritoneum, branches of the sympathetic nerve, and the superior hæmorrhoidal artery; and is crossed at its point of bifurcation by the ureter. It rests on the bodies of the fourth and fifth lumbar vertebræ, with the intervening intervertebral disc. The left common iliac vein lies partly on the inner side, and partly beneath the artery; on its outer side, the artery is in relation with the Psoas magnus muscle.

Left common iliac vein.

Branches.—The common iliac arteries give off small branches to the peritoneum, Psoas magnus, ureters, and the surrounding cellular tissue, and occasionally give origin to the ilio-lumbar, or renal arteries.

Peculiarities.—The *point of origin* varies according to the bifurcation of the aorta. In three-fourths of a large number of cases, the aorta bifurcated either upon the fourth lumbar vertebra, or upon the intervertebral disc between it and the fifth; the bifurcation being, in one case out of nine below, and in one out of eleven above this point. In ten out of every thirteen cases, the vessel bifurcated within half an inch above or below the level of the crest of the ilium: more frequently below than above.

The *point of division* is subject to great variety. In two-thirds of a large number of cases it was between the last lumbar vertebra and the upper border of the sacrum; being above that point in one case out of eight, and below it in one case out of six. The left common iliac artery divides lower down more frequently than the right.

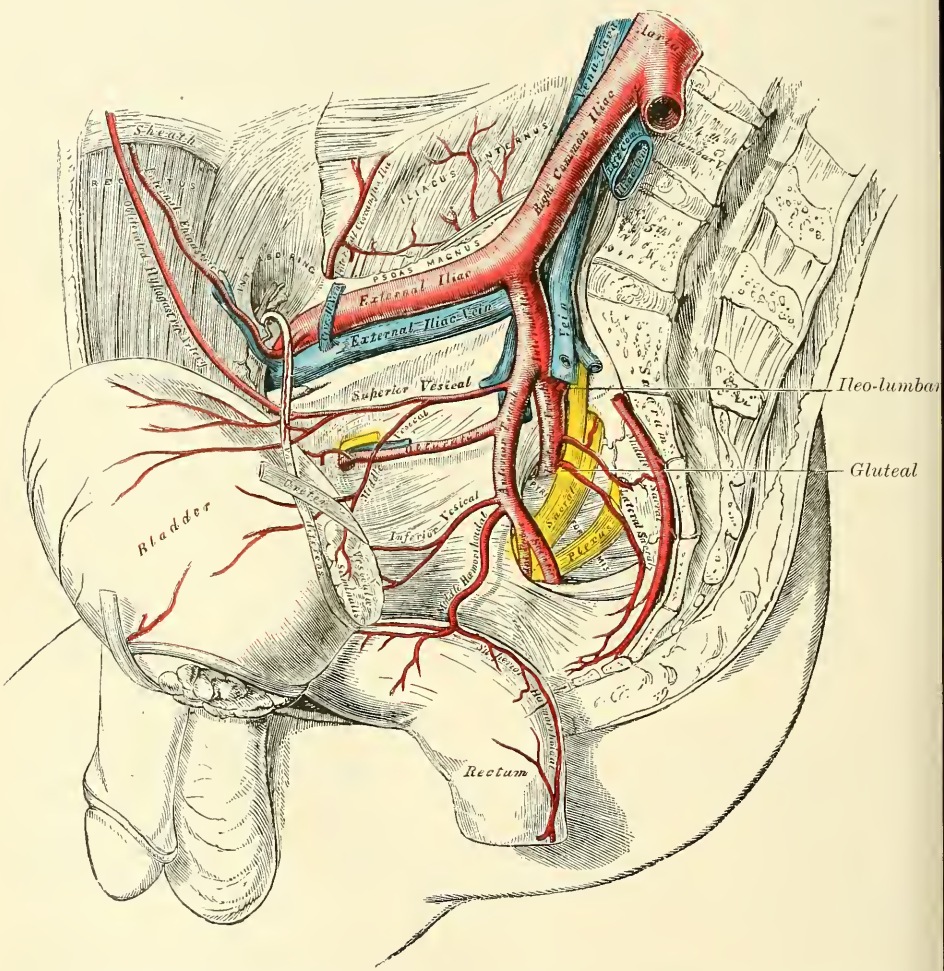
The *relative length*, also, of the two common iliac arteries varies. The right common iliac was the longer in sixty-three cases; the left in fifty-two; whilst they were both equal in fifty-three. The length of the arteries varied in five-sevenths of the cases examined, from an inch and a half to three inches; in about half of the remaining cases, the artery was longer, and in the other half, shorter: the minimum length being less than half an inch,

the maximum four and a half inches. In two instances, the right common iliac has been found wanting, the external and internal iliacs arising directly from the aorta.

Surface Marking.—Draw a zone round the body opposite the highest part of the crest of the ilium; in this line take a point half an inch to the left of the middle line. From this draw two lines to points midway between the anterior superior spines of the ilium and the symphysis pubis. These two diverging lines will represent the course of the common and external iliac arteries. Draw a second zone round the body corresponding to the level of the anterior superior spines of the ilium: the portion of the diverging lines between the two zones will represent the course of the common iliac artery; the portion below the lower zone, that of the external iliac artery.

Surgical Anatomy.—The application of a ligature to the common iliac artery may be required on account of aneurism or hæmorrhage, implicating the external or internal

FIG. 412.—Arteries of the pelvis.



iliacs. The artery may be tied by one of two incisions. 1. An anterior or iliac incision, by which the vessel is approached more directly from the front; and 2. a posterior abdominal or lumbar incision, by which the vessel is reached from behind. If the surgeon select the iliac region, a curved incision, from five to eight inches in length according to the amount of fat, is made, commencing just outside the middle of Poupart's ligament and a finger's breadth above it, and carried outwards towards the anterior superior iliac spine, then upwards towards the ribs, and finally curving inwards towards the umbilicus. The abdominal muscles and transversalis fascia are divided, and the peritoneum raised upwards and inwards, until the Psoas is reached. The artery will be found on the inner side of this muscle, and is to be cleared with a director, especial care being taken on the right side, as here the common iliac veins lie behind the artery. The aneurism needle is to be passed from within outwards. But if the aneurismal tumour should extend high up in the abdomen, along the external iliac, it is better to select the posterior or lumbar

operation, by making an incision partly in the abdomen, partly in the loin. The incision is commenced at the anterior extremity of the last rib, proceeding directly downwards to the ilium; it is then curved forwards along the crest of the ilium, and a little above it, to the anterior superior spine of that bone. The abdominal muscles having been cautiously divided in succession, the transversalis fascia must be carefully cut through, and the peritoneum, together with the ureter, separated from the artery, and pushed aside; the sacro-iliac articulation must then be felt for, and upon it the vessel will be felt pulsating, and may be fully exposed in close connection with its accompanying vein. On the right side, both common iliac veins, as well as the inferior vena cava, are in close connection with the artery, and must be carefully avoided. On the left side, the vein usually lies on the inner side, and behind the artery; but it occasionally happens that the two common iliac veins are joined on the left instead of the right side, which would add much to the difficulty of an operation in such a case. The common iliac artery may be so short that danger may be apprehended from secondary hæmorrhage if a ligature is applied to it. It would be preferable, in such a case, to tie both the external and internal iliacs near their origin.

Collateral Circulation.—The principal agents in carrying on the collateral circulation after the application of a ligature to the common iliac are: the anastomoses of the hæmorrhoidal branches of the internal iliac with the superior hæmorrhoidal from the inferior mesenteric; the anastomoses of the uterine and ovarian arteries, and of the vesical arteries of opposite sides; of the lateral sacral with the middle sacral artery; of the epigastric with the internal mammary, inferior intercostal, and lumbar arteries; of the circumflex iliac with the lumbar arteries; of the ilio-lumbar with the last lumbar artery; of the obturator artery, by means of its pubic branch, with the vessel of the opposite side, and with the deep epigastric.

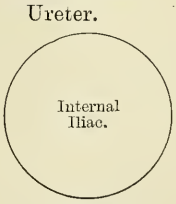
Compression of the Common Iliac Arteries.—The common iliac arteries are most efficiently compressed by Davy's lever. The instrument consists of a gum-elastic tube, about two feet long, in which fits a round wooden 'lever' considerably longer than the tube. A small quantity of olive oil having been injected into the rectum, the gum-elastic tube, softened in hot water, is passed into the bowel sufficiently far to permit its pressing upon the common iliac artery as it lies in the groove between the last lumbar vertebra and the Psoas muscle. The wooden lever is then inserted into the tube, and the projecting end carried towards the opposite thigh and raised, when it acts as a lever of the first order, the anus being the fulcrum. In cases where the meso-rectum is abnormally short it may be impossible, without unjustifiable force, to compress the artery on the right side.

Internal Iliac Artery (fig. 412)

The **internal iliac artery** supplies the walls and viscera of the pelvis, the generative organs, and inner side of the thigh. It is a short, thick vessel, smaller in the adult than the external iliac, and about an inch and a half in length. It arises at the point of bifurcation of the common iliac, and, passing downwards to the upper margin of the great sacro-sciatic foramen, divides into two large trunks, an *anterior* and *posterior*; from its point of bifurcation a partially obliterated cord, the *hypogastric artery*, extends forwards to the bladder.

Relations.—*In front*, with the ureter, which separates it from the peritoneum. *Behind*, with the internal iliac vein, the lumbo-sacral nerve, and Pyriformis muscle. By its *outer side*, near its origin, with the Psoas magnus muscle.

Plan of the Relations of the Internal Iliac Artery



In front.
Peritoneum.
Ureter.

Outer side.
Psoas magnus.

Behind.
Internal iliac vein.
Lumbo-sacral nerve.
Pyriformis muscle.

In the fœtus, the internal iliac artery (*hypogastric*) is twice as large as the external iliac, and appears to be the continuation of the common iliac. Instead of dipping into the pelvis, it passes forwards to the bladder, and ascends along the sides of that viscus to its summit, to which it gives branches; it then passes upwards along the back part of the anterior wall of the abdomen to the umbilicus, converging towards its fellow of the opposite side. Having passed through the umbilical opening, the two arteries twine round the umbilical vein, forming with it the umbilical cord; and, ultimately, ramify in the placenta. The portion of the vessel within the abdomen is called the *hypogastric artery*; and that external to that cavity, the *umbilical artery*.

At birth, when the placental circulation ceases, the upper portion of the hypogastric artery, extending from the summit of the bladder to the umbilicus, contracts, and ultimately dwindles to a solid fibrous cord; but the lower portion, extending from its origin (in what is now the internal iliac artery) for about an inch and a half to the wall of the bladder, and thence to the summit of that organ, is not totally impervious, though it becomes considerably reduced in size, and serves to convey blood to the bladder, under the name of the *superior vesical artery*.

Peculiarities as regards Length.—In two-thirds of a large number of cases, the length of the internal iliac varied between an inch and an inch and a half; in the remaining third, it was more frequently longer than shorter, the maximum length being three inches, the minimum half an inch.

The lengths of the common and internal iliac arteries bear an inverse proportion to each other, the internal iliac artery being long when the common iliac is short, and *vice versâ*.

As regards its Place of Division.—The place of division of the internal iliac varies between the upper margin of the sacrum and the upper border of the sacro-sciatic foramen.

The arteries of the two sides in a series of cases often differed in length, but neither seemed constantly to exceed the other.

Surgical Anatomy.—The application of a ligature to the internal iliac artery may be required in cases of aneurism or hæmorrhage affecting one of its branches. The vessel may be secured by making an incision through the abdominal parietes in the iliac region, in a direction and to an extent similar to that for securing the common iliac; the transversalis fascia having been cautiously divided, and the peritoneum pushed inwards from the iliac fossa towards the pelvis, the finger may feel the pulsation of the external iliac at the bottom of the wound; and, by tracing this vessel upwards, the internal iliac is arrived at, opposite the sacro-iliac articulation. It should be remembered that the vein lies behind, and on the right side, a little external to the artery, and in close contact with it; the ureter and peritoneum, which lie in front, must also be avoided. The degree of facility in applying a ligature to this vessel will mainly depend upon its length. It has been seen that, in the great majority of the cases examined, the artery was short, varying from an inch to an inch and a half; in these cases, the artery is deeply seated in the pelvis; when, on the contrary, the vessel is longer, it is found partly above that cavity. If the artery is very short, as occasionally happens, it would be preferable to apply a ligature to the common iliac, or upon the external and internal iliacs at their origin.

Probably a better method of tying the internal iliac artery is by an abdominal section in the median line and reaching the vessel through the peritoneal cavity. This plan has been advocated by Dennis, of New York, on the following grounds: (1) It no way increases the danger of the operation; (2) it prevents a series of accidents which have occurred during ligature of the artery by the older methods; (3) it enables the surgeon to ascertain the exact extent of disease in the main arterial trunk, and select his spot for the application of the ligature; and (4) it occupies much less time.

Collateral Circulation.—In Professor Owen's dissection of a case in which the internal iliac artery had been tied by Stevens ten years before death, for aneurism of the sciatic artery, the internal iliac was found impervious for about an inch above the point where the ligature had been applied; but the obliteration did not extend to the origin of the external iliac, as the ilio-lumbar artery arose just above this point. Below the point of obliteration, the artery resumed its natural diameter, and continued so for half an inch; the obturator, lateral sacral, and gluteal arising in succession from the latter portion. The obturator artery was entirely obliterated. The lateral sacral artery was as large as a crow's quill, and had a very free anastomosis with the artery of the opposite side, and with the middle sacral artery. The sciatic artery was entirely obliterated as far as its point of connection with the aneurismal tumour; but, on the distal side of the sac, it was continued down along the back of the thigh nearly as large in size as the femoral, being pervious about an inch below the sac by receiving an anastomosing vessel from the profunda.* The circulation

* *Medico-Chirurgical Trans.*, vol. xvi.

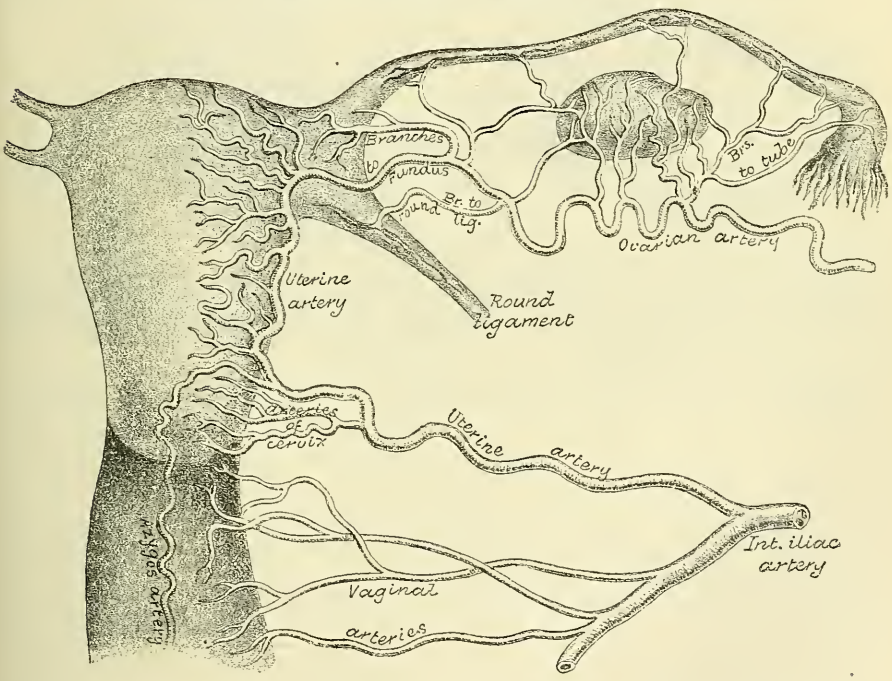
was carried on by the anastomoses of the uterine and ovarian arteries; of the opposite vesical arteries; of the hæmorrhoidal branches of the internal iliac with those from the inferior mesenteric; of the obturator artery, by means of its pubic branch, with the vessel of the opposite side, and with the epigastric and internal circumflex; of the circumflex and perforating branches of the profunda femoris with the sciatic; of the gluteal with the posterior branches of the sacral arteries; of the ilio-lumbar with the last lumbar; of the lateral sacral with the middle sacral; and of the circumflex iliac with the ilio-lumbar and gluteal.

Branches of the Internal Iliac

From the Anterior Trunk.	*From the Posterior Trunk.*
Superior Vesical.	Ilio-lumbar.
Middle Vesical.	Lateral Sacral.
Inferior Vesical.	Gluteal.
Middle Hæmorrhoidal.	
Obturator.	
Internal Pudic.	
Sciatic.	
In female (Uterine.	
(Vaginal.	

The **superior vesical** is that part of the fœtal hypogastric artery which remains pervious after birth. It extends to the side of the bladder, distributing numerous

Fig. 413.—The arteries of the internal organs of generation of the female, seen from behind. (After Hyrtl.)



branches to the apex and body of the organ. From one of these a slender vessel is derived, which accompanies the vas deferens in its course to the testis, where it anastomoses with the spermatic artery. This is the *artery of the vas deferens*. Other branches supply the ureter.

The **middle vesical**, usually a branch of the superior, is distributed to the base of the bladder and under surface of the vesiculæ seminales.

The **inferior vesical** arises from the anterior division of the internal iliac, frequently in common with the middle hæmorrhoidal, and is distributed to the base of the bladder, the prostate gland, and vesiculæ seminales. The branches

distributed to the prostate communicate with the corresponding vessel of the opposite side.

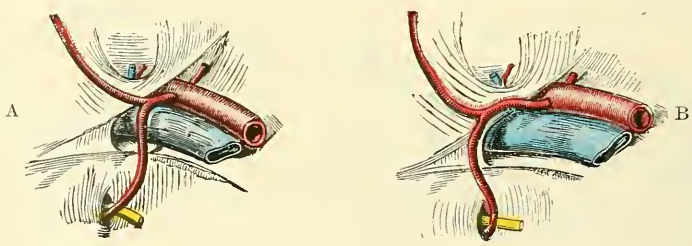
The **middle hæmorrhoidal artery** usually arises together with the preceding vessel. It supplies the anus and parts outside the rectum, anastomosing with the other hæmorrhoidal arteries.

The **uterine artery** passes inwards from the anterior trunk of the internal iliac to the neck of the uterus. Ascending, in a tortuous course on the side of this viscus, between the layers of the broad ligament, it distributes branches to its substance, anastomosing, near its termination, with a branch from the ovarian artery. It gives off branches to the cervex uteri (*cervical*), and branches which descend on to the vagina, and, joining with branches from the vaginal arteries, form a median longitudinal vessel both in front and behind, which descend on the anterior and posterior surfaces of the vagina, and are named the *azygos arteries of the vagina*.

The **vaginal artery** is analogous to the inferior vesical in the male; it descends upon the vagina, supplying its mucous membrane, and sending branches to the neck of the bladder and contiguous part of the rectum. It assists in forming the azygos arteries of the vagina.

The **obturator artery** usually arises from the anterior trunk of the internal iliac, sometimes from the posterior. It passes forwards, below the brim of the pelvis, to the upper part of the obturator foramen, and escaping from the pelvic cavity through a short canal, formed by a groove on the under surface of the

Fig. 414.—Variations in origin and course of obturator artery.



ascending ramus of the os pubis, and the arched border of the obturator membrane, it divides into an internal and an external branch. In the pelvic cavity this vessel lies upon the pelvic fascia, beneath the peritoneum, and a little below the obturator nerve.

Branches.—*Within the pelvis*, the obturator artery gives off an *iliac branch* to the iliac fossa, which supplies the bone and the Iliacus muscle, and anastomoses with the ilio-lumbar artery; a *vesical branch*, which runs backwards to supply the bladder; and a *pubic branch*, which is given off from the vessel just before it leaves the pelvic cavity. This branch ascends upon the back of the os pubis, communicating with offsets from the deep epigastric artery, and with the corresponding vessel of the opposite side. It is placed on the inner side of the femoral ring. *External to the pelvis*, the obturator artery divides into an *internal* and an *external branch*, which are deeply situated beneath the Obturator externus muscle.

The *internal branch* curves downwards along the inner margin of the obturator foramen, lying beneath the Obturator externus muscle; it distributes branches to the Obturator externus muscle, Pectineus, Adductors, and Gracilis, and anastomoses with the external branch, and with the internal circumflex artery.

The *external branch* curves round the outer margin of the foramen, also lying beneath the Obturator externus muscle, to the space between the Gemellus inferior and Quadratus femoris, where it divides into two branches: one, the smaller, courses inwards around the lower margin of the foramen and anastomoses with the internal branch and with the internal circumflex; the other inclines outwards in the groove below the acetabulum, and supplies the muscles attached

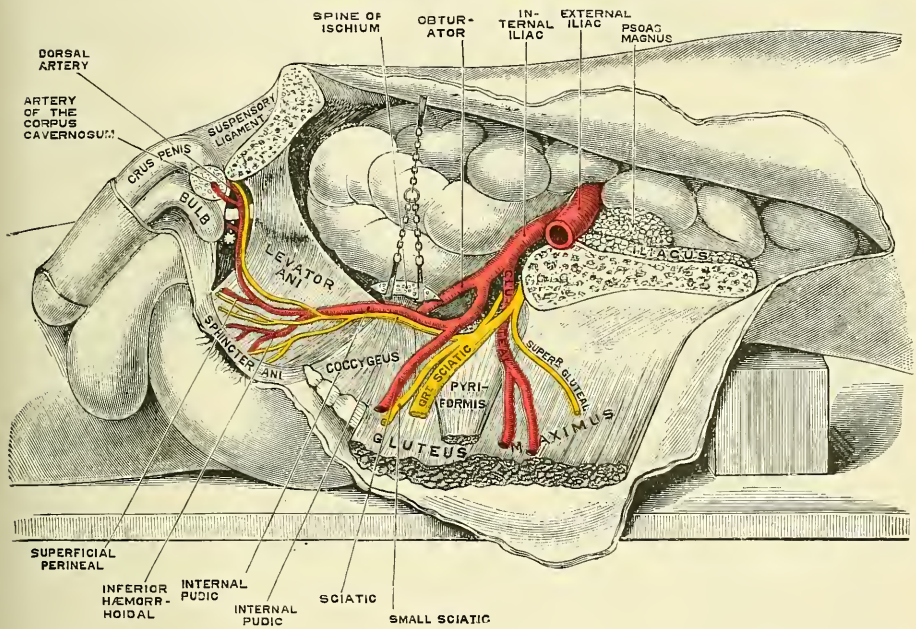
to the tuberosity of the ischium and anastomoses with the sciatic artery. It sends a branch to the hip-joint through the cotyloid notch, which ramifies on the round ligament as far as the head of the femur.

Peculiarities.—In two out of every three cases the obturator arises from the internal iliac; in one case in 3½ from the epigastric; and in about one in seventy-two cases by two roots from both vessels. It arises in about the same proportion from the external iliac artery. The origin of the obturator from the epigastric is not commonly found on both sides of the same body.

When the obturator artery arises at the front of the pelvis from the epigastric, it descends almost vertically to the upper part of the obturator foramen. The artery in this course usually lies in contact with the external iliac vein, and on the outer side of the femoral ring (fig. 414, A); in such cases it would not be endangered in the operation for femoral hernia. Occasionally, however, it curves inwards along the free margin of Gimbernat's ligament (fig. 414, B), and under such circumstances would almost completely encircle the neck of a hernial sac (supposing a hernia to exist in such a case), and would be in great danger of being wounded if an operation were performed.

The **Internal Pudic** is the smaller of the two terminal branches of the anterior trunk of the internal iliac, and supplies the external organs of generation.

FIG. 415.—The internal pudic artery and its branches in the male.



Though the course of the artery is the same in the two sexes, the vessel is much smaller in the female than in the male, and the distribution of its branches somewhat different. The description of its arrangement in the male will first be given, and subsequently the differences which it presents in the female will be mentioned.

The **Internal Pudic Artery in the Male** passes downwards and outwards to the lower border of the great sacro-sciatic foramen, and emerges from the pelvis between the Pyriformis and Coccygeus muscles: it then crosses the spine of the ischium, and re-enters the pelvis through the lesser sacro-sciatic foramen. The artery now crosses the Obturator internus muscle, along the outer wall of the ischio-rectal fossa, being situated about an inch and a half above the lower margin of the ischial tuberosity. It is here contained in a sheath of the obturator fascia, and gradually approaches the margin of the ramus of the ischium, along which it passes forwards and upwards, pierces the superior layer of the deep perineal fascia, and runs forwards along the inner margin of the ramus of the os pubis;

finally, it perforates the inferior layer of the deep perineal fascia, and divides into its two terminal branches, the *dorsal artery of the penis* and the *artery of the corpus cavernosum*.

Relations.—In the first part of its course, within the pelvis, it lies in front of the Pyriformis muscle and sacral plexus of nerves, and on the outer side of the rectum (on the left side). As it crosses the spine of the ischium, it is covered by the Gluteus maximus. In the pelvis, it lies on the outer side of the ischio-rectal fossa, upon the surface of the Obturator internus muscle, contained in a fibrous canal (canal of Alcock) formed by the obturator fascia and the falciform process of the great sacro-sciatic ligament. It is accompanied by the pudic veins and the internal pudic nerve.

Peculiarities.—The internal pudic is sometimes smaller than usual, or fails to give off one or two of its usual branches; in such cases the deficiency is supplied by branches derived from an additional vessel, the *accessory pudic*, which generally arises from the internal pudic artery before its exit from the great sacro-sciatic foramen. It passes forwards along the lower part of the bladder and across the side of the prostate gland to the root of the penis, where it perforates the triangular ligament, and gives off the branches usually derived from the pudic artery. The deficiency most frequently met with is that in which the internal pudic ends as the artery of the bulb; the artery of the corpus cavernosum and arteria dorsalis penis being derived from the accessory pudic. Or the pudic may terminate as the superficial perineal, the artery of the bulb being derived, with the other two branches, from the accessory vessel. Occasionally the accessory pudic artery is derived from one of the other branches of the internal iliac, most frequently the inferior vesical or the obturator.

Surgical Anatomy.—The relation of the accessory pudic to the prostate gland and urethra is of the greatest interest in a surgical point of view, as this vessel is in danger of being wounded in the lateral operation of lithotomy. The student should also study the position of the internal pudic artery and its branches, when running a normal course, with regard to the same operation. The superficial and the transverse perineal arteries are, of necessity, divided in this operation, but the hæmorrhage from these vessels is seldom excessive; should a ligature be required, it can readily be applied on account of their superficial position. The artery of the bulb may be divided if the incision be carried too far forwards, and injury of this vessel may be attended with serious or even fatal consequences. The main trunk of the internal pudic artery may be wounded if the incision be carried too far outwards; but, being bound down by the strong obturator fascia, and under cover of the ramus of the ischium, the accident is not very likely to occur unless the vessel runs an anomalous course.

Branches.—The branches of the internal pudic artery are—

Muscular.	Transverse Perineal.
Inferior Hæmorrhoidal.	Artery of the Bulb.
Superficial Perineal.	Artery of the Corpus Cavernosum.
Dorsal Artery of the Penis.	

The *muscular branches* consist of two sets: one given off in the pelvis; the other, as the vessel crosses the ischial spine. The former are several small offsets which supply the Levator ani, the Obturator internus, the Pyriformis, and the Coccygeus muscles. The branches given off outside the pelvis are distributed to the adjacent part of the Gluteus maximus and External rotator muscles. They anastomose with branches of the sciatic artery.

The *inferior hæmorrhoidal* are two or three small arteries which arise from the internal pudic as it passes above the tuberosity of the ischium. Crossing the ischio-rectal fossa, they are distributed to the muscles and integument of the anal region.

The *superficial perineal artery* supplies the scrotum and muscles and integument of the perinæum. It arises from the internal pudic, in front of the preceding branches, and turns upwards, crossing either over or under the Transversus perinæi muscle, and runs forwards, parallel to the pubic arch, in the interspace between the Accelerator urinæ and Erector penis muscles, both of which it supplies, and is finally distributed to the skin and dartos of the scrotum. In its passage through the perinæum, it lies beneath the superficial perineal fascia.

The *transverse perineal* is a small branch which arises either from the internal

pudic, or from the superficial perineal artery as it crosses the Transversus perinæi muscle. It runs transversely inwards along the cutaneous surface of the Transversus perinæi muscle, which it supplies, as well as the structures between the anus and bulb of the urethra, and anastomoses with the one of the opposite side.

The *artery of the bulb* is a large but very short vessel, which arises from the internal pudic between the two layers of the deep perineal fascia, and, passing nearly transversely inwards between the fibres of the Compressor urethræ muscle, it pierces the bulb of the urethra, in which it ramifies. It gives off a small branch which descends to supply Cowper's gland.

Surgical Anatomy.—This artery is of considerable importance in a surgical point of view, as it is in danger of being wounded in the lateral operation of lithotomy, an accident usually attended in the adult with alarming hæmorrhage. The vessel is sometimes very small, occasionally wanting, or even double. It sometimes arises from the internal pudic earlier than usual, and crosses the perinæum to reach the back part of the bulb. In such a case the vessel could hardly fail to be wounded in the performance of the lateral operation of lithotomy. If, on the contrary, it should arise from an accessory pudic, it lies more forward than usual, and is out of danger in the operation.

The *artery of the corpus cavernosum*, one of the terminal branches of the internal pudic, arises from that vessel while it is situated between the crus penis and the ramus of the os pubis; piercing the crus penis obliquely, it runs forwards in the centre of the corpus cavernosum, to which its branches are distributed.

The *dorsal artery of the penis* ascends between the crus and pubic symphysis, and, piercing the suspensory ligament, runs forwards on the dorsum of the penis to the glans, where it divides into two branches, which supply the glans and prepuce. On the dorsum of the penis, it lies immediately beneath the integument, parallel with the dorsal vein and the corresponding artery of the opposite side. It supplies the integument and fibrous sheath of the corpus cavernosum, sending branches through the sheath to anastomose with the preceding vessel.

The **Internal Pudic Artery in the Female** is smaller than in the male. Its origin and course are similar, and there is considerable analogy in the distribution of its branches. The superficial artery supplies the labia pudendi; the artery of the bulb supplies the bulbi vestibuli and the erectile tissue of the vagina; the artery of the corpus cavernosum supplies the cavernous body of the clitoris; and the arteria dorsalis clitoridis supplies the dorsum of that organ, and terminates in the glans and in the membranous fold corresponding to the prepuce of the male.

The **Sciatic Artery** (fig. 416), the larger of the two terminal branches of the anterior trunk of the internal iliac, is distributed to the muscles at the back of the pelvis. It passes down to the lower part of the great sacro-sciatic foramen, behind the internal pudic artery, resting on the sacral plexus of nerves and Pyriformis muscle, and escapes from the pelvis through this foramen between the Pyriformis and Coccygeus. It then descends in the interval between the trochanter major and tuberosity of the ischium, accompanied by the sciatic nerves, and covered by the Gluteus maximus, and is continued down the back of the thigh supplying the skin, and anastomosing with branches of the perforating arteries.

Within the pelvis, it distributes branches to the Pyriformis, Coccygeus, and Levator ani muscles; some hæmorrhoidal branches, which supply the rectum, and occasionally take the place of the middle hæmorrhoidal artery; and vesical branches to the base and neck of the bladder, vesiculæ seminales, and prostate gland. *External to the pelvis*, it gives off the following branches:—

Coccygeal.	Comes Nervi Ischiadici.
Inferior Gluteal.	Muscular.
Anastomotic.	Articular.

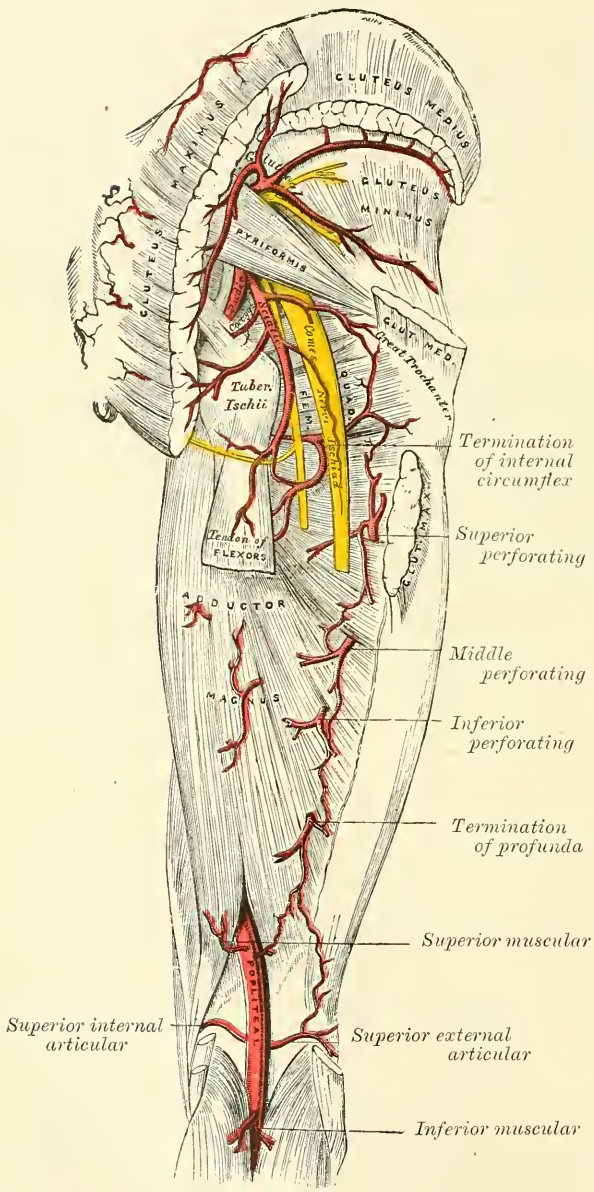
The *coccygeal branch* runs inwards, pierces the great sacro-sciatic ligament,

and supplies the Gluteus maximus, the integument, and other structures on the back of the coccyx.

The *inferior gluteal branches*, three or four in number, supply the Gluteus maximus muscle, anastomosing with the gluteal artery in the substance of the muscle.

The *comes nervi ischiadici* is a long, slender vessel, which accompanies the great sciatic nerve for a short distance; it then penetrates it, and runs in its substance to the lower part of the thigh.

Fig. 416.—The arteries of the gluteal and posterior femoral regions.



The *muscular branches* supply the Gluteus maximus, anastomosing with the Gluteal artery in the substance of the muscle: the external rotators, anastomosing with the internal pudic artery; and the muscles attached to the tuberosity of the ischium, anastomosing with the external branch of the obturator and the internal circumflex arteries.

The *anastomotic artery* is directed downwards across the external rotators and assists in forming the so-called *crucial anastomosis* by anastomosing with the superior perforating and the internal and external circumflex.

The *articular branch*, generally derived from the anastomotic, is distributed to the capsule of the hip-joint.

The **Ilio-lumbar Artery**, given off from the posterior trunk of the internal iliac, turns upwards and outwards between the obturator nerve and lumbosacral cord, to the inner margin of the Psoas muscle, behind which it divides into a lumbar and an iliac branch.

The *lumbar branch* supplies the Psoas and Quadratus lumborum muscles, anastomosing with the last lumbar artery, and sends a small spinal branch through the intervertebral foramen, between the last lumbar vertebra and the sacrum, into the spinal canal, to supply the spinal cord and its membranes.

The *iliac branch* descends to supply the Iliacus muscle; some offsets, running

between the muscle and the bone, anastomose with the iliac branch of the obturator; one of these enters an oblique canal to supply the diploë, whilst others run along the crest of the ilium, distributing branches to the gluteal and abdominal muscles, and anastomose in their course with the gluteal, circumflex iliac, and external circumflex arteries.

The **Lateral Sacral Arteries** (fig. 412) are usually two in number on each side, superior and inferior.

The *superior*, which is of large size, passes inwards, and, after anastomosing with branches from the middle sacral, enters the first or second anterior sacral foramen, is distributed to the contents of the sacral canal in the same manner as the lateral spinal branches from the vertebral, and escaping by the corresponding posterior sacral foramen, supplies the skin and muscles on the dorsum of the sacrum, anastomosing with the gluteal.

The *inferior* passes obliquely across the front of the Pyriformis muscle and sacral nerves to the inner side of the anterior sacral foramina, descends on the front of the sacrum, and anastomoses over the coccyx with the sacra media and opposite lateral sacral artery. In its course it gives off branches, which enter the anterior sacral foramina; these, after giving off branches to be distributed to the contents of the sacral canal in the same manner as the lateral spinal branches from the vertebral, escape by the posterior sacral foramina, and are distributed to the muscles and skin on the dorsal surface of the sacrum, anastomosing with the gluteal.

The **Gluteal Artery** is the largest branch of the internal iliac, and appears to be the continuation of the posterior division of that vessel. It is a short, thick trunk, which passes out of the pelvis above the upper border of the Pyriformis muscle, and immediately divides into a *superficial* and *deep branch*. Within the pelvis, it gives off a few muscular branches to the Iliacus, Pyriformis, and Obturator internus, and just previous to quitting that cavity, a nutrient artery, which enters the ilium.

The *superficial branch* passes beneath the Gluteus maximus, and divides into numerous branches, some of which supply that muscle, whilst others perforate its tendinous origin, and supply the integument covering the posterior surface of the sacrum, anastomosing with the posterior branches of the sacral arteries.

The *deep branch* runs between the Gluteus medius and minimus, and subdivides into two. Of these, the *superior division*, continuing the original course of the vessel, passes along the upper border of the Gluteus minimus to the anterior superior spine of the ilium, anastomosing with the circumflex iliac and ascending branches of the external circumflex artery. The *inferior division* crosses the Gluteus minimus obliquely to the trochanter major, distributing branches to the Glutei muscles, and inosculates with the external circumflex artery. Some branches pierce the Gluteus minimus to supply the hip-joint.

Surface Marking.—The position of the three main branches of the internal iliac, the sciatic, internal pudic, and gluteal, which may occasionally be the object of surgical interference, is indicated on the surface in the following way: a line is to be drawn from the posterior superior iliac spine to the posterior superior angle of the great trochanter, with the limb slightly flexed and rotated inwards: the point of emergence of the *gluteal artery* from the upper part of the sciatic notch will correspond with the junction of the upper with the middle third of this line. A second line is to be drawn from the same point to the middle of the tuberosity of the ischium; the junction of the lower with the middle third marks the point of emergence of the *sciatic* and *pudic arteries* from the great sciatic notch.

Surgical Anatomy.—Any of these three vessels may require ligaturing for a wound or for aneurism, which is generally traumatic, and the operation may be performed by an incision, three or four inches long, in the direction of the fibres of the Gluteus maximus muscle, the middle of the cut corresponding to the point indicating their respective positions.

External Iliac Artery (fig. 412)

The **external iliac artery** is larger in the adult than the internal iliac, and passes obliquely downwards and outwards along the inner border of the Psoas muscle, from the bifurcation of the common iliac to Poupart's ligament, where it enters the thigh and becomes the femoral artery.

Relations.—*In front*, with the peritoneum, subperitoneal areolar tissue, the termination of the ileum on the right side, and the sigmoid flexure on the left, and a thin layer of fascia, derived from the iliac fascia, which surrounds the artery and vein. At its origin it is occasionally crossed by the ureter. The spermatic vessels descend for some distance upon it near its termination, and it is crossed in this situation by the genital branch of the genito-crural nerve and the circumflex iliac vein; the vas deferens curves down along its inner side. *Behind*, it is in relation with the external iliac vein, which, at Poupart's ligament, lies at its inner side; on the left side the vein is altogether internal to the artery. *Externally*, it rests against the Psoas muscle, from which it is separated by the iliac fascia. The artery rests upon this muscle, near Poupart's ligament. Numerous lymphatic vessels and glands are found lying on the front and inner side of the vessel.

Plan of the Relations of the External Iliac Artery

In front.

Peritoneum, intestines, and fascia.

Near Poupart's Ligament:
- Spermatic vessels.
- Genito-crural nerve (genital branch).
- Circumflex iliac vein.
- Lymphatic vessels and glands.

Outer side.

Behind.
External iliac vein.
Psoas magnus.

Surface Marking.—The surface line indicating the course of the external iliac artery has been already given (see page 632).

Surgical Anatomy.—The application of a ligature to the external iliac may be required in cases of aneurism of the femoral artery, or for a wound of the artery. This vessel may be secured in any part of its course, excepting near its upper end, which is to be avoided on account of the proximity of the great stream of blood in the internal iliac, and near its lower end, which should also be avoided, on account of the proximity of the epigastric and circumflex iliac vessels. The patient having been placed in the supine position, an incision should be made, commencing below at a point about three-quarters of an inch above Poupart's ligament, and a little external to its middle, and running upwards and outwards, parallel to Poupart's ligament, to a point one inch internal and one inch above the anterior superior spine of the ilium. When the artery is deeply seated, more room will be required, and may be obtained by curving the incision from the point last named inwards towards the umbilicus for a short distance. Another mode of ligaturing the vessel is the plan advocated by Sir Astley Cooper, by making an incision close to Poupart's ligament from about half an inch outside the external abdominal ring to one inch internal to the anterior superior spine of the ilium. This incision, being made in the course of the fibres of the aponeurosis of the external oblique, is less likely to be followed by a ventral hernia, but there is danger of wounding the epigastric artery, and only the lower end of the vessel can be ligatured. Abernethy, who first tied this artery, made his incision in the course of the vessel. The abdominal muscles and transversalis fascia having been cautiously divided, the peritoneum should be separated from the iliac fossa and raised towards the pelvis; and on introducing the finger to the bottom of the wound the artery may be felt pulsating along the inner border of the Psoas muscle. The external iliac vein

is generally found on the inner side of the artery, and must be cautiously separated from it by the finger-nail, or handle of the knife, and the aneurism needle should be introduced on the inner side, between the artery and vein.

Ligature of the external iliac artery has recently been performed by a transperitoneal method. An incision four inches in length is made in the semilunar line, commencing about an inch below the umbilicus, and carried through the abdominal wall into the peritoneal cavity. The intestines are then pushed upwards and held out of the way by a broad abdominal retractor, and an incision made through the peritoneum at the margin of the pelvis in the course of the artery; the vessel is secured in any part of its course which may seem desirable to the operator. The advantages of this operation appear to be, that if it is found necessary the common iliac artery can be ligatured instead of the external iliac without extension or modification of the incision; and secondly, that the vessel can be ligatured without in any way interfering with the coverings of the sac. Possibly a disadvantage may exist in the greater risk of hernia after this method.

Collateral Circulation.—The principal anastomoses in carrying on the collateral circulation, after the application of a ligature to the external iliac, are—the ilio-lumbar with the circumflex iliac; the gluteal with the external circumflex; the obturator with the internal circumflex; the sciatic with the superior perforating and circumflex branches of the profunda artery; and the internal pudic with the external pudic. When the obturator arises from the epigastric, it is supplied with blood by branches, either from the internal iliac, the lateral sacral, or the internal pudic. The epigastric receives its supply from the internal mammary and inferior intercostal arteries, and from the internal iliac by the anastomoses of its branches with the obturator.

In the dissection of a limb, eighteen years after the successful ligature of the external iliac artery, by Sir A. Cooper, which is to be found in Guy's Hospital Reports, vol. i. p. 50, the anastomosing branches are described in three sets: *An anterior set.*—1. A very large branch from the ilio-lumbar artery to the circumflex iliac; 2. another branch from the ilio-lumbar, joined by one from the obturator, and breaking up into numerous tortuous branches to anastomose with the external circumflex; 3. two other branches from the obturator, which passed over the brim of the pelvis, communicated with the epigastric, and then broke up into a plexus to anastomose with the internal circumflex. *An internal set.*—Branches given off from the obturator, after quitting the pelvis, which ramified among the adductor muscles on the inner side of the hip-joint, and joined most freely with branches of the internal circumflex. *A posterior set.*—1. Three large branches from the gluteal to the external circumflex; 2. several branches from the sciatic around the great sciatic notch to the internal and external circumflex, and the perforating branches of the profunda.

Branches.—Besides several small branches to the Psoas muscle and the neighbouring lymphatic glands, the external iliac gives off two branches of considerable size, the

Deep Epigastric and Deep Circumflex Iliac.

The **Deep Epigastric Artery** arises from the external iliac, a few lines above Poupart's ligament. It at first descends to reach this ligament, and then ascends obliquely along the inner margin of the internal abdominal ring, lying between the transversalis fascia and peritoneum, and, continuing its course upwards, it pierces the transversalis fascia, and, passing over the semilunar fold of Douglas, enters the sheath of the Rectus muscle. It then ascends on the posterior surface of the muscle, and finally divides into numerous branches, which anastomose, above the umbilicus, with the terminal branches of the internal mammary and inferior intercostal arteries (fig. 401). The deep epigastric artery bears a very important relation to the internal abdominal ring as it passes obliquely upwards and inwards from its origin from the external iliac. In this part of its course it lies along the lower and inner margin of the ring, and beneath the commencement of the spermatic cord. As it winds round the internal abdominal ring, it is crossed by the vas deferens in the male and the round ligament in the female.

Branches.—The branches of this vessel are the following: the *cremasteric*, which accompanies the spermatic cord, and supplies the Cremaster muscle and other coverings of the cord, anastomosing with the spermatic artery; a *pubic branch*, which runs along Poupart's ligament, and then descends behind the os pubis to the inner side of the femoral ring, and anastomoses with offsets from the obturator artery; *muscular branches*, some of which are distributed to

the abdominal muscles and peritoneum, anastomosing with the lumbar and circumflex iliac arteries: others perforate the tendon of the External oblique, and supply the integument, anastomosing with branches of the superficial epigastric.

Peculiarities.—The origin of the epigastric may take place from any part of the external iliac between Poupart's ligament and two inches and a half above it; or it may arise below this ligament, from the femoral, or from the deep femoral.

Union with branches.—It frequently arises from the external iliac, by a common trunk with the obturator. Sometimes the epigastric arises from the obturator, the latter vessel being furnished by the internal iliac, or the epigastric may be formed of two branches, one derived from the external iliac, the other from the internal iliac.

Surgical Anatomy.—The deep epigastric artery follows a line drawn from the middle of Poupart's ligament towards the umbilicus; but shortly after this line crosses the linea semilunaris, the direction changes, and the course of the vessel is directly upwards in the line of junction of the inner third with the outer two-thirds of the Rectus muscle. It has important surgical relations, in addition to the fact that it is one of the principal means, through its anastomosis with the internal mammary, in establishing the collateral circulation after ligature of either the common or external iliac arteries. It lies close to the internal abdominal ring, and is therefore *internal* to an oblique inguinal hernia, but *external* to a direct inguinal hernia, as it emerges from the abdomen. It forms the outer boundary of Hesselbach's triangle. It is in close relationship with the spermatic cord, which lies in front of it in the inguinal canal, separated only by the transversalis fascia. The vas deferens hooks round its outer side.

The **Deep Circumflex Iliac Artery** arises from the outer side of the external iliac nearly opposite the epigastric artery. Its ascends obliquely outwards behind Poupart's ligament, contained in a fibrous sheath formed by the junction of the transversalis and iliac fasciæ, to the anterior superior spinous process of the ilium. It then runs along the inner surface of the crest of the ilium to about its middle, where it pierces the Transversalis, and runs backwards between that muscle and the Internal oblique, to anastomose with the iliolumbar and gluteal arteries. Opposite the anterior superior spine of the ilium it gives off a large branch, which ascends between the Internal oblique and Transversalis muscles, supplying them, and anastomosing with the lumbar and epigastric arteries.

ARTERIES OF THE LOWER EXTREMITY

The artery which supplies the greater part of the lower extremity is the direct continuation of the external iliac. It continues as a single trunk from Poupart's ligament to the lower border of the Popliteus muscle, and here divides into two branches, the anterior and posterior tibial, an arrangement exactly similar to what occurs in the upper limb. For convenience of description, the upper part of the main trunk is named femoral, the lower part popliteal.

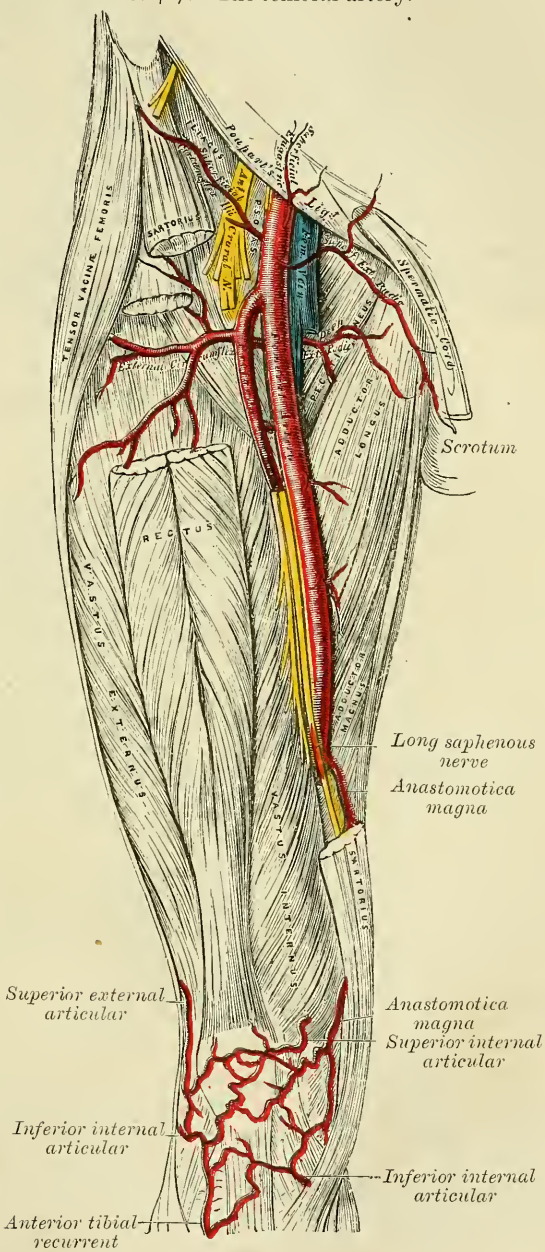
Femoral Artery (fig. 417)

The **femoral artery** commences immediately behind Poupart's ligament, midway between the anterior superior spine of the ilium and the symphysis pubis, and, passing down the fore part and inner side of the thigh, terminates at the opening in the Adductor magnus, at the junction of the middle with the lower third of the thigh, where it becomes the popliteal artery. The vessel, at the upper part of the thigh, lies in front of the hip-joint, just on a line with the innermost part of the head of the femur; in the lower part of its course it is in close relation with the inner side of the shaft of the bone, and between these two parts, the vessel is far away from the bone. In the upper third of the thigh it is contained in a triangular space, called Scarpa's triangle. In the middle third of the thigh it is contained in an aponeurotic canal, called Hunter's canal.

Scarpa's Triangle.—Scarpa's triangle corresponds to the depression seen immediately below the fold of the groin. It is a triangular space, the apex of

which is directed downwards, and the sides formed externally by the Sartorius, internally by the Adductor longus, and above by Poupart's ligament. The floor of the space is formed from without inwards by the Iliacus, Psoas, Pectineus, a small part of the Adductor brevis and the Adductor longus muscles; and it is divided into two nearly equal parts by the femoral vessels, which extend from the middle of its base to its apex: the artery giving off in this situation its cutaneous and profunda branches, the vein receiving the deep femoral and internal saphenous. On the outer side of the femoral artery is the anterior crural nerve dividing into its branches. Besides the vessels and nerves, this space contains some fat and lymphatics.

Fig. 417.—The femoral artery.



Hunter's Canal.—This is the aponeurotic space in the middle third of the thigh, extending from the apex of Scarpa's triangle to the femoral opening in the Adductor magnus muscle. It is bounded, externally, by the Vastus internus; internally, by the Adductor longus and magnus muscles; and covered in by a strong aponeurosis which extends transversely from the Vastus internus, across the femoral vessels to the Adductor longus and magnus muscles; lying on which aponeurosis is the Sartorius muscle. It contains the femoral artery and vein enclosed in their own sheath of areolar tissue, the vein being behind and on the outer side of the artery and the internal or long saphenous nerve lying on the outer side of the vessels.

For convenience of description and also in reference to its surgical anatomy, the femoral artery is divided into a short trunk, about an inch and a half or two inches long, which is known as the *common femoral artery*, and the remainder of the vessel, known as the *superficial femoral*, to distinguish it from the *deep femoral* (profunda femoris); a large branch given off from the common femoral at its termination, and which by its derivation from the parent trunk marks the commencement of the superficial femoral artery.

The **common femoral artery** is very superficial, being covered by the skin and superficial fascia, superficial inguinal lymphatic glands, the iliac portion of the fascia lata, and the prolongation downwards of the Transversalis fascia, which forms the sheath of the vessels. It has in front of it filaments from the crural branch of the genito-crural nerve, the superficial circumflex iliac vein, and occasionally the superficial epigastric vein. It rests on the inner margin of the Psoas muscle, which separates it from the capsular ligament of the hip-joint, and a little lower on the Pectineus muscle; and crossing behind it is the branch to the Pectineus from the anterior crural nerve. Separating the artery from the Psoas and Pectineus muscles is the pubic portion of the fascia lata and the prolongation from the fascia covering the Iliacus muscle which forms the posterior layer of the sheath of the vessels. The anterior crural nerve lies about half an inch to the outer side of the common femoral artery, lying between the Psoas and Iliacus muscles. To the inner side of the artery is the femoral vein, between the margins of the Pectineus and Psoas muscles. The two vessels are enclosed in a strong fibrous sheath, formed by the proper sheath of the vessels, strengthened by the fascia lata (see page 512); the artery and vein are separated, however, from one another by a thin fibrous partition.

Capsule of hip-joint.

The **superficial femoral artery** is only superficial where it lies in Scarpa's triangle. Here it is covered by the skin, superficial and deep fascia, and crossed by the internal cutaneous branch of the anterior crural nerve. In Hunter's canal it is more deeply seated, being covered by the integument, the superficial and deep fascia, the Sartorius and aponeurotic covering of Hunter's canal. The internal saphenous nerve crosses the artery from without inwards. Behind, the artery lies at its upper part on the femoral vein and the profunda artery and vein, which separate it from the Pectineus muscle, and lower down on the Adductor longus and Adductor magnus muscles. To the outer side is the long saphenous nerve and the nerve to the Vastus internus; the Vastus internus muscle and, at its lower part, the femoral vein. To the inner side is the Adductor longus above, and the Adductor magnus and Sartorius below.

The *femoral vein* at Poupart's ligament lies close to the inner side of the artery, separated from it by a thin fibrous partition; but, lower down, it is behind it, and then to its outer side.

The *internal saphenous nerve* is situated on the outer side of the artery, in the middle third of the thigh, beneath the aponeurotic covering of Hunter's canal; but not usually within the sheath of the vessels. The internal cutaneous nerve passes obliquely across the upper part of the sheath of the femoral artery.

Peculiarities.—Double femoral reunited.—Several cases are recorded in which the femoral artery divided into two trunks below the origin of the profunda, and became reunited near the opening in the Adductor magnus, so as to form a single popliteal artery. One of them occurred in a patient operated upon for popliteal aneurism.

Change of Position.—A few cases have been recorded in which the femoral artery was situated at the back of the thigh, the vessel being continuous above with the internal iliac, escaping from the pelvis through the great sacro-sciatic foramen, and accompanying the great sciatic nerve to the popliteal space, where its division occurred in the usual manner. The external iliac in these cases was small, and terminated in the profunda.

Position of the Vein.—The femoral vein is occasionally placed along the inner side of the artery, throughout the entire extent of Scarpa's triangle; or it may be slit so that a large vein is placed on each side of the artery for a greater or less extent.

Origin of the Profunda.—This vessel occasionally arises from the inner side, and, more rarely, from the back of the common trunk; but the more important peculiarity, in a surgical point of view, is that which relates to the height at which the vessel arises from the femoral. In three-fourths of a large number of cases it arose between one or two inches below Poupart's ligament; in a few cases the distance was less than an inch; more rarely, opposite the ligament; and in one case above Poupart's ligament, from the external iliac. Occasionally, the distance between the origin of the vessel and Poupart's ligament exceeds two inches, and in one case it was found to be as much as four inches.

Surface Marking.—The upper two-thirds of a line drawn from a point midway between the anterior superior spine of the ilium and the symphysis pubis to the prominent tuberosity on the inner condyle of the femur, with the thigh abducted and rotated outwards, will indicate the course of the femoral artery.

Surgical Anatomy.—Compression of the femoral artery, which is constantly requisite in amputations and other operations on the lower limb, and also for the cure of popliteal aneurism, is most effectually made immediately below Poupart's ligament. In this situation the artery is very superficial, and is merely separated from the horizontal ramus of the os pubis by the Psoas muscle; so that the surgeon, by means of his thumb or a compressor, may effectually control the circulation through it. This vessel may also be compressed in the middle third of the thigh by placing a compress over the artery, beneath the tourniquet, and directing the pressure from within outwards, so as to compress the vessel against the inner side of the shaft of the femur.

The *application of a ligature* to the femoral artery may be required in cases of

wound or aneurism of the arteries of the leg, the popliteal or femoral;* and the vessel may be exposed and tied in any part of its course. The great depth of this vessel at its lower part, its close connection with important structures, and the density of its sheath, render the operation in this situation one of much greater difficulty than the application of a ligature at its upper part, where it is more superficial.

Ligature of the common femoral artery is usually considered unsafe, on account of the connection of large branches with it: viz. the deep epigastric and the deep circumflex iliac arising just above Poupart's ligament; on account of the number of small branches which arise from it, in its short course, and on account of the uncertainty of the origin of the profunda femoris, which, if it arise high up, would be too close to the ligature for the formation of a firm coagulum. The profunda sometimes arises higher than the point above mentioned, and rarely between two or three inches (in one case four) below Poupart's ligament. It would appear, then, that the most favourable situation for the application of a ligature to the femoral is between four and five inches from its point of origin. In order to expose the artery in this situation, an incision, between three and four inches long, should be made in the course of the vessel, the patient lying in the recumbent position, with the limb slightly flexed and abducted, and rotated outwards. A large vein is frequently met with, passing in the course of the artery to join the internal saphenous vein; this must be avoided, and the fascia lata having been cautiously divided, and the Sartorius exposed, that muscle must be drawn outwards, in order to fully expose the sheath of the vessels. The finger being introduced into the wound, and the pulsation of the artery felt, the sheath should be opened on the outer side of the vessel to a sufficient extent to allow of the introduction of the ligature, but no further; otherwise the nutrition of the coats of the vessel may be interfered with, or muscular branches which arise from the vessel at irregular intervals may be divided. In this part of the operation the long saphenous nerve and the nerve to the Vastus internus, which is in close relation with the sheath, should be avoided. The aneurism needle must be carefully introduced and kept close to the artery, to avoid the femoral vein, which lies behind the vessel in this part of its course.

To expose the artery, in Hunter's canal, an incision should be made through the integument, between three and four inches in length, a finger's breadth internal to the line of the artery, in the middle of the thigh—*i.e.* midway between the groin and the knee. The fascia lata having been divided, and the outer border of the Sartorius muscle exposed, it should be drawn inwards, when the strong fascia which is stretched across from the Adductors to the Vastus internus will be exposed, and must be freely divided; the sheath of the vessels is now seen, and must be opened, and the artery secured by passing the aneurism needle between the vein and artery, in the direction from without inwards. The femoral vein in this situation lies on the outer side of the artery, the long saphenous nerve on its anterior and outer side.

It has been seen that the femoral artery occasionally divides into two trunks below the origin of the profunda. If, in the operation for tying the femoral, two vessels are met with, the surgeon should alternately compress each, in order to ascertain which vessel is connected with the aneurismal tumour, or with the bleeding from the wound, and that one only should be tied which controls the pulsation or hæmorrhage. If, however, it is necessary to compress both vessels before the circulation in the tumour is controlled, both should be tied, as it would be probable that they became reunited, as in the instances referred to above.

In wounds of the femoral artery the question of the mode of treatment is of considerable importance. If the wound in the superficial structures is a large one, the injured vessel must be exposed and tied; but if the wound is a punctured one and the bleeding has ceased, the question will arise whether to cut down upon the artery or to trust to pressure. Mr. Cripps† advises, that if the wound is in the 'upper part of the thigh—that is to say, in a position where the femoral artery is comparatively superficial—the surgeon may enlarge the opening with a good prospect of finding the wounded vessel without an extensive or prolonged operation. If the wound be in the lower half of the thigh, owing to the greater depth of the artery, and the possibility of its being the popliteal that is wounded, the search is rendered a far more severe and hazardous operation, and it should not be undertaken until a thorough trial of pressure has proved ineffectual.'

Great care and attention are necessary for the successful application of pressure. The limb should be carefully bandaged from the foot upwards to the wound, which is not covered, and then onwards to the groin. The wound is then dusted with iodoform or boracic powder, and a conical pad applied over it. Rollers the thickness of the index finger are then placed along the course of the vessel above and below the wound, and the whole carefully bandaged to a back splint with a foot-piece.

Collateral Circulation.—When the common femoral is tied, the main channels for carrying on the circulation are the anastomoses of the gluteal and circumflex iliac arteries above with the external circumflex below; of the obturator and sciatic above with the internal circumflex below; and of the comes nervi ischiadici with the arteries in the ham.

* Ligature of the femoral artery has been also recommended and performed for elephantiasis of the leg and acute inflammation of the knee-joint.—Maunder, *Clin. Soc. Trans.*, vol. ii. p. 37.

† Heath's *Dictionary of Practical Surgery*, vol. i. p. 525.

The principal agents in carrying on the collateral circulation after ligature of the superficial femoral artery are, according to Sir A. Cooper, as follows :—

'The arteria profunda formed the new channel for the blood.' 'The first artery sent off passed down close to the back of the thigh-bone, and entered the two superior articular branches of the popliteal artery.'

'The second new large vessel, arising from the profunda at the same part with the former, passed down by the inner side of the Biceps muscle, to a branch of the popliteal which was distributed to the Gastrocnemius muscle; whilst a third artery, dividing into several branches, passed down with the sciatic nerve behind the knee-joint, and some of its branches united with the inferior articular arteries of the popliteal, with some recurrent branches of those arteries, with arteries passing to the Gastrocnemius, and, lastly, with the origin of the anterior and posterior tibial arteries.'

'It appears then that it is those branches of the profunda which accompany the sciatic nerve that are the principal supporters of the new circulation.' *

In Porta's work † (tab. xii. xiii.) is a good representation of the collateral circulation after ligature of the femoral artery. The patient had survived the operation three years. The lower part of the artery is at least as large as the upper; about two inches of the vessel appear to have been obliterated. The external and internal circumflex arteries are seen anastomosing by a great number of branches with the lower branches of the femoral (muscular and anastomotica magna), and with the articular branches of the popliteal. The branches from the external circumflex are extremely large and numerous. One very distinct anastomosis can be traced between this artery on the outside and the anastomotica magna on the inside, through the intervention of the superior external articular artery, with which they both anastomose; and blood reaches even the anterior tibial recurrent from the external circumflex by means of anastomosis with the same external articular artery. The perforating branches of the profunda are also seen bringing blood round the obliterated portion of the artery into long branches (muscular) which have been given off just below that portion. The termination of the profunda itself anastomoses most freely with the superior external articular. A long branch of anastomosis is also traced down from the internal iliac by means of the comes nervi ischiadici of the sciatic which anastomoses on the popliteal nerves with branches from the popliteal and posterior tibial arteries. In this case the anastomosis had been too free, since the pulsation and growth of the aneurism recurred, and the patient died after ligature of the external iliac.

There is an interesting preparation in the Museum of the Royal College of Surgeons of a limb on which John Hunter had tied the femoral artery fifty years before the patient's death. The whole of the superficial femoral and popliteal artery seems to have been obliterated. The anastomosis by means of the comes nervi ischiadici, which is shown in Porta's plate, is distinctly seen: the external circumflex, and the termination of the profunda artery, seem to have been the chief channels of anastomosis; but the injection has not been a very successful one.

Branches.—The branches of the femoral artery are, the

Superficial Epigastric.		External Circumflex.
Superficial Circumflex Iliac.	Profunda	Internal Circumflex.
Superficial External Pudic.		Three Perforating.
Deep External Pudic.	Muscular.	
	Anastomotica Magna.	

The **superficial epigastric** arises from the femoral, about half an inch below Poupart's ligament, and, passing through the saphenous opening in the fascia lata, ascends on to the abdomen, in the superficial fascia covering the External oblique muscle, nearly as high as the umbilicus. It distributes branches to the superficial inguinal glands, the superficial fascia, and the integument, anastomosing with branches of the deep epigastric.

The **superficial circumflex iliac**, the smallest of the cutaneous branches, arises close to the preceding, and, piercing the fascia lata, runs outwards, parallel with Poupart's ligament, as far as the crest of the ilium, dividing into branches which supply the integument of the groin, the superficial fascia, and the superficial inguinal lymphatic glands, anastomosing with the deep circumflex iliac, and with the gluteal and external circumflex arteries.

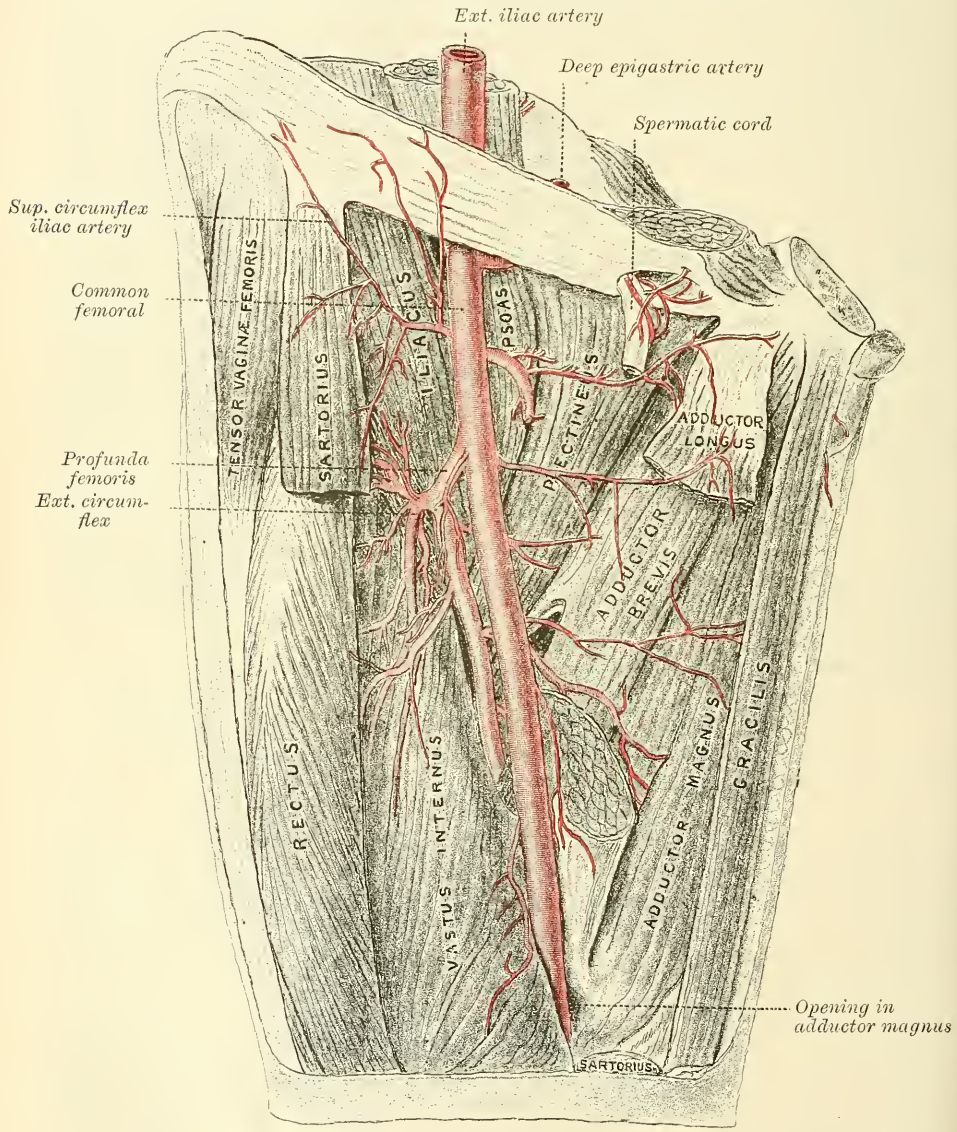
The **superficial external pudic** (superior) arises from the inner side of the femoral artery, close to the preceding vessels, and, after passing through the saphenous opening, courses inwards, across the spermatic cord or round ligament, to be distributed to the integument on the lower part of the abdomen, the penis

* *Med.-Chir. Trans.*, vol. ii. 1811. † *Alterazioni patologiche delle Arterie.*

and scrotum in the male, and the labium in the female, anastomosing with branches of the internal pudic.

The **deep external pudic** (inferior), more deeply seated than the preceding, passes inwards across the Pectineus and Adductor longus muscles, covered by the fascia lata, which it pierces at the inner border of the thigh, its branches being distributed, in the male, to the integument of the scrotum and perinæum; and in the female to the labium, anastomosing with branches of the superficial perineal artery.

Fig. 418.—Femoral artery and its branches, showing profunda. (From a preparation in the Hunterian Museum, Royal College of Surgeons.)

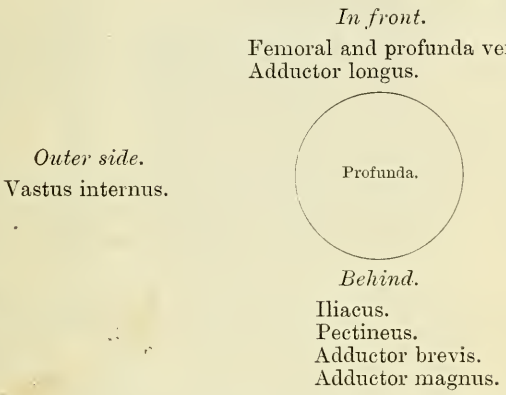


The **Profunda Femoris** (*deep femoral artery*) (fig. 418) nearly equals the size of the superficial femoral. It arises from the outer and back part of the femoral artery, from one to two inches below Poupart's ligament. It at first lies on the outer side of the superficial femoral, and then passes behind it and the femoral vein to the inner side of the femur, and, passing downwards beneath the Adductor longus, terminates at the lower third of the thigh in a small branch, which

pierces the Adductor magnus (and from this circumstance is sometimes called the fourth perforating artery), and is distributed to the Flexor muscles on the back of the thigh, anastomosing with branches of the popliteal and inferior perforating arteries.

Relations.—*Behind*, it lies first upon the Iliacus, and then on the Pectineus, Adductor brevis, and Adductor magnus muscles. *In front*, it is separated from the femoral artery, above by the femoral and profunda veins, and below by the Adductor longus. On its *outer side*, the origin of the Vastus internus separates it from the femur.

Plan of Relations of the Profunda Artery



The profunda gives off the following named branches :—

External circumflex. Internal circumflex. Three perforating.

The **External Circumflex Artery** supplies the muscles on the front of the thigh. It arises from the outer side of the profunda, passes horizontally outwards, between the divisions of the anterior crural nerve, and behind the Sartorius and Rectus muscles, and divides into three sets of branches, ascending, transverse, and descending.

The *ascending branches* pass upwards, beneath the Tensor vaginæ femoris muscle, to the outer side of the hip, anastomosing with the terminal branches of the gluteal and deep circumflex iliac arteries.

The *descending branches*, three or four in number, pass downwards, behind the Rectus, upon the Vasti muscles to which they are distributed, one or two passing beneath the Vastus externus as far as the knee, anastomosing with the superior articular branches of the popliteal artery. These are accompanied by the branch of the anterior crural nerve to the Vastus externus.

The *transverse branches*, the smallest and least numerous, pass outwards over the Crureus, pierce the Vastus externus, and wind round the femur to its back part, just below the great trochanter, anastomosing at the back of the thigh with the internal circumflex, sciatic, and superior perforating arteries.

The **Internal Circumflex Artery**, smaller than the external, arises from the inner and back part of the profunda, and winds round the inner side of the femur, between the Pectineus and Psoas muscles. On reaching the upper border of the Adductor brevis, it gives off two branches, one of which passes inwards to be distributed to the Adductor muscles, the Gracilis, and Obturator externus, anastomosing with the obturator artery; the other descends, and passes beneath the Adductor brevis, to supply it and the great Adductor; while the continuation of the vessel passes backwards, between the Quadratus femoris and upper border of the Adductor magnus, anastomosing with the sciatic, external circumflex, and superior perforating arteries ('the *crucial anastomosis*'). Opposite the hip-joint, this branch gives off an articular vessel, which enters the joint beneath the

transverse ligament; and, after supplying the adipose tissue, passes along the round ligament to the head of the bone.

The **Perforating Arteries** (fig. 416), usually three in number, are so called from their perforating the tendon of the Adductor magnus muscle to reach the back of the thigh. The first is given off above the Adductor brevis, the second in front of that muscle, and the third immediately below it.

The *first* or *superior perforating artery* passes backwards between the Pectineus and Adductor brevis (sometimes perforates the latter); it then pierces the Adductor magnus close to the linea aspera, and divides into branches which supply the Adductor brevis, the Adductor magnus, the Biceps, and Gluteus maximus muscle; anastomosing with the sciatic, internal and external circumflex, and middle perforating arteries.

The *second* or *middle perforating artery*, larger than the first, pierces the tendons of the Adductor brevis and Adductor magnus muscles; and divides into ascending and descending branches, which supply the flexor muscles of the thigh, anastomosing with the superior and inferior perforating. The nutrient artery of the femur is usually given off from this branch.

The *third* or *inferior perforating artery* is given off below the Adductor brevis; it pierces the Adductor magnus, and divides into branches which supply the flexor muscles of the thigh; anastomosing above with the perforating arteries, and below with the terminal branches of the profunda and the muscular branches of the popliteal.

Muscular branches are given off from the superficial femoral throughout its entire course. They vary from two to seven in number, and supply chiefly the Sartorius and Vastus internus.

The **Anastomotica Magna** (fig. 419) arises from the femoral artery just before it passes through the tendinous opening in the Adductor magnus muscle, and immediately divides into a superficial and deep branch.

The *superficial branch* pierces the aponeurotic covering of Hunter's canal, and accompanies the long saphenous nerve to the inner side of the thigh. It passes between the Sartorius and Gracilis muscles, and, piercing the fascia lata, is distributed to the integument of the upper and inner part of the leg, anastomosing with the inferior internal articular.

The *deep branch* descends in the substance of the Vastus internus, lying in front of the tendon of the Adductor magnus, to the inner side of the knee, where it anastomoses with the superior internal articular artery and anterior recurrent branch of the anterior tibial. A branch from this vessel crosses outwards above the articular surface of the femur, forming an anastomotic arch with the superior external articular artery, and supplies branches to the knee-joint.

Popliteal Artery

The **popliteal artery** commences at the termination of the femoral at the opening in the Adductor magnus, and, passing obliquely downwards and outwards behind the knee-joint to the lower border of the Popliteus muscle, divides into the *anterior* and *posterior tibial arteries*. A portion of the artery lies in the popliteal space; but above and below, to a considerable extent, it is covered by the muscles which form the boundaries of the space, and is therefore beyond the confines of the hollow.

The Popliteal Space (fig. 420)

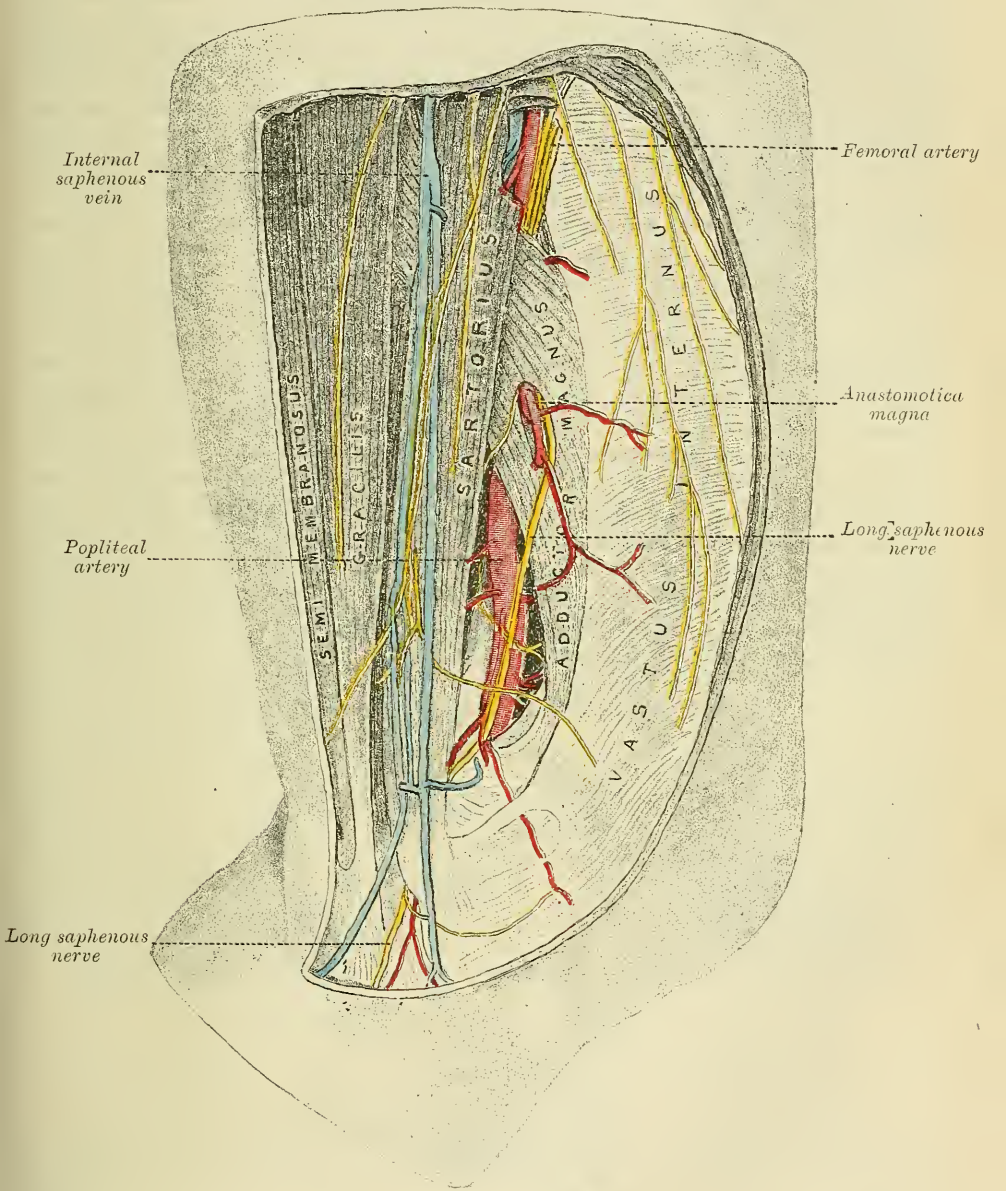
Dissection.—A vertical incision about eight inches in length should be made along the back part of the knee-joint, connected above and below by a transverse incision from the inner to the outer side of the limb. The flaps of integument included between these incisions should be reflected in the direction shown in fig. 366, p. 519.

Boundaries.—The **popliteal space**, or the **ham**, is a lozenge-shaped space, widest at the back part of the knee-joint, and deepest above the articular end of

the femur. It is bounded externally, above the joint, by the Biceps, and, below the joint, by the Plantaris and external head of the Gastrocnemius. Internally, above the joint, by the Semimembranosus, Semitendinosus, Gracilis, and Sartorius; below the joint, by the inner head of the Gastrocnemius.

Above, it is limited by the apposition of the inner and outer hamstring muscles; below, by the junction of the two heads of the Gastrocnemius. The

Fig. 419.—Side view of the popliteal artery. (From a preparation in the Hunterian Museum, Royal College of Surgeons.)



floor is formed by the lower part of the posterior surface of the shaft of the femur, the posterior ligament of the knee-joint, the upper end of the tibia, and the fascia covering the Popliteus muscle, and the space is covered in by the fascia lata.

Contents.—It contains the popliteal vessels and their branches, together with the termination of the external saphenous vein, the internal and external popliteal nerves and some of their branches, the lower extremity of the small sciatic

nerve, the articular branch from the obturator nerve, a few small lymphatic glands, and a considerable quantity of loose adipose tissue.

Position of contained parts.—The internal popliteal nerve descends in the middle line of the space, lying superficial and crossing the artery from without inwards. The external popliteal nerve descends on the outer side of the space, lying close to the tendon of the Biceps muscle. More deeply at the bottom of the space are the popliteal vessels, the vein lying superficial to the artery, to which it is closely united by dense areolar tissue; it lies at first to the outer side of the artery, and then crosses it to gain the inner side below; sometimes the vein is double, the artery lying between the two venæ comites, which are usually connected by short transverse branches. More deeply, and, at its upper part, close to the surface of the bone, is the popliteal artery, and passing off from it at right angles are its articular branches. The articular branch from the obturator nerve descends upon the popliteal artery to supply the knee; and occasionally there is found deep in the space an articular filament from the great sciatic nerve. The popliteal lymphatic glands, four or five in number, are found surrounding the artery: one usually lies superficial to the vessel; another is situated between it and the bone; and the rest are placed on either side of it.

The **Popliteal Artery**, in its course downwards from the aperture in the Adductor magnus to the lower border of the Popliteus muscle, rests first on the inner surface of the femur, and is then separated by a little fat from the hollowed popliteal surface of the bone; in the middle of its course, it rests on the posterior ligament of the knee-joint; and below, on the fascia covering the Popliteus muscle. *Superficially*, it is covered above by the Semimembranosus; in the middle of its course, by a quantity of fat, which separates it from the deep fascia and integument: and below, it is overlapped by the Gastrocnemius, Plantaris, and Soleus muscles, the popliteal vein, and the internal popliteal nerve. The popliteal vein, which is intimately attached to the artery, lies superficial and external to it above; it then crosses it and lies to its inner side. The popliteal nerve is still more superficial and external above, but below the joint it crosses the artery and lies on its inner side. *Laterally*, the artery is bounded by the muscles which are situated on either side of the popliteal space.

Peculiarities in point of Division.—Occasionally the popliteal artery divides prematurely into its terminal branches; this unusual division occurs most frequently opposite the knee-joint.

Unusual Branches.—The artery sometimes divides into the anterior tibial and peroneal, the posterior tibial being wanting, or very small. Occasionally the popliteal is found to divide into three branches, the anterior tibial, and posterior tibial, and peroneal.

Surface Marking.—The course of the upper part of the popliteal artery is indicated by a line drawn from the outer border of the Semimembranosus muscle at the junction of the middle and lower third of the thigh obliquely downwards to the middle of the popliteal space exactly behind the knee-joint. From this point it passes vertically downwards to the level of a line drawn through the lower part of the tubercle of the tibia.

Surgical Anatomy.—The popliteal artery is not infrequently the seat of injury. It may be torn by direct violence, as by the passage of a cart-wheel over the knee, or by hyper-extension of the knee; and in the dead body, at all events, the middle and internal coats may be ruptured by extreme flexion. It may also be lacerated by fracture of the lower part of the shaft of the femur, or by antero-posterior dislocation of the knee-joint. It has been torn in breaking down adhesions in cases of fibrous ankylosis of the knee, and is in danger of being wounded, and in fact has been wounded, in performing Macewen's operation of osteotomy of the lower end of the femur for genu valgum. In addition, Spencer records a case in which the popliteal artery was wounded from in front by a stab just below the knee, the knife passing through the interosseous space. The popliteal artery is more frequently the seat of aneurism than is any other artery in the body, with the exception of the thoracic aorta. This is due no doubt in a great measure to the amount of movement to which it is subjected, and to the fact that it is supported by loose and lax tissue only, and not by muscles as is the case with most arteries.

Ligature of the popliteal artery is required in cases of wound of that vessel, but for aneurism of the posterior tibial, it is preferable to tie the superficial femoral. The popliteal may be tied in the upper or lower part of its course; but in the middle of the ham the operation is attended with considerable difficulty, from the great depth of the artery, and from the extreme degree of tension of the lateral boundaries of the space.

In order to expose the vessel in the upper part of its course, the patient should be placed in the prone position, with the limb extended. An incision about three inches in length should then be made through the integument, along the posterior margin of the Semimembranosus, and the fascia lata having been divided, this muscle must be drawn inwards. The internal popliteal nerve will be first exposed, lying very superficial and external to the artery; beneath this will be seen the popliteal vein, and still deeper, and to its inner side, the artery. The vein and nerve must be cautiously separated from the artery, and the aneurism needle passed around the vessel from without inwards.

To expose the vessel in the lower part of its course, where the artery lies between the two heads of the Gastrocnemius, the patient should be placed in the same position as in the preceding operation. An incision should then be made through the integument in the middle line, commencing opposite the bend of the knee-joint, care being taken to avoid the external saphenous vein and nerve. After dividing the deep fascia, and separating some dense cellular membrane, the artery, vein, and nerve will be exposed, descending between the two heads of the Gastrocnemius. Some muscular branches of the popliteal should be avoided if possible, or, if divided, tied immediately. The leg being now flexed, in order the more effectually to separate the two heads of the Gastrocnemius, the nerve should be drawn inwards and the vein outwards, and the aneurism needle passed between the artery and vein from without inwards.

In cases where the artery has been wounded during an osteotomy of the lower end of the femur, it would be most conveniently secured from the front at the inner side of the thigh. The knee is flexed and the limb placed on its outer side. An incision, three inches long, is made parallel to and immediately behind the tendon of the Adductor magnus from the junction of the middle and lower third of the thigh. Skin, superficial and deep fascia are to be divided, care being taken of the internal saphenous vein; the Adductor magnus is to be drawn forwards, and the inner hamstring tendons backwards, and the artery will be found surrounded by fat. The nerve and vein are usually not seen, as they lie to the outer side of the artery.

The branches of the popliteal artery are, the

Muscular { Superior.	Superior Internal Articular.
Muscular { Inferior or Sural.	Azygos Articular.
Cutaneous.	Inferior External Articular.
Superior External Articular.	Inferior Internal Articular.

The **superior muscular branches**, two or three in number, arise from the upper part of the popliteal artery, and are distributed to the lower part of the Adductor magnus and flexor muscles of the thigh; anastomosing with the inferior perforating and terminal branches of the profunda.

The **inferior muscular (sural)** are two large branches, which are distributed to the two heads of the Gastrocnemius and to the Plantaris muscle. They arise from the popliteal artery opposite the knee-joint.

The **cutaneous branches** arise separately from the popliteal artery or from some of its branches; they descend between the two heads of the Gastrocnemius

muscle, and, piercing the deep fascia, are distributed to the integument of the calf. One branch usually accompanies the short, or external, saphenous vein.

FIG. 420.—The popliteal, posterior tibial, and peroneal arteries.

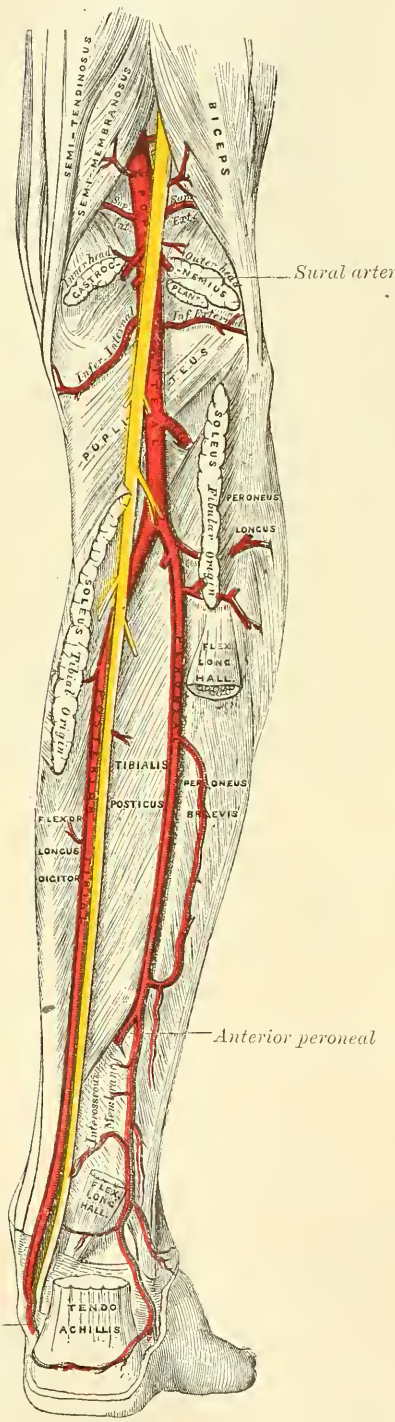

FIG. 421.—Anterior tibial and dorsalis pedis arteries.

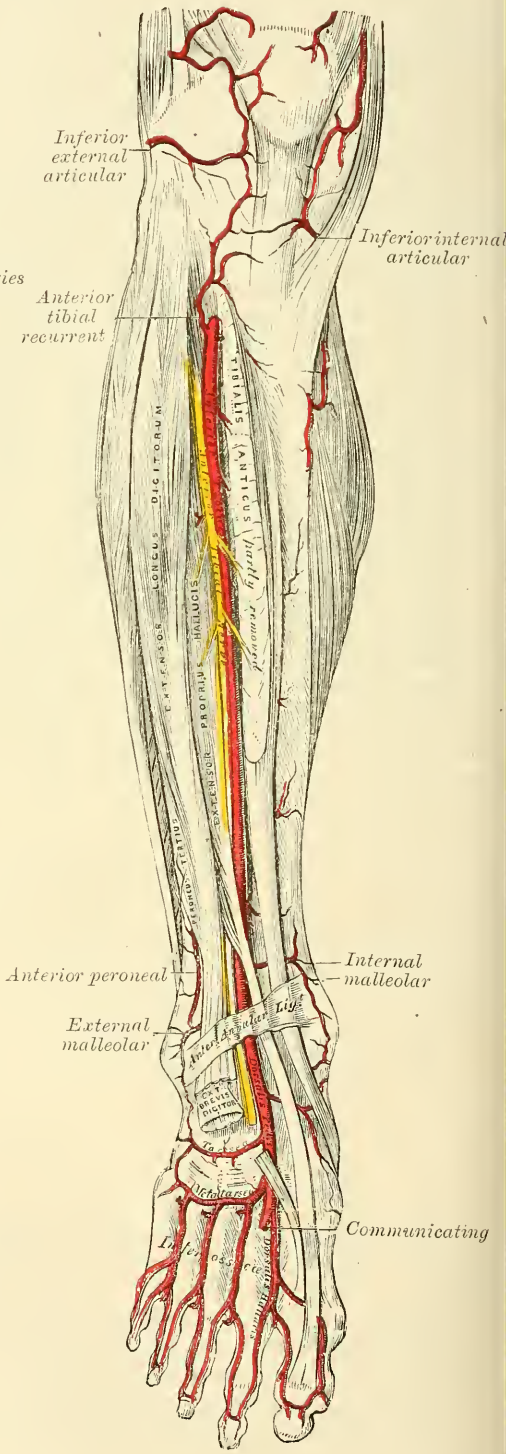

The **superior articular arteries**, two in number, arise one on each side of the popliteal, and wind round the femur immediately above its condyles to the front of the knee-joint. The *internal branch* winds inwards beneath the hamstring muscles, to which it supplies branches, above the inner head of the Gastrocnemius, and passing beneath the tendon of the Adductor magnus, divides into two branches, one of which supplies the Vastus internus, inosculating with the anastomotica magna and inferior internal articular; the other ramifies close to the surface of the femur, supplying it and the knee-joint, and anastomosing with the superior external articular artery. The *external branch* passes above the outer condyle, beneath the tendon of the Biceps, and divides into a superficial and deep branch: the superficial branch supplies the Vastus externus, and anastomoses with the descending branch of the external circumflex, and the inferior external articular arteries; the deep branch supplies the lower part of the femur and knee-joint, and forms an anastomotic arch across the bone with the anastomotica magna and the inferior internal articular arteries.

The **azygos articular** is a small branch, arising from the popliteal artery opposite the bend of the knee-joint. It pierces the posterior ligament, and supplies the ligaments and synovial membrane in the interior of the articulation.

The **inferior articular arteries**, two in number, arise from the popliteal beneath the Gastrocnemius, and wind round the head of the tibia, below the joint. The *internal* one first descends along the upper margin of the Popliteus muscle, to which it gives branches; it then passes below the inner tuberosity, beneath the internal lateral ligament, at the anterior border of which it ascends to the front and inner side of the joint, to supply the head of the tibia and the articulation of the knee, anastomosing with the inferior external articular and superior internal articular arteries. The *external* one passes outwards above the head of the fibula, to the front of the knee-joint, passing in its course beneath the outer head of the Gastrocnemius, the external lateral ligament, and the tendon of the Biceps muscle, and divides into branches, which anastomose with the inferior internal articular artery, the superior external articular artery, and the anterior recurrent branch of the anterior tibial.

Circumpatellar Anastomosis.—Around and above the patella, and on the contiguous ends of the femur and tibia, is a large network of vessels, forming a superficial and deep plexus. The superficial plexus is situated between the fascia and skin round about the patella; the deep plexus, which forms a close network of vessels, lies on the surface of the lower end of the femur and upper end of the tibia around their articular surfaces, and sends numerous offsets into the interior of the joint. The arteries from which this plexus is formed are the two internal and two external articular branches of the popliteal: the anastomotica magna; the terminal branch of the profunda; the descending branch from the external circumflex, and the anterior recurrent branch of the anterior tibial.

Anterior Tibial Artery (fig. 421)

The **anterior tibial artery** commences at the bifurcation of the popliteal, at the lower border of the Popliteus muscle, passes forwards between the two heads of the Tibialis posticus, and through the large oval aperture above the upper border of the interosseous membrane, to the deep part of the front of the leg: it here lies close to the inner side of the neck of the fibula; it then descends on the anterior surface of the interosseous membrane, gradually approaching the tibia; and, at the lower part of the leg, lies on this bone, and then on the anterior ligament of the ankle, to the bend of the ankle-joint, where it lies more superficially, and becomes the *dorsalis pedis*.

Relations.—In the upper two-thirds of its extent, it rests upon the interosseous membrane, to which it is connected by delicate fibrous arches thrown across it. In the lower third, upon the front of the tibia, and the anterior ligament of the ankle-joint. In the upper third of its course, it lies between the Tibialis anticus

and Extensor longus digitorum; in the middle third, between the Tibialis anticus and Extensor proprius hallucis. At the bend of the ankle, it is crossed by the tendon of the Extensor proprius hallucis, and lies between it and the innermost tendon of the Extensor longus digitorum. It is covered, in the upper two-thirds of its course, by the muscles which lie on either side of it, and by the deep fascia; in the lower third, by the integument, anterior annular ligament, and fascia.

The anterior tibial artery is accompanied by two veins (venæ comites) which lie one on each side of the artery; the anterior tibial nerve, coursing round the outer side of the neck of the femur, gets into relation with the outer side of the artery shortly after it has passed through the opening of the interosseous membrane; about the middle of the leg it is placed superficial to it; at the lower part of the artery the nerve is generally again on the outer side.

Peculiarities in Size.—This vessel may be diminished in size, may be deficient to a greater or less extent, or may be entirely wanting, its place being supplied by perforating branches from the posterior tibial, or by the anterior division of the peroneal artery.

Course.—The artery occasionally deviates in its course towards the fibular side of the leg, regaining its usual position beneath the annular ligament at the front of the ankle. In two instances the vessel has been found to approach the surface in the middle of the leg, being covered merely by the integument and fascia below that point.

Surface Marking.—A line drawn from the inner side of the head of the fibula to midway between the two malleoli, will mark the course of the artery; the point where the artery comes in front of the interosseous membrane being in this line, one and a quarter inch below the level of the head of the fibula.

Surgical Anatomy.—The anterior tibial artery may be tied in the upper or lower part of the leg. In the upper part the operation is attended with great difficulty, on account of the depth of the vessel from the surface. An incision, about four inches in length, should be made through the integument, midway between the spine of the tibia and the outer margin of the fibula, the fascia and intermuscular septum between the Tibialis anticus and Extensor longus digitorum being divided to the same extent. The foot must be flexed to relax these muscles, and they must be separated from each other by the finger. The artery is then exposed, deeply seated, lying upon the interosseous membrane, the nerve lying externally, and one of the venæ comites on either side; these must be separated from the artery before the aneurism needle is passed round it.

To tie the vessel in the lower third of the leg above the ankle-joint, an incision about three inches in length should be made through the integument between the tendons of the Tibialis anticus, and Extensor proprius hallucis muscles, the deep fascia being divided to the same extent. The tendon on either side should be held aside, when the vessel will be seen lying upon the tibia, with the nerve on the outer side, and one of the venæ comites on either side.

The branches of the anterior tibial artery are, the

Posterior Recurrent Tibial.	Muscular.
Superior Fibular.	Internal Malleolar.
Anterior Recurrent Tibial.	External Malleolar.

The **posterior recurrent tibial** is not a constant branch, and is given off from the anterior tibial before that vessel passes through the interosseous space. It ascends beneath the Popliteus muscle, which it supplies, and anastomoses with the lower articular branches of the popliteal artery, giving off an offset to the superior tibio-fibular joint.

The **superior fibular** is sometimes given off from the anterior tibial, sometimes from the posterior tibial. It passes outwards, round the neck of the fibula, through the Soleus, which it supplies, and ends in the substance of the Peroneus longus muscle.

The **anterior recurrent tibial** arises from the anterior tibial, as soon as that vessel has passed through the interosseous space; it ascends in the Tibialis anticus muscle, and ramifies on the front and sides of the knee-joint, anastomosing with the articular branches of the popliteal, and with the anastomotica magna assisting in the formation of the circumpatellar plexus.

The **muscular branches** are numerous: they are distributed to the muscles which lie on each side of the vessel, some piercing the deep fascia to supply the integument, others passing through the interosseous membrane, and anastomosing with branches of the posterior tibial and peroneal arteries.

The **malleolar arteries** supply the ankle-joint. The *internal* arises about two inches above the articulation, and passes beneath the tendons of the Extensor proprius hallucis and Tibialis anticus, to the inner ankle, upon which it ramifies, anastomosing with branches of the posterior tibial and internal plantar arteries and with the internal calcanean from the posterior tibial. The *external* passes beneath the tendons of the Extensor longus digitorum and Peroneus tertius, and supplies the outer ankle, anastomosing with the anterior peroneal artery, and with ascending branches from the tarsal branch of the dorsalis pedis.

Dorsalis Pedis Artery (fig. 421)

The **dorsalis pedis**, the continuation of the anterior tibial, passes forwards from the bend of the ankle along the tibial side of the foot to the back part of the first intermetatarsal space, where it divides into two branches, the *dorsalis hallucis* and *communicating*.

Relations.—This vessel, in its course forwards, rests upon the astragalus, navicular, and internal cuneiform bones and the ligaments connecting them, being covered by the integument and fascia, anterior annular ligament, and crossed near its termination by the innermost tendon of the Extensor brevis digitorum. On its *tibial side* is the tendon of the Extensor proprius hallucis; on its *fibular side*, the innermost tendon of the Extensor longus digitorum, and the termination of the anterior tibial nerve. It is accompanied by two veins.

and their ligaments.

Peculiarities in Size.—The dorsal artery of the foot may be larger than usual, to compensate for a deficient plantar artery; or it may be deficient in its terminal branches to the toes, which are then derived from the internal plantar; or its place may be supplied altogether by a large anterior peroneal artery

Position.—This artery frequently curves outwards, lying external to the line between the middle of the ankle and the back part of the first interosseous space.

Surface Marking.—The dorsalis pedis artery is indicated on the surface of the dorsum of the foot by a line drawn from the centre of the space between the two malleoli to the back of the first intermetatarsal space.

Surgical Anatomy.—This artery may be tied, by making an incision through the integument, between two and three inches in length, on the fibular side of the tendon of the Extensor proprius hallucis, in the interval between it and the inner border of the short Extensor muscle. The incision should not extend further forwards than the back part of the first intermetatarsal space, as the artery divides in that situation. The deep fascia being divided to the same extent, the artery will be exposed, the nerve lying upon its outer side.

Branches.—The branches of the dorsalis pedis are, the

Tarsal.	Dorsalis Hallucis.
Metatarsal—Interosseous.	Communicating.

The **tarsal artery** arises from the dorsalis pedis, as that vessel crosses the navicular bone; it passes in an arched direction outwards, lying upon the tarsal bones, and covered by the Extensor brevis digitorum; it supplies that muscle and the articulations of the tarsus, and anastomoses with branches from the metatarsal, external malleolar, peroneal, and external plantar arteries.

The **metatarsal** arises a little anterior to the preceding; it passes outwards to the outer part of the foot, over the bases of the metatarsal bones, beneath the tendons of the short Extensor, its direction being influenced by its point of origin; and it anastomoses with the tarsal and external plantar arteries. This vessel gives off three branches, the *interosseous arteries*, which pass forwards upon the three outer Dorsal interossei muscles, and, in the clefts between the toes, divide into two dorsal collateral branches for the adjoining toes. At the back part of each interosseous space these vessels receive the posterior perforating branches from the plantar arch; and at the fore part of each interosseous space, they are joined by the anterior perforating branches, from the digital arteries. The outermost interosseous artery gives off a branch which supplies the outer side of the little toe.

The **dorsalis hallucis**, or **first dorsal interosseous artery**, runs forwards along the outer border of the first metatarsal bone, and at the cleft between the first and second toes divides into two branches, one of which passes inwards, beneath the tendon of the Extensor proprius hallucis, and is distributed to the inner border of the great toe; the outer branch bifurcates, to supply the adjoining sides of the great and second toes.

The **communicating artery** dips down into the sole of the foot, between the two heads of the First dorsal interosseous muscle, and inosculates with the termination of the external plantar artery, to complete the plantar arch. It here gives off two digital branches: one runs along the inner side of the great toe, on its plantar surface; the other passes forwards along the first interosseous space, and bifurcates for the supply of the adjacent sides of the great and second toes.

Posterior Tibial Artery

The **posterior tibial** is an artery of large size, which extends obliquely downwards from the lower border of the Popliteus muscle, along the tibial side of the leg, to the fossa between the inner ankle and the heel, where it divides beneath the origin of the Abductor hallucis, on a level with a line drawn from the point of the internal malleolus to the centre of the convexity of the heel, into the *internal* and *external plantar arteries*. At its origin it lies opposite the interval between the tibia and fibula; as it descends, it approaches the inner side of the leg, lying behind the tibia, and, in the lower part of its course, is situated midway between the inner malleolus and the tuberosity of the os calcis.

Relations.—It lies successively upon the Tibialis posticus, the Flexor longus digitorum, the tibia, and the back part of the ankle-joint. It is *covered* by the deep transverse fascia, which separates it above from the Gastrocnemius and Soleus muscles: at its termination it is covered by the Abductor hallucis muscle. In the lower third, where it is more superficial, it is covered only by the integument and fascia, and runs parallel with the inner border of the tendo Achillis. It is accompanied by two veins, and by the posterior tibial nerve, which lies at first to the inner side of the artery, but soon crosses it, and is, in the greater part of its course, on its outer side.

Deep transverse fascia.
Posterior tibial nerve.
Abductor hallucis.

Behind the Inner Ankle, the tendons and blood-vessels are arranged in the following order, from within outwards:—First, the tendons of the Tibialis posticus and Flexor longus digitorum, lying in the same groove, behind the inner malleolus, the former being the most internal. External to these is the posterior tibial artery, having a vein on either side; and, still more externally, the posterior tibial nerve. About half an inch nearer the heel is the tendon of the Flexor longus hallucis.

Peculiarities in Size.—The posterior tibial is not unfrequently smaller than usual, or absent, its place being supplied by a large peroneal artery, which passes inwards at the lower end of the tibia, and either joins the small tibial artery, or continues alone to the sole of the foot.

Surface Marking.—The course of the posterior tibial artery is indicated by a line drawn from a point one inch below the centre of the popliteal space to midway between the tip of the internal malleolus and the centre of the convexity of the heel.

Surgical Anatomy.—The *application of a ligature* to the posterior tibial may be required in cases of wound of the sole of the foot, attended with great hæmorrhage, when the vessel should be tied at the inner ankle. In cases of wound of the posterior tibial, it will be necessary to enlarge the opening so as to expose the vessel at the wounded point, excepting where the vessel is injured by a punctured wound from the front of the leg. In cases of aneurism from wound of the artery low down, the vessel should be tied in the middle of the leg. But in aneurism of the posterior tibial high up, it would be better to tie the femoral artery.

To tie the posterior tibial artery at the ankle, a semilunar incision should be made through the integument, about two inches and a half in length, midway between the heel and inner ankle, or a little nearer the latter. The subcutaneous cellular tissue having been divided, a strong and dense fascia, the internal annular ligament, is exposed. This ligament is continuous above with the deep fascia of the leg, covers the vessels and nerves, and is intimately adherent to the sheaths of the tendons. This having been cautiously divided upon a director, the sheath of the vessels is exposed, and, being opened, the artery is seen with one of the venæ comites on each side. The aneurism needle should be passed round the vessel from the heel towards the ankle, in order to avoid the posterior tibial nerve, care being at the same time taken not to include the venæ comites.

The vessel may also be tied in the lower third of the leg by making an incision about three inches in length, parallel with the inner margin of the tendo Achillis. The internal saphenous vein being carefully avoided, the two layers of fascia must be divided upon a director, when the artery is exposed along the outer margin of the Flexor longus digitorum, with one of its venæ comites on either side, and the nerve lying external to it.

To tie the posterior tibial in the middle of the leg is a very difficult operation, on account of the great depth of the vessel from the surface. The patient being placed in the recumbent position, the injured limb should rest on its outer side, the knee being partially bent, and the foot extended, so as to relax the muscles of the calf. An incision about four inches in length should then be made through the integument, a finger's breadth behind the inner margin of the tibia, taking care to avoid the internal saphenous vein. The deep fascia having been divided, the margin of the Gastrocnemius is exposed, and must be drawn aside, and the tibial attachment of the Soleus divided, a director being previously passed beneath it. The artery may now be felt pulsating beneath the deep fascia, about an inch from the margin of the tibia. The fascia having been divided, and the limb placed in such a position as to relax the muscles of the calf as much as possible, the veins should be separated from the artery, and the aneurism needle passed round the vessel from without inwards, so as to avoid wounding the posterior tibial nerve.

The branches of the posterior tibial artery are, the

Peroneal.	Nutrient.
Muscular.	Communicating.

Internal Calcanean.

The **Peroneal Artery** lies, deeply seated, along the back part of the fibular side of the leg. It arises from the posterior tibial, about an inch below the lower border of the Popliteus muscle, passes obliquely outwards to the fibula, and then descends along the inner border of that bone, contained in a fibrous canal between the Tibialis posticus and the Flexor longus hallucis, to the lower third of the leg, where it gives off the *anterior peroneal*. It then passes across the articulation between the tibia and fibula to the outer side of the os calcis, where it gives off its terminal branches, the *external calcanean*.

Relations.—This vessel rests at first upon the Tibialis posticus, and then, for the greater part of its course, in a fibrous canal between the origins of the Flexor longus hallucis and Tibialis posticus, covered or surrounded by the fibres of the Flexor longus hallucis. It is *covered*, in the upper part of its course, by the Soleus and deep transverse fascia; *below*, by the Flexor longus hallucis.

Flexor longus hallucis.

Inner side.
Flexor longus hallucis.

Behind.
Soleus.
Deep transverse fascia.
Flexor longus hallucis.

Peculiarities in Origin.—The peroneal artery may arise three inches below the Popliteus, or from the posterior tibial high up, or even from the popliteal.

Its size is more frequently increased than diminished; and then it either reinforces the posterior tibial by its junction with it, or altogether takes the place of the posterior tibial in the lower part of the leg and foot, the latter vessel only existing as a short muscular branch. In those rare cases where the peroneal artery is smaller than usual, a branch from the posterior tibial supplies its place; and a branch from the anterior tibial compensates for the diminished anterior peroneal artery. In one case the peroneal artery has been found entirely wanting.

The anterior peroneal is sometimes enlarged, and takes the place of the dorsal artery of the foot.

The branches of the peroneal are, the

Muscular.	Communicating.
Nutrient.	Posterior Peroneal.
Anterior Peroneal.	External Calcanean.

Muscular branches.—The peroneal artery, in its course, gives off branches to the Soleus, Tibialis posticus, Flexor longus hallucis, and Peronei muscles.

The *nutrient artery* supplies the fibula.

The *Anterior peroneal* pierces the interosseous membrane, about two inches above the outer malleolus, to reach the fore part of the leg, and, passing down beneath the Peroneus tertius, to the outer ankle, ramifies on the front and outer side of the tarsus, anastomosing with the external malleolar and tarsal arteries.

The *communicating* is given off from the peroneal about an inch from its lower end, and, passing inwards, joins the communicating branch of the posterior tibial.

The *Posterior peroneal* passes down behind the outer ankle to the back of the external malleolus, to terminate in branches which ramify on the outer surface and back of the os calcis.

The *External calcanean* are the terminal branches of the peroneal artery; they pass to the outer side of the heel, and communicate with the external malleolar and, on the back of the heel, with the internal calcanean arteries.

The **nutrient artery** of the tibia arises from the posterior tibial, near its origin, and after supplying a few muscular branches, enters the nutrient canal of that bone, which it traverses obliquely from above downwards. This is the largest nutrient artery of bone in the body.

The **muscular branches** of the posterior tibial are distributed to the Soleus and deep muscles along the back of the leg.

The **communicating branch**, to join a similar branch of the peroneal, runs transversely across the back of the tibia, about two inches above its lower end, passing beneath the Flexor longus hallucis.

The **internal calcanean** are several large arteries, which arise from the posterior tibial just before its division; they are distributed to the fat and integument behind the tendo Achillis and about the heel, and to the muscles on the inner side of the sole, anastomosing with the peroneal and internal malleolar and, on the back of the heel, with the external calcanean arteries.

The **Internal Plantar Artery** (figs. 422, 423), much smaller than the external, passes forwards along the inner side of the foot. It is at first situated above* the Abductor hallucis, and then between it and the Flexor brevis digitorum, both of which it supplies. At the base of the first metatarsal bone, where it has become much diminished in size, it passes along the inner border of the great toe, inosculating with its digital branch.

The **External Plantar Artery**, much larger than the internal, passes obliquely outwards and forwards to the base of the fifth metatarsal bone. It then turns obliquely inwards to the interval between the bases of the first and second metatarsal bones, where it anastomoses with the communicating branch from the dorsalis pedis artery, thus completing the *plantar arch*. As this artery passes outwards, it is first placed between the os calcis and Abductor hallucis, and then between the Flexor brevis digitorum and Flexor accessorius; and as it passes forwards to the base of the little toe, it lies more superficially between the Flexor brevis digitorum and Abductor minimi digiti, covered by the deep fascia and integument. The remaining portion of the vessel is deeply situated; it extends from the base of the metatarsal bone of the little toe to the back part of the first interosseous space, and forms the plantar arch; it is convex forwards, lies

* This refers to the erect position of the body. In the ordinary position for dissection, the artery is deeper than the muscle.

upon the Interossei muscles, opposite the tarsal ends of the metatarsal bones, and is covered by the Adductor obliquus hallucis, the flexor tendons of the toes, and the Lumbricales.

Surface Marking.—The course of the internal plantar artery is represented by a line drawn from the mid-point between the tip of the internal malleolus and the centre of the convexity of the heel to the middle of the under surface of the great toe. The external plantar by a line from the same point to within a finger's breadth of the tuberosity of the fifth metatarsal bone. The plantar arch is indicated by a line drawn from this point: i.e. a finger's breadth internal to the tuberosity of the fifth metatarsal bone transversely across the foot to the back of the first interosseous space.

Surgical Anatomy.—Wounds of the plantar arch are always serious, on account of the depth of the vessel and the important structures which must be interfered with in an attempt to ligature it. Delorme has shown that it may be ligatured from the dorsum of the foot in almost any part of its course by removing a portion of one of the three middle metatarsal bones.

Branches.—The plantar arch, besides distributing numerous branches to the muscles, integument, and fasciæ in the sole, gives off the following branches:—

Posterior Perforating. Digital—Anterior Perforating.

The **Posterior Perforating** are three small branches, which ascend through the back part of the three outer interosseous spaces, between the heads of the Dorsal

Fig. 422.—The plantar arteries. Superficial view.

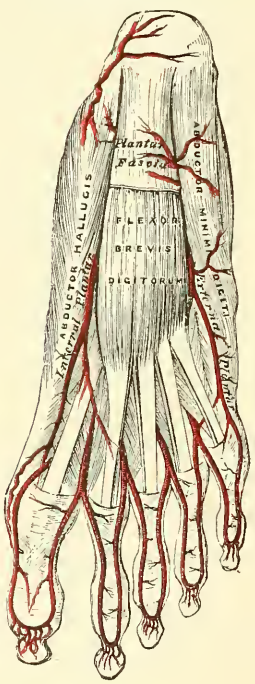

Fig. 423.—The plantar arteries. Deep view.

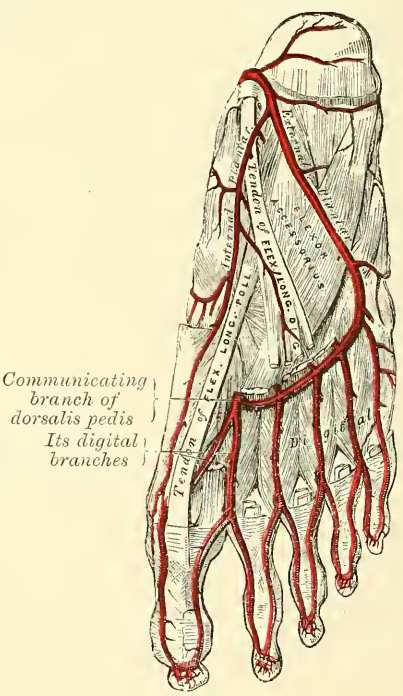


interossei muscles, and anastomose with the interosseous branches from the metatarsal artery.

The **Digital Branches** are four in number, and supply the three outer toes and half the second toe. The *first* passes outwards from the outer side of the plantar arch, and is distributed to the outer side of the little toe, passing in its course beneath the abductor and short flexor muscles. The *second*, *third*, and *fourth* run forwards along the interosseous spaces, and on arriving at the clefts between the toes divide into collateral branches, which supply the adjacent sides of the three outer toes and the outer side of the second. At the bifurcation of the toes, each digital artery sends upwards, through the fore part

of the corresponding interosseous space, a small branch, which inosculates with the interosseous branches of the metatarsal artery. These are the *anterior perforating branches.*

From the arrangement already described of the distribution of the vessels to the toes, it will be seen that both sides of the three outer toes, and the outer side of the second toe, are supplied by branches from the plantar arch ; both sides of the great toe, and the inner side of the second, are supplied by the communicating branch of the dorsalis pedis.

OF THE VEINS

THE Veins are the vessels which serve to return the blood from the capillaries of the different parts of the body to the heart. They consist of two distinct sets of vessels, the *pulmonary* and *systemic*.

The **Pulmonary Veins** are concerned in the circulation in the lungs. Unlike other vessels of this kind, they contain arterial blood, which they return from the lungs to the left auricle of the heart.

The **Systemic Veins** are concerned in the general circulation; they return the venous blood from the body generally to the right auricle of the heart.

The **Portal Vein**, an appendage to the systemic venous system, is confined to the abdominal cavity, returning the venous blood from the viscera of digestion, and carrying it to the liver by a single trunk of large size, the *vena portæ*. This vessel ramifies in the substance of the liver and breaks up into a minute network of capillaries. These capillaries then re-collect to form the hepatic veins, by which the blood is conveyed to the inferior vena cava.

The veins, like the arteries, are found in nearly every tissue of the body. They commence by minute plexuses which receive the blood from the capillaries. The branches which have their commencement in these plexuses unite together into trunks, and these, in their passage towards the heart, constantly increase in size as they receive tributaries, or join other veins. The veins are larger and altogether more numerous than the arteries; hence, the entire capacity of the venous system is much greater than that of the arterial; the pulmonary veins excepted, which only slightly exceed in capacity the pulmonary arteries. From the combined area of the smaller venous branches being greater than the main trunks, it results that the venous system represents a cone, the summit of which corresponds to the heart, its base to the circumference of the body. In form, the veins are perfectly cylindrical like the arteries, their walls being collapsed when empty, and the uniformity of their surface being interrupted at intervals by slight constrictions, which indicate the existence of valves in their interior. They usually retain, however, the same calibre as long as they receive no branches.

The veins communicate very freely with one another, especially in certain regions of the body; and this communication exists between the larger trunks as well as between the smaller branches. Thus, in the cavity of the cranium, and between the veins of the neck, where obstruction would be attended with imminent danger to the cerebral venous system, we find that the sinuses and larger veins have large and very frequent anastomoses. The same free communication exists between the veins throughout the whole extent of the spinal canal, and between the veins composing the various venous plexuses in the abdomen and pelvis, as the spermatic, uterine, vesical, and prostatic.

The systemic veins are subdivided into three sets: superficial, deep, and sinuses.

The **Superficial** or **Cutaneous Veins** are found between the layers of the superficial fascia, immediately beneath the integument; they return the blood from these structures, and communicate with the deep veins by perforating the deep fascia.

The **Deep Veins** accompany the arteries, and are usually enclosed in the same sheath with those vessels. With the smaller arteries—as the radial, ulnar, brachial, tibial, peroneal—they exist generally in pairs, one lying on each side of the vessel, and are called *venæ comites*. The larger arteries—as the axillary, subclavian, popliteal, and femoral—have usually only one accompanying vein. In certain organs of the body, however, the deep veins do not accompany the arteries; for instance, the veins in the skull and spinal canal, the hepatic veins in the liver, and the larger veins returning blood from the osseous tissue.

Sinuses are venous channels, which, in their structure and mode of distribution, differ altogether from the veins. They are found only in the interior of the skull, and are formed by a separation of the layers of the dura mater; their outer coat consisting of fibrous tissue, their inner of an endothelial layer continuous with the lining membrane of the veins.

Veins have thinner walls than arteries, the difference in thickness being due to the small amount of elastic and muscular tissues which the veins contain. The superficial veins usually have thicker coats than the deep veins, and the veins of the lower limb are thicker than those of the upper.

The minute structure of these vessels has been described in the section on General Anatomy

THE PULMONARY VEINS

The *Pulmonary Veins* return the arterial blood from the lungs to the left auricle of the heart. They are four in number, two for each lung. The pulmonary differ from other veins in several respects:—1. They carry arterial instead of venous blood. 2. They are destitute of valves. 3. They are only slightly larger than the arteries they accompany. 4. They accompany those vessels singly. They commence in a capillary network, upon the walls of the air-cells, where they are continuous with the ramifications of the pulmonary artery, and, uniting together, form a single trunk for each lobule. These branches, uniting successively, form a single trunk for each lobe, three for the right, and two for the left lung. The vein from the middle lobe of the right lung unites with that from the upper lobe, in most cases, forming two trunks on each side, which open separately into the left auricle. Occasionally, they remain separate; there are then three veins on the right side. Not unfrequently, the two left pulmonary veins terminate by a common opening.

Within the lung, the branches of the pulmonary artery are *in front*, the veins *behind*, and the bronchi *between* the two.

At the root of the lung, the veins are *in front*, the artery *in the middle*, and the bronchus *behind*.

Within the pericardium, their anterior surface is invested by the serous layer of this membrane. The right pulmonary veins pass behind the right auricle and ascending aorta; the left pass in front of the thoracic aorta, with the left pulmonary artery.

THE SYSTEMIC VEINS

The systemic veins may be arranged into three groups:—1. Those of the head and neck, upper extremity, and thorax, which terminate in the superior vena cava. 2. Those of the lower limb, pelvis, and abdomen, which terminate in the inferior vena cava. 3. The cardiac veins, which open directly into the right auricle of the heart.

VEINS OF THE HEAD AND NECK

The veins of the head and neck may be subdivided into three groups:—1. The veins of the exterior of the head and face. 2. The veins of the neck. 3. The veins of the diploë and the interior of the cranium.

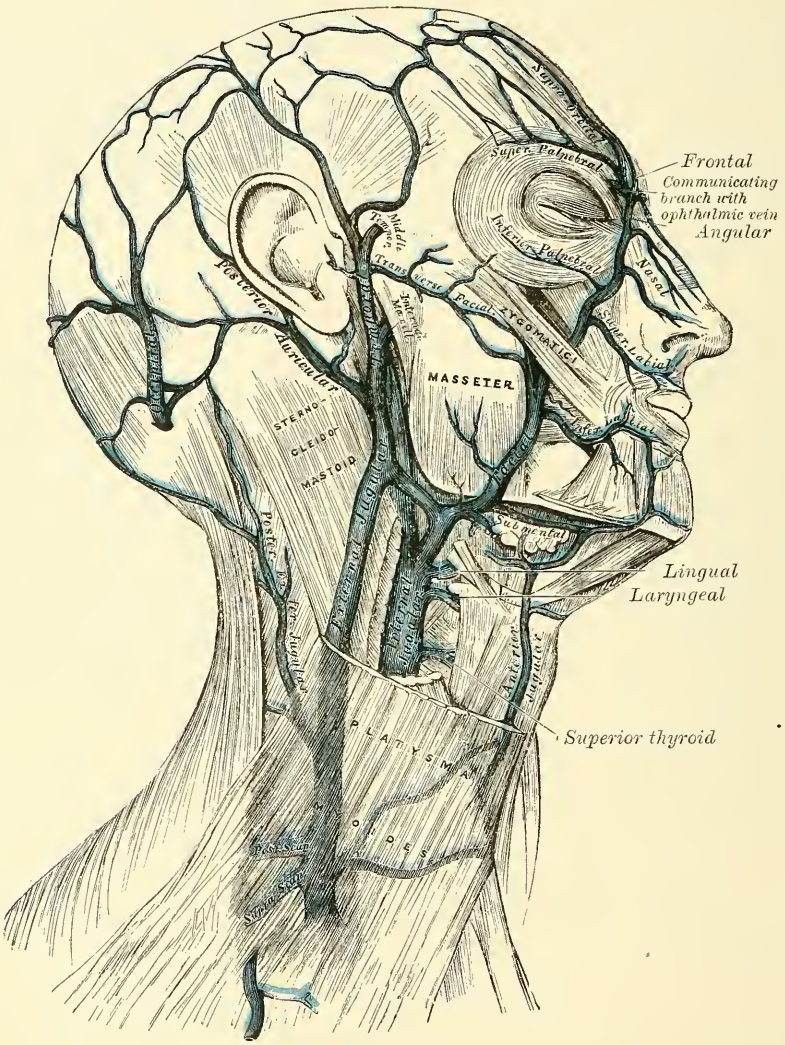
The veins of the exterior of the head and face are, the

Frontal.	Temporal.
Supra-orbital.	Internal Maxillary.
Angular.	Temporo-maxillary.
Facial.	Posterior Auricular.

Occipital.

The **frontal vein** commences on the anterior part of the skull by a venous plexus which communicates with the anterior tributaries of the temporal vein.

Fig. 424.—Veins of the head and neck.



The veins converge to form a single trunk, which runs downwards near the middle line of the forehead parallel with the vein of the opposite side, and unites with it at the root of the nose, by a transverse branch, called the *nasal arch.* Occasionally the frontal veins join to form a single trunk, which bifurcates at the root of the nose into the two angular veins. At the root of the nose the veins diverge, and join the *supra-orbital vein*, at the inner angle of the orbit, to form the *angular vein.*

The **supra-orbital vein** commences on the forehead, communicating with the anterior temporal vein, and runs downwards and inwards, superficial to the

Occipito-frontalis muscle, receiving tributaries from the neighbouring structures, and joins the frontal vein at the inner angle of the orbit to form the *angular vein.*

The **angular vein** formed by the junction of the frontal and supra-orbital veins runs obliquely downwards and outwards, on the side of the root of the nose, and receives the veins of the ala nasi on its inner side, and the superior palpebral veins on its outer side ; it moreover communicates with the ophthalmic vein, thus establishing an important anastomosis between this vessel and the cavernous sinus. Some small veins from the dorsum of the nose terminate in the nasal arch.

The **facial vein** commences at the side of the root of the nose, being a direct continuation of the angular vein. It passes obliquely downwards and outwards, beneath the Zygomaticus major and minor muscles, descends along the anterior border of the Masseter, crosses over the body of the lower jaw, with the facial artery, and, passing obliquely outwards and backwards, beneath the Platysma and cervical fascia, unites with a branch of communication from the temporo-maxillary vein, to form a trunk of large size (*common facial vein*) which enters the internal jugular. From near its termination a communicating branch often runs down the anterior border of the Sterno-mastoid to join the lower part of the anterior jugular.

Tributaries.—The facial vein receives, near the angle of the mouth, communicating tributaries of considerable size (the *deep facial* or *anterior internal maxillary vein*) from the pterygoid plexus. It is also joined by the inferior palpebral, the superior and inferior labial veins, the buccal veins from the cheek, and the masseteric veins. Below the jaw it receives the submental, the inferior palatine, which returns the blood from the plexus around the tonsil and soft palate ; the submaxillary vein, which commences in the submaxillary gland ; and, generally, the ranine vein.

Surgical Anatomy.—There are some points about the facial vein which render it of great importance in surgery. It is not so flaccid as are most superficial veins, and, in consequence of this, remains more patent when divided. It has, moreover, no valves. It communicates freely with the intracranial circulation, not only at its commencement by its tributaries, the angular and supra-orbital veins, communicating with the ophthalmic vein, a tributary of the cavernous sinus ; but also by its deep branch, which communicates through the pterygoid plexus with the cavernous sinus by branches which pass through the foramen ovale and foramen lacerum medium (see page 678). These facts have an important bearing upon the surgery of some diseases of the face. For on account of its patency the facial vein favours septic absorption, and therefore any phlegmonous inflammation of the face following a poisoned wound is liable to set up thrombosis in the facial vein, and detached portions of the clot may give rise to purulent foci in other parts of the body. And on account of its communications with the cerebral sinuses, these thrombi are apt to extend upwards into them, and so induce a fatal issue.

The **Temporal Vein** commences by a minute plexus on the side and vertex of the skull, which communicates with the frontal and supra-orbital veins in front, the corresponding vein of the opposite side, and the posterior auricular and occipital veins behind. From this network, anterior and posterior branches are formed which unite above the zygoma, forming the trunk of the vein. This trunk is joined in this situation by a large vein, the *middle temporal,* which receives the blood from the substance of the Temporal muscle and pierces the fascia at the upper border of the zygoma. The temporal vein then descends between the external auditory meatus and the condyle of the jaw, enters the substance of the parotid gland, and unites with the internal maxillary vein to form the temporo-maxillary vein.

Tributaries.—The temporal vein receives in its course some parotid veins, an articular branch from the articulation of the jaw, anterior auricular veins from the external ear, and a vein of large size, the *transverse facial,* from the side of the face. The middle temporal vein, previous to its junction with the temporal vein, receives a branch, the *orbital vein,* which is formed by some external

palpebral branches, and passes backwards between the layers of the temporal fascia.

The **Internal Maxillary Vein** is a vessel of considerable size, receiving branches which correspond with those of the internal maxillary artery. Thus it receives the middle meningeal veins, the deep temporal, the pterygoid, masseteric, buccal, alveolar, some palatine veins, and the inferior dental. These branches form a large plexus, the *pterygoid*, which is placed between the Temporal and External pterygoid, and partly between the Pterygoid muscles. This plexus communicates very freely with the facial vein, and with the cavernous sinus, by branches through the foramen Vesalii at the base of the skull. The trunk of the vein then passes backwards, behind the neck of the lower jaw, and unites with the temporal vein, forming the temporo-maxillary vein.

The **Temporo-maxillary Vein**, formed by the union of the temporal and internal maxillary veins, descends in the substance of the parotid gland on the outer surface of the external carotid artery, between the ramus of the jaw and the Sterno-mastoid muscle, and divides into two branches, one of which passes inwards to join the facial vein ; the other is joined by the posterior auricular vein and becomes the external jugular.

The **Posterior Auricular Vein** commences upon the side of the head, by a plexus which communicates with the tributaries of the temporal and occipital veins. The vein descends behind the external ear and joins the temporo-maxillary vein, forming the external jugular. This vessel receives the stylo-mastoid vein, and some tributaries from the back part of the external ear.

The **Occipital Veins** commence at the back part of the vertex of the skull, by a plexus, in a similar manner to the other veins. These unite and form one or two veins, which follow the course of the occipital artery, passing deeply beneath the muscles of the back part of the neck, and terminate in the internal jugular, occasionally in the external jugular vein. As these veins pass across the mastoid portion of the temporal bone, one of them receives the mastoid vein, which thus establishes a communication with the lateral sinus.

Veins of the Neck

The veins of the neck, which return the blood from the head and face, are the

External Jugular. Anterior Jugular.
Posterior External Jugular. Internal Jugular.
Vertebral.

The **External Jugular Vein** receives the greater part of the blood from the exterior of the cranium and deep parts of the face, being formed by the junction of the posterior division of the temporo-maxillary and posterior auricular veins. It commences in the substance of the parotid gland, on a level with the angle of the lower jaw, and runs perpendicularly down the neck, in the direction of a line drawn from the angle of the jaw to the middle of the clavicle. In its course it crosses the Sterno-mastoid muscle, and runs parallel with its posterior border as far as its attachment to the clavicle, where it perforates the deep fascia, and terminates in the subclavian vein, on the outer side of or in front of the Scalenus anticus muscle. In the neck it is separated from the Sterno-mastoid by the anterior layer of the deep cervical fascia, and is covered by the Platysma, the superficial fascia, and the integument. This vein is crossed about its middle by the superficialis colli nerve, and its upper half is accompanied by the auricularis magnus nerve. The external jugular vein varies in size, bearing an inverse proportion to that of the other veins of the neck ; it is occasionally double. It is provided with two pairs of valves, the lower pair being placed at its entrance into the subclavian vein, the upper pair in most cases about an inch and a half above the clavicle. The portion of vein between the two sets of valves is often

dilated, and is termed the *sinus*. These valves do not prevent the regurgitation of the blood, or the passage of injection from below upwards.*

Surgical Anatomy.—Venesection used formerly to be performed on the external jugular vein, but is now probably never resorted to. The anatomical point to be remembered in performing this operation is to cut across the fibres of the Platysma myoides in opening the vein, so that by their contraction they will expose the orifice in the vein and so allow the flow of blood.

Tributaries.—This vein receives the occipital occasionally, the posterior external jugular, and, near its termination, the suprascapular and transverse cervical veins. It communicates with the anterior jugular, and, in the substance of the parotid, receives a large branch of communication from the internal jugular.

The **Posterior External Jugular Vein** commences in the occipital region and returns the blood from the integument and superficial muscles in the upper and back part of the neck, lying between the Splenius and Trapezius muscles. It runs down the back part of the neck, and opens into the external jugular just below the middle of its course.

The **Anterior Jugular Vein** commences near the hyoid bone from the convergence of several superficial veins from the submaxillary region. It passes down between the median line and the anterior border of the Sterno-mastoid and, at the lower part of the neck, passes beneath that muscle to open into the termination of the external jugular, or into the subclavian vein (fig. 431). This vein varies considerably in size, bearing almost always an inverse proportion to the external jugular. Most frequently there are two anterior jugulars, a right and left; but occasionally only one. This vein receives some laryngeal veins, and occasionally a small thyroid vein. Just above the sternum, the two anterior jugular veins communicate by a transverse trunk, which receives tributaries from the inferior thyroid veins. It also communicates with the internal jugular. There are no valves in this vein.

The **Internal Jugular Vein** collects the blood from the interior of the cranium, from the superficial parts of the face, and from the neck. It commences just external to the jugular foramen, at the base of the skull, being formed by the coalescence of the lateral and inferior petrosal sinuses (fig. 429). At its origin it is somewhat dilated, and this dilatation is called the *sinus*, or *gulf*, of the internal jugular vein. It runs down the side of the neck in a vertical direction, lying at first on the outer side of the internal carotid, and then on the outer side of the common carotid, and at the root of the neck unites with the subclavian vein to form the innominate vein. The internal jugular vein, at its commencement, lies upon the Rectus capitis lateralis, and behind the internal carotid and the nerves passing through the jugular foramen; lower down, the vein and artery lie upon the same plane, the glosso-pharyngeal and hypoglossal nerves passing forwards between them; the pneumogastric descends between and behind them in the same sheath, and the spinal accessory passes obliquely outwards, behind the vein. At the root of the neck the vein of the right side is placed at a little distance from the artery; on the left side, it usually lies over the artery at its lower part. The right internal jugular vein crosses the first part of the subclavian artery. The vein is of considerable size, but varies in different individuals, the left one being usually the smaller. It is provided with a pair of valves, which are placed at its point of termination, or from half to three-quarters of an inch above it.

Tributaries.—This vein receives in its course the facial, lingual, pharyngeal, superior and middle thyroid veins, and sometimes the occipital. At its point of junction with the common facial vein it becomes greatly increased in size.

* The student may refer to an interesting paper by Dr. Struthers, 'On Jugular Venesection in Asphyxia, anatomically and experimentally considered, including the Demonstration of Valves in the Veins of the Neck,' in the *Edinburgh Medical Journal* for November 1856.

The **lingual veins** commence on the dorsum, sides, and under surface of the tongue, and, passing backwards, following the course of the lingual artery and its branches, terminate in the internal jugular. Sometimes the ranine vein, which is a branch of considerable size, commencing below the tip of the tongue, joins the lingual. Generally, however, it passes backwards, crosses the Hyo-glossus muscle in company with the hypoglossal nerve, and joins the facial.

The **pharyngeal vein** commences in a minute plexus, the *pharyngeal*, at the back part and sides of the pharynx, and, after receiving meningeal tributaries, and the Vidian and spheno-palatine veins, terminates in the internal jugular. It occasionally opens into the facial, lingual, or superior thyroid vein.

The **superior thyroid vein** commences in the substance and on the surface of the thyroid gland, by tributaries corresponding with the branches of the superior thyroid artery, and terminates in the upper part of the internal jugular vein.

The **middle thyroid vein** collects the blood from the lower part of the lateral lobe of the thyroid gland, and, being joined by some veins from the larynx and trachea, terminates in the lower part of the internal jugular vein.

The **facial** and **occipital veins** have been described above.

Surgical Anatomy.—The internal jugular vein occasionally requires ligature in cases of septic thrombosis of the lateral sinus from suppuration in the middle ear, in order to prevent septic emboli being carried into the general circulation. This operation has been performed recently in several cases, with the most satisfactory results. The cases are generally those of chronic disease of the middle ear, with discharge of pus which perhaps has existed for many years. The patient is seized with acute septic inflammation, spreading to the mastoid cells, and consequent on this, septic thrombosis of the lateral sinus extending to the internal jugular vein. Such cases are always extremely grave, for there is a danger of a portion of the septic clot being detached and causing septic embolism in the thoracic viscera. This may be mechanically prevented by ligature of the internal jugular vein in the middle of the neck. The operation is a comparatively simple one, and may be performed by an incision similar to that employed in ligature of the common carotid artery.

The **Vertebral Vein** commences in the occipital region, by numerous small tributaries, from the deep muscles at the upper and back part of the neck; these pass outwards and enter the foramen in the transverse process of the atlas, and descend, forming a dense plexus around the vertebral artery, in the canal formed by the transverse processes of the cervical vertebræ. This plexus unites at the lower part of the neck into two main trunks, one of which emerges from the foramen in the transverse process of the sixth cervical vertebra, and the other through that of the seventh, and, uniting, form a single vessel, which terminates at the root of the neck in the back part of the innominate vein near its origin, its mouth being guarded by a pair of valves. On the right side, it crosses the first part of the subclavian artery.

Tributaries.—The vertebral vein receives in its course a vein from the inside of the skull through the posterior condyloid foramen; muscular veins, from the muscles in the prevertebral region; dorsi-spinal veins, from the back part of the cervical portion of the spine; meningo-rachidian veins, from the interior of the spinal canal; the anterior and posterior vertebral veins; and close to its termination it is joined by a small vein from the first intercostal space which accompanies the superior intercostal artery.

The **anterior vertebral vein** commences in a plexus around the transverse processes of the upper cervical vertebræ, descends in company with the ascending cervical artery between the Scalenus anticus and Rectus capitis anticus major muscles, and opens into the vertebral vein just before its termination.

The **posterior vertebral vein** (the **deep cervical**) accompanies the profunda cervicis artery, lying between the Complexus and Semispinalis colli. It commences in the suboccipital region by communicating branches from the occipital vein and tributaries from the deep muscles at the back of the neck. It receives

tributaries from the plexuses around the spinous processes of the cervical vertebræ, and terminates in the lower end of the vertebral vein.

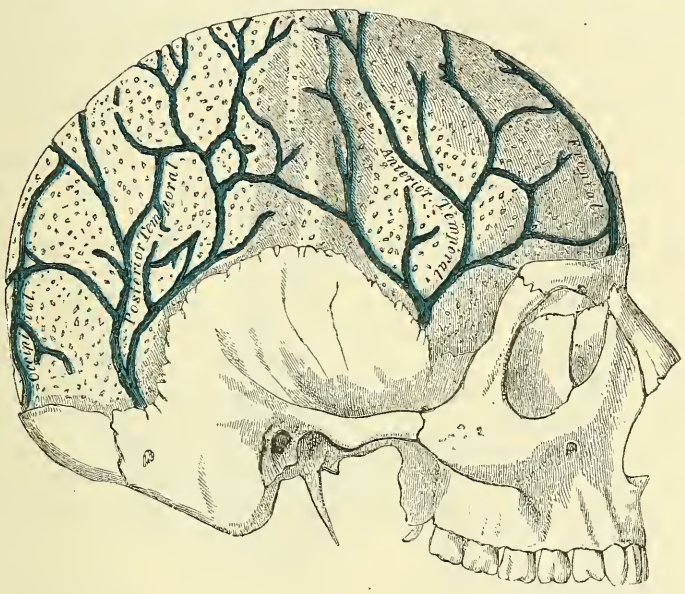
Veins of the Diploë

The diploë of the cranial bones is channelled in the adult by a number of tortuous canals, which are lined by a more or less complete layer of compact tissue.

The veins they contain are large and capacious, their walls being thin, and formed only of endothelium resting upon a layer of elastic tissue, and they present, at irregular intervals, pouch-like dilatations, or *culs-de-sac*, which serve as reservoirs for the blood. These are the veins of the diploë; they can only be displayed by removing the outer table of the skull.

In adult life, as long as the cranial bones are distinct and separable, these veins are confined to the particular bones; but in old age, when the sutures are

Fig. 425.—Veins of the diploë as displayed by the removal of the outer table of the skull.



united, they communicate with each other, and increase in size. These vessels communicate, in the interior of the cranium, with the meningeal veins, and with the sinuses of the dura mater; and, on the exterior of the skull, with the veins of the pericranium. They are divided into the *frontal*, which opens, into the supra-orbital vein, by an aperture in the supra-orbital notch; the *anterior temporal*, which is confined chiefly to the frontal bone, and opens into one of the deep temporal veins, after escaping by an aperture in the great wing of the sphenoid; the *posterior temporal*, which is confined to the parietal bone, and terminates in the lateral sinus by an aperture at the posterior inferior angle of the parietal bone; and the *occipital*, the largest of the four, which is confined to the occipital bone, and opens either into the occipital vein, or internally into the lateral sinus or torcular Herophili.

Cerebral Veins

The **Cerebral Veins** are remarkable for the extreme thinness of their coats in consequence of the muscular tissue in them being wanting, and for the absence of valves. They may be divided into two sets: the superficial which are placed on the surface, and the deep veins which occupy the interior of the organ.

The **Superficial Cerebral Veins** ramify upon the surface of the brain, being lodged in the sulci, between the convolutions, a few running across the convolutions. They receive branches from the substance of the brain, and terminate in the sinuses. They are named, from the position they occupy, superior, median, and inferior cerebral veins.

The **Superior Cerebral Veins**, eight to twelve in number on each side, return the blood from the convolutions on the superior surface of the hemisphere ; they pass forwards and inwards towards the great longitudinal fissure, where they receive the *median cerebral veins* ; near their termination, they become invested with a tubular sheath of the arachnoid membrane, and open into the superior longitudinal sinus, in the opposite direction to the course of the current of the blood.

The **Median Cerebral Veins** return the blood from the convolutions of the mesial surface of the corresponding hemisphere ; they open into the superior cerebral veins ; or occasionally into the inferior longitudinal sinus.

The **Inferior Cerebral Veins** ramify on the lower part of the outer and on the under surface of the cerebral hemisphere. Some, collecting tributaries from the under surface of the anterior lobes of the brain, terminate in the cavernous sinus. One vein of large size, the *middle cerebral vein*, commences on the under surface of the temporo-sphenoidal lobe, and, running along the fissure of Sylvius, opens into the cavernous sinus. Another large vein, the *great anastomotic vein of Trolard*, commences on the parietal lobe, runs along the horizontal limb of the fissure of Sylvius, and opens into the anterior part of the cavernous sinus under the lesser wing of the sphenoid. Others commence on the under surface of the base of the brain, and unite to form from three to five veins, which open into the superior petrosal and lateral sinuses from before backwards.

The **Deep Cerebral,** or **Ventricular Veins** (*venæ Galeni*), are two in number. They are formed by the union of two veins, the *vena corporis striati*, and the *choroid vein*, on either side. They run backwards, parallel with one another, between the layers of the velum interpositum, and pass out of the brain at the great transverse fissure, between the posterior extremity, or *splenium*, of the corpus callosum and the tubercula quadrigemina, to enter the straight sinus. The two veins usually unite to form one before opening into the straight sinus. Just before their union they receive the basilar vein.

The **vena corporis striati** commences in the groove between the corpus striatum and thalamus opticus, receives numerous veins from both of these parts, and unites behind the anterior pillar of the fornix with the choroid vein, to form one of the venæ Galeni.

The **choroid vein** runs along the whole length of the outer border of the choroid plexus, receiving veins from the hippocampus major, the fornix and corpus callosum, and unites, at the anterior extremity of the choroid plexus, with the vein of the corpus striatum.

The **Basilar Vein** commences at the anterior perforated space at the base of the brain by the union of a small anterior cerebral vein, which courses backwards between the anterior lobes of the cerebrum, with the deep Sylvian vein, which descends through the lower part of the Sylvian fissure. It passes backwards round the crus cerebri, receiving the inferior striate vein from the corpus striatum, interpeduncular veins from the interpeduncular space, ventricular veins from the middle cornu of the lateral ventricles, and tributaries from the uncinate convolution, and enters the vein of Galen just before its junction with the vein of the opposite side.

The **Cerebellar Veins** occupy the surface of the cerebellum, and are disposed in three sets, superior, inferior, and lateral. The *superior* pass forwards and inwards, across the superior vermiform process, and terminate in the straight sinus ; some open into the venæ Galeni. The *inferior cerebellar veins*, of large size, run transversely outwards, and terminate by two or three trunks in the lateral sinuses. The *lateral anterior cerebellar veins* terminate in the superior petrosal sinuses.

The perivascular lymphatics alluded to above (see page 58) are especially found in connection with the vessels of the brain. These vessels are enclosed in a sheath, which acts as a lymphatic channel, through which the lymph is carried to the subarachnoid and subdural spaces, from which it is returned into the general circulation.

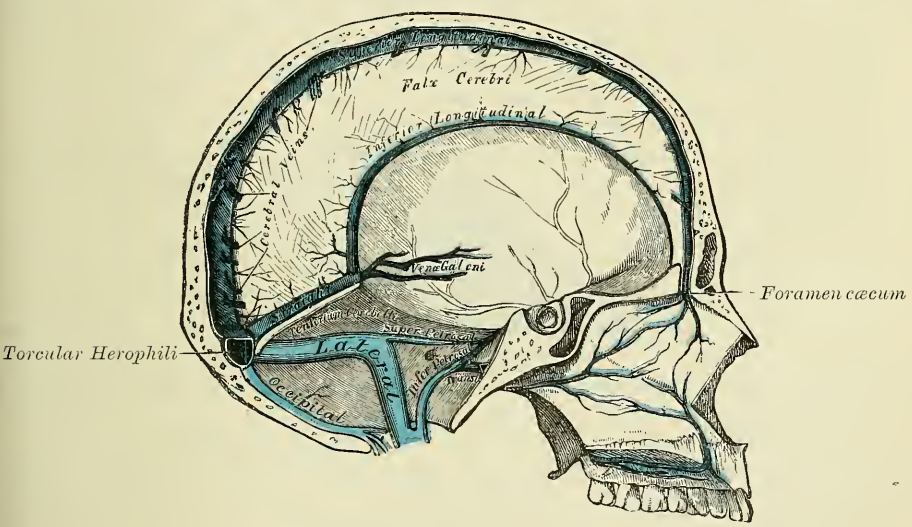
Sinuses of the Dura Mater

The sinuses of the dura mater are venous channels, analogous to the veins, their outer coat being formed by the dura mater; their inner, by a continuation of the lining membrane of the veins. They are fourteen in number, and are divided into two sets: 1. Those situated at the upper and back part of the skull: 2. those at the base of the skull. The former are, the

Superior Longitudinal Sinus.	Straight Sinus.
Inferior Longitudinal Sinus.	Lateral Sinuses.
Occipital Sinus.	

The **Superior Longitudinal Sinus** occupies the attached margin of the falx cerebri. Commencing at the foramen cæcum, through which it constantly communicates by a small branch with the veins of the nasal fossæ, it runs from before

Fig. 426.—Vertical section of the skull, showing the sinuses of the dura mater.



backwards, grooving the inner surface of the frontal, the adjacent margins of the two parietal, and the superior division of the crucial ridge of the occipital bone, and terminates by opening into the torcular Herophili. The sinus is triangular in form, narrow in front, and gradually increasing in size as it passes backwards. On examining its inner surface, it presents the internal openings of the superior cerebral veins, which run, for the most part, from behind forwards, and open chiefly at the back part of the sinus, their orifices being concealed by fibrous folds; numerous fibrous bands (*chordæ Willisii*) are also seen, extending transversely across the inferior angle of the sinus; and, lastly, some small, white, projecting bodies, the *glandulæ Pacchioni*. This sinus receives the superior cerebral veins, numerous veins from the diploë and dura mater, and, at the posterior extremity of the sagittal suture, veins from the pericranium, which pass through the parietal foramen.

The *torcular Herophili* is the dilated extremity of the superior longitudinal sinus. It is of irregular form, and is lodged on one side (generally the right) of the internal occipital protuberance. From it the lateral sinus of the side to

which it is deflected is derived. It receives also the blood from the occipital sinus.

The **Inferior Longitudinal Sinus**, more correctly described as the *inferior longitudinal vein*, is contained in the posterior part of the free margin of the falx cerebri. It is of a cylindrical form, increases in size as it passes backwards, and terminates in the straight sinus. It receives several veins from the falx cerebri, and occasionally a few from the mesial surface of the hemispheres.

The **Straight Sinus** is situated at the line of junction of the falx cerebri with the tentorium. It is triangular in form, increases in size as it proceeds backwards, and runs obliquely downwards and backwards from the termination of the inferior longitudinal sinus to the lateral sinus of the opposite side to that into which the superior longitudinal sinus is prolonged. It communicates by a cross branch with the torcular Herophili. Beside the inferior longitudinal sinus, it receives the venæ Galeni and the superior cerebellar veins. A few transverse bands cross its interior.

The **Lateral Sinuses** are of large size, and are situated in the attached margin of the tentorium cerebelli. They commence at the internal occipital protuberance; the one, generally the right, being the direct continuation of the superior longitudinal sinus, the other of the straight sinus. They pass outwards and forwards, describing a slight curve with its convexity upwards, to the base of the petrous portion of the temporal bone, then curve downwards and inwards on each side to reach the jugular foramen, where they terminate in the internal jugular vein. Each sinus rests, in its course, upon the inner surface of the occipital, the posterior inferior angle of the parietal, the mastoid portion of the temporal, and on the occipital, again, just before its termination. These sinuses are frequently of unequal size, that formed by the superior longitudinal sinus being the larger, and they increase in size as they proceed from behind forwards. The horizontal portion is of a triangular form, the curved portion semicylindrical. Their inner surface is smooth, and not crossed by the fibrous bands found in the other sinuses. These sinuses receive the blood from the superior petrosal sinuses at the base of the petrous portion of the temporal bone, and they unite with the inferior petrosal sinus, just external to the jugular foramen, to form the internal jugular vein (fig. 429). They communicate with the veins of the pericranium by means of the mastoid and posterior condyloid veins, and they receive some of the inferior cerebral and inferior cerebellar veins, and some veins from the diploë.

The **Occipital** is the smallest of the cranial sinuses. It is generally single, but occasionally there are two. It is situated in the attached margin of the falx cerebelli. It commences by several small veins around the margin of the foramen magnum, one of which joins the termination of the lateral sinus; it communicates with the posterior spinal veins, and terminates in the torcular Herophili.

The sinuses at the base of the skull are, the

Cavernous Sinuses.	Superior Petrosal Sinuses.
Circular Sinus.	Inferior Petrosal Sinuses.
Transverse Sinus.	

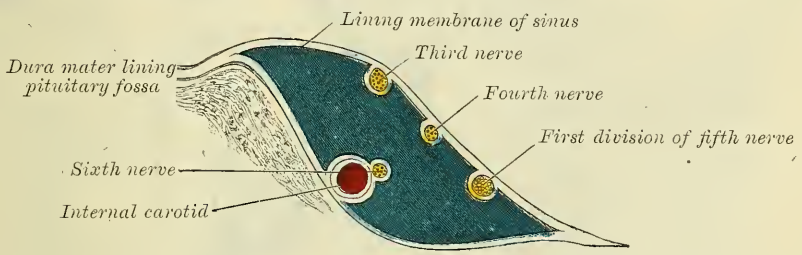
The **Cavernous Sinuses** are named from their presenting a reticulated structure, due to their being traversed by numerous interlacing filaments. They are two in number, of irregular form, larger behind than in front, and are placed one on each side of the sella turcica, extending from the sphenoidal fissure to the apex of the petrous portion of the temporal bone; they receive anteriorly the ophthalmic vein through the sphenoidal fissure, and open behind into the petrosal sinuses. On the inner wall of each sinus is found the internal carotid artery, accompanied by filaments of the carotid plexus and by the sixth nerve; and on its outer wall, the third, fourth, and ophthalmic division of the fifth nerve. These parts are separated from the blood flowing along the sinus by the lining membrane, which

is continuous with the inner coat of the veins. The cavernous sinuses receive some of the cerebral veins; they communicate with the lateral sinuses by means of the superior and inferior petrosal sinuses, and with the facial vein through the ophthalmic vein. They also communicate with each other by means of the circular sinus.

Surgical Anatomy.—An arterio-venous communication may be established between the cavernous sinus and the carotid artery, as it lies in it, giving rise to a pulsating tumour in the orbit. These communications may be the result of injury, such as a bullet wound, a stab, or a blow or fall sufficiently severe to cause a fracture of the base of the skull in this situation; or they may occur idiopathically, from the rupture of an aneurism or a diseased condition of the internal carotid artery. The disease begins with sudden noise and pain in the head, followed by exophthalmos, and development of a pulsating tumour at the margin of the orbit, with thrill and the characteristic bruit. In some cases the opposite orbit becomes affected by the passage of the arterial blood into the opposite sinus by means of the circular sinus. Or the arterial blood may find its way through the emissary veins (see page 678) into the pterygoid plexus, and thence into the veins of the face. Pulsating tumours of the orbit may also be due to traumatic aneurism of one of the orbital arteries, and symptoms resembling those of pulsating tumour may be produced by pressure on the ophthalmic vein, as it enters the sinus, by an aneurism of the internal carotid artery.

The **ophthalmic** is a large vein, which connects the angular vein at the inner angle of the orbit with the cavernous sinus; it pursues the same course as the ophthalmic artery, and receives tributaries corresponding to the branches derived

Fig. 427.—Plan showing the relative position of the structures in the right cavernous sinus, viewed from behind.



from that vessel. Forming a short single trunk, it passes through the inner extremity of the sphenoidal fissure, and terminates in the cavernous sinus.

The Inferior Ophthalmic Vein.—Sometimes the veins from the floor of the orbit collect into a separate trunk, the *inferior ophthalmic vein*, which either passes out of the orbit through the spheno-maxillary fissure to join the pterygoid plexus of veins; or else, passing backwards through the sphenoidal fissure, it enters the cavernous sinus, either by a separate opening, or in common with the ophthalmic vein.

The **Circular Sinus** is formed by two transverse vessels, which connect together the two cavernous sinuses; the one passing in front and the other behind the pituitary body, and thus forming with the cavernous sinuses a venous circle around that body. The anterior one is usually the larger of the two, and one or other is occasionally found to be absent.

The **Superior Petrosal Sinus** is situated along the superior border of the petrous portion of the temporal bone, in the front part of the attached margin of the tentorium. It is small and narrow, and connects together the cavernous and lateral sinuses at each side. It receives a cerebellar vein (*anterior lateral cerebellar*) from the anterior border of the cerebellum, and a vein from the internal ear.

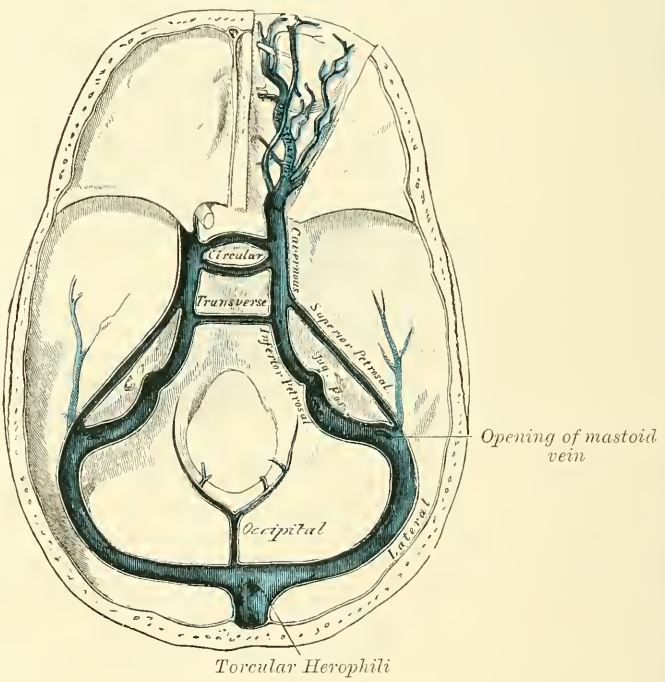
The **Inferior Petrosal Sinus** is situated in the groove formed by the junction of the posterior border of the petrous portion of the temporal with the basilar process of the occipital. It commences in front at the termination of the cavernous sinus, and behind joins the lateral sinus after it has passed through

the jugular foramen; the junction of these two sinuses forming the commencement of the internal jugular vein.

The junction of the two sinuses takes place at the lower border of, or just external to, the jugular foramen. The exact relation of the parts to one another in the foramen is as follows: the inferior petrosal sinus is in front, with the meningeal branch of the ascending pharyngeal artery, and is directed obliquely downwards and backwards; the lateral sinus is situated at the back part of the foramen with a meningeal branch of the occipital artery, and between the two are the glosso-pharyngeal, pneumogastric, and spinal accessory nerves. These three sets of structures are divided from each other by two processes of fibrous tissue. The junction of the sinuses takes place superficial to the nerves, so that these latter lie a little internal to the venous channels in the foramen (see fig. 429). These sinuses are semicylindrical in form.

The **Transverse Sinus**, or **basilar sinus**, consists of several interlacing veins between the layers of the dura mater over the basilar process of the occipital

Fig. 428.—The sinuses at the base of the skull.



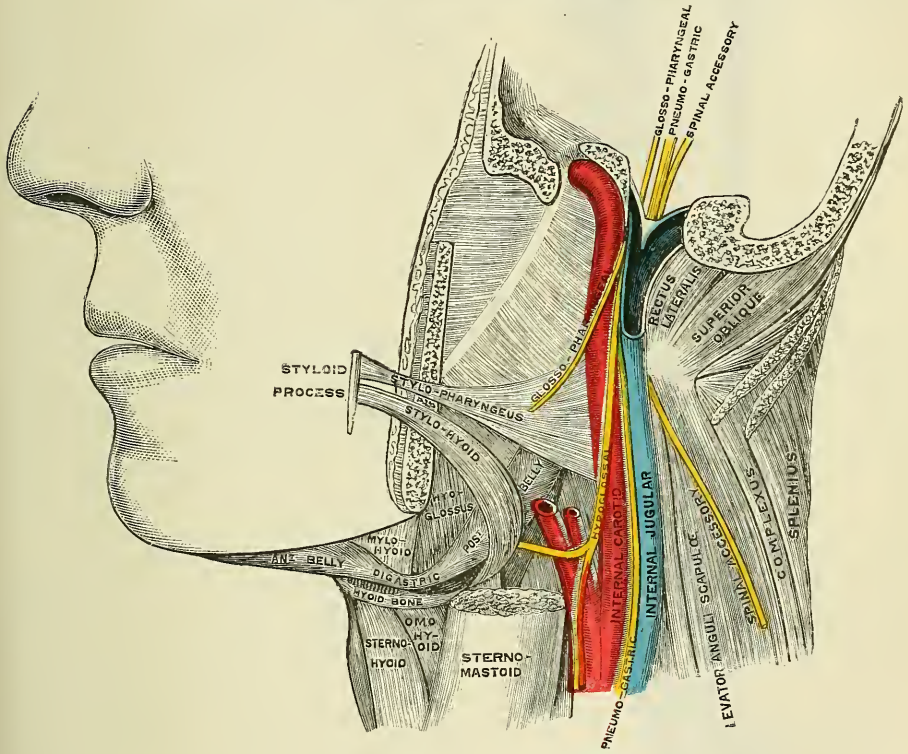
bone, which serve to connect the two inferior petrosal sinuses. With them the anterior spinal veins communicate.

Emissary Veins.—The emissary veins are vessels which pass through apertures in the cranial wall and establish communications between the sinuses inside the skull and the veins external to it. Some of these are always present, others only occasionally so. They vary much in size in different individuals. The principal emissary veins are the following:—1. A vein, almost always present, which passes through the mastoid foramen and connects the lateral sinus with the posterior auricular or with an occipital vein. 2. A vein, which passes through the parietal foramen and connects the superior longitudinal sinus with the veins of the scalp. 3. A plexus of minute veins, which pass through the anterior condyloid foramen and connect the occipital sinus with the vertebral vein and deep veins of the neck. 4. An inconstant vein, which passes through the posterior condyloid foramen and connects the lateral sinus with the deep veins of the

neck. 5. One or two veins of considerable size, which pass through the foramen ovale and connect the cavernous sinus with the pterygoid and pharyngeal plexuses. 6. Two or three small veins, which pass through the foramen lacerum medium and connect the cavernous sinus with the pterygoid and pharyngeal plexuses. 7. There is sometimes a small vein passing through the foramen of Vesalius connecting the same parts. 8. A plexus of veins passing through the carotid canal and connecting the cavernous sinus with the internal jugular vein.

Surgical Anatomy.—These emissary veins are of great importance in surgery. In addition to them there are, however, other communications between the intra- and extra-cranial circulation. As, for instance, the communication of the angular and supra-orbital veins with the ophthalmic vein, at the inner angle of the orbit (page 669) and the communication of the veins of the scalp with the diploic veins (page 673). Through these communications inflammatory processes commencing on the outside of the skull may travel inwards, leading to osteo-phlebitis of the diploë and inflammation of the membranes of the brain. To this must be attributed one of the principal dangers of scalp wounds and other injuries of the scalp.

Fig. 429.—Relation of structures in jugular foramen.



By means of these emissary veins blood may be abstracted almost directly from the intra-cranial circulation. For instance, leeches applied behind the ear abstract blood almost directly from the lateral sinus, through the vein passing through the mastoid foramen. Again, epistaxis in children will frequently relieve severe headache, the blood which flows from the nose being derived from the longitudinal sinus by means of the vein which passes through the foramen cæcum, which is another communication between the intra-cranial and extra-cranial circulation which is constantly found in children.

VEINS OF THE UPPER EXTREMITY AND THORAX

The Veins of the Upper Extremity are divided into two sets, *superficial* and *deep*.

The **Superficial Veins** are placed immediately beneath the integument between the two layers of superficial fascia.

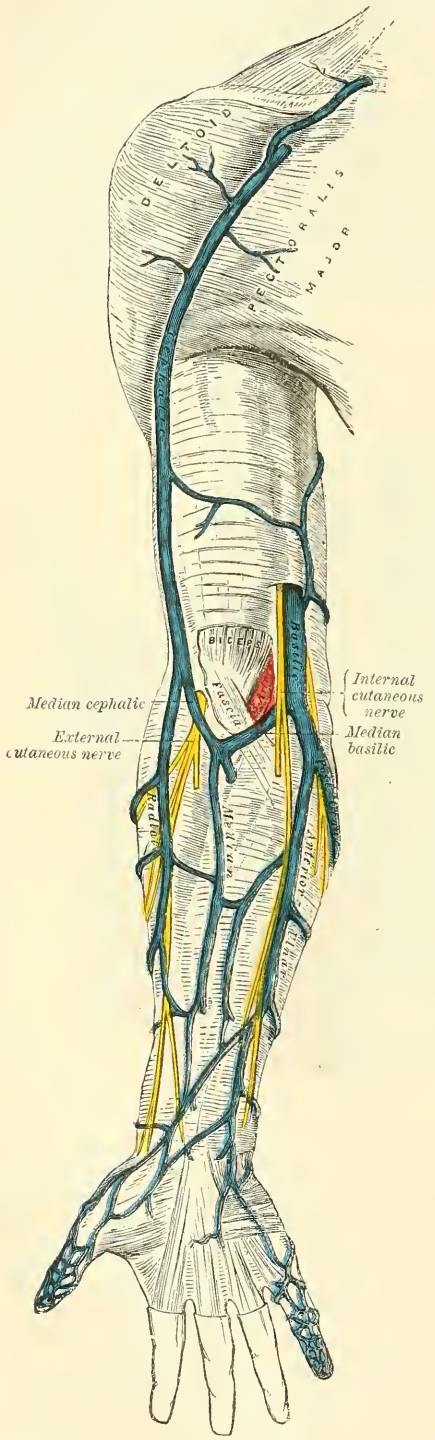
The **Deep Veins** accompany the arteries, and constitute the venæ comites of those vessels.

Both sets of vessels are provided with valves which are more numerous in the deep than in the superficial.

The superficial veins of the upper extremity are, the

Superficial Veins of the Hand.
Anterior Ulnar.
Posterior Ulnar.
Common Ulnar.
Radial.
Median.
Median Basilic.
Median Cephalic.
Basilic.
Cephalic.

Fig. 430.—The superficial veins of the upper extremity.



The **Superficial Veins of the Hand and Fingers** are principally situated on the dorsal surface, and form two plexuses, an inner and outer, on the back of the hand. The inner plexus is formed by the veins from the little finger (*vena salvatella*), the ring finger, and the ulnar side of the middle finger; from it the anterior and posterior ulnar veins are derived. The outer plexus is formed by veins from the thumb, the index finger, and radial side of the middle finger; from it the radial vein is derived. These two plexuses communicate on the back of the hand, forming the superficial arch of veins in this situation. The superficial veins from the palm of the hand form a plexus in front of the wrist, from which the median vein is derived.

The **Anterior Ulnar Vein** commences on the anterior surface of the ulnar side of the hand and wrist, and ascends along the anterior surface of the ulnar side of the forearm to the bend of the elbow, where it joins with the posterior ulnar vein to form the common ulnar. Occasionally it opens separately into the median basilic vein. It communicates with branches of the median vein in front, and with the posterior ulnar behind.

The **Posterior Ulnar Vein** commences on the posterior surface of the ulnar side of the wrist. It runs on the posterior surface of the ulnar side of the forearm, and just below the elbow unites with the anterior ulnar vein to form the common ulnar, or else joins the median basilic to form the basilic. It communicates with the deep veins of the palm by a branch which emerges from beneath the Abductor minimi digiti muscle.

The **Common Ulnar** is a short trunk which is not constant. When it exists it is formed by the junction of the two preceding veins, and, passing upwards and outwards, joins the median basilic to form the basilic vein. When it does not exist, the anterior and posterior ulnar veins open separately into the median basilic vein.

The **Radial Vein** commences from the dorsal surface of the wrist, communicating with the deep veins of the palm by a branch which passes through the first interosseous space. It forms a large vessel, which ascends along the radial side of the forearm, and receives numerous veins from both its surfaces. At the bend of the elbow it unites with the median cephalic to form the cephalic vein.

The **Median Vein** ascends on the front of the forearm, and communicates with the anterior ulnar and radial veins. At the bend of the elbow it receives a branch of communication from the deep veins, and divides into two branches, the median cephalic and median basilic, which diverge from each other as they ascend.

The **Median Cephalic**, usually the smaller of the two, passes outwards in the groove between the Supinator longus and Biceps muscles, and joins with the radial to form the cephalic vein. The branches of the external cutaneous nerve pass beneath this vessel.

The **Median Basilic Vein** passes obliquely inwards, in the groove between the Biceps and Pronator radii teres, and joins the common ulnar to form the basilic. This vein passes in front of the brachial artery, from which it is separated by a fibrous expansion (the *bicipital fascia*) which is given off from the tendon of the Biceps to the fascia covering the Flexor muscles of the forearm. Filaments of the internal cutaneous nerve pass in front as well as behind this vessel.*

Venesection is usually performed at the bend of the elbow, and as a matter of practice the largest vein in this situation is commonly selected. This is usually the median basilic, and there are anatomical advantages and disadvantages in selecting this vein. The advantages are, that in addition to its being the largest, and therefore yielding a greater supply of blood, it is the least movable and can be easily steadied on the bicipital fascia on which it rests. The disadvantages are, that it is in close relationship with the brachial artery, separated only by the bicipital fascia; and formerly, when venesection was frequently practised, arterio-venous aneurism was no uncommon result of this practice. Another disadvantage is, that the median basilic is crossed by some of the branches of the internal cutaneous nerve, and these may be divided in the operation, giving rise to 'traumatic neuralgia of extreme intensity' (Tillaux).

The **Basilic Vein** is of considerable size, formed by the coalescence of the common ulnar vein with the median basilic. It passes upwards along the inner side of the Biceps muscle, pierces the deep fascia a little below the middle of the arm, and, ascending in the course of the brachial artery, to the lower border of the tendons of the Latissimus dorsi and Teres major muscles, it is continued onwards as the axillary vein.

The **Cephalic Vein** courses along the outer border of the Biceps muscle, lying in the same groove with the upper external cutaneous branch of the musculo-spiral nerve, to the upper third of the arm; it then passes in the interval between the Pectoralis major and Deltoid muscles, lying in the same groove with the descending branch of the acromial-thoracic artery. It pierces the costo-coracoid membrane, and crossing the axillary artery, it terminates in the axillary vein just below the clavicle. This vein is occasionally connected with the external jugular or subclavian, by a branch which passes from it upwards in front of the clavicle.

The **Deep Veins of the Upper Extremity** follow the course of the arteries,

* Cruveilhier says: 'Numerous varieties are observed in the disposition of the veins of the elbow; sometimes the common median vein is wanting; but in those cases, its two branches are furnished by the radial vein, and the cephalic is almost always in a rudimentary condition. In other cases, only two veins are found at the bend of the elbow, the radial and ulnar, which are continuous, without any demarcation, with the cephalic and basilic.'

forming their venæ comites. They are generally two in number, one lying on each side of the corresponding artery, and they are connected at intervals by short transverse branches.

There are two digital veins, accompanying each artery along the sides of the fingers: these, uniting at their base, pass along the interosseous spaces in the palm, and terminate in the two venæ comites which accompany the superficial palmar arch. Branches from these vessels on the radial side of the hand accompany the superficialis volæ, and on the ulnar side terminate in the deep ulnar veins. The deep ulnar veins, as they pass in front of the wrist, communicate with the interosseous and superficial veins, and, at the elbow, unite with the deep radial veins to form the venæ comites of the brachial artery.

The **Interosseous Veins** accompany the anterior and posterior interosseous arteries. The anterior interosseous veins commence in front of the wrist, where they communicate with the deep radial and ulnar veins; at the upper part of the forearm they receive the posterior interosseous veins, and terminate in the venæ comites of the ulnar artery.

The **Deep Palmar Veins** accompany the deep palmar arch, being formed by tributaries which accompany the ramifications of that vessel. They communicate with the deep ulnar veins at the inner side of the hand, and on the outer side terminate in the venæ comites of the radial artery. At the wrist, they receive a dorsal and a palmar tributary from the thumb, and unite with the deep radial veins. Accompanying the radial artery, these vessels terminate in the venæ comites of the brachial artery.

The **Brachial Veins** are placed one on each side of the brachial artery, receiving tributaries corresponding with the branches given off from that vessel: at the lower margin of the Subscapularis, they join the axillary vein.

These deep veins have numerous anastomoses, not only with each other, but also with the superficial veins.

The **Axillary Vein** is of large size, and is the continuation upwards of the basilic vein. It commences at the lower border of the tendons of the Teres major and Latissimus dorsi, increases in size as it ascends, by receiving tributaries corresponding with the branches of the axillary artery, and terminates immediately beneath the clavicle at the outer border of the first rib, where it becomes the subclavian vein. This vessel is covered in front by the Pectoral muscles and costo-coracoid membrane, and lies on the thoracic side of the axillary artery, which it partially overlaps. Near its termination it receives the cephalic vein. This vein is provided with a pair of valves, opposite the lower border of the Subscapularis muscle; valves are also found at the termination of the cephalic and subscapular veins.

Surgical Anatomy.—There are several points of surgical interest in connection with the axillary vein. Being more superficial, larger, and slightly overlapping the axillary artery, it is more liable to be wounded in the operation of extirpation of the axillary glands, especially as these glands, when diseased, are apt to become adherent to the vessel. When wounded, there is always a danger of air being drawn into its interior, and death resulting. This is due not only to the fact that it is near the thorax and therefore liable to be influenced by the respiratory movements, but also because it is adherent by its anterior surface to the costo-coracoid membrane, and therefore if wounded is likely to remain patulous and favour the chance of air being sucked in. This adhesion of the vein to the fascia prevents its collapsing, and therefore favours the furious bleeding which takes place in these cases.

To avoid wounding the axillary vein in the extirpation of cancerous glands from the axilla, no sharp cutting instruments should be used after the axillary cavity has been freely exposed, and care should be taken to use no undue force in isolating the glands. Should the vein be so embedded in the malignant deposit that the latter cannot be removed without taking away a part of the vein, this must be done, the vessel having been first ligatured above and below.

The **Subclavian Vein**, the continuation of the axillary, extends from the outer border of the first rib to the inner end of the clavicle, where it unites with the internal jugular to form the innominate vein. It is in relation, in front, with the clavicle and Subclavius muscle; behind, with the subclavian artery, from

which it is separated internally by the Scalenus anticus muscle and phrenic nerve. Below, it rests in a depression on the first rib and upon the pleura. Above, it is covered by the cervical fascia and integument.

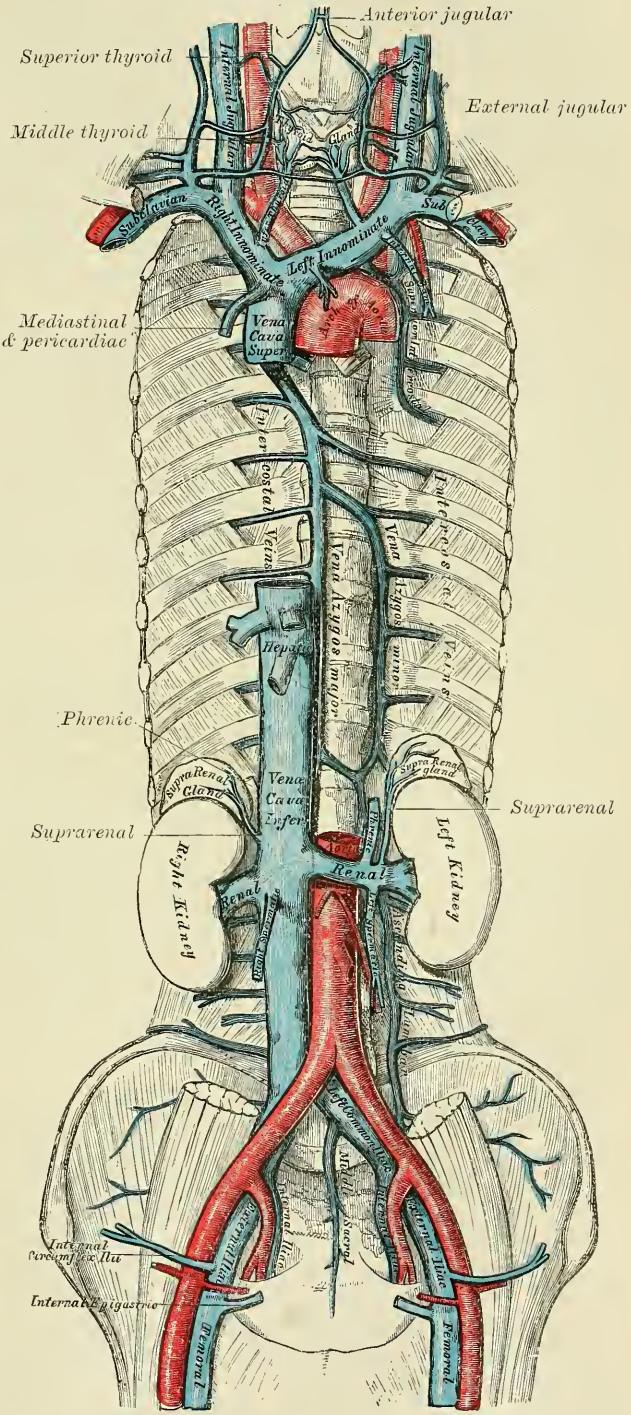
The subclavian vein occasionally rises in the neck to a level with the third part of the subclavian artery, and in two instances has been seen passing with this vessel behind the Scalenus anticus. This vessel is usually provided with valves about an inch from its termination in the innominate, just external to the entrance of the external jugular vein.

Tributaries.—It receives the external and anterior jugular veins and a small branch from the cephalic, outside the Scalenus; and on the inner side of that muscle, the internal jugular vein. At the angle of junction with the internal jugular, the left subclavian vein receives the thoracic duct; while the right subclavian vein receives the right lymphatic duct.

The **Innominate** or **Brachio-cephalic Veins** (fig. 431) are two large trunks, placed one on each side of the root of the neck, and formed by the union of the internal jugular and subclavian veins of the corresponding side.

The **Right Innominate Vein** is a short vessel, an inch in length, which commences at the inner end of the clavicle, and, passing almost vertically downwards, joins with the left innominate vein just below the cartilage of the first rib, close to the right border of the sternum, to form the superior vena

Fig. 431.—The venæ cavæ and azygos veins, with their formative branches.



cava. It lies superficial and external to the innominate artery; on its right side the pleura is interposed between it and the apex of the lung. This vein, at the angle of junction of the internal jugular with the subclavian, receives the right vertebral vein; and, lower down, the right internal mammary, right inferior thyroid, and sometimes the right superior intercostal veins.

The **Left Innominate Vein**, about two and a half inches in length, and larger than the right, passes from left to right across the upper and front part of the chest, at the same time inclining downwards, to unite with its fellow of the opposite side, forming the *superior vena cava*. It is in relation, in front, with the first piece of the sternum, from which it is separated by the Sterno-hyoid and Sterno-thyroid muscles, the thymus gland or its remains, and some loose areolar tissue. Behind, it lies across the roots of the three large arteries arising from the arch of the aorta. This vessel is joined by the left vertebral, left internal mammary, left inferior thyroid, and the left superior intercostal veins, and occasionally some thymic and pericardiac veins. There are no valves in the innominate veins.

Peculiarities.—Sometimes the innominate veins open separately into the right auricle; in such cases the right vein takes the ordinary course of the superior vena cava; but the left vein, after communicating by a small branch with the right one, passes in front of the root of the left lung, and, turning to the back of the heart, receives the cardiac veins, and terminates in the back of the right auricle. This occasional condition of the veins in the adult is a regular one in the fœtus at an early period, and the two vessels are persistent in birds and some mammalia. The subsequent changes which take place in these vessels are the following: The communicating branch between the two trunks enlarges and forms the future left innominate vein; the remaining part of the left trunk is obliterated as far as the heart, where it remains pervious, and forms the coronary sinus: a remnant of the obliterated vessel is seen in adult life as a fibrous band passing along the back of the left auricle and in front of the root of the left lung, called by Mr. Marshall the *vestigial fold of the pericardium*.

The **internal mammary veins**, two in number to each artery, follow the course of that vessel, and receive branches corresponding with those derived from it. The two veins of each side unite into a single trunk, which terminates in the innominate vein.

The **inferior thyroid veins**, two, frequently three or four, in number, arise in the venous plexus on the thyroid body, communicating with the middle and superior thyroid veins. They form a plexus in front of the trachea, behind the Sterno-thyroid muscle. From this plexus, a left vein descends and joins the left innominate trunk, and a right vein passes obliquely downwards and outwards across the innominate artery to open into the right innominate vein, just at its junction with the superior vena cava. These veins receive œsophageal, tracheal, and inferior laryngeal veins, and are provided with valves at their termination in the innominate veins.

The **Superior Intercostal Veins** return the blood from the upper intercostal spaces.

The *right superior intercostal*, much smaller than the left, closely corresponds with the superior intercostal artery, receiving the blood from the first, or first and second intercostal spaces, and, passing downwards, terminates in the vena azygos major. Occasionally it opens into the right innominate vein.

The *left superior intercostal* is always larger than the right, but varies in size in different subjects, being small when the left upper azygos vein is large, and *vice versâ*. It is usually formed by branches from the two or three upper intercostal spaces, and, passing across the arch of the aorta, terminates in the left innominate vein. The left bronchial vein and the left superior phrenic open into it.

The **Superior Vena Cava** receives the blood which is conveyed to the heart from the whole of the upper half of the body. It is a short trunk, varying from two inches and a half to three inches in length, formed by the junction of the two innominate veins. It commences immediately below the cartilage of the first rib close to the sternum on the right side, and, descending vertically, enters

the pericardium about an inch and a half above the heart, and terminates in the upper part of the right auricle opposite the upper border of the third left costal cartilage. In its course it describes a slight curve, the convexity of which is turned to the right side.

Relations.—*In front*, with the pericardium and process of cervical fascia which is continuous with it; this separates it from the thymus gland, and from the sternum; *behind*, with the root of the right lung. On its *right side*, with the phrenic nerve and right pleura; on its *left side*, with the commencement of the innominate artery and the ascending part of the aorta. The portion contained within the pericardium is covered by the serous layer of that membrane, in its anterior three-fourths. It receives the vena azygos major just before it enters the pericardium, and several small veins from the pericardium and parts in the mediastinum. The superior vena cava has no valves.

The **Azygos Veins** connect together the superior and inferior venæ cavæ, supplying the place of those vessels in the part of the chest which is occupied by the heart.

The larger, or *right azygos vein* (vena azygos major), commences opposite the first or second lumbar vertebra, by a branch from the right lumbar veins (the *ascending lumbar*); sometimes by a branch from the right renal vein, or from the inferior vena cava. It enters the thorax through the aortic opening in the Diaphragm, and passes along the right side of the vertebral column to the fourth dorsal vertebra, where it arches forward over the root of the right lung, and terminates in the superior vena cava, just before that vessel enters the pericardium. Whilst passing through the aortic opening of the Diaphragm, it lies with the thoracic duct on the right side of the aorta; and in the thorax, it lies upon the intercostal arteries, on the right side of the aorta and thoracic duct, and is partly covered by pleura.

Tributaries.—It receives nine or ten lower intercostal veins of the right side, the vena azygos minor, several œsophageal, mediastinal, and pericardial veins; near its termination, the right bronchial vein; and generally the right superior intercostal vein. A few imperfect valves are found in this vein; but its tributaries are provided with complete valves.

The intercostal veins on the left side, below the two or three upper intercostal spaces, usually form two trunks, named the left lower, and the left upper, azygos veins.

The *left lower*, or *smaller azygos vein* (vena azygos minor), commences in the lumbar region, by a branch from one of the lumbar veins (*ascending lumbar*), or from the left renal. It passes into the thorax, through the left crus of the Diaphragm, and, ascending on the left side of the spine, as high as the eighth dorsal vertebra, passes across the column, behind the aorta and thoracic duct, to terminate in the right azygos vein. It receives the four or five lower intercostal veins of the left side, and some œsophageal and mediastinal veins.

The *left upper azygos vein* varies according to the size of the left superior intercostal. It receives veins from the intercostal spaces between the left superior intercostal vein and highest tributary of the left lower azygos. They are usually two or three in number, and join to form a trunk which ends in the right azygos vein, or in the left lower azygos. It sometimes receives the left bronchial vein. When this vein is small, or altogether wanting, the left superior intercostal vein will extend as low as the fifth or sixth intercostal space.*

* For an account of the arrangement of the azygos and superior intercostal veins in a number of consecutive cases from the same dissecting-room, see a paper by Mr. B. G. Morison, *Journ. of Anat. and Phys.* vol. xiii. p. 346. The most important difference between his description and that in the text is, that he always found two superior intercostal veins on both sides; the vein from the first space being separate, and joining the corresponding innominate vein. The lower (and larger) superior intercostal vein he describes as opening into the azygos on the right, and innominate on the left side.

Surgical Anatomy.—In obstruction of the inferior vena cava, the azygos veins are one of the principal means by which the venous circulation is carried on, connecting as they do the superior and inferior venæ cavæ and communicating with the common iliac veins by the ascending lumbar veins and with many of the tributaries of the inferior vena cava.

The *bronchial veins* return the blood from the substance of the lungs; that of the right side opens into the vena azygos major, near its termination; that of the left side, into the left superior intercostal vein or left upper azygos vein.

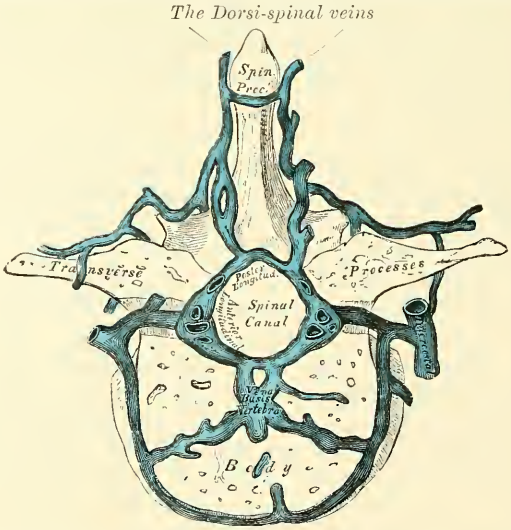
The Spinal Veins

The numerous venous plexuses placed upon and within the spine may be arranged into four sets.

1. Those placed on the exterior of the spinal column (*the dorsi-spinal veins*).
2. Those situated in the interior of the spinal canal, between the vertebræ and the theca vertebralis (*meningo-rachidian veins*).
3. The veins of the bodies of the vertebræ (*venæ basis vertebrarum*).
4. The veins of the spinal cord (*medulli-spinal*).

1. The **Dorsi-spinal Veins** commence by small branches, which receive their blood from the integument of the back of the spine, and from the muscles in the vertebral grooves. They form a complicated network, which surrounds the spinous processes, the laminæ, and the transverse and articular processes of all the vertebræ. At the bases of the transverse processes, they communicate, by

Fig. 432.—Transverse section of a dorsal vertebra, showing the spinal veins.



means of ascending and descending branches, with the veins surrounding the contiguous vertebræ, and they join with the veins in the spinal canal by branches which perforate the ligamenta subflava. Other branches pass obliquely forwards between the transverse processes, and communicate with the intraspinal veins through the intervertebral foramina. They terminate by joining the vertebral veins in the neck, the intercostal veins in the thorax, and the lumbar and sacral veins in the loins and pelvis.

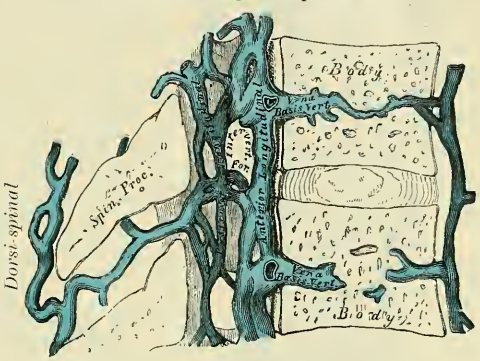
2. The **Meningo-rachidian Veins.**—The principal veins contained in the spinal canal are situated between the theca vertebralis and the vertebræ. They consist of two longitudinal plexuses, one of which runs along the posterior surface of the bodies of the vertebræ (*anterior longitudinal spinal veins*). The other plexus (*posterior longitudinal spinal veins*) is placed on the inner or anterior surface of the laminæ of the vertebræ.

The *Anterior Longitudinal Spinal Veins* consist of two large, tortuous veins which extend along the whole length of the vertebral column, from the foramen

magnum, where they communicate by a venous ring around that opening, to the base of the coccyx, being placed one on each side of the posterior surface of the bodies of the vertebræ, along the margin of the posterior common ligament. These veins communicate together opposite each vertebra by transverse trunks, which pass beneath the ligament, and receive the large *venæ basis vertebrarum* from the interior of the body of each vertebra. The anterior longitudinal spinal veins are least developed in the cervical and sacral regions. They are not of uniform size throughout, being alternately enlarged and constricted. At the intervertebral foramina they communicate with the dorsi-spinal veins, and with the vertebral veins in the neck, with the intercostal veins in the dorsal region, and with the lumbar and sacral veins in the corresponding regions.

The *Posterior Longitudinal Spinal Veins*, smaller than the anterior, are situated one on each side, between the inner surface of the laminæ and the theca vertebralis. They communicate (like the anterior), opposite each vertebra, by transverse trunks; and with the anterior longitudinal veins, by lateral transverse branches, which pass from behind forwards. These veins, by branches which perforate the ligamenta subflava, join with the dorsi-spinal veins. From them branches are given off, which pass through the intervertebral foramina and join the vertebral, intercostal, lumbar, and sacral veins.

Fig. 433.—Vertical section of two dorsal vertebræ, showing the spinal veins.



3. The **Veins of the Bodies of the Vertebræ** (*venæ basis vertebrarum*) emerge from the foramina on their posterior surface, and join the transverse trunk connecting the anterior longitudinal spinal veins. They are contained in large, tortuous channels in the substance of the bones, similar in every respect to those found in the diploë of the cranial bones. These canals lie parallel to the upper and lower surface of the bones. They commence by small openings on the front and sides of the bodies of the vertebræ, through which communicating branches from the veins external to the bone pass into its substance, and converge to the principal canal, which is sometimes double towards its posterior part, and open into the corresponding transverse branch uniting the anterior longitudinal veins. They become greatly developed in advanced age.

4. The **Veins of the Spinal Cord** (*medulli-spinal*) consist of a minute, tortuous, venous plexus which covers the entire surface of the cord, being situated between the pia mater and arachnoid. These vessels emerge chiefly from the median furrows, and are largest in the lumbar region. Near the base of the skull they unite, and form two or three small trunks, which communicate with the vertebral veins, and then terminate in the inferior cerebellar veins, or in the inferior petrosal sinuses. Each of the spinal nerves is accompanied by a branch as far as the intervertebral foramina, where they join the other veins from the spinal canal.

There are no valves in the spinal veins.

VEINS OF THE LOWER EXTREMITY, ABDOMEN, AND PELVIS

The Veins of the Lower Extremity are subdivided, like those of the upper, into two sets, superficial and deep: the superficial veins being placed beneath the integument, between the two layers of superficial fascia; the deep veins accompanying the arteries, and forming the venæ comites of those vessels. Both sets

of veins are provided with valves, which are more numerous in the deep than in the superficial set. These valves are also more numerous in the lower than in the upper limb.

Fig. 434.—The internal or long saphenous vein and its branches.

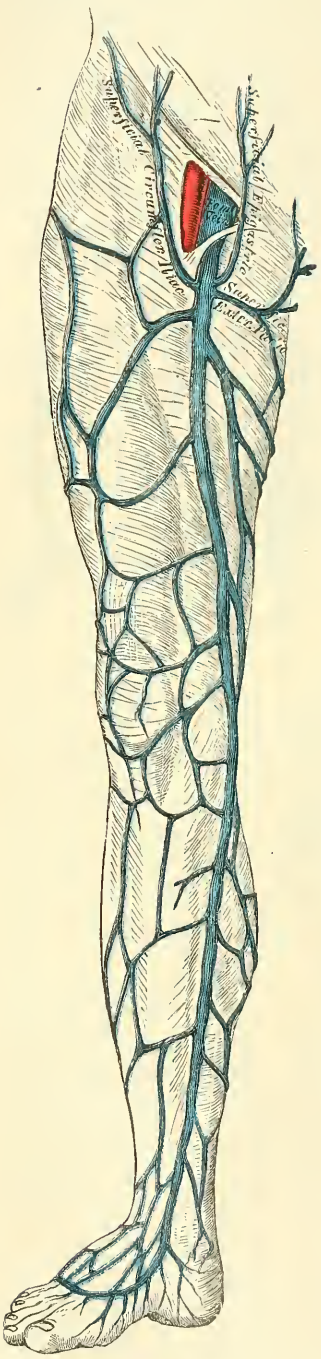


Fig. 435.—External or short saphenous vein.

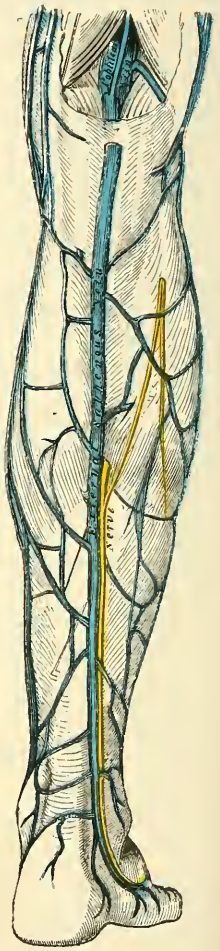


The **Superficial Veins of the Lower Extremity** are the *internal* or *long saphenous*, and the *external* or *short saphenous*.

On the dorsum of the foot is a venous arch, situated in the superficial structures over the anterior extremities of the metatarsal bones. It has its convexity directed forwards, and receives digital tributaries from the upper surface of the toes; at its concavity it is joined by numerous small veins, which form a plexus on the dorsum of the foot. The arch terminates internally in the long saphenous, externally in a short saphenous vein.

The **internal** or **long saphenous vein** (fig. 434) commences at the inner side of the arch on the dorsum of the foot; it descends in front of the inner malleolus, and along the inner side of the leg, behind the inner margin of the tibia, accompanied by the internal saphenous nerve. At the knee, it passes backwards behind the inner condyle of the femur, ascends along the inside of the thigh, and, passing through the saphenous opening in the fascia lata, terminates in the femoral vein about an inch and a half below Poupart's ligament. This vein receives in its course cutaneous tributaries from the leg and thigh, and at the saphenous opening the superficial epigastric, superficial circumflex iliac, and external pudic veins. The veins from the inner and back part of the thigh frequently unite to form a large vessel, which enters the main trunk near the saphenous opening; and sometimes those on the outer side of the thigh join to form another large vessel; so that occasionally three large veins are seen converging from different parts of the thigh towards the saphenous opening. The internal saphenous vein communicates in the foot with the internal plantar vein; in the leg, with the posterior tibial veins, by branches which perforate the tibial

origin of the Soleus muscle, and also with the anterior tibial veins; at the knee, with the articular veins; in the thigh, with the femoral vein by one or more branches. The valves in this vein vary from two to six in number; they are more numerous in the thigh than in the leg.

The **external** or **short saphenous vein** (fig. 435) commences at the outer side of the arch on the dorsum of the foot; it ascends behind the outer malleolus, and along the outer border of the tendo Achillis, across which it passes at an acute angle to reach the middle line of the posterior aspect of the leg. Passing directly upwards, it perforates the deep fascia in the lower part of the popliteal space, and terminates in the popliteal vein, between the heads of the Gastrocnemius muscle.* It receives numerous large tributaries from the back part of the leg, and communicates with the deep veins on the dorsum of the foot, and behind the outer malleolus. Before it perforates the deep fascia, it gives off a communicating branch, which passes upwards and inwards to join the internal saphenous vein. This vein has a variable number of valves, from three to nine (Gay), one of which is always found near its termination in the popliteal vein. The external saphenous nerve lies close beside this vein.

Surgical Anatomy.—The saphena veins are of considerable surgical importance, since a varicose condition of these vessels is more frequently met with than those in other parts of the body, except perhaps the spermatic and hæmorrhoidal veins. The course of the internal saphenous is in front of the tip of the malleolus, over the subcutaneous surface of the lower end of the tibia, and then along the internal border of this bone, to the back part of the internal condyle of the femur, whence it follows the course of the Sartorius muscle and is represented on the surface by a line drawn from the posterior border of the Sartorius, on a level with the internal condyle, to the saphenous opening. The short saphenous lies behind the external malleolus, and from this follows the middle line of the calf to just below the ham. It is not generally so apparent beneath the skin as the internal saphenous. Both these veins in the leg are accompanied by nerves, the internal saphenous being joined by its companion nerve just below the level of the knee-joint. No doubt much of the pain of varicose veins in the leg is due to this fact. On the Continent the internal saphenous vein as it rests on the tibia just above the malleolus is sometimes selected for venesection.

The **Deep Veins of the Lower Extremity** accompany the arteries and their branches, and are called the *venæ comites* of those vessels.

The **external** and **internal plantar veins** unite to form the **posterior tibial veins**. These latter accompany the posterior tibial artery, and are joined by the *peroneal veins*.

The **anterior tibial veins** are formed by a continuation upwards of the venæ comites of the dorsalis pedis artery. They pass between the tibia and fibula, through the large oval aperture above the interosseous membrane, and form, by their junction with the posterior tibial, the popliteal vein.

The valves in the deep veins are very numerous.

The **Popliteal Vein** is formed by the junction of the venæ comites of the anterior and posterior tibial vessels; it ascends through the popliteal space to the tendinous aperture in the Adductor magnus, where it becomes the femoral vein. In the lower part of its course, it is placed internal to the artery; between the heads of the Gastrocnemius, it is superficial to that vessel; but above the knee-joint, it is close to its outer side. It receives the sural veins from the Gastrocnemius muscle, the articular veins, and the external saphenous. The valves in this vein are usually four in number.

The **Femoral Vein** accompanies the femoral artery through the upper two-thirds of the thigh. In the lower part of its course it lies external to the artery; higher up, it is behind it; and at Poupart's ligament, it lies to its inner side, and

* Mr. Gay calls attention to the fact that the external saphenous vein often (he says invariably) penetrates the fascia at or about the point where the tendon of the Gastrocnemius commences, and runs below the fascia in the rest of its course, or sometimes among the muscular fibres, to join the popliteal vein. See Gay on *Varicose Disease of the Lower Extremities*, p. 24, where there is also a careful and elaborate description of the branches of the saphena veins.

on the same plane. It receives numerous muscular tributaries: the profunda femoris and deep external pudic veins join it near Poupart's ligament, and about an inch and a half below the internal saphenous vein. The valves in this vein are four or five in number.

The **External Iliac Vein** commences at the termination of the femoral, beneath the crural arch, and passing upwards along the brim of the pelvis, terminates opposite the sacro-iliac synchondrosis, by uniting with the internal iliac to form the common iliac vein. On the right side, it lies at first along the inner side of the external iliac artery; but as it passes upwards, gradually inclines behind it. On the left side, it lies altogether on the inner side of the artery. It receives, immediately above Poupart's ligament, the deep epigastric and deep circumflex iliac veins and a small pubic vein, corresponding to the pubic branch of the obturator artery. According to Friedreich, it frequently contains one and sometimes two valves.

The Deep Epigastric Veins.—Two veins accompany the deep epigastric artery; they usually unite into a single trunk before their termination in the external iliac vein.

The Deep Circumflex Iliac Veins.—Two veins accompany the deep circumflex iliac artery. These unite into a single trunk which crosses the external iliac artery just above Poupart's ligament, and terminates in the external iliac vein.

The **Internal Iliac Vein** is formed by the venæ comites of the branches of the internal iliac artery, the umbilical arteries excepted. It receives the blood from the exterior of the pelvis by the gluteal, sciatic, internal pudic, and obturator veins; and from the organs in the cavity of the pelvis by the hæmorrhoidal and vesico-prostatic plexuses in the male, and the uterine and vaginal plexuses in the female. The vessels forming these plexuses are remarkable for their large size, their frequent anastomoses, and the number of valves which they contain. The internal iliac vein lies at first on the inner side, and then behind the internal iliac artery, and terminates opposite the sacro-iliac articulation, by uniting with the external iliac to form the common iliac vein. This vessel has no valves.

The *internal pudic veins* (*venæ comites*) have the same course as the internal pudic artery. They receive tributaries corresponding to the branches of the artery except the tributary corresponding to the dorsal artery of the penis, that is, the dorsal vein of the penis, which opens into the prostatic plexus.

The *hæmorrhoidal plexus* surrounds the lower end of the rectum, being formed by the superior hæmorrhoidal veins, tributaries of the inferior mesenteric. It commences as a series of dilated pouches, about twelve in number, which are arranged circularly at the verge of the anus and are connected by transverse branches. From these pouches veins, about six in number, pass upwards in a straight direction in the submucous tissue for about three inches; they then pierce the muscular coat and become arranged in a circular manner at right angles to the long axis of the gut, and eventually unite to form the superior hæmorrhoidal vein.

Surgical Anatomy.—The veins of this plexus are apt to become dilated and varicose, and form piles. This is due to several anatomical reasons: the vessels are contained in very loose, lax connective tissue, so that they get less support from surrounding structures than most other veins, and are less capable of resisting increased blood pressure: the condition is favoured by gravitation, being influenced by the erect posture, either sitting or standing, and by the fact that the superior hæmorrhoidal and portal veins have no valves: the veins pass through muscular tissue and are liable to be compressed by its contraction, especially during the act of defæcation: they are affected by every form of portal obstruction.

The *vesico-prostatic plexus* surrounds the neck and base of the bladder and prostate gland. It communicates with the hæmorrhoidal plexus behind, and receives the dorsal vein of the penis, which enters the pelvis beneath the subpubic ligament. This plexus is supported upon the sides of the bladder by a

reflection of the pelvic fascia. The veins composing it are very liable to become varicose, and often contain hard, earthy concretions, called *phleboliths*.

Surgical Anatomy.—This plexus is wounded in the lateral operation of lithotomy, and it is through it that septic matter finds its way into the general circulation after this operation.

The *dorsal vein of the penis* is a vessel of large size, which returns the blood from the body of that organ. At first it consists of two branches, which are contained in the groove on the dorsum of the penis, and it receives veins from the glands, the corpus spongiosum, and numerous superficial veins; these unite near the root of the penis into a single trunk, which passes through the suspensory ligament of the penis, pierces the triangular ligament beneath the pubic arch, and divides into two branches, which enter the prostatic plexus.

The *vaginal plexus* surrounds the vagina, being especially developed at the orifice of the canal; it communicates with the vesical plexus in front, and with the hæmorrhoidal plexus behind.

The *uterine plexus* is situated along the sides and superior angles of the uterus, between the layers of the broad ligament, receiving large venous canals (the *uterine sinuses*) from the substance of the uterus. The veins composing this plexus anastomose frequently with each other and with the ovarian veins. They are not tortuous like the arteries.

The **Common Iliac Veins** are formed by the union of the external and internal iliac veins in front of the sacro-iliac articulation; passing obliquely upwards towards the right side, they terminate upon the intervertebral substance between the fourth and fifth lumbar vertebræ, where the veins of the two sides unite at an acute angle to form the inferior vena cava. The *right common iliac* is shorter than the left, nearly vertical in its direction, and ascends behind and then to the outer side of its corresponding artery. The *left common iliac*, longer and more oblique in its course, is at first situated on the inner side of the corresponding artery, and then behind the right common iliac. Each common iliac receives the ilio-lumbar, and sometimes the lateral sacral veins. The left receives, in addition, the middle sacral vein. No valves are found in these veins.

The **middle sacral veins** accompany the corresponding artery along the front of the sacrum, and terminate in the left common iliac vein; occasionally in the angle of junction of the two iliac veins.

Peculiarities.—The left common iliac vein, instead of joining with the right in its usual position, occasionally ascends on the left side of the aorta as high as the kidney, where, after receiving the left renal vein, it crosses over the aorta, and then joins with the right vein to form the vena cava. In these cases, the two common iliacs are connected by a small communicating branch at the spot where they are usually united.*

The **Inferior Vena Cava** returns to the heart the blood from all the parts below the Diaphragm. It is formed by the junction of the two common iliac veins on the right side of the intervertebral substance between the fourth and fifth lumbar vertebræ. It passes upwards along the front of the spine, on the right side of the aorta, and, having reached the under surface of the liver, is contained in a groove in its posterior surface. It then perforates the central tendon of the Diaphragm, enters the pericardium, where it is covered by its serous layer, and terminates in the lower and back part of the right auricle. At its termination in the auricle it is provided with a valve, the *Eustachian*, which is of large size during fœtal life.

Relations.—*In front*, from below upwards, with the mesentery, right spermatic artery, transverse portion of the duodenum, the pancreas, portal vein, and the posterior surface of the liver, which partly and occasionally completely surrounds it; *behind*, with the vertebral column, the right crus of the Diaphragm, the right renal and lumbar arteries, right semilunar ganglion; on the *left side* with the aorta.

* See two cases which have been described by Mr. Walsham in the *St. Bartholomew's Hospital Reports*, vols. xvi. and xvii.

Peculiarities.—In Position.—This vessel is sometimes placed on the left side of the aorta, as high as the left renal vein, after receiving which it crosses over to its usual position on the right side; or it may be placed altogether on the left side of the aorta, as far upwards as its termination in the heart: in such cases, the abdominal and thoracic viscera, together with the great vessels, are all transposed.

Point of Termination.—Occasionally the inferior vena cava joins the right azygos vein, which is then of large size. In such cases, the superior cava receives the whole of the blood from the body before transmitting it to the right auricle, except the blood from the hepatic veins, which passes directly into the right auricle.

Tributaries.—It receives in its course the following veins :—

Lumbar.	Suprarenal.
Right Spermatic.	Phrenic.
Renal.	Hepatic.

The **lumbar veins**, four in number on each side, collect the blood by dorsal tributaries from the muscles and integument of the loins, and by abdominal tributaries from the walls of the abdomen, where they communicate with the epigastric veins. At the spine, they receive veins from the spinal plexuses, and then pass forwards, round the sides of the bodies of the vertebræ beneath the Psoas magnus, and terminate at the back part of the inferior cava. The left lumbar veins are longer than the right, and pass behind the aorta. The umbar veins are connected together by a longitudinal vein which passes in front of the transverse processes of the lumbar vertebræ, and is called the *ascending lumbar*. It forms the most frequent origin of the corresponding vena azygos, and serves to connect the common iliac, ilio-lumbar, lumbar, and azygos veins of the corresponding side of the body.

The **spermatic veins** emerge from the back of the testis, and receive tributaries from the epididymis; they unite and form a convoluted plexus, called the *spermatic plexus* (*plexus pampiniformis*), which forms the chief mass of the cord; the vessels composing this plexus are very numerous, and ascend along the cord in front of the vas deferens; below the external abdominal ring they unite to form three or four veins, which pass along the spermatic canal, and, entering the abdomen through the internal abdominal ring, coalesce to form two veins, which ascend on the Psoas muscle, behind the peritoneum, lying one on each side of the spermatic artery, and unite to form a single vein, which opens on the right side into the inferior vena cava, at an acute angle; on the left side into the left renal vein, at a right angle. The spermatic veins are provided with valves.* The left spermatic vein passes behind the sigmoid flexure of the colon, and is thus exposed to pressure from the contents of that bowel.

Surgical Anatomy.—The spermatic veins are very frequently varicose, constituting the disease known as varicocele. Though it is quite possible that the originating cause of this affection may be a congenital abnormality either in the size or number of the veins of the pampiniform plexus, still it must be admitted that there are many anatomical reasons why these veins should become varicose: viz. the imperfect support afforded to them by the loose tissue of the scrotum; their great length; their vertical course; their dependent position; their plexiform arrangement in the scrotum, with their termination in one small vein in the abdomen; their few and imperfect valves; and the fact that they may be subjected to pressure in their passage through the abdominal wall.

The **ovarian veins** are analogous to the spermatic in the male; they form a plexus near the ovary and in the broad ligament and Fallopian tube, communicating with the uterine plexus. They terminate in the same way as the spermatic veins in the male. Valves are occasionally found in these veins. These vessels, like the uterine veins, become much enlarged during pregnancy.

* Rivington has pointed out that a valve is usually found at the orifices of both the right and left spermatic veins. When no valves exist at the opening of the left spermatic vein into the left renal vein, valves are generally present in the left renal vein within a quarter of an inch from the orifice of the spermatic vein. (*Journal of Anatomy and Physiology*, vol. vii. p. 163.)

The **renal veins** are of large size, and placed in front of the renal arteries.* The left is longer than the right, and passes in front of the aorta, just below the origin of the superior mesenteric artery. It receives the left spermatic, the left inferior phrenic, and, generally, the left suprarenal veins. It opens into the vena cava, a little higher than the right.

The **suprarenal veins** terminate, on the right side, in the vena cava ; on the left side, in the left renal or phrenic vein.

The **phrenic veins** follow the course of the phrenic arteries. The *two superior*, of small size, accompany the phrenic nerve and comes nervi phrenici artery, and join the internal mammary. The *two inferior phrenic veins* follow the course of the phrenic arteries, and terminate, the right in the inferior vena cava, the left in the left renal vein.

The **hepatic veins** commence in the substance of the liver, in the capillary terminations of the portal vein and hepatic artery: these tributaries, gradually uniting, usually form three large veins, which converge towards the posterior surface of the liver, and open into the inferior vena cava, whilst that vessel is situated in the groove at the back part of this organ. Of these three veins, one from the right, and another from the left lobe, open obliquely into the inferior vena cava; that from the middle of the organ and lobulus Spigelii having a straight course. The hepatic veins run singly, and are in direct contact with the hepatic tissue. They are destitute of valves.

Portal System of Veins

The portal venous system is composed of four large veins which collect the venous blood from the viscera of digestion. The trunk formed by their union (*vena portæ*) enters the liver and ramifies throughout its substance; and its branches, again emerging from that organ as the hepatic veins, terminate in the inferior vena cava. The branches in this vein are in all cases single, and destitute of valves.

The veins forming the portal system are, the

Superior Mesenteric.	Inferior Mesenteric.
Splenic.	Gastric.

The **superior mesenteric vein** returns the blood from the small intestines, and from the cæcum and ascending and transverse portions of the colon, corresponding with the distribution of the branches of the superior mesenteric artery. The large trunk formed by the union of these branches ascends along the right side and in front of the corresponding artery, passes in front of the transverse portion of the duodenum, and unites, behind the upper border of the pancreas, with the splenic vein to form the vena portæ. It receives the right gastro-epiploic vein.

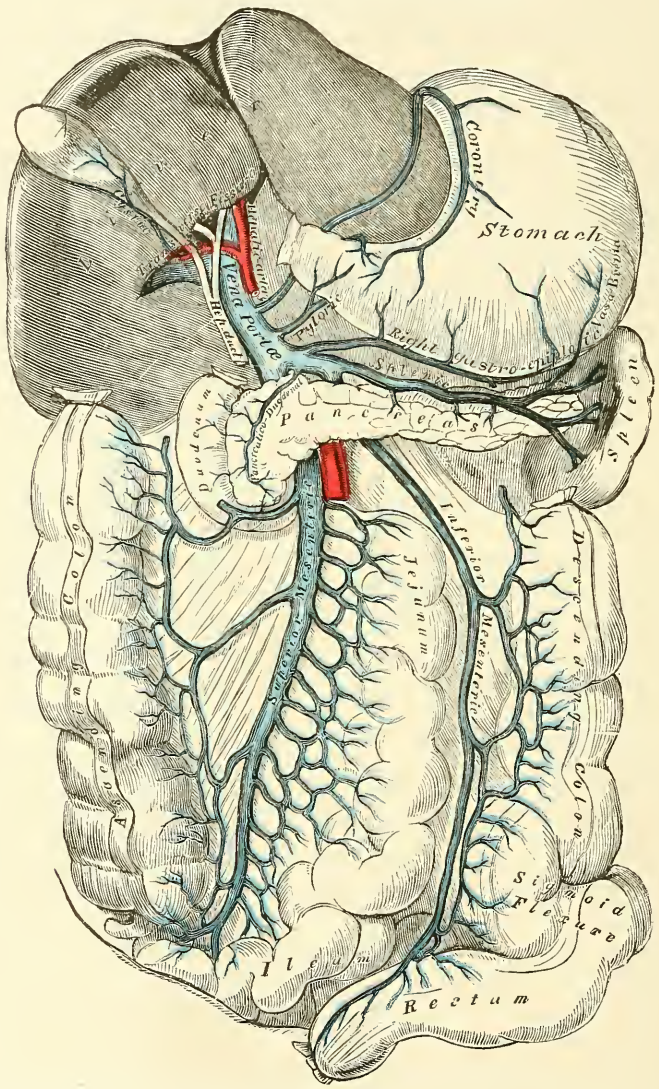
The **splenic vein** commences by five or six large branches, which return the blood from the substance of the spleen. These uniting form a single vessel, which passes from left to right, grooving the upper and back part of the pancreas, below the artery, and terminates at its greater end by uniting at a right angle with the superior mesenteric to form the vena portæ. The splenic vein is of large size, and not tortuous like the artery. It receives the vasa brevia from the left extremity of the stomach, the left gastro-epiploic vein, pancreatic branches from the pancreas, the pancreatico-duodenal vein, and the inferior mesentric vein.

The **inferior mesenteric vein** returns the blood from the rectum, sigmoid flexure, and descending colon, corresponding with the ramifications of the

* The student may observe that all veins above the Diaphragm, which do not lie on the same plane as the arteries which they accompany, lie in front of them: and that all veins below the Diaphragm, which do not lie on the same plane as the arteries which they accompany, lie behind them, except the renal and profunda femoris vein.

branches of the inferior mesenteric artery. Ascending beneath the peritoneum in the lumbar region, it passes behind the transverse portion of the duodenum and pancreas, and terminates in the splenic vein. Its hæmorrhoidal branches inosculate with those of the internal iliac, and thus establish a communication between the portal and the general venous system.*

Fig. 436.—Portal vein and its branches.



Note.—In this diagram the right gastro-epiploic vein opens into the splenic vein; generally it empties itself into the superior mesenteric, close to its termination.

The **gastric veins** are two in number: one, a small vein, corresponds to the pyloric branch of the hepatic artery; the other, considerably larger, corresponds

* Besides this anastomosis between the portal vein and the branches of the vena cava other anastomoses between the portal and systemic veins are formed by the communication between the gastric veins and the œsophageal veins which empty themselves into the vena azygos minor; between the left renal vein and the veins of the intestines, especially of the colon and duodenum; between the veins of the round ligament of the liver and the portal veins; and between the superficial branches of the portal veins of the liver and the phrenic veins, as pointed out by Mr. Kiernan. (See *Physiological Anatomy*, by Todd and Bowman, 1859, vol. ii. p. 348.)

to the gastric artery. The former (*pyloric*, Walsham) runs along the lesser curvature of the stomach towards the pyloric end, receives branches from the pylorus and duodenum, and ends in the vena portæ. The latter (*coronary*, Walsham) begins near the pylorus, runs along the lesser curvature of the stomach, towards the œsophageal opening, and then curves downwards and backwards between the folds of the lesser omentum to end in the vena portæ.

The **Portal Vein** is formed by the junction of the superior mesenteric and splenic veins, their union taking place in front of the vena cava, and behind the upper border of the great end of the pancreas. Passing upwards through the right border of the lesser omentum to the under surface of the liver, it enters the transverse fissure, where it is somewhat enlarged, forming the *sinus* of the portal vein, and divides into two branches, which accompany the ramifications of the hepatic artery and hepatic duct throughout the substance of the liver. Of these two branches the right is the larger, but the shorter, of the two. The portal vein is about three or four inches in length, and, whilst contained in the lesser omentum, lies behind and between the hepatic duct and artery, the former being to the right, the latter to the left. These structures are accompanied by filaments of the hepatic plexus of nerves, and numerous lymphatics, surrounded by a quantity of loose areolar tissue (*capsule of Glisson*), and placed between the layers of the lesser omentum. The vena portæ receives the gastric and cystic veins: the latter vein sometimes terminates in the right branch of the vena portæ. Within the liver, the portal vein receives the blood from the branches of the hepatic artery.

Cardiac Veins

The veins which return the blood from the substance of the heart are, the

Anterior Cardiac Vein.	Right Cardiac Veins.
Posterior Cardiac Vein.	Right or Small Coronary Sinus.
Left Cardiac Veins.	Left or Great Coronary Sinus.

Venæ Thebesii.

The **Anterior Cardiac Vein** (sometimes called *Great Cardiac Vein*) is a vessel of considerable size, which commences at the apex of the heart, and ascends along the anterior interventricular groove to the base of the ventricles. It then curves to the left side, around the auriculo-ventricular groove, between the left auricle and ventricle, to the back part of the heart, and opens into the great coronary sinus, its aperture being guarded by two valves. It receives, in its course, tributaries from both ventricles, but especially the left, and also from the left auricle; one of these, ascending along the thick margin of the left ventricle, is of considerable size. The vessels joining it are provided with valves.

The **Posterior Cardiac Vein** commences by small tributaries, at the apex of the heart, communicating with those of the preceding. It ascends along the posterior interventricular groove to the base of the heart, and terminates in the great coronary sinus, its orifice being guarded by a valve. It receives the veins from the posterior surface of both ventricles.

The **Left Cardiac Veins** are three or four small vessels, which collect the blood from the posterior surface of the left ventricle, and open into the lower border of the great coronary sinus.

The **Right Cardiac Veins** are three or four small vessels, which collect the blood from the anterior surface of the right ventricle. One of these (the *vein of Galen*), larger than the rest, runs along the right border of the heart. They open separately into the lower part of the right auricle.

The **Right** or **Small Coronary Sinus** runs along the groove between the right auricle and ventricle, to open into the right extremity of the great coronary sinus. It receives blood from the back part of the right auricle and ventricle.

The **Left** or **Great Coronary Sinus** is that portion of the anterior cardiac vein which is situated in the posterior part of the left auriculo-ventricular groove. It

is about an inch in length, presents a considerable dilatation, and is covered by the muscular fibres of the left auricle. It receives the veins enumerated above, and an *oblique vein* from the back part of the left auricle, the remnant of the obliterated left innominate trunk of the fœtus, described by Mr. Marshall. The great coronary sinus terminates in the right auricle, between the inferior vena cava and the auriculo-ventricular aperture, its orifice being guarded by a semilunar fold of the lining membrane of the heart, the *coronary valve*. All the veins joining this vessel, excepting the oblique vein above mentioned, are provided with valves.

The **Venæ Thebesii** are numerous minute veins, which return the blood directly from the muscular substance, without entering the venous current. They open by minute orifices (*foramina Thebesii*) on the inner surface of the right auricle.

OF THE LYMPHATICS

THE Lymphatics have derived their name from the appearance of the fluid contained in their interior (*lympha*, water). They are also called *absorbents*, from the property they possess of absorbing certain materials from the tissues and conveying them into the circulation.

The lymphatic system includes not only the lymphatic vessels and the glands through which they pass, but also the *lacteal* or *chyliferous vessels*. The lacteals are the lymphatic vessels of the small intestine, and differ in no respect from the lymphatics generally, excepting that they contain a milk-white fluid, the *chyle*, during the process of digestion, and convey it into the blood through the thoracic duct.

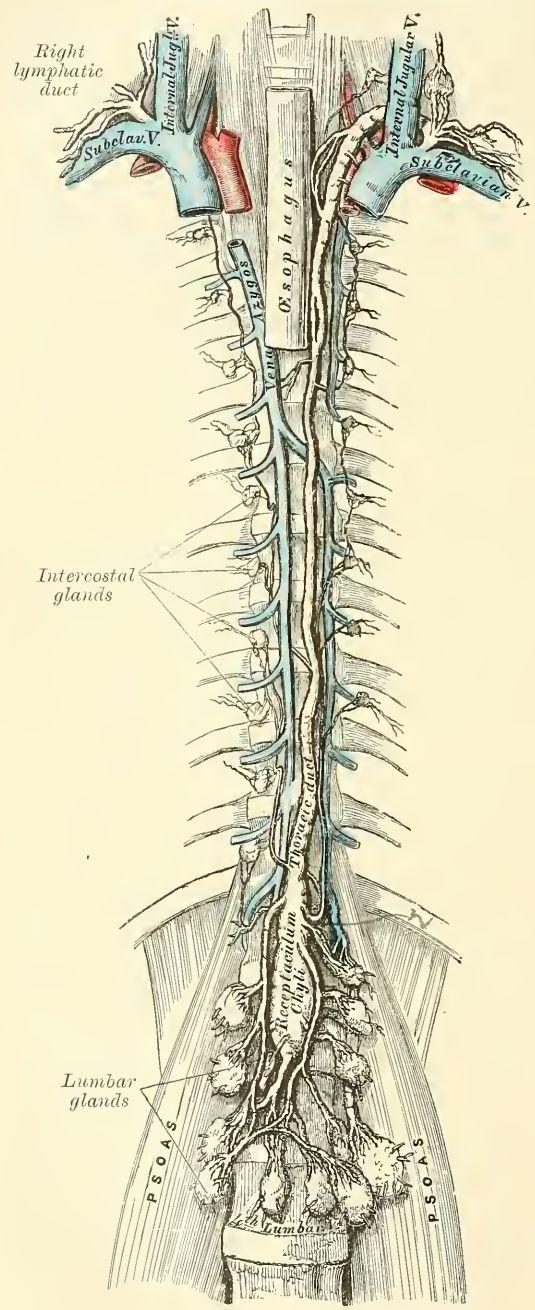
The lymphatics are exceedingly delicate vessels, the coats of which are so transparent that the fluid they contain is readily seen through them. They retain a nearly uniform size, being interrupted at intervals by constrictions, which give them a knotted or beaded appearance. These constrictions are due to the presence of valves in their interior. Lymphatics have been found in nearly every texture and organ of the body which contain blood-vessels. Such non-vascular structures as cartilage, the nails, cuticle, and hair have none, but with these exceptions it is probable that eventually all parts will be found to be permeated by these vessels.

The lymphatics are arranged into a superficial and deep set. The superficial lymphatics, on the surface of the body, are placed immediately beneath the integument, accompanying the superficial veins; they join the deep lymphatics in certain situations by perforating the deep fascia. In the interior of the body they lie in the submucous areolar tissue, throughout the whole length of the gastro-pulmonary and genito-urinary tracts; and in the subserous tissue in the cranial, thoracic, and abdominal cavities. The method of their origin has been described along with the other details of their minute anatomy (page 58). Here it will be sufficient to say that a plexiform network of minute lymphatics may be found interspersed among the proper elements and blood-vessels of the several tissues; the vessels composing which, as well as the meshes between them, are much larger than those of the capillary plexus. From these networks small vessels emerge, which pass, either to a neighbouring gland, or to join some larger lymphatic trunk. The deep lymphatics, fewer in number, and larger than the superficial, accompany the deep blood-vessels. Their mode of origin is probably similar to that of the superficial vessels. The lymphatics of any part or organ exceed the veins in number, but in size they are much smaller. Their anastomoses also, especially those of the large trunks, are more frequent, and are effected by vessels equal in diameter to those which they connect, the continuous trunks retaining the same diameter.

The **lymphatic** or **absorbent glands**, named also *conglobate glands*, are small, solid, glandular bodies, situated in the course of the lymphatic and lacteal vessels. In size they vary from a hemp-seed to an almond, and their colour, on section, is of a pinkish-grey tint, excepting the bronchial glands, which in the adult are mottled with black. Each gland has a layer or capsule of cellular tissue investing it, from which prolongations dip into its substance, forming partitions. The

lymphatic and lacteal vessels pass through these bodies in their passage to the thoracic and lymphatic ducts. A lymphatic or lacteal vessel, previous to entering a gland, divides into several small branches, which are named *afferent vessels*. As they enter, their external coat becomes continuous with the capsule of the gland, and the vessels, much thinned, and consisting only of their internal or endothelial coat, pass into the gland, and branch out upon and in the tissue of the capsule; these branches opening into the lymph sinuses of the gland. From these sinuses fine branches proceed to form a plexus, the vessels of which unite to form a single *efferent vessel*, which, on emerging from the gland, is again invested with an external coat. Further details on the minute anatomy of the lymphatic vessels and glands will be found in the chapter on General Anatomy.

Fig. 437.—The thoracic and right lymphatic duct.



Thoracic Duct

The **thoracic duct** (fig. 437) conveys the great mass of the lymph and chyle into the blood. It is the common trunk of all the lymphatic vessels of the body, excepting those of the right side of the head, neck, and thorax, and right upper extremity, the right lung, right side of the heart, and the convex surface of the liver. It varies in length from fifteen to eighteen inches in the adult, and extends from the second lumbar vertebra to the root of the neck. It commences in the abdomen by a triangular dilatation, the *receptaculum chyli* (*reservoir* or *cistern of Pecquet*), which is situated upon the front of the body of the second lumbar vertebra, to the right side and behind the aorta, by the side of the right crus of the Diaphragm. It ascends into the thorax through the aortic opening in the Diaphragm, lying to the right of the aorta, and is placed in the posterior mediastinum in front of the vertebral column, lying between the aorta and vena azygos major. Opposite the fourth dorsal vertebra, it inclines towards the left side and ascends behind the

arch of the aorta, on the left side of the œsophagus, and behind the first portion of the left subclavian artery to the upper orifice of the thorax. Opposite the seventh cervical vertebra, it turns outwards, and then curves downwards over the subclavian artery, and in front of the Scalenus anticus muscle, so as to form an arch; and terminates in the left subclavian vein, at its angle of junction with the left internal jugular vein. The thoracic duct, at its commencement, is about equal in size to the diameter of a goose-quill, diminishes considerably in its calibre in the middle of the thorax, and is again dilated just before its termination. It is generally flexuous in its course, and constricted at intervals so as to present a varicose appearance. The thoracic duct not unfrequently divides in the middle of its course into two branches of unequal size, which soon reunite, or into several branches which form a plexiform interlacement. It occasionally divides, at its upper part, into two branches, of which the one on the left side terminates in the usual manner, while that on the right opens into the right subclavian vein, in connection with the right lymphatic duct. The thoracic duct has numerous valves throughout its whole course, but they are more numerous in the upper than in the lower part: at its termination it is provided with a pair of valves, the free borders of which are turned towards the vein, so as to prevent the passage of venous blood into the duct.

Tributaries.—The thoracic duct, at its commencement, receives four or five large trunks from the abdominal lymphatic glands, and also the trunk of the lacteal vessels. Within the thorax, it is joined by the lymphatic vessels from the left half of the wall of the thoracic cavity, the lymphatics from the sternal and intercostal glands, those of the left lung, left side of the heart, trachea, and œsophagus; and, just before its termination, it receives the lymphatics of the left side of the head and neck, and left upper extremity.

Structure (fig. 63).—The thoracic duct is composed of three coats, which differ in some respects from those of the lymphatic vessels. The *internal coat* consists of a single layer of flattened lanceolate-shaped endothelial cells, with serrated borders; of a subendothelial layer similar to that found in the arteries; and an elastic fibrous coat, the fibres of which run in a longitudinal direction. The *middle coat* consists of a longitudinal layer of white connective tissue with elastic fibres, external to which are several laminæ of muscular tissue, the fibres of which are for the most part disposed transversely, but some are oblique or longitudinal, and intermixed with elastic fibres. The *external coat* is composed of areolar tissue, with elastic fibres and isolated fasciculi of muscular fibres.

The **Right Lymphatic Duct** is a short trunk, about half an inch in length, and a line or a line and a half in diameter. It terminates in the right subclavian vein, at its angle of junction with the right internal jugular vein. Its orifice is guarded by two semilunar valves, which prevent the passage of venous blood into the duct.

Tributaries.—It receives the lymph from the right side of the head and neck, the right upper extremity, the right side of the thorax, the right lung and right side of the heart, and from part of the convex surface of the liver.

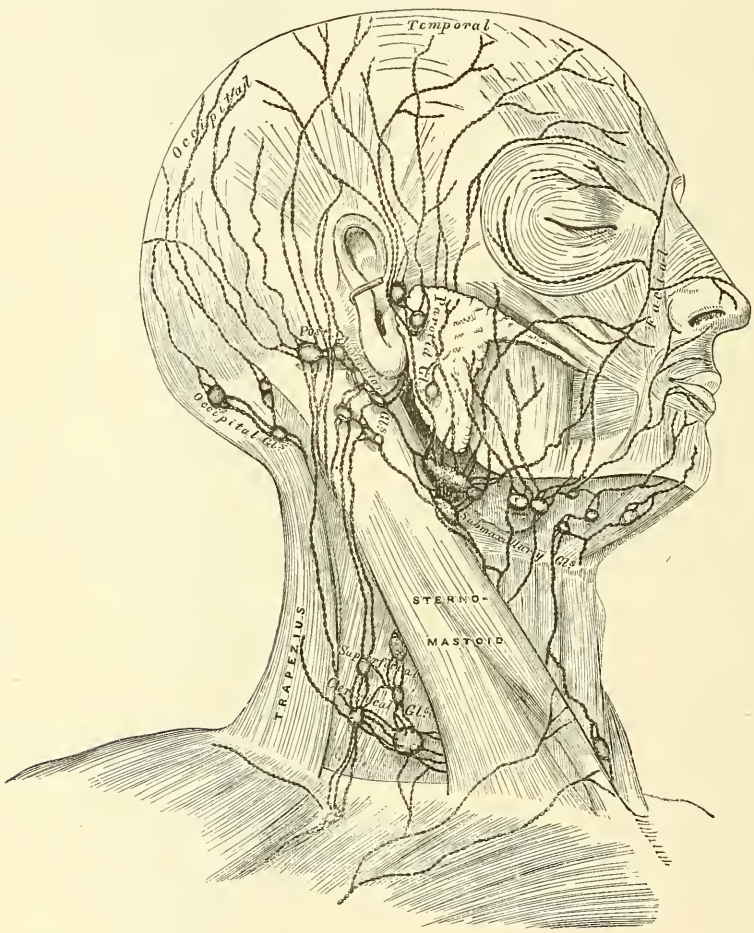
Lymphatics of the Head, Face, and Neck

The **Lymphatic Glands of the Head** (fig. 438) are of small size, few in number, and confined to its posterior region. They are the *occipital*, and *posterior auricular*. The *occipital* are placed at the back of the head along the attachment of the Occipito-frontalis muscle. The *posterior auricular* are placed near the upper end of the Sterno-mastoid muscle. Both these sets of glands are affected in cutaneous eruptions and other diseases of the scalp. In the face, the superficial lymphatic glands are more numerous: they are the *parotid*, some of which are superficial and others deeply placed in the substance of the parotid gland; the *zygomatic*, situated under the zygoma; the *buccal*, on the surface of the Buccinator muscle; and the *internal maxillary*, the largest, beneath the ramus of the lower jaw.

The **lymphatic vessels of the scalp** are divided into an *anterior* and a *posterior set*, which follow the course of the temporal and occipital vessels. The *temporal* accompany the temporal artery in front of the ear, to the parotid lymphatic glands, from which they proceed to the lymphatic glands of the neck. The *occipital* follow the course of the occipital artery, descend to the occipital and posterior auricular lymphatic glands, and from thence join the cervical glands.

The **Lymphatic Vessels of the Face** are divided into two sets, *superficial* and *deep*.

Fig. 438.—The superficial lymphatics and glands of the head, face, and neck.

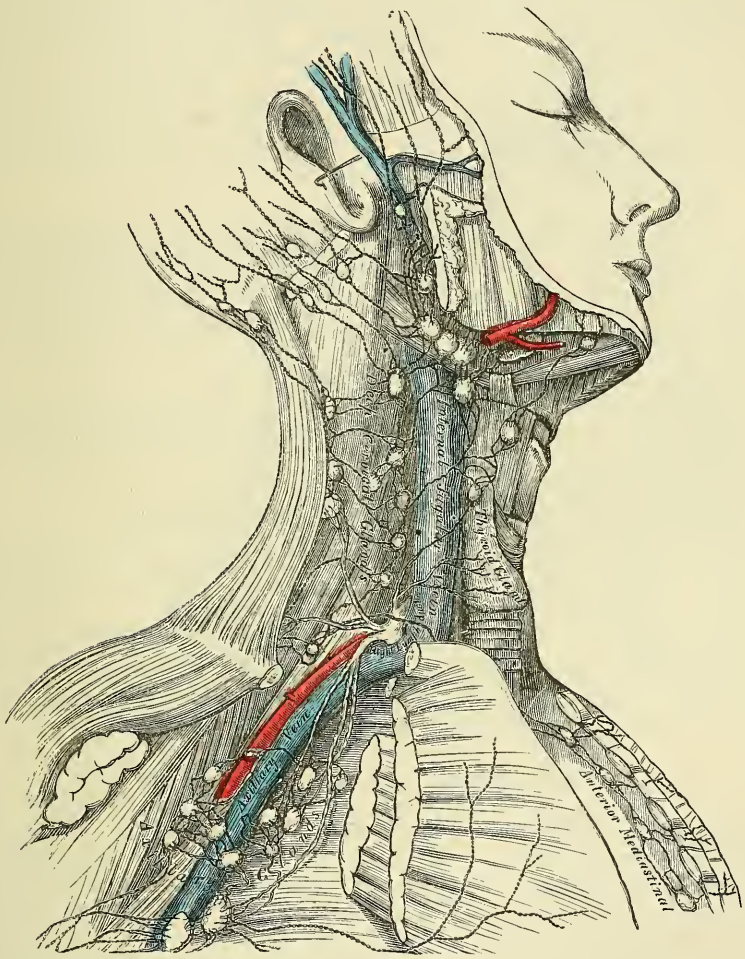


The **superficial lymphatic vessels of the face** are more numerous than those of the head, and commence over its entire surface. Those from the frontal region accompany the frontal vessels; they then pass obliquely across the face, running with the facial vein, pass through the buccal glands on the surface of the Buccinator muscle, and join the submaxillary lymphatic glands. The latter receive the lymphatic vessels from the lips, and are often found enlarged in cases of malignant disease of those parts.

The **deep lymphatic vessels of the face** are derived from the pituitary membrane of the nose, the mucous membrane of the mouth and pharynx, and the contents of the temporal and orbital fossæ; they accompany the branches of the internal maxillary artery, and terminate in the internal maxillary and cervical lymphatic glands.

The **lymphatic vessels of the cranium** consist of two sets, the *meningeal* and *cerebral*. The *meningeal lymphatics* accompany the meningeal vessels, escape through foramina at the base of the skull, and join the deep cervical lymphatic glands. The *cerebral lymphatics* are described by Eshmann as being situated between the arachnoid and pia mater, as well as in the choroid plexuses of the lateral ventricles ; they accompany the trunks of the carotid and vertebral arteries, and probably pass through foramina at the base of the skull, to terminate in the deep cervical glands. They have not at present been demonstrated in the dura mater, or in the substance of the brain.

Fig. 439.—The deep lymphatics and glands of the neck and thorax.



The **Lymphatic Glands of the Neck** are divided into two sets, *superficial* and *deep*.

The **superficial cervical glands** may be arranged in three sets :—(1) The *submaxillary*, ten to fifteen in number, situated beneath the body of the lower jaw in the submaxillary triangle ; (2) *suprahyoid*, situated in the middle line of the neck, between the anterior bellies of the two digastric muscles ; and (3) *cervical*, placed in the course of the external jugular vein between the Platysma and deep fascia. They are most numerous at the root of the neck, in the triangular interval between the clavicle, the Sterno-mastoid, and the Trapezius, where they are continuous with the axillary glands. A few small glands are also found on the front and sides of the larynx.

The **deep cervical glands** (fig. 439) are numerous and of large size ; they form a chain along the sheath of the carotid artery and internal jugular vein, lying by the side of the pharynx, œsophagus, and trachea, and extending from the base of the skull to the thorax, where they communicate with the lymphatic glands in that cavity. They are subdivided into two sets : an *upper*, ten to twenty in number, situated about the bifurcation of the common carotid and along the upper part of the internal jugular vein ; and a *lower*, ten to fifteen in number, clustered around the lower part of the internal jugular vein, and extending outwards into the supra-clavicular fossa, where they are continuous with the axillary glands. Internally, this set is continuous with the mediastinal glands.

The **superficial** and **deep cervical lymphatic vessels** are a continuation of those already described on the cranium and face. After traversing the glands in those regions, they pass through the chain of glands which lie along the sheath of the carotid vessels, being joined by the lymphatics from the pharynx, œsophagus, larynx, trachea, and thyroid gland. At the lower part of the neck, after receiving some lymphatics from the thorax, they unite into a single trunk, which terminates, on the left side, in the thoracic duct ; on the right side, in the right lymphatic duct.

Surgical Anatomy.—The cervical glands are very frequently the seat of tuberculous trouble. This condition is most usually set up by some lesion in those parts from which they receive their lymph. This excites some inflammation, which subsequently takes on a tuberculous character. It is very desirable therefore for the surgeon, in dealing with these cases, to possess a knowledge of the relation of the respective groups of glands to the periphery. The following table is extracted from Mr. Treves's work on ' Scrofula and its Gland Diseases.'

Scalp.—Posterior part = suboccipital and mastoid glands. Frontal and parietal portions = parotid glands.

Lymphatic vessels from the scalp also enter the superficial cervical set of glands.

Skin of face and neck = submaxillary, parotid, and superficial cervical glands.

External ear = superficial cervical glands.

Lower lip = submaxillary and suprahyoid glands.

Buccal cavity = submaxillary and upper set of deep cervical glands.

Gums of lower jaw = submaxillary glands.

Tongue.—Anterior portion = suprahyoid and submaxillary glands. Posterior portion = upper set of deep cervical glands.

Tonsils and palate = upper set of deep cervical glands.

Pharynx.—Upper part = parotid and retro-pharyngeal glands. Lower part = upper set of deep cervical glands.

Larynx, orbit, and roof of mouth = upper set of deep cervical glands.

Nasal fossæ = retro-pharyngeal glands, upper set of deep cervical glands. Some lymphatic vessels from posterior part of the fossæ enter the parotid glands.

Lymphatics of the Upper Extremity

The **Lymphatic Glands of the Upper Extremity** (fig. 440) are divided into two sets, *superficial* and *deep*.

The **superficial lymphatic glands** are few and of small size. There are occasionally two or three in front of the elbow, and one or two above the internal condyle of the humerus, near the basilic vein.

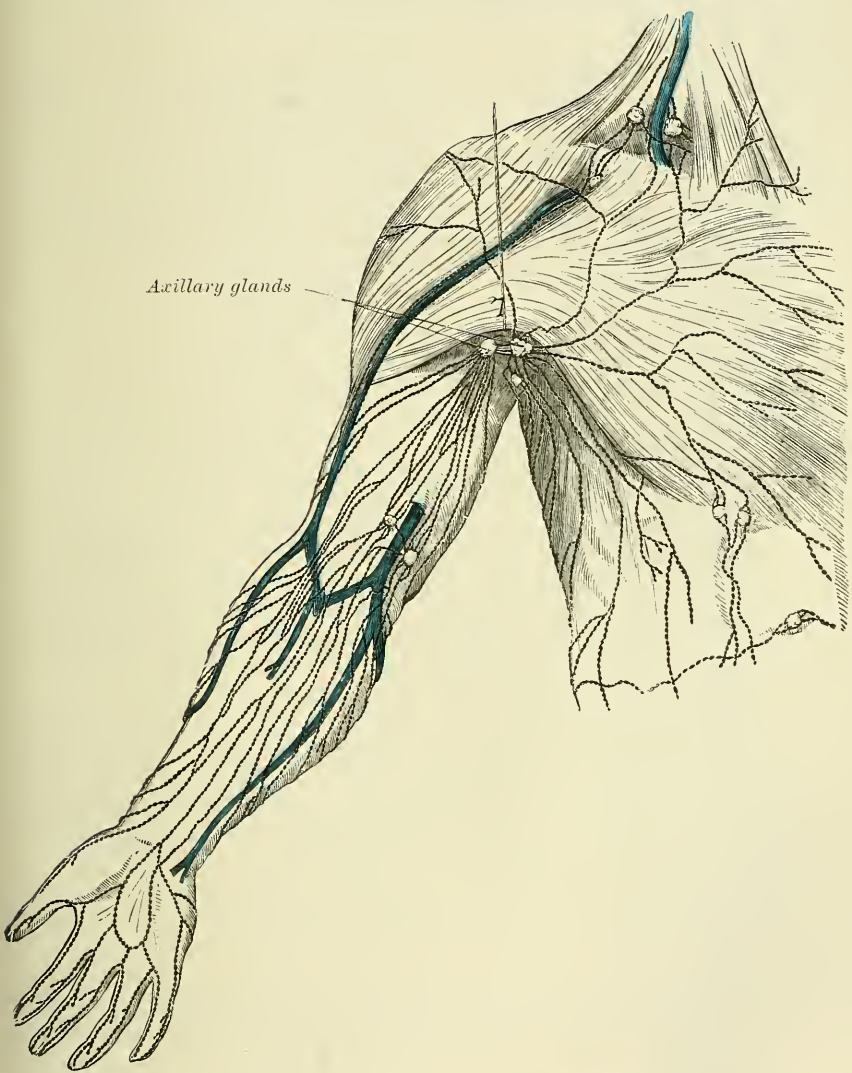
The **deep lymphatic glands** are few in number and are subdivided into those in the forearm, the arm, and the axilla. In the *forearm*, a few small ones are occasionally found in the course of the radial and ulnar vessels. In the *arm*, there is a chain of small glands along the inner side of the brachial artery. One, sometimes two, fairly constant glands are situated a little above and in front of the inner condyle of the humerus. In the *axilla* they are of large size, and usually ten or twelve in number. A chain of these glands surrounds the axillary vessels, embedded in a quantity of loose areolar tissue ; they receive the lymphatic vessels from the arm ; others are dispersed in the areolar tissue of the axilla : the remainder are arranged in two series, a small chain running along the lower border of the Pectoralis major, receiving the lymphatics from the front of the chest and mamma ; and others are placed along the lower margin of

the posterior wall of the axilla, which receive the lymphatics from the integument of the back. Two or three subclavian lymphatic glands are placed immediately beneath the clavicle; it is through these that the axillary and deep cervical glands communicate with each other.

Surgical Anatomy.—In malignant diseases, tumours, or other affections implicating the upper part of the back and shoulder, the front of the chest and mamma, the upper part of the front and side of the abdomen, or the hand, forearm, and arm, the axillary glands are liable to be found enlarged.

The **lymphatic vessels of the upper extremity** are divided into two sets, *superficial* and *deep*.

Fig. 440.—The superficial lymphatics and glands of the upper extremity.



The **superficial lymphatic vessels of the upper extremity** commence on the fingers; two vessels running along either side of each finger, one on the palmar and the other on the dorsal surface. Those on the palmar surface form an arch in the palm of the hand, from which are derived two sets of vessels, which pass up the forearm, taking the course of the subcutaneous veins. The lymphatics from the dorsal surface of the fingers form a plexus on the back of the hand,

and, winding around the inner and outer borders of the forearm, unite with those in front. Those from the inner border of the hand accompany the ulnar veins along the inner side of the forearm to the bend of the elbow, where they are joined by some lymphatics from the outer side of the forearm; they then follow the course of the basilic vein, communicate with the glands immediately above the elbow, and terminate in the axillary glands, joining with the deep lymphatics. The superficial lymphatics from the outer and back part of the hand accompany the radial veins to the bend of the elbow. They are less numerous than the preceding. At the bend of the elbow, the greater number join the basilic group; the rest ascend with the cephalic vein on the outer side of the arm, some crossing the upper part of the Biceps obliquely, to terminate in the axillary glands, whilst one or two accompany the cephalic vein in the cellular interval between the Pectoralis major and Deltoid, and enter the subclavian lymphatic glands.

The **deep lymphatic vessels of the upper extremity** accompany the deep blood-vessels. In the forearm they consist of four sets, corresponding with the radial, ulnar, and interosseous arteries; they pass through the glands occasionally found in the course of those vessels, and communicate at intervals with the superficial lymphatics. In their course upwards, some of them pass through the glands which lie upon the brachial artery; they then enter the axillary and subclavian glands, and at the root of the neck terminate, on the left side, in the thoracic duct, and on the right side in the right lymphatic duct.

Lymphatics of the Lower Extremity

The **Lymphatic Glands of the Lower Extremity** are divided into two sets, *superficial* and *deep*. The superficial are confined to the inguinal region, forming the *superficial inguinal lymphatic glands*.

The **superficial inguinal lymphatic glands**, placed immediately beneath the integument, are of large size, and vary from eight to ten in number. They are divisible into two groups: an upper *oblique* set, disposed irregularly along Poupart's ligament, which receive the lymphatic vessels from the integument of the scrotum, penis, parietes of the abdomen, perineal and gluteal regions, and the mucous membrane of the urethra; and an inferior *vertical* set, which surround the saphenous opening in the fascia lata; a few being sometimes continued along the saphenous vein to a variable extent. This latter group receive the superficial lymphatic vessels from the lower extremity.

Surgical Anatomy.—These glands frequently become enlarged in diseases implicating the parts from which their lymphatics originate. Thus in malignant or syphilitic affections of the prepuce and penis, or of the labia majora in the female, in cancer scroti, in abscess in the perinæum, or in any other diseases affecting the integument and superficial structures in those parts, or the subumbilical part of the abdominal wall, or the gluteal region, the upper chain of glands is almost invariably enlarged, the lower chain being implicated in diseases affecting the lower limb.

The **deep lymphatic glands** are, the anterior tibial, popliteal, deep inguinal, gluteal, and ischiatic.

The **anterior tibial gland** is not constant in its existence. It is generally found by the side of the anterior tibial artery, upon the interosseous membrane at the upper part of the leg. Occasionally, two glands are found in this situation.

The **popliteal glands**, four or five in number, are of small size; they surround the popliteal vessels, embedded in the cellular tissue and fat of the popliteal space.

The **deep inguinal glands** are placed beneath the deep fascia around the femoral artery and vein. They are of small size, and communicate with the superficial inguinal glands through the saphenous opening.

The **gluteal** and **ischiatic glands** are placed, the former above, the latter

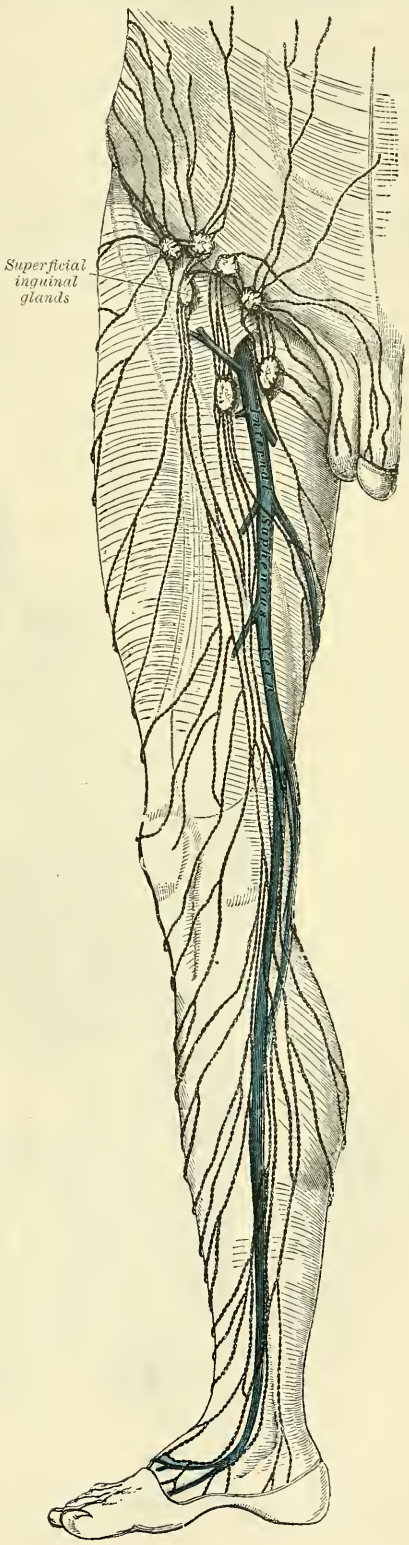
below, the Pyriformis muscle, resting on their corresponding vessels as they pass through the great sacro-sciatic foramen.

The **Lymphatic Vessels of the Lower Extremity**, like the veins, may be divided into two sets, *superficial* and *deep*.

The **superficial lymphatic vessels** are placed beneath the integument in the superficial fascia, and are divisible into two groups: an internal group, which follow the course of the internal saphenous vein; and an external group, which accompany the external saphenous. The *internal group*, the larger, commence on the inner side and dorsum of the foot; they pass, some in front, and some behind the inner ankle, run up the leg with the internal saphenous vein, pass with it behind the inner condyle of the femur, and accompany it to the groin, where they terminate in the group of superficial inguinal lymphatic glands which surround the saphenous opening. Some of the efferent vessels from these glands pierce the cribriform fascia and sheath of the femoral vessels, and terminate in a lymphatic gland contained in the femoral canal, thus establishing a communication between the lymphatics of the lower extremity and those of the trunk; others pierce the fascia lata, and join the deep inguinal glands. The *external group* arise from the outer side of the foot, ascend in front of the leg, and, just below the knee, cross the tibia from without inwards, to join the lymphatics on the inner side of the thigh. Others commence on the outer side of the foot, pass behind the outer malleolus, and accompany the external saphenous vein along the back of the leg, where they enter the popliteal glands.

The **deep lymphatic vessels of the lower extremity** are few in number, and accompany the deep blood-vessels. In the leg, they consist of three sets, the anterior tibial, peroneal, and posterior tibial, which accompany the corresponding blood-vessels, two or three to each artery; they ascend with the blood-vessels, and enter the lymphatic glands in the popliteal

Fig. 441.—The superficial lymphatics and glands of the lower extremity.



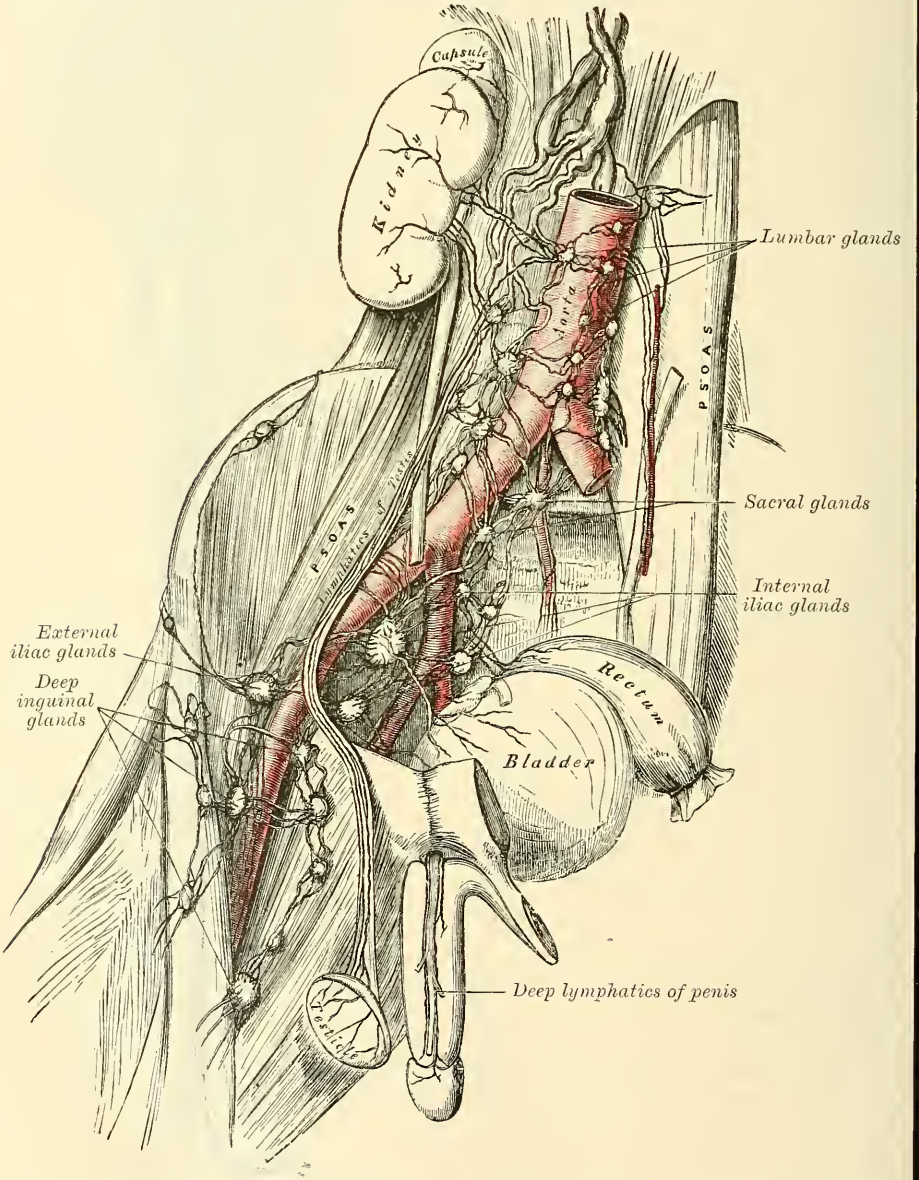
space; the efferent vessels from these glands accompany the femoral vein, and join the deep inguinal glands; from these, the vessels pass beneath Poupart's ligament, and communicate with the chain of glands surrounding the external iliac vessels.

The deep lymphatic vessels of the gluteal and ischiatic regions follow the course of the blood-vessels, and join the gluteal and ischiatic glands at the great sacro-sciatic foramen.

Lymphatics of the Pelvis and Abdomen

The **Lymphatic Glands in the Pelvis** are, the external iliac, the internal iliac, and the sacral. Those of the abdomen are the lumbar glands.

Fig. 442.—The deep lymphatic vessels and glands of the abdomen and pelvis.



The **external iliac glands** form an uninterrupted chain round the external iliac vessels, three being placed round the commencement of the vessels just

behind the crural arch. They communicate below with the deep inguinal lymphatic glands, and above with the lumbar glands.

The **internal iliac glands** surround the internal iliac vessels; they receive the lymphatic vessels corresponding to the branches of the internal iliac artery, and communicate with the lumbar glands.

The **sacral glands** occupy the sides of the anterior surface of the sacrum, some being situated in the meso-rectal fold. These and the internal iliac glands are affected in malignant disease of the bladder, rectum, or uterus.

The **lumbar glands** are very numerous; they are situated on the front of the lumbar vertebræ, surrounding the common iliac vessels, the aorta, and vena cava; they receive the lymphatic vessels from the lower extremities and pelvis, as well as from the testes and some of the abdominal viscera; the efferent vessels from these glands unite into a few large trunks, which, with the lacteals, form the commencement of the thoracic duct. In addition to these there are a few small *lateral lumbar glands*, which lie between the transverse processes of the vertebræ, behind the Psoas muscle, and receive lymphatics from the back. In some cases of malignant disease these glands become enormously enlarged, completely surrounding the aorta and vena cava, and occasionally greatly contracting the calibre of those vessels. In all cases of malignant disease of the testis, and in malignant disease of the lower limb, before any operation is attempted, careful examination of the abdomen should be made, in order to ascertain if any enlargement exists; and if any should be detected, all operative measures should be avoided as fruitless.

The **Lymphatic Vessels of the Abdomen and Pelvis** may be divided into two sets, *superficial* and *deep*.

The **superficial lymphatic vessels of the walls of the abdomen and pelvis** follow the course of the superficial blood-vessels. Those derived from the integument of the lower part of the abdomen below the umbilicus follow the course of the superficial epigastric vessels and converge to the superior group of the superficial inguinal glands; a deeper set accompany the deep epigastric vessels, and communicate with the external iliac glands. The superficial lymphatics from the sides of the lumbar part of the abdominal wall wind round the crest of the ilium, accompanying the superficial circumflex iliac vessels, to join the superior group of the superficial inguinal glands; the greater number, however, run backwards along with the ilio-lumbar and lumbar vessels, to join the lateral lumbar glands.

The **superficial lymphatic vessels of the gluteal region** turn horizontally round the outer side of the nates, and join the superficial inguinal glands.

The **superficial lymphatic vessels of the scrotum and perinæum** follow the course of the external pudic vessels, and terminate in the superficial inguinal glands.

The **superficial lymphatic vessels of the penis** occupy the sides and dorsum of the organ, the latter receiving the lymphatics from the skin covering the glans penis; they all converge to the upper chain of the superficial inguinal glands. The **deep lymphatic vessels of the penis** follow the course of the internal pudic vessels, and join the internal iliac glands.

In the female, the lymphatic vessels of the mucous membrane of the labia, nymphæ, and clitoris terminate in the upper chain of the inguinal glands.

The **deep lymphatic vessels of the abdomen and pelvis** take the course of the principal blood-vessels. Those of the parietes of the pelvis, which accompany the gluteal, ischiatic, and obturator vessels, follow the course of the internal iliac artery, and ultimately join the lumbar lymphatics.

The efferent vessels from the inguinal glands enter the pelvis beneath Poupart's ligament, where they lie in close relation with the femoral vein; they then pass through the chain of glands surrounding the external iliac vessels, and finally terminate in the lumbar glands. They receive the deep epigastric and circumflex iliac lymphatics.

The **lymphatic vessels of the bladder** arise from the entire surface of the organ *; the greater number run beneath the peritoneum on its posterior surface and, after passing through the lymphatic glands in that situation, join with the lymphatics from the prostate and vesiculæ seminales, and enter the internal iliac glands.

The **lymphatic vessels of the rectum** are of large size; after passing through some small glands that lie upon its outer wall and in the meso-rectum, they pass to the sacral glands.

The **lymphatic vessels of the uterus** consist of two sets, *superficial* and *deep*; the former being placed beneath the peritoneum, the latter in the substance of the organ. The lymphatics of the cervix uteri, together with those from the vagina, enter the internal iliac and sacral glands; those from the body and fundus of the uterus pass outwards in the broad ligaments, and, being joined by the lymphatics from the ovaries, broad ligaments, and Fallopian tubes, ascend with the ovarian vessels to open into the lumbar glands. In the unimpregnated uterus they are small; but during gestation they become very greatly enlarged.

The **lymphatic vessels of the testicle** consist of two sets, *superficial* and *deep*; the former commence on the surface of the tunica vaginalis, the latter in the epididymis and body of the testis. They form several large trunks, which ascend with the spermatic cord, and, accompanying the spermatic vessels into the abdomen, terminate in the lumbar glands; hence the enlargement of these glands in malignant disease of the testis.

The **lymphatic vessels of the kidney** arise on the surface, and also in the interior of the organ; they join at the hilum, and, after receiving the lymphatic vessels from the ureter and suprarenal capsules, open into the lumbar glands.

The **lymphatic vessels of the liver** are divisible into two sets, *superficial* and *deep*. The former arise in the subperitoneal areolar tissue over the entire surface of the organ. Those on the convex surface may be divided into four groups:—1. Those which pass from behind forwards, consisting of three or four branches, which ascend in the longitudinal ligament, and unite to form a single trunk, which passes up between the fibres of the Diaphragm, behind the ensiform cartilage, to enter the anterior mediastinal glands, and finally ascends to the root of the neck, to terminate in the right lymphatic duct. 2. Another group, which also incline from behind forwards, are reflected over the anterior margin of the liver, to its under surface, and from thence pass along the longitudinal fissure to the glands in the gastro-hepatic omentum. 3. A third group incline outwards to the right lateral ligament, and, uniting into one or two large trunks, pierce the Diaphragm, and run along its upper surface to enter the anterior mediastinal glands; or, instead of entering the thorax, turn inwards across the crus of the Diaphragm, and open into the commencement of the thoracic duct. 4. The fourth group incline outwards from the surface of the left lobe of the liver to the left lateral ligament, pierce the Diaphragm, and, passing forwards, terminate in the glands in the anterior mediastinum.

The *superficial lymphatics on the under surface of the liver* are divided into three sets:—1. Those on the right side of the gall-bladder enter the lumbar glands. 2. Those surrounding the gall-bladder form a remarkable plexus; they accompany the hepatic vessels, and open into the glands in the gastro-hepatic omentum. 3. Those on the left of the gall-bladder pass to the œsophageal glands, and to the glands which are situated along the lesser curvature of the stomach.

The *deep lymphatics* accompany the branches of the portal vein and the hepatic artery and duct through the substance of the liver; passing out at the transverse fissure, they enter the lymphatic glands along the lesser curvature of the stomach and behind the pancreas, or join with one of the lacteal vessels previous to its termination in the thoracic duct.

* Curnow states that they are confined to the base of the organ.

The **lymphatic glands of the stomach** are of small size ; they are placed along the lesser and greater curvatures, some within the gastro-splenic omentum, whilst others surround the cardiac and pyloric orifices.

The **lymphatic vessels of the stomach** consist of two sets, *superficial* and *deep* ; the former originating in the subserous, and the latter in the submucous coat. They follow the course of the blood-vessels, and may consequently be arranged into three groups. The *first group* accompany the gastric vessels along the lesser curvature, receiving branches from both surfaces of the organ, and pass to the glands around the pylorus. The *second group* pass from the great end of the stomach, accompanying the vasa brevia, and enter the splenic lymphatic glands. The *third group* run along the greater curvature with the right gastro-epiploic vessels, and terminate at the root of the mesentery in one of the principal lacteal vessels.

The **lymphatic glands of the spleen** occupy the hilum. Its *lymphatic vessels* consist of two sets, superficial and deep ; the former are placed beneath its peritoneal covering, the latter in the substance of the organ ; they accompany the blood-vessels, passing through a series of small glands, and, after receiving the lymphatics from the pancreas, ultimately pass into the thoracic duct.

The Lymphatic System of the Intestines

The **lymphatic glands of the small intestine** are placed between the layers of the mesentery, occupying the meshes formed by the superior mesenteric vessels, and hence called *mesenteric glands*. They vary in number from a hundred to a hundred and fifty ; and in size, from that of a pea to that of a small almond. These glands are most numerous, and largest above, near the duodenum, and below, opposite the termination of the ileum in the colon. This latter group becomes enlarged and infiltrated with deposit in cases of fever accompanied with ulceration of the intestines.

The **lymphatic glands of the large intestine** are much less numerous than the mesenteric glands ; they are situated along the vascular arches formed by the arteries previous to their distribution, and even sometimes upon the intestine itself. They are fewest in number along the transverse colon, where they form an uninterrupted chain with the mesenteric glands.

The **lymphatic vessels of the small intestine** are called **lacteals** from the milk-white fluid they usually contain ; they consist of two sets, superficial and deep : the former lie between the layers of the muscular coat and between the muscular and peritoneal coats, taking a longitudinal course along the outer side of the intestine ; the latter occupy the submucous tissue, and course transversely round the intestine, accompanied by the branches of the mesenteric vessels ; they pass between the layers of the mesentery, enter the mesenteric glands, and finally unite to form two or three large trunks which terminate in the thoracic duct.

The **lymphatic vessels of the large intestine** consist of two sets : those of the cæcum, ascending and transverse colon, which after passing through their proper glands, enter the mesenteric glands ; and those of the descending colon, sigmoid flexure, and rectum, which pass to the lumbar glands.

The Lymphatics of the Thorax

The **Lymphatic Glands of the Thoracic Wall** are, the intercostal, internal mammary, anterior mediastinal, and posterior mediastinal.

The **intercostal glands** are small, irregular in number, and situated on each side of the spine, near the costo-vertebral articulations, some being placed between the two planes of intercostal muscles.

The **internal mammary glands** are placed at the anterior extremity of each intercostal space, by the side of the internal mammary vessels.

The **anterior mediastinal glands** are placed in the loose areolar tissue of the anterior mediastinum, some lying upon the Diaphragm in front of the pericardium, and others round the great vessels at the base of the heart.

The **posterior mediastinal glands** are situated in the areolar tissue in the posterior mediastinum, forming a continuous chain by the side of the aorta and œsophagus; they communicate on each side with the intercostal, below with the lumbar, and above with the deep cervical glands.

The **Superficial Lymphatic Vessels of the Front of the Thorax** run across the great Pectoral muscle, and those on the back part of this cavity lie upon the Trapezius and Latissimus dorsi; they all converge to the axillary glands. The lymphatics from the greater part of the mammary gland pass outwards to the lower border of the Pectoralis major muscle, where they enter a chain of small glands, situated in the axillary space along the lower border of its anterior boundary. Some few lymphatics from the inner side of the mammary gland pass through the intercostal spaces to reach the anterior mediastinal glands.

The **Deep Lymphatic Vessels of the Thoracic Wall** are, the intercostal, internal mammary, and diaphragmatic.

The **intercostal lymphatic vessels** follow the course of the intercostal vessels, receiving lymphatics from the intercostal muscles and pleura; they pass backwards to the spine, and unite with lymphatics from the back part of the thorax and spinal canal. After traversing the intercostal glands, they pass down the spine, and terminate in the thoracic duct.

The **internal mammary lymphatic vessels** follow the course of the internal mammary vessels; they commence in the muscles of the abdomen above the umbilicus, communicating with the epigastric lymphatics, ascend between the fibres of the Diaphragm at its attachment to the ensiform appendix, and in their course behind the costal cartilages are joined by the intercostal lymphatics; they terminate on the right side in the right lymphatic duct, on the left side in the thoracic duct.

The **lymphatic vessels of the Diaphragm** follow the course of their corresponding vessels, and terminate, some in front in the anterior mediastinal and internal mammary glands, some behind in the intercostal and posterior mediastinal lymphatics.

The **Lymphatic Glands of the Viscera of the Thorax** are the bronchial glands.

The **bronchial glands** are situated round the bifurcation of the trachea and roots of the lungs. They are ten or twelve in number, the largest being placed opposite the bifurcation of the trachea, the smallest round the bronchi and their primary divisions for some little distance within the substance of the lungs. In infancy they present the same appearance as lymphatic glands in other situations; in the adult they assume a brownish tinge, and in old age a deep black colour. Occasionally, they become sufficiently enlarged to compress and narrow the canal of the bronchi; and they are often the seat of tubercle or cretaceous deposits.

The **lymphatic vessels of the lung** consist of two sets, *superficial* and *deep*: the former are placed beneath the pleura, forming a minute plexus, which covers the outer surface of the lung; the latter accompany the blood-vessels, and run along the bronchi: they both terminate at the root of the lungs in the bronchial glands. The efferent vessels from these glands, two or three in number, ascend upon the trachea to the root of the neck, traverse the tracheal and œsophageal glands, and terminate on the left side in the thoracic duct, and on the right side in the right lymphatic duct.

The **cardiac lymphatic vessels** consist of two sets, *superficial* and *deep*: the former arise in the subserous areolar tissue of the surface, and the latter in the deeper tissues of the heart. They follow the course of the coronary vessels: those of the right side unite into a trunk at the root of the aorta, which, ascending across the arch of that vessel, passes backwards to the trachea, upon which it ascends, to terminate at the root of the neck in the right lymphatic duct. Those

of the left side unite into a single vessel at the base of the heart, which, passing along the pulmonary artery, and traversing some glands at the root of the aorta, ascends on the trachea to terminate in the thoracic duct.

The **thymic lymphatic vessels** arise from the under surface of the thymus gland, and terminate on each side in the internal jugular veins.

The **thyroid lymphatic vessels** arise from either lateral lobe of this organ; they converge to form a short trunk, which terminates on the right side in the right lymphatic duct, on the left side in the thoracic duct.

The **lymphatic vessels of the œsophagus** form a plexus round that tube, traverse the glands in the posterior mediastinum, and after communicating with the pulmonary lymphatic vessels near the roots of the lungs, terminate in the thoracic duct.

NERVOUS SYSTEM

THE Nervous System is composed: 1. Of a series of large centres of nerve-matter, called, collectively, the *cerebro-spinal centres* or *axis*. 2. Of smaller centres, termed *ganglia*. 3. Of *nerves*, connected either with the cerebro-spinal axis or the ganglia. And 4. Of certain modifications of the peripheral terminations of the nerves, forming the organs of the external senses.

The **Cerebro-spinal Centre** consists of two parts, the spinal cord and the encephalon: the latter may be subdivided into the cerebrum, the cerebellum, the pons Varolii, and the medulla oblongata.

THE SPINAL CORD AND ITS MEMBRANES

Dissection.—To dissect the cord and its membranes, it will be necessary to lay open the whole length of the spinal canal. For this purpose, the muscles must be separated from the vertebral grooves, so as to expose the spinous processes and laminæ of the vertebræ; and the latter must be sawn through on each side, close to the roots of the transverse processes, from the third or fourth cervical vertebra above, to the sacrum below. The vertebral arches having been displaced by means of a chisel, and the separate fragments removed, the dura mater will be exposed, covered by a plexus of veins and a quantity of loose areolar tissue, often infiltrated with serous fluid. The arches of the upper vertebræ are best divided by means of a strong pair of cutting bone-forceps.

Membranes of the Cord

The membranes which envelop the spinal cord are three in number. The most external is the *dura mater*, a strong fibrous membrane, which forms a loose sheath around the cord. The most internal is the *pia mater*, a cellulo-vascular membrane which closely invests the entire surface of the cord. Between the two is the *arachnoid membrane*, a non-vascular membrane, which envelops the cord, and is connected to the pia mater by slender filaments of connective tissue.

The **Dura Mater** of the cord, continuous with that which invests the brain, is a loose sheath which surrounds the cord, and is separated from the bony walls of the spinal canal by a quantity of loose areolar tissue, and a plexus of veins. It is attached to the circumference of the foramen magnum, and to the posterior common ligament, especially at the lower end of the spinal canal, by fibrous slips; and extends below as far as the second or third piece of the sacrum; here it converges to form a blunt cone, from the apex of which it descends as a sheath for the filum terminale to the back of the coccyx, where it blends with the periosteum. The sheath is much larger than is necessary for its contents, and its size is greater in the cervical and lumbar regions than in the dorsal. Its inner surface is smooth. On each side may be seen the double openings which transmit the two roots of the corresponding spinal nerve, the fibrous layer of the dura mater being continued in the form of a tubular prolongation on them as they pass through these apertures. These prolongations of the dura mater are short in the upper part of the spine, but become gradually longer below, forming a number of tubes of fibrous membrane, which enclose the sacral nerves, and are contained in the spinal canal.

The chief peculiarities of the dura mater of the cord, as compared with that investing the brain, are the following:—

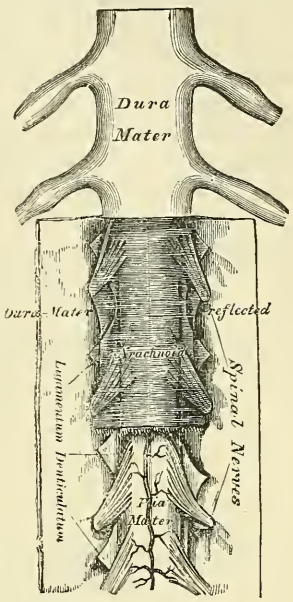
The dura mater of the cord is not adherent to the bones of the spinal canal, which have an independent periosteum.

It does not send partitions into the fissures of the cord, as in the brain.

Its fibrous laminæ do not separate, to form venous sinuses, as in the brain.

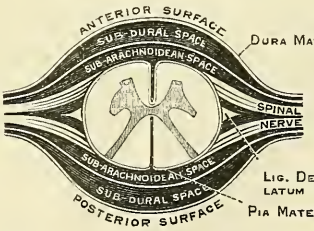
Structure.—The dura mater consists of white fibrous and elastic tissue, arranged in bands or lamellæ, which, for the most part, are parallel with one another and have a longitudinal arrangement. Its internal surface is covered by a layer of endothelial cells, which gives this surface its smooth appearance. It is sparingly supplied with vessels; and some few nerves have been traced into it.

Fig. 443.—The spinal cord and its membranes.



The **Arachnoid** is exposed by slitting up the dura mater, and reflecting that membrane to either side (fig. 443). It is a thin, delicate, tubular membrane, which invests the surface of the cord, and is connected to the pia mater by slender filaments of connective tissue. Above, it is continuous with the cerebral arachnoid; on each side it is continued on the various nerves, so as to form a sheath for them as they pass outwards to the intervertebral foramina. The outer surface of the arachnoid is in contact with the inner surface of the dura mater, and the two are, here and there, connected together by isolated connective-tissue trabeculæ, especially on the posterior surface of the cord. For the most part, however, the membranes are not connected together, and the interval between them is named the *subdural space*. The inner surface of the arachnoid is separated from the pia mater by a considerable interval, which is called the *subarachnoidean space*. The space is largest at the lower part of the spinal canal, and encloses the mass of nerves which form the cauda equina. Superiorly it is continuous with the cranial subarachnoid space, and communicates with the general ventricular cavity of the brain, by means of an opening in the pia mater, at the inferior boundary of the fourth ventricle (*foramen of Majendie*). It contains an abundant serous secretion, the *cerebro-spinal fluid*. This secretion is sufficient in amount to expand the arachnoid membrane, so as to completely fill up the whole of the space included in the dura mater. The subarachnoidean space is occupied by trabeculæ of delicate connective tissue, connecting the pia mater on the one hand with the arachnoid membrane on the other. This is named *subarachnoid tissue*. In addition to this it is partially subdivided by a longitudinal membranous partition, which serves to connect the arachnoid with the pia mater, opposite the posterior median fissure. This partition is incomplete, and cribriform in structure, consisting of bundles of white fibrous tissue, interlacing with each other. This space is to be regarded as, in reality, a great lymph-space, from which the lymph carried to it by the perivascular lymphatics (see page 58) is conveyed back into the circulation.

Fig. 444.—Transverse section of the spinal cord and its membranes.



Structure.—The arachnoid is a delicate membrane, made up of closely arranged interlacing bundles of connective tissue in several layers.

The **Pia Mater** of the cord is exposed on the removal of the arachnoid

(fig. 443). It covers the entire surface of the cord, to which it is very intimately adherent, forming its neurilemma, and sending a process downwards into its anterior fissure. It also forms a sheath for each of the filaments of the spinal nerves, and invests the nerves themselves. A longitudinal fibrous band extends along the middle line on its anterior surface, called by Haller the *linea splendens*; and a somewhat similar band, the *ligamentum denticulatum*, is situated on each side. At the point where the cord terminates, the pia mater becomes contracted, and is continued down as a long, slender filament (*filum terminale*), which descends through the centre of the mass of nerves forming the cauda equina, and is blended with the sheath of dura mater, on a level with the second or third sacral vertebra. It assists in maintaining the cord in its position during the movements of the trunk, and is from this circumstance called the *central ligament* of the spinal cord. It contains a little grey nervous substance, which may be traced for some distance into its upper part, and is accompanied by a small artery and vein. At the upper part of the cord, the pia mater presents a greyish, mottled tint, which is owing to yellow or brown pigment-cells scattered among the elastic fibres.

Structure.—The pia mater of the cord is less vascular in structure, but thicker and denser, than the pia mater of the brain, with which it is continuous. It consists of two layers: an outer composed of bundles of connective-tissue fibres, arranged for the most part longitudinally; and an inner consisting of stiff bundles of the same tissue, which present peculiar angular bends, and is covered on both surfaces by a layer of endothelium. Between the two layers are a number of cleft-like lymphatic spaces, which communicate with the subarachnoid cavity, and a number of blood-vessels, which are enclosed in a perivascular sheath, derived from the inner layer of the pia mater, into which the lymphatic spaces open. It is also supplied with nerves, which are derived from the sympathetic.

The **Ligamentum Denticulatum** (fig. 443) is a narrow fibrous band, situated on each side of the spinal cord, throughout its entire length, and separating the anterior from the posterior roots of the spinal nerves. It has received its name from the serrated appearance which it presents. Its inner border is continuous with the pia mater, at the side of the cord. Its outer border presents a series of triangular, dentated serrations, the points of which are fixed at intervals to the dura mater. These serrations are twenty-one in number, on each side, the first being attached to the dura mater, opposite the margin of the foramen magnum between the vertebral artery and the hypoglossal nerve; and the last near the lower end of the cord. Its use is to support the cord in the fluid by which it is surrounded.

Surgical Anatomy.—Evidence of great value in the diagnosis of meningitis may be obtained by puncturing the theca of the cord and withdrawing some of the cerebro-spinal fluid, and the operation is regarded by some as curative, under the supposition that the draining away of the cerebro-spinal fluid would relieve the patient by diminishing the intra-cranial pressure. The operation is performed by inserting a trocar, of the smallest size, between the lamina of the third and fourth or the fourth and fifth lumbar vertebræ through the ligamentum subflava. The spinal cord even of a child at birth does not reach below the third lumbar vertebra, and therefore the canal may be punctured between the third and fourth vertebra without any risk of injuring its contents. The point of puncture is indicated by laying the child on its side and dropping a perpendicular line from the highest point of the crest of the ilium; this will cross the upper border of the spine of the fourth lumbar vertebra, and will indicate the level at which the trocar should be inserted a little to one side of the median line.

The Spinal Cord

The **Spinal Cord** (*medulla spinalis*) is the cylindrical elongated part of the cerebro-spinal axis which is contained in the vertebral canal. Its length is usually about seventeen or eighteen inches, and its weight, when divested of its membranes and nerves, about one ounce and a half; its proportion to the

encephalon being about 1 to 33. It does not nearly fill the canal in which it is contained, its investing membranes being separated from the surrounding walls by areolar tissue and a plexus of veins. It occupies, in the adult, the upper two-thirds of the vertebral canal, extending from the upper border of the atlas to the lower border of the body of the first lumbar vertebra, where it terminates in a slender filament of grey substance, which is continued for some distance into the *filum terminale*. In the fœtus, before the third month it extends to the bottom of the sacral canal; but after this period it gradually recedes from below, as the growth of the bones composing the canal is more rapid in proportion than that of the cord; so that in the child at birth the cord extends as far as the third lumbar vertebra. Its position varies also according to the degree of curvature of the spinal column, being raised somewhat in flexion of the spine. On examining its surface, it presents a difference in its diameter in different parts, being marked by two enlargements, an upper or cervical, and a lower or lumbar. The cervical enlargement, which is the larger, extends from about the third cervical to the first or second dorsal vertebra: its greatest diameter is in the transverse direction, and it corresponds with the origin of the nerves which supply the upper extremities. The lower, or lumbar, enlargement is situated opposite the last two or three dorsal vertebræ, its greatest diameter being from before backwards. It corresponds with the origin of the nerves which supply the lower extremities. In form, the spinal cord is a flattened cylinder.

Fissures.—It presents on its anterior surface, along the middle line, a longitudinal fissure, the *anterior median fissure*; and, on its posterior surface, another fissure, which also extends along the entire length of the cord, the *posterior median fissure*. These fissures penetrate through the greater part of the thickness of the cord, and incompletely divide it into two symmetrical halves, united in the middle line by a transverse band of nervous substance, the *commissure*.

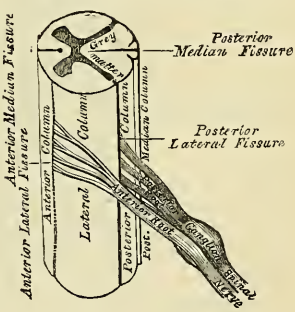


Fig. 445.—Spinal cord. Side view. Plan of the fissures and columns.

The **Anterior Median Fissure** is wider, but of less depth than the posterior, extending into the cord for about one-third of its thickness, and is deepest at the lower part of the cord. It contains a prolongation from the pia mater; and its floor is formed by the *anterior white commissure*, which is perforated by numerous blood-vessels, passing to the centre of the cord.

The **Posterior Median Fissure** is not an actual fissure, as the space between the lateral halves of the posterior part of the cord is crossed by connective tissue and numerous blood-vessels, so that no actual hiatus exists, and there is consequently no prolongation of the pia mater into it. It extends into the cord to about one half its depth, and its floor is formed by the *posterior grey commissure*.

Lateral Fissures.—On each side of the posterior median fissure, along the line of attachment of the posterior roots of the nerves, a delicate fissure may be seen, leading down to the grey matter which approaches the surface in this situation; this is called the *postero-lateral fissure* of the spinal cord. On the posterior surface of the spinal cord, between the posterior median fissure and the postero-lateral fissure on each side, is a slight longitudinal furrow, marking off two slender tracts, the *posterior median columns*. These are most distinct in the cervical region, but are stated by Foville to exist throughout the whole length of the cord. On each side of the anterior median fissure is the place of origin of the anterior roots of the spinal nerves as they emerge from the cord. This is called, by some anatomists, the *antero-lateral fissure* of the cord, although no actual fissure exists in this situation, for the anterior roots enter the cord in several bundles, which spread over a longitudinal strip of some breadth.

Columns of the Cord.—Each half of the spinal cord is thus divided into four columns: an anterior column, a lateral column, a posterior column, and a posterior median column. This division, however, is very imperfect, since the limit between the so-called anterior and lateral columns cannot be defined on account of the bundles of the anterior roots being spread over a considerable area. It is therefore customary to divide each half of the spinal cord into a small *posterior column*, which is bounded internally by the posterior median fissure, and externally by the postero-lateral fissure and a large *antero-lateral* column, which comprises the rest of the cord.

Structure of the Cord.—If a transverse section of the spinal cord be made, it will be seen to consist of white and grey nervous substance. The white matter is situated externally, and constitutes the greater part. The grey substance occupies the centre, and is so arranged as to present on the surface of the section two crescentic masses, placed one in each lateral half of the cord, united together by a transverse band of grey matter, the *grey commissure*. Each crescentic mass has an anterior (ventral) and posterior (dorsal) horn. The posterior horn is long

Fig. 446.—Transverse sections of the cord.

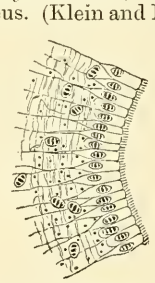
Fig. 447.—From a transverse section through the spinal cord of a calf. Magnified about 180 diameters, showing part of the central canal and the tissue immediately around it, viz. the central grey nucleus. (Klein and Noble Smith.)



The canal is lined with epithelium, composed of ciliated, more or less conical, cells; in most instances a filamentous process passes from the cell into the tissue underneath. This tissue contains, in a hyaline matrix, a network of fibrils; most of these run horizontally; others have a longitudinal course, and appear therefore here cut transversely, i.e. as small dots. The nuclei correspond to the cells of the neuroglia, the cell-substance not being shown. Both the nuclei of the neuroglia cells and those of the epithelium contain three or more large disc-shaped particles.

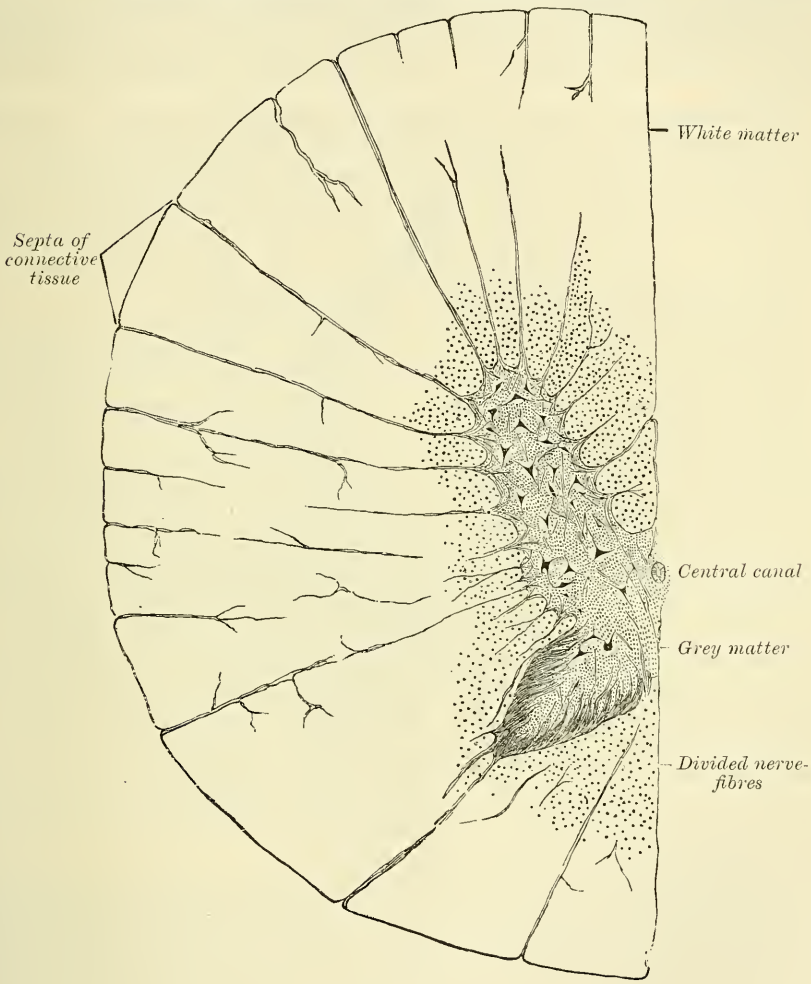
and narrow, and approaches the surface of the postero-lateral fissure, near which it presents a slight enlargement, the *caput cornu*: from this it tapers, to form the *apex cornu*, which at the surface of the cord becomes continuous with the fibres of the posterior roots of the spinal nerves. The anterior horn is short and thick, and does not quite reach the surface, but extends towards the point of attachment of the anterior roots of the nerves. Its margin presents a dentate or stellate appearance. Owing to the projections towards the surface of the anterior and posterior horns of the grey matter, each half of the cord is divided, more or less completely, into three columns, anterior, middle, and posterior: the anterior and middle being joined to form the antero-lateral column, as the anterior horn does not quite reach the surface.

The **commissure of the spinal cord** is composed of white and grey fibres, hence called the white and grey commissures. The *white commissure* is formed of medullated nerve-fibres, which pass horizontally between the grey matter of the anterior horn and the anterior white column of the one side into similar parts on the other. The fibres are oblique in direction; many which enter at the posterior part of the commissure on the one side leave it at the anterior part of

the commissure on the other, and *vice versâ*, a decussation taking place in the middle line.

The *grey commissure*, which connects the two crescentic masses of grey matter, is separated from the bottom of the anterior median fissure by the anterior white commissure. It consists of transverse medullated nerve-fibres, with a considerable quantity of neuroglia between them. The fibres when they reach the lateral crescents diverge: some pass backwards to the posterior roots; others spread out, at various angles, into the crescent.

Fig. 448.—Transverse section through the cervical portion of the spinal cord of a calf. Magnified 40 diameters. (Klein and Noble Smith.)



Running through the grey commissure of the whole length of the cord is a minute canal, which is barely visible to the naked eye in the human cord, but is proportionally larger in some of the lower vertebrata. It is called the *central canal*, and opens above into the fourth ventricle, and terminates below in a somewhat dilated extremity. It is surrounded by an area of neuroglia, which, in a recent state, has a gelatinous appearance, and in which there are no fibres. This is sometimes called the *substantia gelatinosa centralis*. When hardened in alcohol or chromic salts it has a finely reticulated appearance. The canal is lined in the fœtus by columnar ciliated epithelium, but in the adult the cilia have disappeared, and the canal is filled with their remains.

The mode of arrangement of the grey matter, and its amount in proportion to the white, vary in different parts of the cord. Thus, the posterior horns are long and narrow, in the cervical region; short and narrower, in the dorsal; short, but wider, in the lumbar region. In the cervical region, the crescentic portions are small, and the white matter more abundant than in any other region of the cord. In the dorsal region, the grey matter is least developed, the white matter being also small in quantity. In the lumbar region, the grey matter is more abundant than in any other region of the cord. Towards the lower end of the cord, the white matter gradually ceases. The crescentic portions of the grey matter soon blend into a single mass, which forms the only constituent of the extreme point of the cord.

Minute Anatomy of the Cord.—The cord consists of an outer part, composed of medullated nerve-fibres, which is the *white substance*; and of a central part, the *grey matter*: both supported in a peculiar kind of connective tissue, called *neuroglia*.

The **neuroglia** consists of a homogeneous transparent matrix, of a network of very delicate fibrillæ, and of stellate or branched cells, the *neuroglia cells*.

In addition to forming a ground substance, in which the nerve-fibres, nerve-cells, and blood-vessels are embedded, a considerable accumulation of neuroglia takes place in three situations—(1) on the surface of the cord, beneath the pia mater; (2) around the central canal; and (3) in the posterior part of the posterior horn, forming the substantia cinerea gelatinosa.

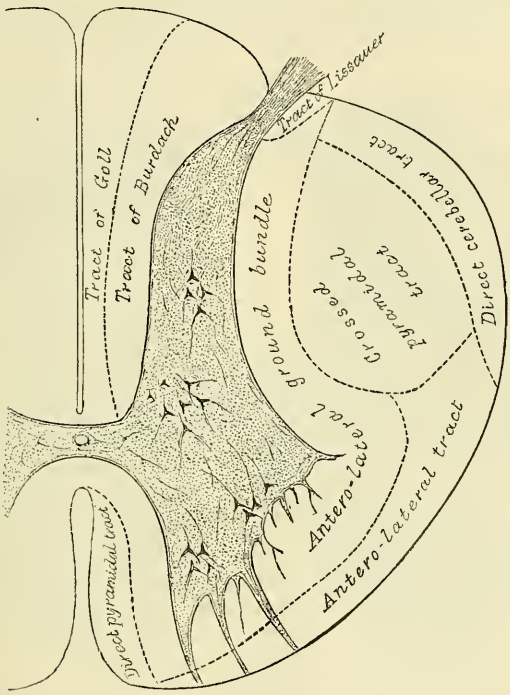
The **white substance of the cord** consists of medullated nerve-fibres, disposed longitudinally, with blood-vessels and neuroglia. On transverse section of the white substance of the cord, stained with carmine, a very striking object is presented. It is seen to be studded all over with minute dots, surrounded by a white area, and this again by a dark circle (fig. 453). This is due to the longitudinal medullated fibres seen on section. The dot is the axis-cylinder, the white area the substance of Schwann, and the dark circle the tubular membrane of the fibres, which seems to consist of several laminæ. Externally, the neuroglia is seen to form a sheath closely investing the outer surface of the cord immediately beneath the pia mater, from which numerous septa pass inwards and separate the respective bundles of fibres and extend between the individual nerve-fibres, acting as a supporting medium, in which they are embedded.

There are, however, also oblique and transverse fibres in the white substance. These are principally found (1) at the bottom of the anterior median fissure, forming the white commissure; the fibres passing from the grey matter of the anterior horn and the white matter of the anterior column of the one side to that of the other; (2) horizontal or oblique fibres passing from the roots of the nerves into the grey matter; and (3) fibres leaving the grey matter and pursuing a longer or shorter horizontal course between the bundles of longitudinal fibres with which many of them are continuous.

Conducting tracts.—It is impossible to trace the course of the nerve-fibres in their passage through the cord; but the investigation of pathological lesions has shown that the white matter of the cord consists of certain columns or tracts of fibres; for it has been found that separate lesions are strictly limited to certain well-determined parts of the cord without involving neighbouring regions. That these parts or fasciculi correspond to so many distinct anatomical systems, each endowed with special functions, seems abundantly proved by the researches of Flechsig and others on the development of the spinal cord during the later periods of utero-gestation and in the newly born infant. By these researches several tracts can be traced along the greater part of the cord and into or from the encephalon. Thus (1) in the antero-lateral column of the cord, on either side of the anterior median fissure, a portion of the column may be divided off as the *direct pyramidal tract* (*Fasciculus of Türck*). This tract is only found in the upper part of the cord, it gradually diminishes as it is traced downwards, and disappears about the middle of the dorsal region of the cord. It consists of

centrifugal or descending fibres, which can be traced downwards from the pyramid of the medulla of the same side, and which are derived from the motor area of the cerebral cortex. It is believed that the fibres of this tract decussate in their course down the cord, and gradually pass through the anterior white commissure and through the grey matter of the opposite side to the crossed pyramidal tract, and that this explains the gradual diminution and eventua. disappearance of the tract. (2) In the hinder part of the antero-lateral column is a somewhat triangular area, larger than the preceding, which is named the *crossed pyramidal tract.* This also consists of descending fibres, which are derived from the pyramid of the medulla of the opposite side, decussation taking place at the upper part of the cord. The fibres are derived from the motor area of the cerebral cortex of the opposite side to the tract. Thus it will be seen that all the fibres from the motor area, which descend through the internal capsule, the crus cerebri and the pons Varolii to the pyramidal body of the medulla,

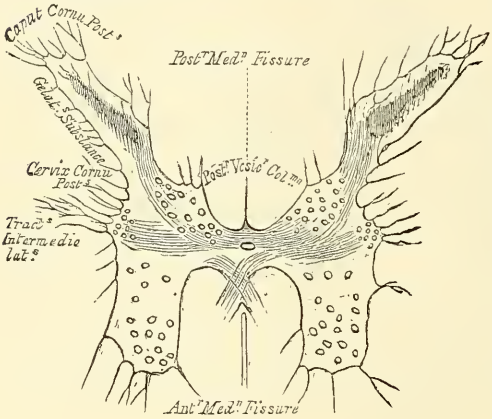
Fig. 449.—Columns of the cord.



decussate; some at the upper part of the cord, and these descend through it as the crossed pyramidal tract; and others, which descend as the direct pyramidal tract and cross through the anterior commissure of the cord to reach the crossed pyramidal tract of the opposite side. (3) The *antero-lateral* tract (Gower's tract) is an extensive tract which skirts the circumference of the anterior three-quarters of the antero-lateral column of the cord. It extends from the front of the crossed pyramidal tract where it is thickest, and gradually narrows off as it reaches the direct pyramidal tract. It consists of centripetal or ascending fibres derived from the posterior roots of the spinal nerves, and can be traced upwards through the medulla and pons to the cerebellum. If the spinal cord is divided in the cervical region some scattered fibres in this column degenerate in a downward direction. This would seem to prove therefore that it contains some descending fibres, which are believed to be derived from the cerebellum of the same side. (4) The *direct cerebellar tract* is situated at the circumference of the cord behind the preceding and external to the crossed pyramidal tract,

occupying a narrow area which extends backwards as far as the postero-lateral fissure, or nearly so. It commences at the level of the upper lumbar region, and increases in size as it ascends and passes through the restiform body of the medulla to the cerebellum. Its fibres are derived from the cells of the posterior vesicular column of Clarke in the grey matter of the cord. (5) Close to the point where the posterior roots enter the cord, in the antero-lateral column, is a small collection of fibres, which is known as the *tract of Lissauer*; it is formed by some of the fibres of the posterior roots which run upwards in the tract for a short distance, and then enter the posterior horn of the grey matter. (6) The rest of the antero-lateral column of the spinal cord is occupied by the *antero-lateral ground bundle*. It surrounds the anterior cornu and separates the antero-lateral tract and the crossed pyramidal tract from the grey matter of the cord. It consists of (*a*) longitudinal commissural fibres, which unite the groups of cells in the anterior horn with one another; (*b*) of fibres which pass across the anterior commissure from the grey matter of the opposite side; and (*c*) fibres belonging to the anterior roots of the nerves, which pass through it before leaving the cord.

Fig. 450.—Transverse section of the grey substance of the spinal cord, near the middle of the dorsal region. Magnified 13 diameters.



In the posterior column of the cord there are two tracts. They are marked off from each other by the slight longitudinal furrow on the surface of the cord. The part which has been described previously as the posterior median column pretty nearly corresponds to the one tract, the *tract of Goll*, and the remainder of the posterior column corresponding to the other, the *tract of Burdach*. (7) The *tract of Goll* consists of long, small fibres derived from the posterior roots of the spinal nerves, which ascend to the medulla oblongata, where they end in the nucleus gracilis. The tract increases as it ascends. (8) The *tract of Burdach* consists of shorter, but larger, fibres than the preceding; they are, however, derived from the same source, the posterior roots; they ascend only for a short distance in the tract, and then enter the grey matter and come into close relationship with the posterior vesicular column of Clarke.

The **grey substance of the cord** occupies its central part in the shape of two crescentic horns, joined together by a commissure. Each of these crescents has an anterior and posterior cornu.

The *posterior horn* consists of a slightly narrowed portion, at its base, where it is connected with the rest of the grey substance—this is the *cervix cornu*; from this it gradually expands into the main part of the horn, the *caput cornu*; around its extremity is a lamina or layer of gelatinous material, which covers the head like a cap, and from this it tapers almost to a point, which approaches the surface of the cord at the postero-lateral groove.

The gelatinous substance is a peculiar accumulation of neuroglia (Klein) similar to that found around the central canal (page 717), and has been named by Rolando the *substantia cinerea gelatinosa*.

The *anterior horn of the grey substance* in the cervical and lumbar swellings, where it gives origin to the nerves of the extremities, is much larger than in any other region, and contains several distinct groups of large and variously shaped cells.

In addition to this, in certain parts of the cord, other horns or projections of

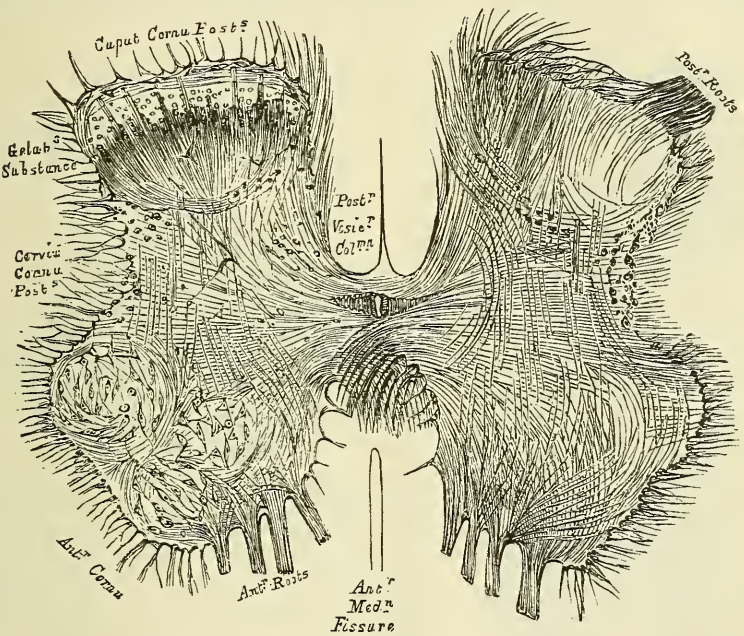
the grey matter may be seen on transverse section. One of these, the *lateral horn*, is found projecting outwards from the lateral region of the grey matter on a level with the grey commissure in the cervical and upper part of the dorsal region of the cord; and a second, *Clarke's vesicular column*, is found on the inner side of the posterior horn near the grey commissure, in the upper cervical or dorsal regions, or at the point of exit of the lower lumbar nerves.

The grey commissure is situated behind the white commissure, which separates it from the bottom of the anterior median fissure.

The **grey substance of the cord** consists of—(1) nerve-fibres of variable but smaller average diameter than those of the columns; (2) nerve-cells of various shapes and sizes, with from two to eight processes; (3) blood vessels and connective tissue.

The *nerve-fibres* of the grey matter of the posterior horn are for the most part composed of a minute and dense network of minute fibrils, which is termed

FIG. 451.—Transverse section of the grey substance of the spinal cord through the middle of the lumbar enlargement. On the left side of the figure groups of large cells are seen; on the right side, the course of the fibres is shown without the cells. Magnified 13 diameters.



'Gerlach's nerve network,' intermingled with nerves of a larger size. This network is continuous with the medullated fibres of the posterior nerve-roots on the one hand (Dieters), and with the branched processes of the ganglion-cells on the other (Gerlach), so that the ganglion-cells are connected with the medullated fibres of the posterior nerve-roots only indirectly through the nerve network. The arrangement of the fibres in the anterior horn of the grey matter appears to be somewhat different; here the medullated fibres of the anterior nerve-roots are directly continuous with some of the processes of the ganglion cells, others of the processes of the ganglion-cells communicating with Gerlach's nerve network.

The *nerve-cells* of the grey matter are of two kinds, (1) large branched nerve-vesicles which are collected into groups as seen on transverse section, but which are really columns of cells placed longitudinally in the grey matter; and (2) small round cells which resemble free nuclei, and are found scattered throughout the whole of the grey matter.

In the anterior horn is a constant group, situated at the anterior part of the

cornu, and sometimes termed the *vesicular column of the anterior cornu.* It consists of two groups of cells: one mesial, near the anterior column; the other lateral, near the lateral column. At the base of the posterior horn on its inner side, and joining the grey commissure, is a group of nerve-cells, which give rise to the projection mentioned above as being seen on transverse section in the upper part of the cord, which is called *Clarke's posterior vesicular column.*

At the junction of the anterior and posterior cornu, in the outer portion of the grey matter, is a third group of cells, the *tractus intermedio-lateralis.* In certain regions of the cord these cells extend in amongst the fibres of the white matter of the lateral column, and give rise to the lateral horn. In addition to these groups a few large scattered cells are found in the posterior horn, extending into the substantia cinerea gelatinosa.

Origin of the Spinal Nerves.—The roots of the spinal nerves are attached to the surface of the cord, opposite the horns of grey matter, and the deep origin of

Fig. 452.—Longitudinal section of the white and grey substance of the spinal cord, through the middle of the lumbar enlargement. Magnified 14 diameters.

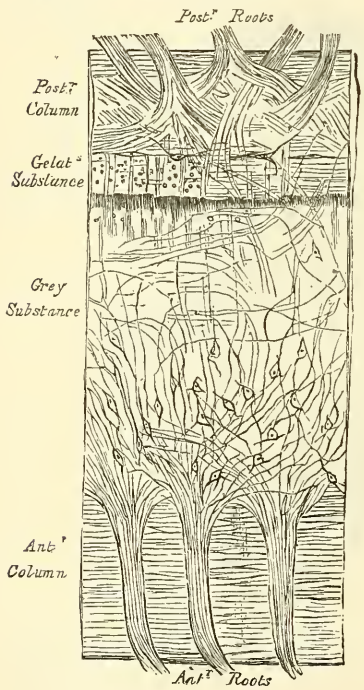


Fig. 453.—Transverse section through the white matter of the spinal cord of a calf. Magnified about 300 diameters. (Klein and Noble Smith.)

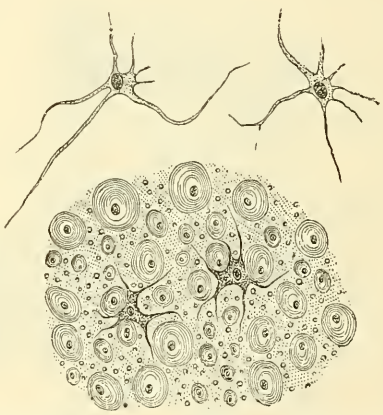


In the upper part are shown two isolated flattened nucleated cells of the neuroglia, under a somewhat higher power than the rest. In the bulk of the figure the nerve-fibres are seen in transverse section. They are of different sizes, and possess a laminated medullary sheath surrounding the axis-cylinder; which was deeply stained in the preparation, and is here represented by a black dot. The nerve-fibres are embedded in the neuroglia. This contains, in a matrix, which appears sometimes granular, sometimes homogeneous, numerous elastic fibrils, seen here in transverse section as minute dots, on account of their having a course parallel to the long axis of the cord. Amongst the neuroglia are also seen two branched connective-tissue cells—neuroglia cells.

their fibres is from nerve-cells embedded in the grey matter, either directly or through Gerlach's nerve network. The fibres of the anterior roots after traversing the white matter enter the anterior horn of grey matter; here they join cells and eventually pass in four different directions, (1) some to the direct pyramidal tract of the same side, (2) others to the crossed pyramidal of the same side, (3) a third set, across the commissure to the opposite side, and (4) a last set, into the tractus intermedio-lateralis. The fibres of the posterior root consist of two sets (1) one, the lateral fibres pass upwards in the tract of Lissauer and then enter the posterior horn; (2) the other, or mesial set, enter Burdach's column and pass in different directions, some to the nerve-cells in the posterior horn, others to the cells in Clarke's column, and others to Goll's column, either of the same or opposite side of the body.

THE BRAIN AND ITS MEMBRANES

Dissection.—To examine the brain with its membranes, the skull-cap must be removed. In order to effect this, saw through the external table, the section commencing, in front, about an inch above the margin of the orbit, and extending, behind, to a level with the occipital protuberance. Then break the internal table with the chisel and hammer, to avoid injuring the investing membranes or brain; loosen, and forcibly detach the skull-cap, when the dura mater will be exposed. The adhesion between the bone and the dura mater is very intimate, and much more so in the young subject than in the adult.

The membranes of the brain are, the dura mater, arachnoid membrane, and pia mater.

Dura Mater

The **Dura Mater** is a thick and dense inelastic fibrous membrane, which lines the interior of the skull. Its outer surface is rough and fibrillated, and adheres closely to the inner surface of the bones, forming their internal periosteum, this adhesion being most marked opposite the sutures and at the base of the skull. Its inner surface is smooth, and lined by a layer of epithelial cells. It sends three processes inwards, into the cavity of the skull, for the support and protection of the different parts of the brain: and is prolonged to the outer surface of the skull, through the various foramina which exist at the base, and thus becomes continuous with the pericranium; its fibrous layer forms sheaths for the nerves which pass through these apertures. At the base of the skull, it sends a fibrous prolongation into the foramen cæcum; it sends a series of tubular prolongations round the filaments of the olfactory nerves as they pass through the cribriform plate, and also round the nasal nerve as it passes through the nasal slit; a prolongation is also continued through the sphenoidal fissure into the orbit, and another is continued into the same cavity through the optic foramen forming a sheath for the optic nerve, which is continued as far as the eyeball. In the posterior fossa it sends a process down the internal auditory meatus, ensheathing the facial and auditory nerves; another through the jugular foramen, forming a sheath for the structures which pass through this opening, and a third through the anterior condyloid foramen. Around the margin of the foramen magnum it is closely adherent to the bone, and is continuous with the dura mater lining the spinal canal. In certain situations, as already mentioned (page 667), the fibrous layers of this membrane separate, to form sinuses for the passage of venous blood. Upon the outer surface of the dura mater, in the situation of the longitudinal sinus, may be seen numerous small whitish bodies, the *glandulæ Pacchioni*.

Structure.—The dura mater consists of white fibrous and elastic tissues, arranged in flattened laminæ, which are divisible into two layers, the fibres of the two layers intersecting each other obliquely. A layer of nucleated epithelial cells, similar to those found on serous membranes, lines its inner surface; these were formerly regarded as belonging to the arachnoid membrane.

Its *arteries* are very numerous, but are chiefly distributed to the bones. Those found in the anterior fossa are the anterior meningeal branches of the anterior and posterior ethmoidal and internal carotid, and a branch from the middle meningeal. In the middle fossa are the middle and small meningeal branches of the internal maxillary, a branch from the ascending pharyngeal, which enters the skull through the foramen lacerum medium basis cranii; branches from the internal carotid, and a recurrent branch from the lachrymal. In the posterior fossa are meningeal branches from the occipital: one of which enters the skull through the jugular foramen, and the other through the mastoid foramen; the posterior meningeal, from the vertebral; occasionally meningeal branches from the ascending pharyngeal, which enter the skull, one at the jugular foramen, the other at the anterior condyloid foramen; and a branch from the middle meningeal.

The *veins*, which return the blood from the dura mater, and partly from the

bones, anastomose with the diploic veins. These vessels terminate in the various sinuses, with the exception of two which accompany the middle meningeal artery, and pass out of the skull at the foramen spinosum to join the internal maxillary vein.

The *nerves* of the dura mater are, the recurrent branch of the fourth, and filaments from the Gasserian ganglion, from the ophthalmic and hypoglossal nerves, and from the sympathetic.

Processes of the Dura Mater.—The processes of the dura mater, sent inwards into the cavity of the skull, are three in number: the falx cerebri, the tentorium cerebelli, and the falx cerebelli.

The *falx cerebri*, so named from its sickle-like form, is a strong arched process of the dura mater, which descends vertically in the longitudinal fissure between the two hemispheres of the brain. It is narrow in front, where it is attached to the crista galli of the ethmoid bone; and broad behind, where it is connected with the upper surface of the tentorium. Its upper margin is convex, and attached to the inner surface of the skull as far back as the internal occipital protuberance. In this situation it is broad, and contains the superior longitudinal sinus. Its lower margin is free, concave, and presents a sharp curved edge, which contains the inferior longitudinal sinus.

The *tentorium cerebelli* is an arched lamina of dura mater, elevated in the middle, and inclining downwards towards the circumference. It covers the upper surface of the cerebellum, and supports the occipital lobes of the brain, and prevents them pressing upon the cerebellum. It is attached, behind, by its convex border to the transverse ridges upon the inner surface of the occipital bone, and there encloses the lateral sinuses; in front, to the superior margin of the petrous portion of the temporal bone on either side, enclosing the superior petrosal sinuses; and at the apex of this bone, the free or internal border and the attached or external border meet, and, forming two processes, cross one another and are continued forwards, to be attached to the anterior and posterior clinoid processes respectively. Along the middle line of its upper surface the posterior border of the falx cerebri is attached, the straight sinus being placed at their point of junction. Its anterior border is free and concave, and presents a large oval opening for the transmission of the crura cerebri.

The *falx cerebelli* is a small triangular process of dura mater, received into the indentation between the two lateral lobes of the cerebellum behind. Its base is attached, above, to the under and back part of the tentorium; its posterior margin to the lower division of the vertical crest on the inner surface of the occipital bone. As it descends, it sometimes divides into two smaller folds, which are lost on the sides of the foramen magnum.

Glandulæ Pacchioni or Arachnoidal Villi

The so-called glandulæ Pacchioni are numerous small whitish granulations usually collected into clusters of variable size, which are found in the following situations:—1. Upon the outer surface of the dura mater, in the vicinity of the superior longitudinal sinus, being received into little depressions on the inner surface of the calvarium. 2. On the inner surface of the dura mater. 3. In the superior longitudinal sinus. 4. On the pia mater, near the margin of the hemispheres.

These bodies are not glandular in structure, but simply enlarged normal villi of the arachnoid. In their growth they perforate the dura mater, and are thus found on its outer surface, and when of large size they cause absorption of the bone, and come to be lodged in pits or depressions on the inner table of the skull. The manner in which they perforate the dura mater is as follows:—at an early period of their growth they project through minute holes in the inner layer of the dura mater, which open into large venous spaces situated in the tissues of the membrane, on either side of the longitudinal sinus and communicating with it.

In their onward growth the villi push the outer layer of the dura mater before them, and this forms over them a delicate membranous sheath. In structure they consist of spongy trabecular tissue, covered over by a membrane, which is continuous with the arachnoid. The space between these two coverings, derived from the dura mater and arachnoid respectively, corresponds to and is continuous with the subdural space. The spongy tissue of which they are composed is continuous with the trabecular tissue of the subarachnoid space; so that fluid injected into the subarachnoid space finds its way into the Pacchionian bodies; and through their coverings filters into the superior longitudinal sinus. They are supposed to be the means by which excess of cerebro-spinal fluid is got rid of, when its quantity is increased above normal.

These bodies are not found in infancy, and very rarely until the third year. They are usually found after the seventh year; and from this period they increase in number as age advances. Occasionally they are wanting.

Arachnoid Membrane

The arachnoid (ἀράχνη εἶδος, *like a spider's web*), so named from its extreme thinness, is a delicate membrane which envelops the brain, lying between the pia mater internally and the dura mater externally; from this latter membrane it is separated by a space, the *subdural space.*

It invests the brain loosely, being separated from direct contact with the cerebral substance by the pia mater, and a quantity of loose areolar tissue, the *subarachnoidean.* On the upper surface of the cerebrum the arachnoid is thin and transparent, and may be easily demonstrated by injecting a stream of air beneath it by means of a blowpipe; it passes over the convolutions without dipping down into the sulci between them. At the base of the brain the arachnoid is thicker, and slightly opaque towards the central part; it covers the anterior lobes, and extends across between the two temporo-sphenoidal lobes so as to leave a considerable interval between it and the brain, the *anterior subarachnoidean space* (Cisterna pontis); it is in contact with the pons and under surface of the cerebellum; but between the hemispheres of the cerebellum and the medulla oblongata another considerable interval is left between it and the brain, called the *posterior subarachnoidean space* (Cisterna magna). These two spaces communicate together across the crura cerebelli. The arachnoid membrane surrounds the nerves which arise from the brain, and encloses them in loose sheaths as far as their point of exit from the skull.

The *subarachnoid space* is the interval between the arachnoid and pia mater. It is not, properly speaking, a *space*, for it is occupied everywhere by a spongy tissue consisting of trabeculæ of delicate connective tissue, which pass from the pia mater to the arachnoid, and in the meshes of which the subarachnoid fluid is contained. This so-called space is small on the surface of the hemispheres; but at the base of the brain the subarachnoid tissue is less abundant and its meshes larger, where it forms the Cisterna pontis et magna mentioned above. In addition to these two large spaces, a third is formed on the upper surface of the corpus callosum, for the arachnoid stretches across from one cerebral hemisphere to the other immediately beneath the free border of the falx cerebri, and thus leaves a space in which the anterior cerebral arteries are contained. Another space is found in the fissure of Sylvius, for the arachnoid stretches across from the anterior to the middle lobe of the brain, without dipping down to the bottom of the fissure, and in this space the middle cerebral artery ramifies. The subarachnoid space communicates with the general ventricular cavity of the brain by means of three openings: one of these is in the middle line at the inferior boundary of the fourth ventricle, where an opening in the pia-matral covering of this cavity, the *foramen of Majendie*, exists and permits the passage of fluid from the one space to the other. The other two communications are at the extremities of the lateral recesses of the fourth ventricle, behind the upper roots

of the glosso-pharyngeal nerves ; they are named the *foramina of Key and Retzius.* It is stated by Merkel that the lateral ventricles also communicate with the subarachnoid space at the apices of their descending horns.

The subdural space also contains fluid; this is, however, small in quantity compared with the cerebro-spinal fluid and is probably of the nature of lymph.

The *cerebro-spinal fluid* fills up the subarachnoid space. It is a clear, limpid fluid, having a saltish taste, and a slightly alkaline reaction. According to Lassaigne, it consists of 98·5 parts of water, the remaining 1·5 per cent. being solid matters, animal and saline. It varies in quantity, being most abundant in old persons, and is quickly reproduced. Its chief use is probably to afford mechanical protection to the nervous centres, and to prevent the effects of concussions communicated from without.

Structure.—The arachnoid consists of bundles of white fibrous and elastic tissue intimately blended together. Its outer surface is covered with a layer of endothelium. From its inner surface are given off a number of bundles of fine connective tissue, which form a sponge-like trabecular network in the subarachnoid space, in the interstices of which the cerebro-spinal fluid is contained. Vessels of considerable size, but few in number, and, according to Bochdalek, a rich plexus of nerves derived from the motor division of the fifth, the facial, and the spinal accessory nerves, are found in the arachnoid.

Pia Mater

The pia mater is a vascular membrane, and derives its blood from the internal carotid and vertebral arteries. It consists of a minute plexus of blood-vessels, held together by an extremely fine areolar tissue. It invests the entire surface of the brain, dipping down between the convolutions and laminæ, and is prolonged into the interior, forming the velum interpositum and choroid plexuses of the fourth ventricle. Upon the surfaces of the hemispheres, where it covers the grey matter of the convolutions, it is very vascular, and gives off from its inner surface a multitude of minute vessels, which extend perpendicularly for some distance into the cerebral substance. At the base of the brain, in the situation of the anterior and posterior perforated spaces, a number of long straight vessels are given off, which pass through the white matter to reach the grey substance in the interior. On the cerebellum the membrane is more delicate, and the vessels from its inner surface are shorter. The pia mater of the spinal cord is thicker, firmer, and less vascular than that of the brain, and as it is traced upwards over the medulla it is seen to preserve these characters. At the upper border of the medulla it is prolonged over the lower half of the fourth ventricle, forming a covering for it (tela choroidea inferior) before it is reflected on to the under surface of the cerebellum.

According to Fohmann and Arnold, this membrane contains numerous lymphatic vessels. Its nerves are derived from the sympathetic, and also from the third, fifth, sixth, facial, glosso-pharyngeal, pneumogastric, and spinal accessory. They accompany the branches of the arteries.

Divisions of the Brain

The **brain** (*encephalon*) is that portion of the cerebro-spinal axis which is contained in the cranial cavity. It is divided into four principal parts: viz. the cerebrum, the cerebellum, the pons Varolii, and the medulla oblongata.

The **cerebrum** forms the largest portion of the encephalon, and occupies a considerable part of the cavity of the cranium, resting in the anterior and middle fossæ of the base of the skull, and separated posteriorly from the cerebellum by the tentorium cerebelli. About the middle of its under surface is a narrow constricted portion, part of which, the *crura cerebri*, is continued onwards into the

pons Varolii below, and through it to the medulla oblongata and spinal cord; whilst another portion, the *crura cerebelli*, passes down into the cerebellum.

The **cerebellum** (*little-brain*, or *after-brain*) is situated in the inferior occipital fossæ, being separated from the under surface of the occipital lobes of the cerebrum by the tentorium cerebelli. It is connected to the rest of the encephalon by means of connecting bands, called *crura*: of these, two ascend to the cerebrum, two descend to the medulla oblongata, and two blend together in front, forming the pons Varolii.

The **pons Varolii** is that portion of the encephalon which rests upon the upper part of the basilar process of the occipital bone and body of the sphenoid bone. It constitutes the bond of union of the various segments above named, receiving, above, the crura from the cerebrum; at the sides, the crura from the cerebellum; and below, the medulla oblongata.

The **medulla oblongata** extends from the lower border of the pons Varolii to the upper part of the spinal cord. It lies beneath the cerebellum, resting on the lower part of the basilar groove of the occipital bone.

Weight of the Encephalon.—The average weight of the brain, in the adult male, is 49½ oz., or a little more than 3 lb. avoirdupois; that of the female, 44 oz.; the average difference between the two being from 5 to 6 oz. The prevailing weight of the brain, in the male, ranges between 46 oz. and 53 oz.; and, in the female, between 41 oz. and 47 oz. In the male, the maximum weight out of 278 cases was 65 oz. and the minimum weight 34 oz. The maximum weight of the adult female brain, out of 191 cases, was 56 oz., and the minimum weight 31 oz. According to Luschka, the average weight of a man's brain is 1,424 grammes (about 45 oz.), of a woman's 1,272 grammes (about 41 oz.); and according to Krause, 1,570 grammes (about 48½ oz.) for the male, and 1,350 grammes (about 43 oz.) for the female. It appears that the weight of the brain increases rapidly up to the seventh year, more slowly to between sixteen and twenty, and still more slowly to between thirty and forty, when it reaches its maximum. Beyond this period, as age advances and the mental faculties decline, the brain diminishes slowly in weight, about an ounce for each subsequent decennial period. These results apply alike to both sexes.

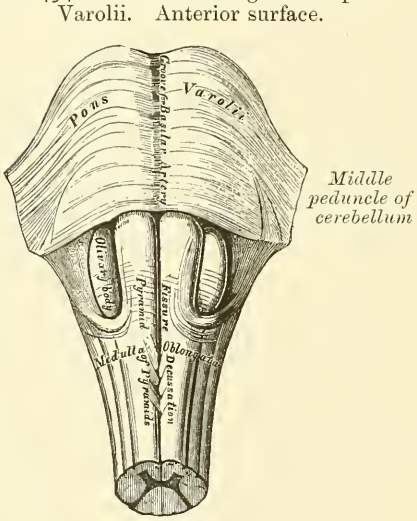
The size of the brain was formerly said to bear a general relation to the intellectual capacity of the individual. Cuvier's brain weighed rather more than 64 oz., that of the late Dr. Abercrombie 63 oz., and that of Dupuytren 62½ oz. On the other hand, the brain of an idiot seldom weighs more than 23 oz. But these facts are by no means conclusive, and it is well known that these weights have been equalled by the brains of persons who never displayed any remarkable intellect. Dr. Haldennan, of Cincinnati, has recorded the case of a mulatto, aged 45, whose brain weighed 68⅜ oz.; he had been a slave, and was never regarded as particularly intelligent; he was illiterate, but is said to have been reserved, meditative, and economical. Dr. Ensor, district medical officer at Port Elizabeth, reports that the brain of Carey, the Irish informer, weighed 61 oz. M. Nikiforoff has published an article on the subject of the weight of brains in the *Novosti*. According to him, the weight of the brain has no influence whatever on the mental faculties. It ought to be remembered that the significance of the weight of the brain should depend upon the proportion it bears to the dimensions of the whole body and to the age of the individual. It is equally important to know what was the cause of death, for long illness or old age exhausts the brain. To define the real degree of development of the brain, it is therefore necessary to have a knowledge of the condition of the whole body; and, as this is usually lacking, the mere record of weight possesses little significance.

The human brain is heavier than that of all the lower animals, excepting the elephant and whale. The brain of the former weighs from eight to ten pounds; and that of a whale, in a specimen seventy-five feet long, weighed rather more than five pounds.

Medulla Oblongata

The **medulla oblongata**, or **bulb**, is the upper enlarged part of the spinal cord, and extends from the lower margin of the foramen magnum to the lower border of the pons Varolii. It is directed from above obliquely downwards and backwards; its anterior surface rests on the basilar groove of the occipital bone, its posterior surface is received into the fossa between the hemispheres of the cerebellum, forming the floor of the fourth ventricle. It is pyramidal in form, its broad extremity directed upwards, its lower end being narrow at its point of connection with the cord. It measures an inch in length, three-quarters of an inch in breadth at its widest part, and half an inch in thickness. Its surface is marked, in the median line, in front and behind, by an *anterior* and *posterior median fissure*, which are continuous with those of the spinal cord. The anterior fissure contains a fold of pia mater, and terminates just below the pons in a *cul-de-sac*, the *foramen cæcum*. It is interrupted at its lower part by some bundles of fibres, which cross obliquely from one side to the other, forming the decussation of the pyramids. The posterior is a deep but narrow fissure, continued upwards to about the middle of the medulla, where it expands into the fourth ventricle. These two fissures divide the medulla into two symmetrical halves, each lateral half presenting elongated eminences which are continuous with the columns of the cord. By taking the lines along which some of the cranial nerves emerge from the medulla, as landmarks, we may divide the surface of this portion of the nervous system into three columns, just in the same way as the spinal cord is divided into three columns by the lines corresponding to the points of exit of the anterior and posterior roots of the spinal nerves. The anterior column comprises that portion which is situated between the anterior median fissure and the fibres of origin of the hypoglossal nerve: this column is called the *pyramid*. The lateral column comprises that portion which is situated between the fibres of origin of the hypoglossal nerve and the fibres of origin of the glosso-pharyngeal, pneumogastric, and spinal accessory nerves. In the lower part of the medulla this column is single, and is called the lateral tract; but in the upper part an oval-shaped body comes forward between it and the pyramid, pushing aside the lateral tract. This is called the *olivary body*. The posterior column comprises that portion which is situated between the fibres of origin of the glosso-pharyngeal, pneumogastric, and spinal accessory nerves, and the posterior median fissure. This column is marked by slight furrows marking off smaller columns, and these in the lower part of the medulla are named, from without inwards, the *funiculus of Rolando*, the *funiculus cuneatus*, and the *funiculus gracilis*; in the upper part of the medulla, the funiculus of Rolando and the funiculus cuneatus appear to become fused together, forming a single body called the *restiform body*.

Fig. 454.—Medulla oblongata and pons Varolii. Anterior surface.



The **pyramids** are two pyramidal bundles of white matter, placed one on either side of the anterior median fissure, and separated from the olivary body, which is external to them, by a slight depression. At the lower border of the pons they are somewhat constricted; they then become enlarged, and taper as

they descend, being continuous below, by their outer portion, with the anterior columns of the cord (*direct pyramidal tract*), and by their inner portion with the decussating fibres, seen in the anterior median fissure, which are derived from the lateral column of the cord (*crossed pyramidal tract*). For, on separating the pyramids below, it will be observed that their innermost fibres form from four to five bundles on each side, which decussate with one another across the anterior median fissure; this decussation, however, is not formed of fibres from the anterior column of the cord, but from the deep portion of the lateral columns (*crossed pyramidal tract*) which pass forwards to the surface on the inner side of the anterior columns. The outermost fibres do not decussate; they are derived, as just stated, from the anterior column of the cord.

The **lateral column**, in the lower part of the medulla, is of the same width as the lateral column of the cord, and appears on the surface to be a direct continuation of it. As a matter of fact it is only a part of the lateral column of the spinal cord which is continued upwards into this column; for, as we have just seen, the crossed pyramidal tract passes into the pyramid of the opposite side, and the direct cerebellar tract of the cord passes into the restiform body. The rest of the lateral column of the cord can be traced vertically upwards into this area. In the upper part of the medulla, the lateral tract, on account of the interpolation of the olivary body, becomes concealed by this body.

The **olivary body** is a prominent oval mass, situated behind the pyramid, from which it is separated by a slight groove, along which the hypoglossal nerve arises. It is separated externally from the restiform body by a longitudinal narrow band of fibres, prolonged upwards from the lateral tract, and by a groove, from which the glosso-pharyngeal, pneumogastric, and spinal accessory nerves arise. It is equal in breadth to the pyramid; is a little broader above than below, and is about half an inch in length, being separated above from the pons Varolii by a slight depression, in which is sometimes to be seen a band of arched fibres. Numerous white fibres (*superficial arciform fibres*) are seen winding across the lower half of the pyramid and the olivary body to enter the restiform body.

The **funiculus of Rolando** is a longitudinal prominence, on the outer side of the lateral tract. It begins at the lower end of the medulla by a tapering extremity, and gradually enlarging as it ascends, forms at a level with the lower border of the olivary body a slight prominence, known as the *tubercle of Rolando*. It is caused by the substantia gelatinosa of Rolando of the cord gradually finding its way to the surface, so as to form a prominence there. About half an inch below the pons it appears to blend with the funiculus cuneatus. In front, it is separated from the lateral tract by a distinct groove, the continuation upwards of the postero-lateral groove of the cord; behind, the separation from the funiculus cuneatus is much less distinct.

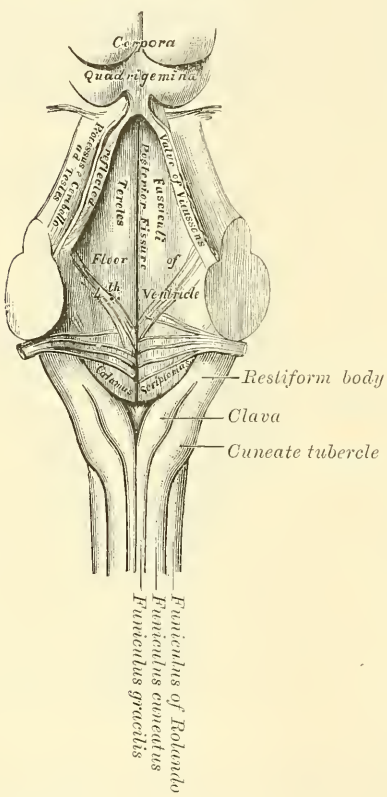
The **funiculus cuneatus** is the direct continuation upwards of the posterior lateral column (tract of Burdach) of the cord. It is situated between the funiculus of Rolando and the funiculus gracilis; it enlarges as it ascends, and forms, opposite the lower extremity of the fourth ventricle, a slight eminence or enlargement, the *tuberculum cuneatum*, which is best marked in children. About half an inch below the pons it appears to blend with the funiculus of Rolando.

The **restiform bodies** appear on the surface to be the direct continuation upwards of the funiculus of Rolando and the funiculus cuneatus. But they also receive the arched fibres (arciform), presently to be described, and fibres derived from the lateral column of the cord, or the *direct cerebellar tract*. The restiform bodies are the largest prominences of the medulla, and are placed between the lateral tracts in front and the funiculus gracilis behind, from both of which they are separated by slight grooves. As they ascend they diverge from each other, assist in forming the lower part of the lateral boundaries of the fourth ventricle, and then enter the corresponding hemisphere of the cerebellum, forming its inferior peduncles.

The **funiculus gracilis** is the direct continuation upwards of the posterior median column of the cord (tract of Goll). It is a narrow white cord, placed parallel to and along the side of the posterior median fissure. It is separated from the funiculus cuneatus below and the restiform body above by a slight groove, which is continuous with the groove on the surface of the cord, which marks off the posterior median column. At first the funiculi of the two sides lie in close contact on either side of the posterior median fissure. Opposite the apex of the fourth ventricle they form an enlargement (*clava*), and then diverging, form the lateral boundaries of the lower part of the fourth ventricle, and gradually tapering off they soon become no longer traceable.

The **posterior surface of the medulla oblongata** forms part of the floor of the fourth ventricle. This portion is of a triangular form, bounded on each side by the diverging funiculi graciles and restiform bodies, and is that part of the ventricle which, from its resemblance to the point of a pen, is called *calamus scriptorius*. The divergence of the funiculi graciles and restiform bodies opens to view the grey matter of the medulla, which is continuous below with the grey matter of the cord. In the middle line is seen a longitudinal furrow, which ends below near the point of the calamus, in a somewhat cleft-like space, the *ventricle of Arantius*, which opens by a minute hole into the central canal of the cord.

Fig. 455.—Posterior surface of the medulla oblongata.



The **arciform** or **arcuate fibres,** which have been mentioned as forming part of the restiform body, are found in the upper half of the medulla, both crossing its surface and traversing its substance. They are divided for the purpose of description into two sets—superficial and deep. The *superficial arciform fibres* have already been alluded to as crossing the pyramid and olivary body on each side. They emerge from the anterior median fissure, in which they can be traced to enter the raphé and cross it, after which they become no longer traceable. After emerging from the anterior median fissure they cross the pyramid and olivary body, and enter the restiform body. As they cross the olivary body they are reinforced by some of the deep arciform fibres which come to the surface on the inner side of, or through, this structure. The *deep arciform fibres* are described with the Microscopic Anatomy of the Medulla.

Structure.—The medulla oblongata, like the spinal cord, consists of both grey and white matter, and exhibits in section both these structures arranged in certain definite masses. The fibres of the several columns of the cord enter the medulla, and in it undergo a rearrangement, some of them passing through it to the pons Varolii, the cerebrum, and the cerebellum, while others end in its grey substance. Some fibres take origin in the medulla, and are continued onwards to the cerebrum and cerebellum. The structure of the medulla will be best understood by tracing its several parts upwards from the spinal cord.

The **pyramid** is composed of fibres derived from the direct pyramidal tract of the anterior column of the cord of its own side, and from the crossed pyramidal

tract of the lateral column of the opposite half of the cord. Those fibres which are derived from the direct pyramidal tract, and which in the cord lie close to the median fissure, are in the medulla placed to the outer side of the pyramid, being pushed aside, as it were, by the interpolation of the fibres derived from the crossed pyramidal tract, which are much more numerous. The crossed pyramidal fibres ascend from the lateral column of the spinal cord, and, passing through the anterior grey cornua and across the median fissure, form the inner part of the pyramid. The fibres of the pyramid may be traced upwards through the pons to the crus cerebri of its own side. All the fibres of the anterior column of the cord are not continued into the pyramid of the medulla; some of them pass backwards, and enter the *formatio reticularis*, which is described with the Microscopic Anatomy of the Medulla.

The **olivary body** when cut across obliquely is seen to be composed, externally of white fibres, internally of a grey layer, the *corpus dentatum*, which is arranged in the form of a hollow capsule, open at its upper and inner part and presenting a zigzag or dentated outline. White fibres enter the interior of this capsule by the aperture at its upper and inner part, constituting the *olivary peduncle*.

The **lateral tract of the medulla** is the continuation upwards of part of the lateral column of the cord. The fibres from it divide into three sets: one set, the most numerous, pass deeply behind the olivary body, and ascend through the formatio reticularis to the pons; a second set pass across the anterior median fissure to join the pyramid, forming the *crossed pyramidal set*; the third set, few in number, form a small band, which passes backwards to the restiform body to enter the cerebellum, forming the *lateral cerebellar tract*.

The **funiculus of Rolando**, which is a longitudinal prominence on the outer side of the lateral tract, is now seen to be the enlarged head of the posterior cornu of the grey matter which is displaced laterally in consequence of the increase in size of the posterior columns of the medulla, so that it lies almost at right angles to the posterior median fissure, and approaching the surface forms a prominence which is covered over by a very thin layer of white matter, derived from the funiculus cuneatus. Its most prominent part on the surface is called the *tubercle of Rolando*.

The **funiculus cuneatus** is the direct continuation upwards of the postero-lateral column of the cord. Its white fibres are derived from this region of the cord. The fibres appear to end in the grey matter which forms the so-called nucleus of this column; this nucleus, at first narrow, gradually enlarges, and produces, externally, the eminence mentioned above as the tuberculum cuneatum.

The **funiculus gracilis** is the direct continuation upwards of the posterior median column of the cord. It consists entirely of white fibres, which are continuous with those of this region of the cord. Like the funiculus cuneatus its fibres appear to end in its so-called nucleus, which produces externally the prominence mentioned above as the *clava*.

The **restiform body** is mainly constituted by the fusing together of the funiculus of Rolando and the funiculus cuneatus, to which are added the arciform fibres of the medulla and the direct cerebellar tract from the lateral column of the cord. In addition to these, a bundle of fibres has been described by Solly as passing from the anterior column of the cord obliquely upwards below the olivary body to the restiform body. The white fibres of the restiform body are continued upwards to the cerebellum, forming its inferior peduncle.

Microscopic Anatomy of the Medulla.—If the cranial nerves emerging from the medulla are traced into its substance, it will be seen that they divide each hemisphere of the medulla into three wedge-shaped areas, which have been named the anterior, lateral, and posterior areas of the medulla.

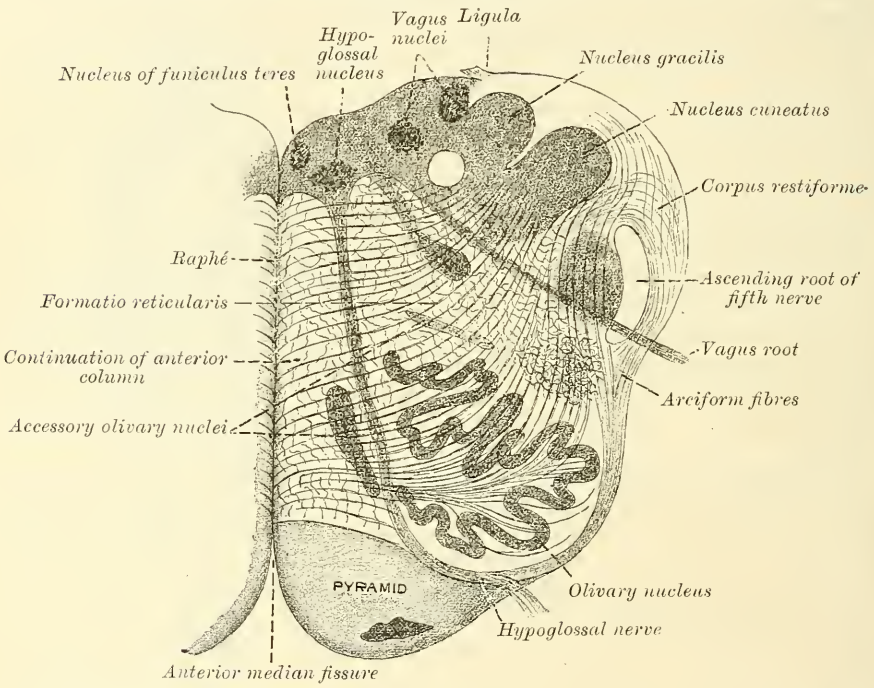
The *anterior area* comprises that portion which is situated between the anterior median fissure and the fibres of origin of the hypoglossal nerve. On the surface of the medulla this area corresponds to the pyramid.

The *lateral area* comprises that portion which is situated between the fibres of

origin of the hypoglossal nerve and the fibres of origin of the glosso-pharyngeal, pneumogastric, and spinal accessory nerves. On the surface of the medulla, in its lower part, this area is single, and is called the lateral tract; but in the upper part an oval-shaped body comes forward between it and the pyramid, pushing aside the lateral tract. This oval-shaped body is the olivary body.

The *posterior area* comprises that portion which is situated between the fibres of origin of the glosso-pharyngeal, pneumogastric, and spinal accessory nerves and the posterior median fissure. On the surface of the medulla, this area is marked by slight furrows marking off smaller columns; these, in the lower part of the medulla, are named, from without inwards, the funiculus of Rolando, the funiculus cuneatus, and the funiculus gracilis; in the upper part of the medulla, the funiculus of Rolando and the funiculus cuneatus appear to become fused together, forming a single body, called the restiform body.

Fig. 456.—Section of the medulla oblongata at about the middle of the olivary body. (Schwalbe.)



The Arciform fibres.—*Deep set.*—The deep arciform fibres are more numerous than the superficial set; they traverse the whole area of the upper half of the medulla, except the pyramid. They pass from the raphé; some become superficial and join the superficial arciform fibres; while others remain deep and pass to the restiform body and to the nuclei of the funiculus cuneatus and funiculus gracilis.

The raphé.—The raphé is situated in the middle line of the medulla, above the decussation of the pyramids. It consists of nerve-fibres intermingled with nerve-cells. The fibres have different directions which can only be seen in suitable microscopic sections; thus—

1. Some are antero-posterior; these are continuous in front with the superficial arciform fibres.

2. Some are longitudinal; these are derived from the arciform fibres, which on entering the raphé change their direction and become longitudinal.

3. Some are oblique; these are continuous with the deep arciform fibres which pass from the raphé.

Some of the fibres of the raphé arise from the nuclei on the floor of the fourth ventricle.

The formatio reticularis.—In the substance of the medulla behind the pyramid and olivary body is a peculiar reticulated structure, which has received the name of *formatio reticularis*; the appearance it presents in sections of the medulla is due to its being composed of bundles of fibres running at right angles to each other, some being longitudinal, others transverse.

The longitudinal fibres are derived—

1. From the anterior column of the cord after the direct pyramidal tract has passed into the pyramid.
2. From the olivary body.
3. From the lateral column of the cord after the crossed pyramidal tract has passed into the pyramid.
4. From the funiculus cuneatus and funiculus gracilis.

The transverse fibres are the deep arciform fibres.

In the lateral part of this reticular structure grey matter containing large nerve-cells is found.

The Grey Matter of the Medulla oblongata.—The grey matter of the medulla oblongata is partly continuous with the grey matter of the cord, and partly arranged in independent masses. It contains many multipolar ganglion-cells. In the lower part of the medulla, the grey matter, which is continuous with that of the cord, is arranged in the shape of two crescentic horns with their convexities towards each other and connected by a central commissure; but in the upper part it loses its crescentic arrangement, becomes more abundant, and is disposed with less regularity.

The caput of the posterior horns becomes enlarged, and gradually shifted outwards, so that they form rounded masses, close under the lateral tract, and produce the prominence on the surface called the funiculus of Rolando. The neck of the cornu diminishes in size, and is broken up into a reticular formation by the passage of longitudinal and transverse fibres through it, so that the caput is separated from the rest of the grey matter.

As the central canal expands into the fourth ventricle, the rest of the posterior horn of grey matter is pushed outwards into the funiculus cuneatus and funiculus gracilis; in each of these funiculi it forms a distinct accumulation of grey matter, constituting the nucleus cuneatus and the nucleus gracilis.

The anterior horn of grey matter is broken up by the passage through it of the crossed pyramidal tract from the lateral column of the cord. By this means the anterior portion of the horn is completely isolated from the remainder, and constitutes the lateral nucleus of grey matter which is situated near the surface of the lateral tract.

The greater part of the rest of the anterior horn being permeated by the decussating fibres presents a reticular formation. A small part of the base of the anterior cornu comes to the surface of the floor of the fourth ventricle, and is exposed to view by the divergence of the funiculus cuneatus and funiculus gracilis. It forms a continuous mass, which gradually increases in size and forms the eminence of the fasciculus teres.

In it is a group of nerve-cells, which form the nucleus from which the roots of the hypoglossal nerve arise.

At the base of the posterior cornu, in the lower part of the medulla, is a group of cells, which, if traced upwards, are found to be pushed on one side; so that in the floor of the fourth ventricle they are outside the hypoglossal nucleus and form a second eminence, the *ala cinerea*: from it arise the roots of the accessory portion of the spinal accessory, pneumogastric, and glosso-pharyngeal nerves. Outside this again, and towards the upper part of the medulla, is another group of cells from which most of the fibres of the auditory nerve take origin.

Another independent mass of grey matter is found in the olivary body forming the corpus dentatum. It consists of a grey layer arranged in the form of a hollow

capsule, open at its upper and inner part, and presenting a zigzag or dentated outline. White fibres enter the interior of this capsule by the aperture at its upper and inner part, constituting the olivary peduncles. Some of these fibres terminate in the cells of the corpus dentatum, while others are continued through the grey layer to join the arciform fibres. Furthermore, two small isolated bands of grey matter are seen, one on the dorsal and the other on the mesial aspect of the corpus dentatum: these are known as *accessory olivary nuclei.*

Pons Varolii

The **pons Varolii** (*tuber annulare*) is the bond of union of the various segments of the encephalon, connecting the cerebrum above, the medulla oblongata below, and the cerebellum behind. It is situated above the medulla oblongata, below the crura cerebri, and between the hemispheres of the cerebellum.

Its *anterior* ventral *surface* presents a broad transverse band of white fibres, which arches like a bridge across the upper part of the medulla, extending between the two hemispheres of the cerebellum. This surface projects considerably beyond the level of these parts, is of quadrangular form, rests upon the clivus of the sphenoid bone, and is limited before and behind by very prominent margins. It presents along the middle line a longitudinal groove, wider in front than behind, which lodges the basilar artery: numerous transverse striæ are also observed on each side, which indicate the course of its superficial fibres.

Its *posterior* dorsal *surface* forms a part of the floor of the fourth ventricle.

At each side its fibres become contracted into a thick rounded cord, the *crus cerebelli,* which enters the substance of the cerebellum, constituting its middle peduncle.

Structure.—The pons Varolii consists of two parts, which differ in appearance and structure from each other: the anterior or ventral half consists for the most part of fibres arranged in transverse and longitudinal bundles with a small amount of grey matter; the posterior or dorsal half is a continuation of the reticular formation of the medulla with the grey matter of the floor of the fourth ventricle. The anterior or ventral half consists of three layers of fibres: (1) superficial transverse fibres; (2) superficial longitudinal fibres; (3) deep transverse fibres. These three layers are not, however, completely differentiated from each other, for some transverse fibres may be seen between the bundles of the longitudinal fibres. The superficial transverse fibres (fig. 457) pass from the crus or middle peduncle of the cerebellum to the median raphé of the pons, where they meet and interlace with those coming from the opposite side. They then dip deeply into the substance of the pons and pass to the crus cerebri of the opposite side. The superficial longitudinal fibres enter the pons below as a single mass, being the continuation upwards of the fibres of the pyramids of the medulla; as they ascend they become broken up into bundles by some of the transverse fibres passing through them, and are continued into the superficial portion of the crus cerebri, much increased in number from being reinforced by the fibres derived from the nerve-cells in the deep transverse strata.

The deep transverse fibres form a much thicker layer than the superficial set, and contain much grey matter between them. The fibres pass from the crus or middle peduncle of the cerebellum to the median raphé of the pons, where they meet and interlace with those coming from the opposite side.

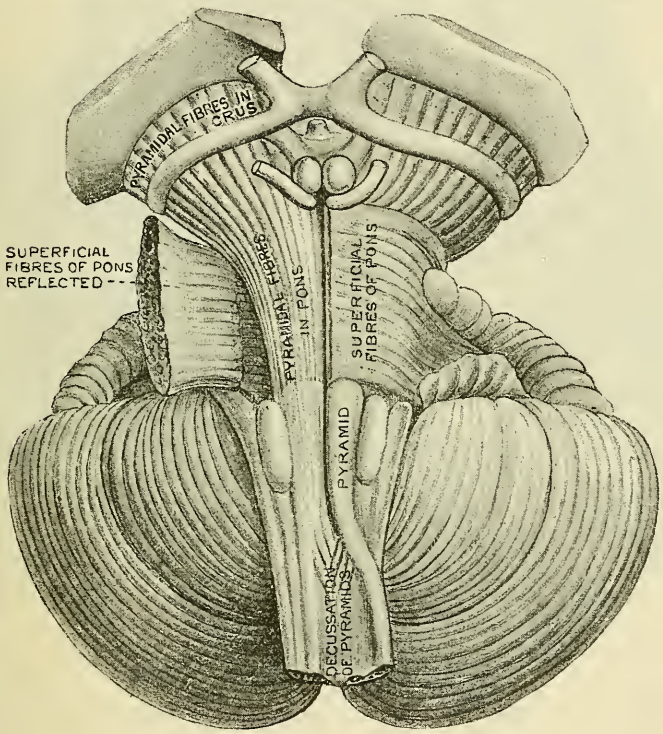
The posterior or dorsal portion of the pons is chiefly constituted by a continuation upwards of the reticular formation of the medulla and by the grey matter of the floor of the fourth ventricle.

Microscopic Anatomy of the Pons.—This presents the same reticular structure as in the medulla, consisting of longitudinal fibres continued upwards from the medulla, with interlacing transverse fibres between which is interspersed grey matter with nerve-cells, especially in the deeper layers. Many of the deep transverse fibres join the nerve-cells, which are situated in the grey matter (*nuclei*

pontis) of this layer. From these cells other fibres are given off which ascend through the pons to the crus cerebri.

In the lower part of this portion of the pons is a small isolated collection of grey matter, the *superior olivary nucleus*, enclosed by some of the deep transverse fibres, called the *trapezium*. It is situated close to the medulla, behind the superficial longitudinal fibres from the pyramid and immediately above the olivary body. The fibres of the trapezium, which are probably connected with the cells of the nucleus, pass to the middle peduncle of the cerebellum. Near the floor of the fourth ventricle important collections of nerve-cells are found, from which some of the cranial nerves arise. One of these forms the nucleus of the sensory root of the fifth nerve; a second, the nucleus of the motor part of the same nerve; a third, the nucleus of the sixth nerve; and a fourth, the nucleus of the facial nerve. The nucleus of the auditory nerve, situated just at the junction of the pons and medulla, is prolonged upwards into the pons.

Fig. 457.—Superficial dissection of the medulla oblongata and pons. (Ellis.)



Septum.—The posterior part of the pons is subdivided into lateral halves by a medium septum, but this does not extend into the anterior half, being here obliterated by the transverse fibres. It is formed mainly by the decussation and change in the direction of fibres as they cross the middle line.

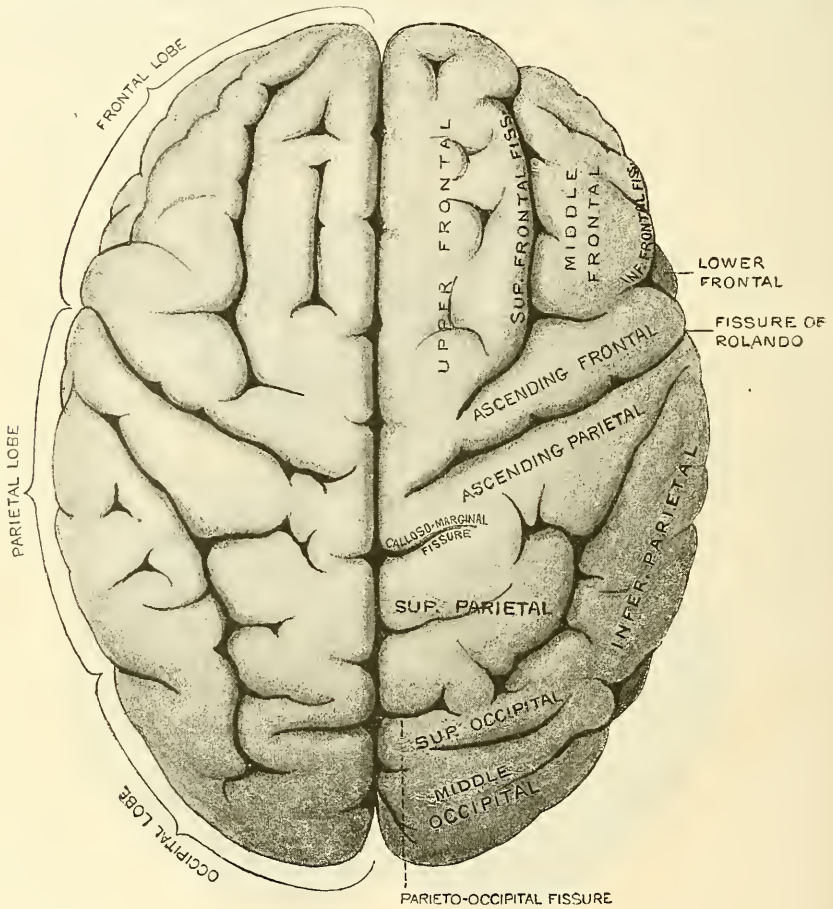
Cerebrum

The **cerebrum** constitutes the largest portion of the encephalon. Its under surface or base is of an irregular form, resting in front on the anterior and middle fossæ of the skull, and behind upon the tentorium cerebelli. Its upper surface is of an ovoid form, broader behind than in front, convex in its general outline, and divided into lateral halves or hemispheres, right and left, by the *great longitudinal fissure*, which extends throughout the entire length of the cerebrum in the middle

line, reaching down to the base of the brain in front and behind, but interrupted in the middle by a broad transverse commissure of white matter, the *corpus callosum*, which connects the two hemispheres together. This fissure lodges the falx cerebri, and indicates the original development of the brain by two lateral halves.

Each hemisphere presents an outer surface, which is convex to correspond with the vault of the cranium; an inner surface, which is flattened, and in contact with the opposite hemisphere (the two inner surfaces forming the sides of the

Fig. 458.—Upper surface of the brain, the arachnoid having been removed.



longitudinal fissure); and an under surface or base, of an irregular form, which rests in front on the anterior and middle fossæ of the base of the skull, and behind upon the tentorium cerebelli.

Upper Surface of the Cerebrum (fig. 458)

If the arachnoid and pia mater are removed, the entire surface of each hemisphere will be seen to present a number of depressions (*fissures* and *sulci*) separating a number of convoluted eminences (the *convolutions* or *gyri*).

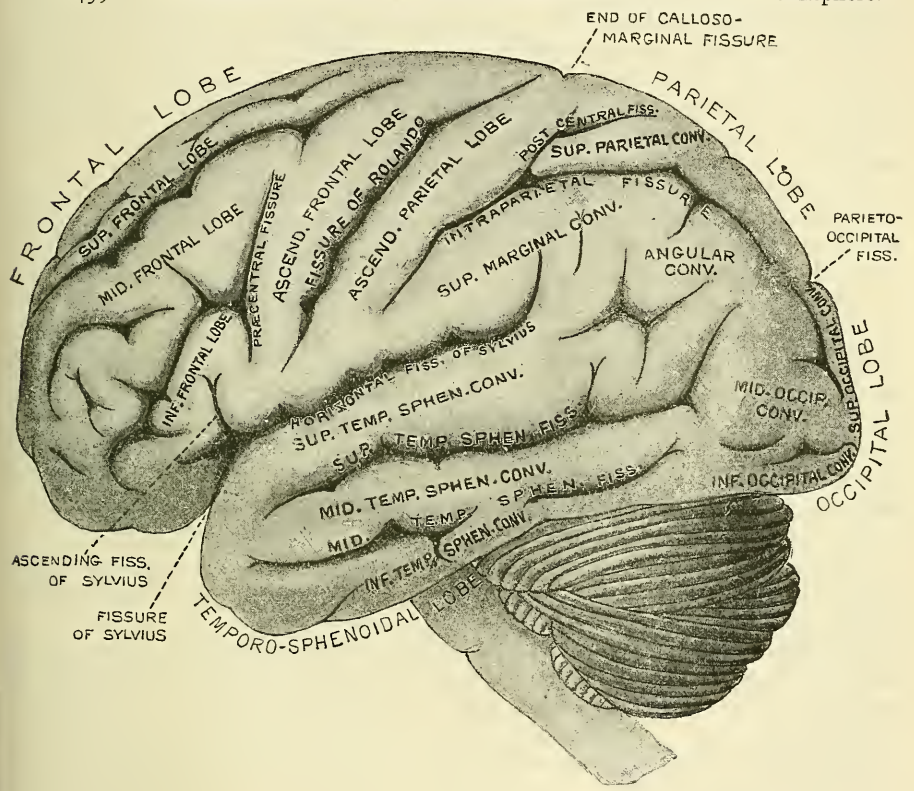
The depressions are of two kinds, *fissures* and *sulci*. The *fissures* are few in number; they are constant in their arrangement, and are produced by the foldings of the cerebrum during the process of development. They involve both grey and white matter. The *sulci* are more numerous; they are superficial depressions of the grey matter, which is folded inwards and only indents the central

white substance; they vary in different brains and in different parts of the same brain.

The Convolutions.—There is no accurate resemblance between the convolutions in different brains, nor are they exactly symmetrical on the two sides of the same brain, but their general arrangement or plan is fairly constant. Certain infoldings of the cerebrum take place at an early period of development and form important landmarks, which are constant and can without difficulty be recognised; but the secondary depressions and convolutions vary considerably.

The number and extent of the convolutions, as well as their depth, appear to bear a close relation to the intellectual power of the individual, as is shown in their increasing complexity of arrangement as we ascend from the lowest mammalia up to man. Thus they are absent in some of the lower orders of mammalia, and they increase in number and extent through the higher orders.

Fig. 459.—Convolutions and fissures of the outer surface of the cerebral hemisphere.



In man they present the most complex arrangement. Again, in the child, at birth, before the intellectual faculties are exercised, the convolutions have a very simple arrangement, presenting few undulations; and the sulci between them are less deep than in the adult. In old age, when the mental faculties have diminished in activity, the convolutions become much less prominently marked.

The convolutions on the outer convex surface of the hemisphere are the largest and most complicated convolutions of the brain; their general direction is more or less oblique; they frequently branch like the letter Y in their course upwards and backwards, towards the longitudinal fissure: these convolutions attain tbeir greatest development in man, and are especially characteristic of the human brain.

Structure of the Convolutions.—The outer surface of each convolution, as

well as the sides and bottom of the sulci between them, are composed of grey matter, which is here called the *cortical substance*. The interior of each convolution is composed of white matter; and white fibres also blend with the grey matter at the sides and bottom of the sulci. By this arrangement the convolutions are adapted to increase the amount of grey matter without occupying much additional space, while they also afford a greater extent of surface for the termination of the white fibres in grey matter.

The Lobes and Fissures of the Brain.—Each hemisphere of the brain on its external surface is divided into five lobes, the division being made by the main fissures and by imaginary lines drawn to connect them (fig. 459).

The fissures dividing the five lobes on the external surface of the hemispheres are three in number, and are named: *fissure of Sylvius*, *fissure of Rolando*, and *parieto-occipital fissure*.

The **fissure of Sylvius** begins at the base of the brain at the anterior perforated space, and passes outwards to the external surface of the hemisphere. It gives off a short *anterior limb*, which passes forwards; and another, *ascending limb*, which passes upwards into the inferior frontal convolution. It is then continued backwards, as the *horizontal limb*, and terminates in the parietal lobe after curving upwards for a short distance. It separates the frontal and parietal lobes from the temporo-sphenoidal, and occupies the middle third of the lateral surface of the hemisphere.

The **fissure of Rolando** is situated about the middle of the outer surface of the hemisphere. It commences at or near the longitudinal fissure, and runs downwards and forwards to terminate a little above the horizontal limb of the fissure of Sylvius, and about half an inch behind the ascending limb of the same fissure. It separates the frontal from the parietal lobe.

The **parieto-occipital fissure** is only seen to a slight extent on the outer surface of the hemisphere, and is not so distinctly marked as the others. The portion on the outer surface of the hemisphere is sometimes called the *external parieto-occipital fissure*, to distinguish it from the continuation of the sulcus on the internal surface of the hemisphere, which would then be termed the *internal parieto-occipital fissure*. It commences about midway between the posterior extremity of the brain and the fissure of Rolando, and runs downwards and forwards for about an inch. It divides the parietal and occipital lobes.

These three fissures divide the external surface of the hemisphere into five lobes: the *frontal*, the *parietal*, the *occipital*, the *temporo-sphenoidal*, and the *central* or *island of Reil*.

The **frontal lobe** is that portion of the brain which is situated in front of the fissure of Rolando and above the horizontal limb of the fissure of Sylvius. Its under surface rests on the orbital plate of the frontal bone, and is termed the *orbital lobe*.

The outer surface of the frontal lobe presents three sulci, which divide it into four primary convolutions. 1. The *precentral sulcus* runs upwards through this lobe, parallel to the lower half of the fissure of Rolando. It divides off a convolution, which lies between it and the fissure of Rolando, and which is called the *ascending frontal convolution*. 2 and 3. From it two sulci, the *superior* and *inferior frontal sulci*, run forwards and downwards and divide the remainder of the outer surface of the lobe—namely, that part in front of the precentral sulcus—into three principal convolutions, named respectively the *superior*, *middle*, and *inferior frontal convolutions*.

The under surface of the frontal lobe, which rests on the orbital plate of the frontal bone, is named the *orbital lobe* (fig. 460). It presents a well-marked groove or sulcus for the olfactory tract. The convolution internal to this sulcus forms part of the marginal gyrus, hereafter to be described. External to the sulcus this surface of the frontal lobe is divided into three convolutions by a well-marked sulcus, the *orbital* or *tri-radiate sulcus*. These are named, from their positions, the *internal*, *anterior*, and *posterior orbital convolutions*, and are

the continuation respectively of the superior, middle, and inferior frontal convolutions.

The *ascending frontal convolution* is a simple convolution, bounded in front by the precentral sulcus, behind by the fissure of Rolando, and extending from the upper margin of the hemisphere above to a little behind the bifurcation of the fissure of Sylvius below.

The *superior frontal convolution* is situated between the margin of the longitudinal fissure and the superior frontal sulcus. It extends above on to the inner aspect of the hemisphere, forming the marginal convolution, and in front on to the orbital surface, forming the internal orbital convolution. It is much divided by secondary sulci.

The *middle frontal convolution* is situated between the superior and inferior frontal sulci, and extends from the precentral sulcus to the lower margin of the lobe, where it forms the anterior orbital convolution.

The *inferior frontal convolution* is situated below the inferior frontal sulcus, and extends from the lower part of the precentral sulcus, circling round the ascending and anterior limbs of the fissure of Sylvius to the under surface of the lobe, where it forms the posterior orbital convolution.

The **parietal lobe** is situated between the frontal and occipital lobes, and is not much more than half the size of the former. It is bounded in front by the fissure of Rolando; behind, by the external parieto-occipital fissure, and a line drawn in continuation of that sulcus over the hemisphere; and below, by the horizontal limb of the fissure of Sylvius, and a line connecting this with the lower end of the superior occipital sulcus. Above, it extends to the longitudinal fissure. It presents for examination two sulci and three convolutions.

The *intraparietal sulcus* commences close to the horizontal limb of the fissure of Sylvius, about midway between the fissure of Rolando and the upturned extremity of the fissure of Sylvius. It first runs upwards parallel to and behind the lower half of the fissure of Rolando, and then turns backwards, extending nearly to the termination of the external parieto-occipital fissure, where it sometimes becomes continuous with the superior occipital sulcus. The ascending portion of this sulcus separates off a convolution, the *ascending parietal*, which lies between it and the fissure of Rolando, whilst the horizontal portion divides the remainder of the parietal lobe into two other convolutions, the *superior* and *inferior parietal*.

The *post-central sulcus* is a slightly marked groove, which is sometimes a branch of the intraparietal sulcus, being given off where the ascending portion of this sulcus turns backwards. It lies parallel to and behind the upper part of the fissure of Rolando, and separates the ascending from the superior parietal convolution.*

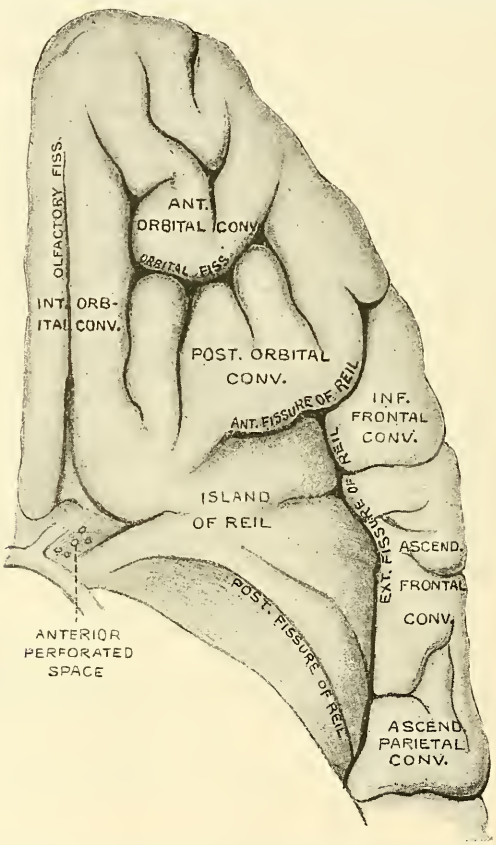
The *ascending parietal convolution* is bounded in front by the fissure of Rolando, behind by the ascending portion of the intraparietal and the post-

* Professor Cunningham describes these two sulci, the intraparietal and post-central, somewhat differently. He regards them as both belonging to the intraparietal sulcus, which he divides into three parts: the ascending portion of the intraparietal, as described above, he terms the *ramus verticalis inferior*; the horizontal portion as the *ramus horizontalis*; while the post-central sulcus he denominates the *ramus verticalis superior*. He states that considerable variability is exhibited in the relation to each other of these different parts of the intraparietal sulcus, but that the one in which the three parts of the sulcus are confluent is by far the most constant condition. Sometimes, however, the three parts of the sulcus may be all separate, or the ramus horizontalis confluent with the ramus verticalis inferior, the ramus verticalis superior remaining separate; or, again, the vertical limbs may be confluent and the horizontal limb separate; or, finally, the ramus horizontalis may be joined to the lower end of the ramus verticalis superior, while the lower vertical limb is separate. The connection which sometimes exists between the intraparietal sulcus and the occipital lobe he calls the *ramus occipitalis*. In the majority of cases, however, the occipital ramus is separated from the main portion of the intraparietal sulcus by a superficial or deep bridging convolution. *Journal of Anatomy and Physiology*, vol. xxiv. part ii. p. 135.

central sulci. It extends from the great longitudinal fissure above to the horizontal limb of the fissure of Sylvius below. It lies parallel with the ascending frontal convolution, with which it is connected below, and also generally above, the termination of the fissure of Rolando.

The *superior parietal convolution* is bounded in front by the post-central sulcus which separates it from the previous convolution, but with which it is usually connected above the upper extremity of the sulcus; behind, it is bounded by the external parieto-occipital fissure, below the termination of which it is connected with the occipital lobe by a narrow convolution, the *first annectant gyrus*; below, it is separated from the inferior parietal convolution by the horizontal portion of the intraparietal sulcus; and above, it is continuous on the inner surface of the hemisphere with the quadrate lobe.

Fig. 460.—Convolutions and fissures of the under surface of the anterior lobe.



The *inferior parietal convolution* is that portion of the parietal lobe which is situated between the ascending portion of the intraparietal sulcus in front, the horizontal portion of the same sulcus above, the horizontal limb of the fissure of Sylvius below, and the posterior boundary of the parietal lobe behind. It is subdivided into two convolutions by an indistinct groove. One, the *supramarginal*, lies behind the lower end of the intraparietal sulcus and above the horizontal limb of the fissure of Sylvius. It is connected, in front, with the ascending parietal convolution beneath the intraparietal sulcus, and with the superior temporo-sphenoidal convolution behind, round the posterior extremity of the fissure of Sylvius. The other, the *angular*, is connected in front with the foregoing, and with the middle temporo-sphenoidal convolution by a process which curves round the superior temporo-sphenoidal or parallel sulcus. It is connected with the occipital lobe by the *second annectant gyrus*.

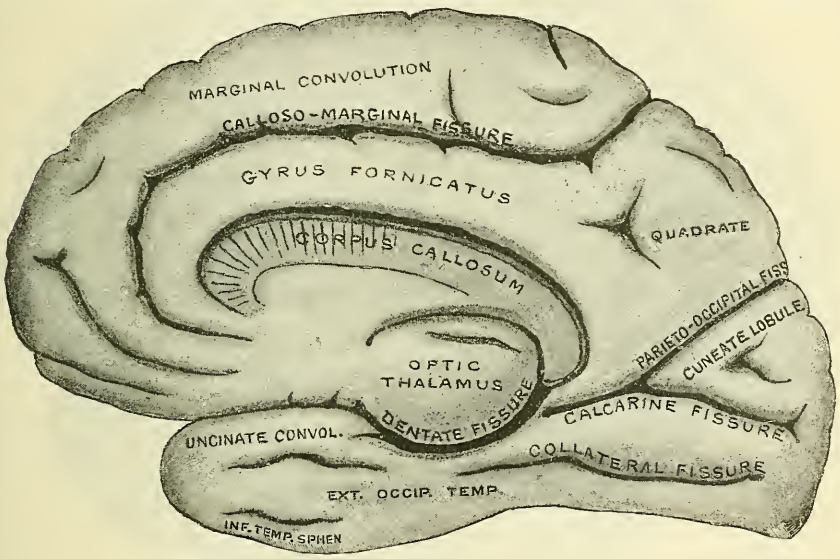
The **occipital lobe** is triangular in shape and forms the posterior extremity of the hemisphere. It is bounded in front by the external parieto-occipital fissure and a line drawn from the extremity of this in the direction of the fissure across the outer surface of the hemisphere. It is continuous below and in front with the temporo-sphenoidal lobe, and above with the parietal. It is divided on the outer surface of the hemisphere into three convolutions by two indistinct sulci, the *superior* and *middle occipital sulci*. They are directed backwards across the lobe, being frequently small and ill-marked; the superior is sometimes continuous with the horizontal portion of the intraparietal sulcus.

The *superior occipital convolution* is situated above the superior sulcus, and is connected to the superior parietal convolution by the *first annectant gyrus*.

The *middle occipital convolution* is situated between the superior and middle occipital sulci, and is connected to the angular convolution by the *second annectant gyrus*, and to the middle temporo-sphenoidal by the *third annectant gyrus*.

The *inferior occipital convolution* is situated below the middle occipital sulcus, and is sometimes separated from the external occipito-temporal convolution on

FIG. 461.—Convolutions and fissures of the inner surface of the cerebral hemisphere.



the under surface of the hemisphere by an inconstant sulcus, the *inferior occipital sulcus*. It is connected to the inferior temporo-sphenoidal convolution by the *fourth annectant gyrus*.

The **temporo-sphenoidal lobe** is that portion of the hemisphere which is lodged in the middle fossa of the base of the skull. In front and above, it is limited by the fissure of Sylvius; behind, it is connected with the parietal and occipital lobes, and is limited artificially by a line continuing the direction of the external parieto-occipital fissure across the outer surface of the hemisphere. It is divided into three convolutions by two sulci. The superior of these runs parallel to the horizontal limb of the fissure of Sylvius. It is named the *superior temporo-sphenoidal* or *parallel sulcus*, and is well marked and constant. The second, the *middle temporo-sphenoidal*, is not so well marked or constant; it takes the same course at a lower level.

The *superior temporo-sphenoidal convolution* is situated between the horizontal limb of the fissure of Sylvius and the superior temporo-sphenoidal sulcus. It is continuous behind with the supramarginal convolution.

The *middle temporo-sphenoidal convolution* is situated between the superior

and middle sulci of the same name, and is continuous behind with the angular and middle occipital convolutions.

The *inferior temporo-sphenoidal convolution* is situated below the middle temporo-sphenoidal sulcus, and is separated from the external occipito-temporal convolution, on the under surface of the hemisphere, by a sulcus which is called the *inferior temporo-sphenoidal sulcus*. It is connected with the inferior occipital convolution.

The **central lobe,** or **island of Reil** (fig. 460), is situated in the fissure of Sylvius, at the base of the brain ; it is separated, in front, from the posterior orbital convolution by a nearly transverse sulcus, the *anterior sulcus of Reil* ; externally, from the inferior frontal convolution and the lower ends of the ascending frontal and parietal convolutions, by another deep sulcus, the *external sulcus of Reil* ; and posteriorly, from the temporo-sphenoidal lobe, by a third sulcus, the *posterior*

sulcus of Reil. It is a triangular-shaped prominent cluster of about six convolutions, the *gyri operti*, so called from being covered in by the fissure. By the removal of these convolutions the extraventricular part of the corpus striatum would be reached.

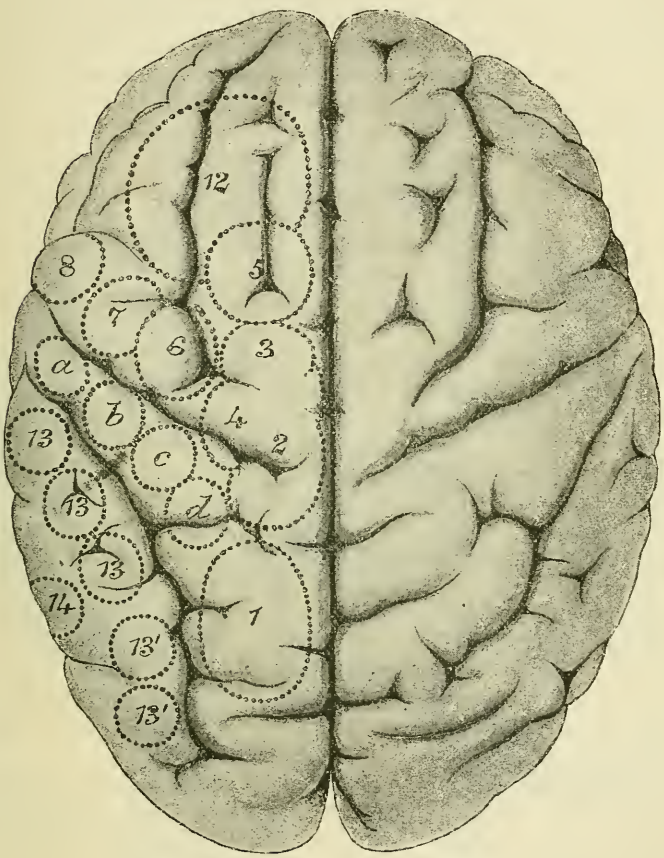
On the **inner** or **median surface of the hemispheres** the arrangement of the convolutions is less complex ; they are generally well defined, and some of them being of great length, there is not the same subdivision into smaller lobes as on the external surface (fig. 461). The fissures on the internal surface are five in number, and are named the *calloso-marginal*, the *parieto-occipital*, the *calcarine*, the *collateral*, and the *dentate*.

The **calloso-marginal fissure** is seen in front, commencing below the anterior extremity of the corpus callosum ; it at first runs forwards and upwards parallel

with the rostrum of the corpus callosum, and, winding round the genu of that body, it continues from before backwards, between the upper margin of the hemisphere and the convolution of the corpus callosum, to about midway between the anterior and posterior extremities of the brain, where it turns upwards to reach the upper margin of the inner surface of the hemisphere a short distance behind the superior extremity of the furrow of Rolando. It separates the marginal convolution from the gyrus fornicatus or convolution of the corpus callosum.

The **parieto-occipital fissure** (*internal parieto-occipital*) is the continuation of the fissure of the same name seen on the outer surface of the hemisphere. It

Fig. 463.—Top view of the brain of man, showing the localisation of various functions. (After Ferrier.)



References the same as in the preceding figure.

extends in an oblique direction downwards and forwards to join the calcarine fissure on a level with the hinder end of the corpus callosum. It separates the quadrate from the cuneate lobe.

The **calcarine fissure** commences, usually by two branches, at the back of the hemisphere, runs nearly horizontally forwards, and is joined by the parieto-occipital fissure, and continues nearly as far as the posterior extremity of the corpus callosum, to terminate a little below the level of this commissure. It separates the cuneate lobe from the uncinate gyrus, and causes the prominence known as the hippocampus minor or calcar avis, whence its name.

The **collateral fissure** is situated below the preceding, being separated from it by the uncinate gyrus. It runs forwards, from the posterior extremity of the brain, nearly as far as the commencement of the fissure of Sylvius. It runs between the internal and external occipito-temporal convolutions. It lies below

the posterior and middle horn of the lateral ventricle, and causes the prominence known as the eminentia collateralis.

The **dentate** or **hippocampal fissure** commences immediately below the posterior extremity of the corpus callosum, and runs forward to terminate at the recurved part of the uncinate gyrus. It corresponds with the prominence of the hippocampus major in the descending horn of the lateral ventricle.

The lobes or convolutions seen on the internal surface of the hemisphere are six in number, and are named: *gyrus fornicatus, marginal, quadrate, cuneate, uncinate* or *internal occipito-temporal*, and the *external occipito-temporal.*

The **gyrus fornicatus**, or convolution of the corpus callosum, is a well-marked lobe which begins just in front of the anterior perforated space at the base of the brain; it ascends in front of the genu of the corpus callosum, and runs backwards along the upper surface of this body to its posterior extremity, where it joins the uncinate convolution. It is bounded above in the greater part of its extent by the calloso-marginal fissure, which separates it from the marginal convolution; behind the spot where this fissure turns upwards it is continuous with the quadrate lobe.

The **marginal convolution** is situated above the preceding, and has received its name from its position along the border of the hemisphere. It commences in front of the anterior perforated space, runs along the margin of the longitudinal fissure on the under surface of the orbital lobe, being bounded externally by the sulcus for the olfactory tract; it then turns upwards to the upper surface of the hemisphere, and runs backwards, forming the marginal convolution, on the inner surface, to the point where the calloso-marginal fissure turns upwards to reach the superior border of the hemisphere.

The **quadrate lobe** (*precuneus*) is the marginal convolution of the longitudinal fissure behind the calloso-marginal sulcus, lying between this fissure in front and the internal parieto-occipital behind. It joins the gyrus fornicatus below, and is continuous above with the superior parietal convolution.

The **cuneate** or **occipital lobule** is triangular in shape, being situated between the internal parieto-occipital and calcarine fissures, which, as above mentioned, meet behind the posterior extremity of the gyrus fornicatus.

The **uncinate** or **internal occipito-temporal convolution** extends from the posterior extremity of the hemisphere to the fissure of Sylvius, being bounded above by the calcarine and dentate fissure and separated below from the external occipito-temporal convolution by the collateral fissure. From the anterior extremity a narrow portion is recurved or bent backwards in the form of a hook, which is sometimes called the *crochet* or *uncus*. The back part of this convolution —that is, the part below the calcarine fissure—is sometimes known as the *lingual lobule* or *gyrus*.

The **external occipito-temporal convolution** is of considerable length, and lies between the collateral fissure and the inferior temporo-sphenoidal sulcus, which latter separates it from the inferior temporo-sphenoidal convolution on the outer surface of the hemisphere.

Besides the great primary convolutions above named and described, and which can be recognised in almost any well-developed brain, there are a great number of secondary convolutions which pass from one primary convolution to another, and often render the arrangement of the latter somewhat obscure; of these, the connections of the occipital lobe, above mentioned, and which are named *annectant convolutions*, may be taken as examples.

Cerebral Localisation and Topography.—Within the last few years physiological and pathological research have gone far to prove that the surface of the brain may be mapped out into series of definite areas, each one of which is intimately connected with some well-defined function. And this is especially true with regard to the convolutions on either side of the fissure of Rolando, which are believed by most physiologists of the present day to be concerned in motion, those grouped around the fissure being associated with movements of the extremities of the opposite side of the body, and those around the lower end of the fissure being related to movements of the mouth and tongue.

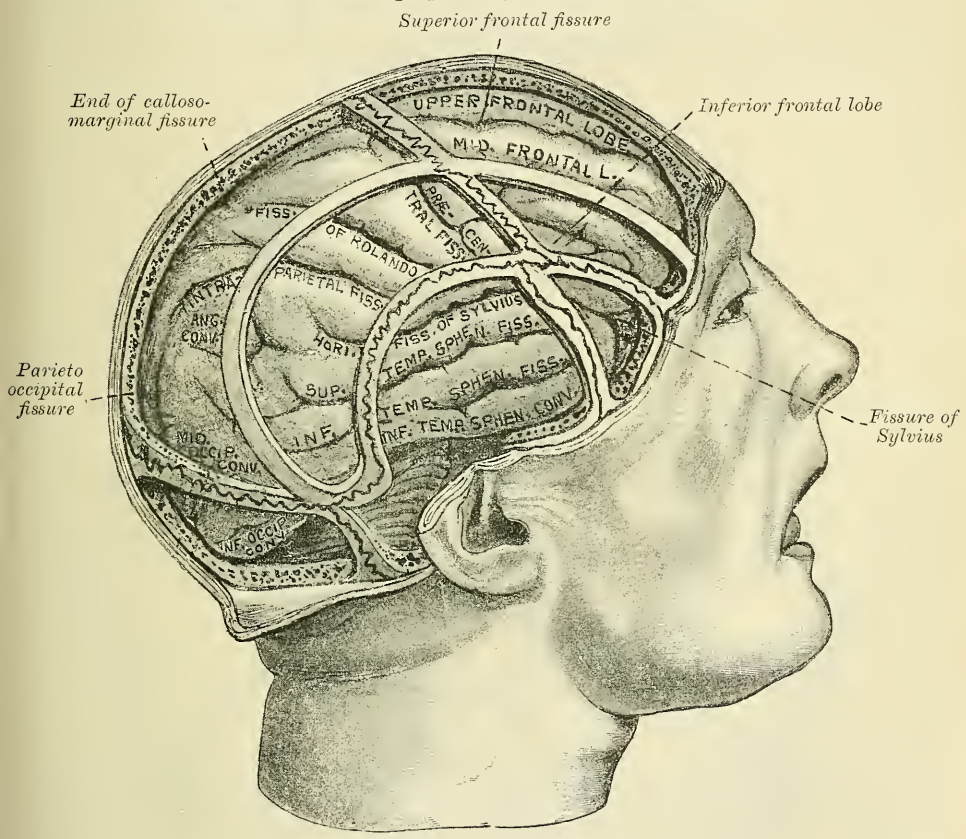
This is not the place, nor can space be given, to describe these localities. But the two

accompanying woodcuts from Ferrier (figs. 462, 463) have been introduced, and will serve to indicate the position of these areas as far as they have been at present ascertained.

The relation of the principal fissures and convolutions of the cerebrum to the outer surface of the scalp has been the subject of much recent investigation, and many systems have been devised by which one may localise these parts from an examination of the external surface of the head.

These plans can only be regarded as approximately correct for several reasons: in the first place, because the relations of the convolutions and sulci to the surface are found to be very variable in different individuals; secondly, because the surface area of the scalp is greater than the surface area of the brain, so that lines drawn on the one cannot correspond exactly to sulci or convolutions on the other; and thirdly, because the sulci and convolutions in two individuals are never precisely alike. Nevertheless, the principal fissures and convolutions can be mapped out with sufficient accuracy for all practical purposes, so that any particular convolution can be generally exposed by removing with the trephine a certain portion of the skull's area.

Fig. 464.—Drawing to illustrate cranio-cerebral topography. (Macalister.)
Taken from a cast prepared by Professor Cunningham.



The various landmarks on the outside of the skull, which can be easily felt, and which serve as indications of the position of the parts beneath, have been already referred to (see page 204), and the relation of the fissures and convolutions to these landmarks is as follows:—

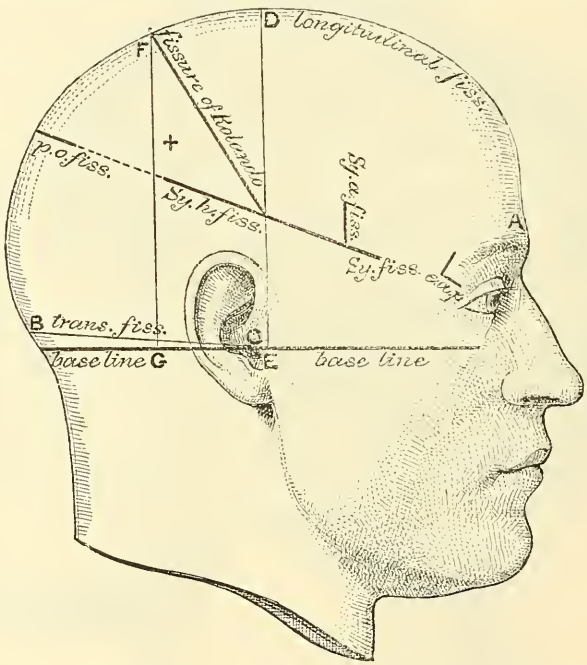
Longitudinal Fissure.—This corresponds to a line drawn from the glabella at the root of the nose to the external occipital protuberance.

The Fissure of Sylvius.—The position of the fissure of Sylvius and its horizontal limb is marked by a line starting from a point one inch and a quarter horizontally behind the external angular process of the frontal bone to a point three-quarters of an inch below the most prominent point of the parietal eminence. The first three-quarters of an inch will represent the main fissure, the remainder the horizontal limb. The bifurcation of the fissure is, therefore, two inches behind and about a quarter of an inch above the level of the external angular process. The ascending limb of the fissure passes upwards from this point parallel to, and immediately behind, the coronal suture.

Fissure of Rolando.—To find the upper end of the fissure of Rolando, a measurement should be taken from the glabella to the external occipital protuberance. The position of

the top of the sulcus will be, measuring from in front, 55·6 per cent. of the whole distance from the glabella to the external occipital protuberance. Professor Thane adopts a somewhat simpler method. He divides the distance from the glabella to the external occipital protuberance over the top of the head into two equal parts, and having thus defined the middle point of the vertex, he takes half an inch behind it as the top of the sulcus. This is not quite so accurate as the former method, but it is sufficiently so for all practical purposes, and, on account of its simplicity, is very generally adopted. From this point the fissure runs downwards and forwards for $3\frac{3}{4}$ inches, its axis making an angle of 67° with the middle line. Cunningham states that this angle more nearly averages 71·5°. In order to mark this groove, two strips of metal may be employed: one, the shorter, being fixed to the middle of the other at the angle mentioned. If the longer strip is now placed along the sagittal suture so that the junction of the two strips is over the point corresponding to the top of the furrow, the shorter, oblique strip will indicate the direction, and $3\frac{3}{4}$ inches will mark the length of the furrow. Dr. Wilson has devised an instrument, called a cystometer, which combines the scale of measurements for localising the fissure, with data for representing its length and direction.* Professor Thane gives the lower end of the furrow as 'close to the posterior limb, and about half an inch behind the bifurcation of the fissure of Sylvius.' So that, according to this anatomist, a line drawn from a point

Fig. 465.—Relation of the principal fissures and convolutions of the cerebrum to the outer surface of the scalp. (Reid.)



half an inch behind the mid-point between the glabella and external occipital protuberance to this spot would mark out the fissure of Rolando. Dr. Reid adopts a different method (fig. 465). He first indicates, on the surface, the longitudinal fissure and the horizontal limb of the fissure of Sylvius (as above). He then draws two perpendicular lines from his 'base-line' (that is, a line from the lowest part of the infra-orbital margin through the middle of the external auditory meatus to the back of the head) to the top of the cranium, one (D E, fig. 465) from the depression in front of the external auditory meatus, and the other (F G, fig. 465) from the posterior border of the mastoid process at its root. He has thus described on the surface of the head a four-sided figure (F D G E, fig. 465), and a diagonal line from the posterior superior angle to the anterior perpendicular line where it is crossed by the fissure of Sylvius will represent the furrow.

The *parieto-occipital fissure* on the upper surface of the cerebrum runs outwards at right angles to the great longitudinal fissure for about an inch, from a point $\frac{1}{5}$th of an inch in front of the lambda (posterior fontanelle). Reid states that if the horizontal limb of the fissure of Sylvius be continued onwards to the sagittal suture, the last inch of this line will indicate the position of the sulcus.

The *precentral sulcus* lies in a line drawn vertically downwards from the point of

* *Lancet*, vol. i. 1888, p. 408.

junction of the sagittal and coronal sutures. It begins four-fifths of an inch in front of the middle of the fissure of Rolando, and extends nearly, but not quite, to the horizontal limb of the fissure of Sylvius.

The *superior frontal fissure* runs backwards from the supra-orbital notch, parallel with the line of the longitudinal fissure to $\frac{2}{5}$th of an inch in front of the line indicating the position of the fissure of Rolando.

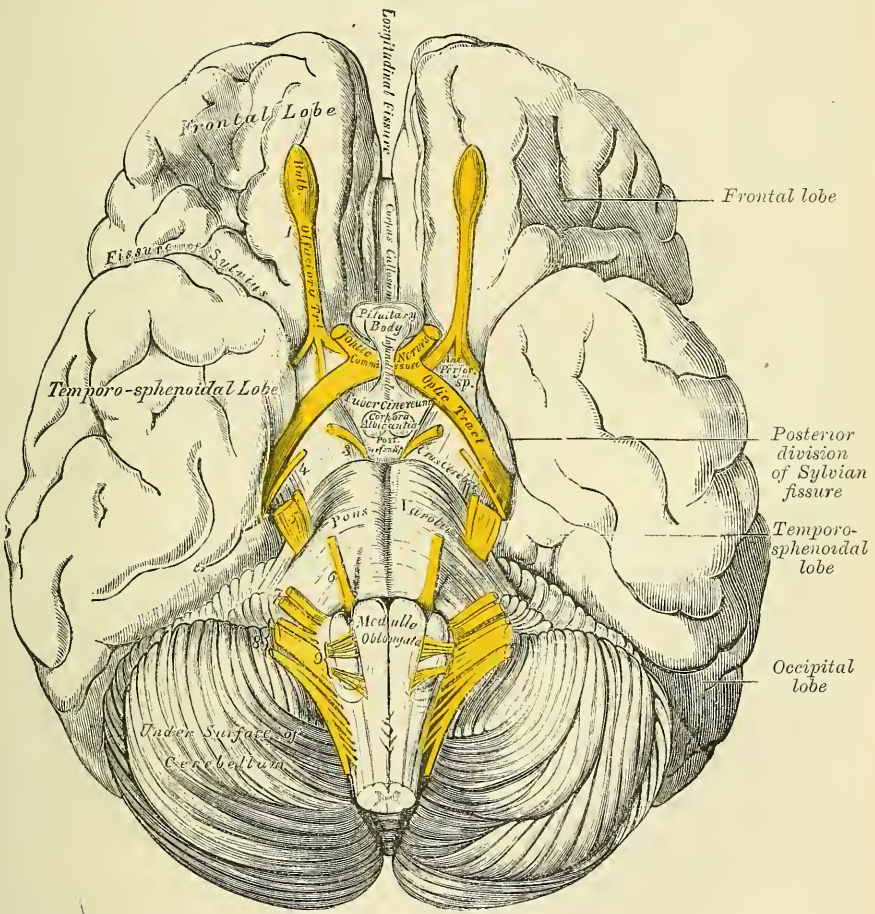
The *inferior frontal fissure* follows the course of the superior temporal ridge on the frontal bone.

The *intraparietal fissure* begins on a level with the junction of the middle and lower third of the fissure of Rolando, on a line carried across the head from the back of the root of one auricle to that of the other. After passing upwards, it curves backwards, lying parallel to the longitudinal fissure, midway between it and the parietal eminence; it then curves downwards to end midway between the posterior fontanelle and the parietal eminence.

Cerebrum. Under Surface or Base (fig. 466)

The under surface of each hemisphere presents a subdivision into three lobes, named, from their position, *anterior*, *middle*, and *posterior*.

Fig. 466.—Base of the brain.



The **anterior** or **frontal lobe**, of a triangular form, with its apex backwards, is somewhat concave, and rests upon the convex surface of the roof of the orbit, being separated from the middle lobe by the fissure of Sylvius. The **middle lobe**, which is more prominent, is received into the middle fossa of the base of the skull, and comprises the under part of the temporo-sphenoidal lobe. The **posterior** or **occipital lobe** rests upon the tentorium, its extent forwards being limited by the anterior margin of the cerebellum.

The various objects exposed to view on the under surface of the cerebrum, in and near the middle line, are here arranged in the order in which they are met with from before backwards.

Longitudinal fissure.
Corpus callosum and its peduncles.
Lamina cinerea.
Olfactory tract.
Fissure of Sylvius.
Anterior perforated space.
Optic commissure.
Tuber cinereum.
Infundibulum.
Pituitary body.
Corpora albicantia.
Posterior perforated space.
Crura cerebri.

The **longitudinal fissure** partially separates the two hemispheres from each other: it divides the two frontal lobes in front; and on raising the cerebellum and pons, it will be seen completely separating the two occipital lobes. Of these two portions of the longitudinal fissure, that which separates the occipital lobes is the longer. The intermediate portion of the fissure is filled up by the great transverse band of white matter, the *corpus callosum*. In the fissure between the two frontal lobes the anterior cerebral arteries ascend on the corpus callosum.

The **corpus callosum** terminates at the base of the brain by a concave margin, which is connected with the tuber cinereum through the intervention of a thin layer of grey substance, the *lamina cinerea*. This may be exposed by gently raising and drawing back the optic commissure. A white band may be observed on each side, passing from the under surface of the corpus callosum, backwards across the posterior margin of the anterior space to the temporo-sphenoidal lobe; here they join the inner root of the olfactory tract: these bands are called the *peduncles of the corpus callosum*. They may be traced upwards around the genu to become continuous with the *striæ longitudinales*, or *nerves of Lancisi*, on the upper surface of the corpus callosum (page 751). Laterally, this portion of the corpus callosum extends into the frontal lobe.

The **lamina cinerea** is a thin layer of grey substance, extending backwards above the optic commissure from the termination of the corpus callosum to the tuber cinereum; it is continuous on each side with the grey matter of the anterior perforated space, and forms the anterior part of the inferior boundary of the third ventricle.

The **olfactory tract**, with its bulb, is seen on each side of the longitudinal fissure upon the under surface of each frontal lobe.

The **fissure of Sylvius** separates the frontal from the temporo-sphenoidal lobe, and lodges the middle cerebral artery. It begins at the outer side of a depression, at the bottom of which is the anterior perforated space. This depression is called the *vallecula Sylvii*. At its commencement is seen a point of medullary substance, corresponding to a subjacent band of white fibres, connecting the frontal and temporo-sphenoidal lobes, and called the *fasciculus unciformis*. On following this fissure outwards, it divides into two branches, enclosing portions of the frontal and parietal lobes, which overhang and cover the upper part of a prominent cluster of isolated convolutions called the *island of Reil*, or *central lobe*. The overhanging portion of the frontal and parietal lobe is called the *operculum of the insula*.

The **anterior perforated space** is situated at the inner side of the fissure of Sylvius. It is of a triangular shape, bounded, in front, by the orbital convolutions of the frontal lobe and the roots of the olfactory tract; behind, by the optic tract; externally, by the temporo-sphenoidal lobe and commencement of the fissure of Sylvius; internally, it is continuous with the lamina cinerea, and crossed by the peduncle of the corpus callosum. It is of a greyish colour, and corresponds to the under surface of the corpus striatum, a large mass of grey matter, situated in the interior of the brain; it has received its name from being perforated by numerous minute apertures for the transmission of small straight vessels into

the substance of the corpus striatum, constituting the antero-median and antero-lateral ganglionic branches of the anterior and middle cerebral arteries.

The **optic commissure** is situated in the middle line, immediately in front of the tuber cinereum and below the lamina cinerea.* It is the point of junction between the two optic nerves.

Immediately behind the diverging optic tracts, and between them and the peduncles of the cerebrum (*crura cerebri*), is a lozenge-shaped interval, the *inter-peduncular space*, in which are found the following parts: the tuber cinereum, infundibulum, pituitary body, corpora albicantia, and the posterior perforated space.

The **tuber cinereum** is an eminence of grey matter, situated between the optic tracts and extending from the corpora albicantia to the optic commissure, to which it is attached; it is connected with the surrounding parts of the cerebrum, forms part of the floor of the third ventricle, and is continuous with the grey substance in that cavity. From the middle of its under surface a conical tubular process of grey matter, about two lines in length, is continued downwards and forwards, to be attached to the posterior lobe of the pituitary body: this is the *infundibulum*. Its canal, which is funnel-shaped, communicates with the third ventricle.

The **pituitary body** (*hypophysis cerebri*) is a small reddish-grey vascular mass, weighing from five to ten grains, and of an oval form, situated in the sella Turcica, in connection with which it is retained by a process of dura mater derived from the inner wall of the cavernous sinus. This process covers in the pituitary fossa, enclosing the pituitary body, and having a small hole in its centre through which the infundibulum passes.

Structure.—The pituitary body is very vascular, and consists of two lobes, separated from one another by a fibrous lamina. Of these, the anterior is the larger, of an oblong form, and somewhat concave behind, where it receives the posterior lobe, which is round. The two lobes differ both in development and structure. The *anterior lobe*, of a dark, yellowish-grey colour, is developed from the ectoderm of the buccal cavity, and resembles to a considerable extent, in microscopic structure, the thyroid body. It consists of a number of isolated vesicles and slightly convoluted alveoli, lined by epithelium and united together by connective tissue. The epithelium is columnar and occasionally ciliated. The alveoli sometimes contain a colloid material, similar to that found in the thyroid body, and their walls are surrounded by a close network of lymphatics and capillary blood-vessels. The *posterior lobe* is developed by an outgrowth from the embryonic brain, and during fœtal life contains a cavity which communicates through the infundibulum with the cavity of the third ventricle. In the adult it becomes firmer and more solid, and consists of a sponge-like connective tissue arranged in the form of reticulating bundles, between which are branched cells, some of them containing pigment. In the lower animals the two lobes are quite distinct, and it is only in the mammalia that they become connected together.

The **corpora albicantia**, or **mammillaria**, are two small, round, white masses, each about the size of a pea, placed side by side immediately behind the tuber cinereum. They are formed by the anterior crura of the fornix, hence called the *bulbs of the fornix*, which, after descending to the base of the brain, are folded upon themselves before passing upwards to the thalami optici. They are composed externally of white substance, and internally of grey matter; the grey matter of the two being connected by a transverse commissure of the same material. At an early period of fœtal life they are blended together into one large mass, but become separated about the seventh month.

The **posterior perforated space** (*pons Tarini*) corresponds to a whitish-grey substance placed between the corpora albicantia in front, the pons Varolii behind,

* That is to say, the commissure is superficial to the lamina in the order of dissection when the base is uppermost.

and the crura cerebri on each side. It forms the back part of the floor of the third ventricle. It is perforated by numerous small orifices for the passage of the postero-median ganglionic branches of the posterior cerebral and posterior communicating arteries.

The **crura cerebri** (*peduncles of the cerebrum*) are two thick cylindrical bundles of white matter, which emerge from the anterior border of the pons, and diverge as they pass forwards and outwards to enter the under part of either hemisphere. Each crus is about three-quarters of an inch in length, and somewhat broader in front than behind. They are marked upon their surface with longitudinal striæ, and each is crossed, just before entering the hemisphere, by a flattened white band, the *optic tract*, which is adherent by its upper border to the peduncle. The third nerve may be seen emerging from a groove on the inner side of each crus, and the fourth nerve winding round its outer side from above.

Structure of the Crura.—Each crus consists of a superficial layer of longitudinal white fibres, the *crusta*, continued upwards from the pons; of a deeper layer, a prolongation of the reticular formation, termed the *tegmentum*; and of an intermediate stratum of grey matter, the *locus niger*.

The *crusta*, or the superficial layer of longitudinal fibres, consists of coarse bundles of nerve-fibres, which are collected on the under or free surface of the crus. It is formed almost entirely of longitudinal fibres continuous with the pyramidal fibres of the medulla and pons, those derived from the medulla occupying the central portion of the crusta, those added in the pons being placed laterally. The fibres pass to the cerebral hemispheres, entering the internal capsule.

The *tegmentum* forms the deeper part of the crus cerebri, and is united below with its fellow of the opposite side by a prolongation of the septum of the pons but separated above by the posterior perforated space. It consists of longitudinal bundles of white fibres, interlaced by transverse fibres, together with a quantity of grey matter with scattered nerve-cells. It forms a well-marked *formatio reticularis* similar to that found in the pons and medulla, with which it is continuous, receiving, however, a bundle of fibres (*superior peduncle*) from the cerebellum. Above, the fibres enter the optic thalamus.

The *locus niger* is a mass of grey matter, situated between the crusta and tegmentum, and projecting here and there between the bundles of the former. It is thicker at the inner than at the outer side, and is traversed in its mesial part by the fibres of origin of the third nerve. It contains irregular nerve-cells, in which are lodged numerous dark pigment-granules.

The posterior lobes of the cerebrum are concealed from view by the upper surface of the cerebellum and pons Varolii. When these parts are raised, the two hemispheres are seen to be separated by the great longitudinal fissure, this fissure being interrupted by the posterior rounded border of the corpus callosum.

General Arrangement of the Parts composing the Cerebrum

As the peduncles or crura of the cerebrum enter the hemispheres, they diverge from one another, so as to leave an interval between them, the *interpeduncular space*. As they ascend, the component fibres of each pass through two large masses of grey matter, the ganglia of the brain, called the *thalamus opticus* and *corpus striatum*, which project as rounded eminences from the upper and inner side of each peduncle. The hemispheres are connected together, above these masses, by the great transverse commissure, the *corpus callosum*; the interval left between its under surface, the upper surface of the ganglia, and the parts closing the interpeduncular space, forms the general ventricular cavity. The upper part of this cavity is subdivided into two by a vertical septum, the *septum lucidum*; and thus the two lateral ventricles are formed. The lower part of the cavity forms the third ventricle, which communicates with the lateral ventricles above, and with the fourth ventricle behind. The fifth ventricle is the interval left between the two layers composing the septum lucidum.

Interior of the Cerebrum

If the upper part of either hemisphere is removed with a scalpel, about half an inch above the level of the corpus callosum, its internal white matter will be exposed. It is an oval-shaped centre, of white substance, surrounded on all sides by a narrow convoluted margin of grey matter which presents an equal thickness in nearly every part. This white central mass has been called the *centrum ovale minus*. Its surface is studded with numerous, minute red dots (*puncta vasculosa*), produced by the escape of blood from divided blood-vessels. In inflammation or great congestion of the brain, these are very numerous, and of a dark colour. If the remaining portion of one hemisphere is slightly separated from the other, a broad band of white substance will be observed connecting them at the bottom of the longitudinal fissure; this is the *corpus callosum*. The margins of the hemispheres which overlap this portion of the brain are called the *labia cerebri*. Each labium is part of the convolution of the corpus callosum (*gyrus fornicatus*) already described; and the space between it and the upper surface of the corpus callosum has been termed the *ventricle of the corpus callosum* or *callosal fissure* (fig. 470).

The hemispheres should now be sliced off, to a level with the corpus callosum, when the white substance of that structure will be seen connecting the two hemispheres. The large expanse of medullary matter now exposed, surrounded by the convoluted margin of grey substance, is called the *centrum ovale majus* of Vieussens.

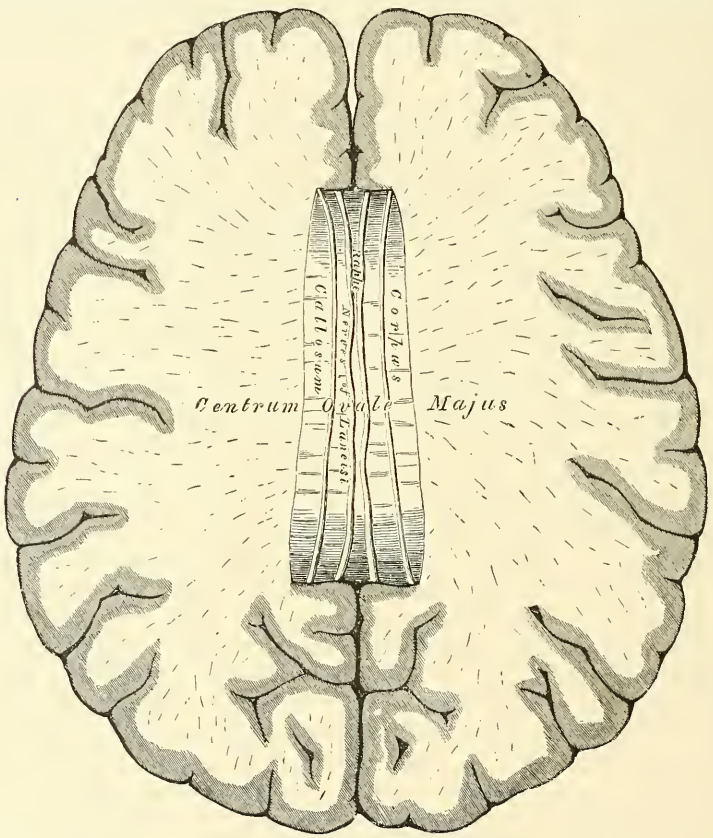
The **corpus callosum** is a thick stratum of transverse fibres, exposed at the bottom of the longitudinal fissure. It connects the two hemispheres of the brain, forming their great transverse commissure; and forms the roof of the space in the interior of each hemisphere, the *lateral ventricle*. It is about four inches in length, extending to within an inch and a half of the anterior, and to within two inches and a half of the posterior, part of the brain. It is somewhat broader behind than in front, and is thicker at either end than in its central part, being thickest behind. It presents a somewhat arched form (figs. 474, 5), from before backwards, and in front forms a distinct bend, named the *genu*, and is then continued downwards and backwards between the frontal lobes to the base of the brain, where it is connected, through the lamina cinerea, with the tuber cinereum. The reflected portion of the corpus callosum is called the *beak* or *rostrum*; it becomes gradually narrower as it descends, and is attached by its lateral margins to the frontal lobes. At its termination the corpus callosum gives off two bundles of white substance, which, diverging from one another, pass backwards, across the anterior perforated space, temporo-sphenoidal lobe, where they join the inner root of the olfactory tract. They are called the *peduncles of the corpus callosum*. Posteriorly, the corpus callosum forms a thick rounded fold, called the *splenium*, or *pad*, which is free for a little distance, as it curves forwards, and is then continuous with the fornix. On its upper surface, the structure of the corpus callosum is very apparent, being collected into coarse transverse bundles. Along the middle line is a linear depression, the *raphé*, bounded laterally by two or more slightly elevated longitudinal bands, called the *striæ longitudinales* or *nerves of Lancisi*; and, still more externally, other longitudinal striæ are seen, beneath the convolutions which rest on the corpus callosum. These are the *striæ longitudinales laterales* or *tæniæ tectæ*. The under surface of the corpus callosum is continuous behind with the fornix, being separated from it in front by the septum lucidum, which forms a vertical partition between the two ventricles. On each side, the fibres of the corpus callosum extend into the substance of the hemispheres, connecting them together. The greater thickness of the two extremities of this commissure is explained by the fact that the fibres from the anterior and posterior parts of each hemisphere cannot pass directly across, but have to take a curved direction.

An incision should now be made through the corpus callosum, on either side of the raphé, when two large irregular-shaped cavities will be exposed, which extend through a great part of the length of each hemisphere. These are the lateral ventricles.

The **lateral ventricles** are serous cavities, formed by the upper part of the general ventricular space in the interior of the brain. They are lined by a thin diaphanous lining membrane (the *ependyma*), covered by nucleated epithelium, with cilia scattered here and there in patches. It is moistened by a serous fluid, which is sometimes, even in health, secreted in considerable quantity. These cavities are two in number, one in each hemisphere, and they are separated from each other by a vertical septum, the *septum lucidum*.

Each lateral ventricle consists of a central cavity, or *body*, and three smaller cavities or *cornua*, which extend from it in different directions. The anterior cornua curves forwards and outwards into the substance of the frontal lobe. The posterior cornu, called the *digital cavity*, curves backwards into the occipital lobe. The middle cornu descends into the temporo-sphenoidal lobe.

FIG. 467.—Section of the brain. Made on a level with the corpus callosum.



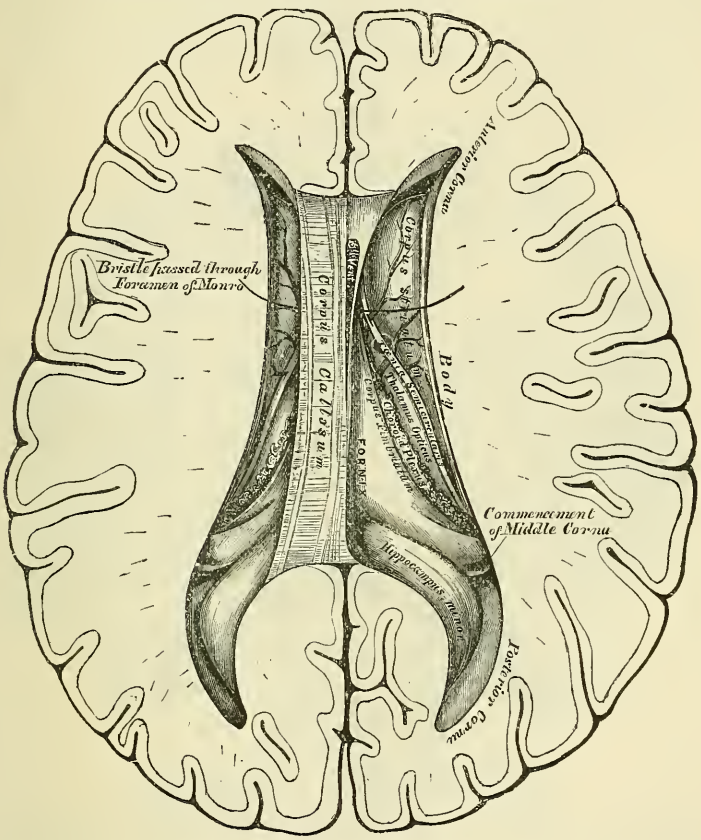
The *central cavity*, or body of the lateral ventricle, is triangular in form. It is bounded, above, by the under surface of the corpus callosum, which forms the roof of the cavity. Internally is a vertical partition, the *septum lucidum*, which separates it from the opposite ventricle, and connects the under surface of the corpus callosum with the fornix. Its floor is formed by the following parts, enumerated in their order of position, from before backwards: the *corpus striatum*, *tænia semicircularis*, *optic thalamus*, *choroid plexus*, *fornix*, and commencement of its *corpus fimbriatum*.

The *anterior cornu* is triangular in form, passing outwards into the frontal lobe, and curving round the anterior extremity of the corpus striatum. It is bounded, above, by the corpus callosum; below and externally, by the corpus striatum; and in front, by the reflected portion of the corpus callosum.

The *posterior cornu*, or *digital cavity*, curves backwards into the substance of the occipital lobe, its direction being backwards and outwards, and then inwards. On its inner wall is seen a longitudinal eminence, which is produced by the extension inwards of the calcarine sulcus; this is called the *hippocampus minor*, or *calcar avis*. Between the middle and posterior horns a smooth eminence is observed, which varies considerably in size in different subjects. It is called the *eminentia collateralis*.

The *middle* or *descending cornu*, the largest of the three, traverses the middle lobe of the brain, forming in its course a remarkable curve round the back of the optic thalamus. It passes, at first, backwards, outwards, and downwards, and then curves round the crus cerebri, forwards and inwards, nearly to the point of

Fig. 468.—The lateral ventricles of the brain.

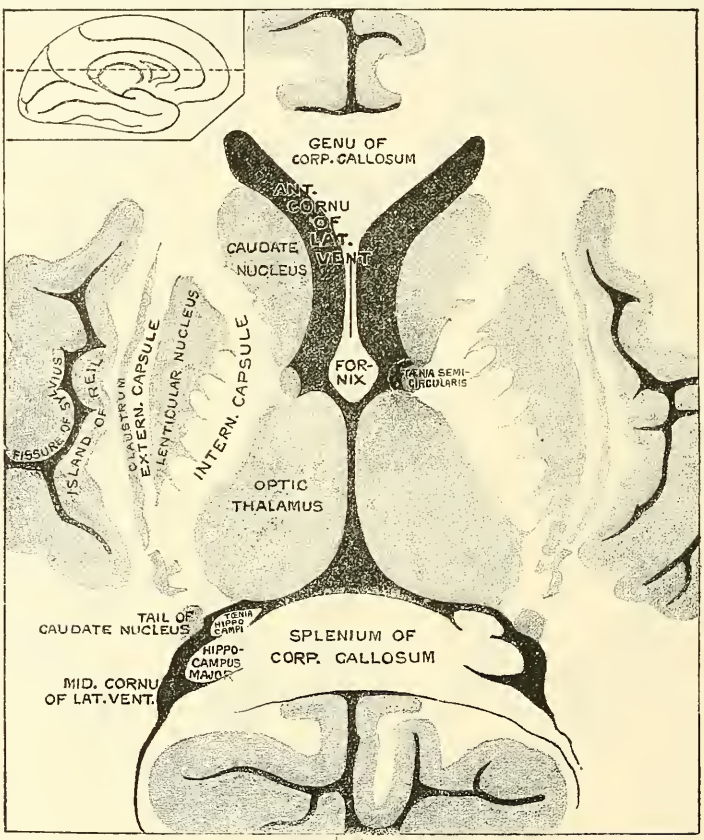


the middle lobe, close to the fissure of Sylvius. Its upper boundary, or roof, is formed by the fibres of the corpus callosum, passing downwards and outwards into the temporo-sphenoidal lobe, with which are incorporated the posterior fibres of the nucleus caudatus and tænia semicircularis, which are prolonged into it. Its lower boundary, or floor, presents for examination the following parts: the *hippocampus major*, *pes hippocampi*, *eminentia collateralis*, or *pes accessorius*, *corpus fimbriatum of the fornix*, *choroid plexus*, *fascia dentata*, *transverse fissure*.

The **corpus striatum** has received its name from the striped appearance which its section presents, in consequence of diverging white fibres being mixed with the grey matter which forms the greater part of its substance. The greater portion of this body is embedded in the white substance of the hemisphere, and is therefore external to the ventricle. It is termed the *extraventricular portion*,

or the *nucleus lenticularis*; a part, however, is visible in the ventricle and its anterior cornu; this is the *intraventricular portion*, or the *nucleus caudatus*. The intraventricular portion is a pear-shaped mass of grey matter; its broad extremity is directed forwards into the fore part of the body and anterior cornu of the lateral ventricle; its narrow end is directed outwards and backwards, and lies on the outer side of the optic thalamus, and is continued into the roof of the descending cornu: it is covered by the serous lining of the cavity, and crossed by some veins of considerable size. It is separated from the extraventricular portion by a lamina of white matter, which is called the *internal capsule*, in contradistinction to a lamina of white matter which covers the outer surface of the extraventricular portion of the corpus striatum, and which is called the

Fig. 469.—Middle part of a horizontal section through the cerebrum at the level of the dotted line in the small figure of one hemisphere. (From Ellis, after Dalton.)

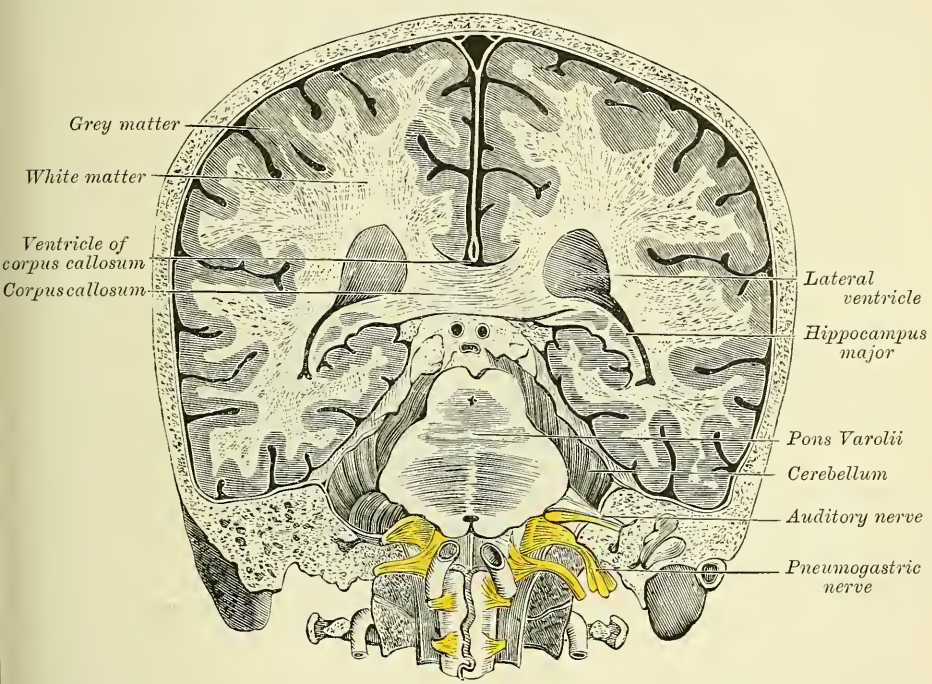


external capsule. The internal capsule is formed by fibres of the crusta of the crus cerebri, supplemented by fibres derived from the nuclei on each side. In horizontal section it is seen to be somewhat abruptly curved, with its convexity inwards; the prominence of the curve is called the *genu*, and projects between the intraventricular portion of the corpus striatum and the optic thalamus (fig. 469). The extraventricular portion of the corpus striatum, or nucleus lenticularis, is oval in form. It does not extend as far forwards or backwards as the nucleus caudatus. It is bounded externally by a lamina of white matter called the *external capsule*, which is covered on its outer surface by a thin layer of grey matter termed the *claustrum*. The claustrum presents ridges and furrows on its outer surface, corresponding to the convolutions and sulci of the island of Reil, with the white matter of which it is in immediate relation.

The **tænia semicircularis** is a narrow, whitish, semi-transparent band of medullary substance, situated in the depression between the nucleus caudatus and optic thalamus. Anteriorly its connections are somewhat obscure, but probably some of its fibres, if not all, are continued into the anterior pillar of the fornix. It passes upwards and backwards through the lateral ventricle, and is continued into the roof of its middle or descending horn, at the extremity of which it enters a mass of grey matter, the nucleus amygdalæ. Beneath it is a large vein (*vena corporis striati*), which receives numerous small veins from the surface of the corpus striatum and optic thalamus, and joins the venæ Galeni.

The **choroid plexus** is a highly vascular, fringe-like structure, which borders a triangular fold of pia mater, the *velum interpositum*, which lies on the under surface of the fornix and forms the roof of the third ventricle. As this mem-

Fig. 470.—Transverse vertical section of the brain, through the fore part of the foramen magnum, looked at from the front. (After Hirschfeld and Leveillé.)



brane reaches the lateral borders of the fornix it projects from under its edge, and, becoming fringed, it forms the choroid plexus, which is seen on the floor of the lateral ventricle. In front, the choroid plexus is small and tapering, and communicates with the choroid plexus of the opposite side, through an oval aperture, the *foramen of Monro*. Posteriorly, it descends into the middle horn of the lateral ventricle, where it joins with the pia mater through the transverse fissure. In structure, it consists of minute and highly vascular villous processes, containing an afferent and efferent vessel, and covered by a single layer of flattened epithelium, the cells of which often contain a yellowish fat molecule. The arteries of the choroid plexus enter the ventricle at the descending cornu, and, after ramifying through its substance, send branches into the substance of the brain. The veins of the choroid plexus terminate in the venæ Galeni.

The **corpus fimbriatum** (*tænia hippocampi*) is a narrow, white, tape-like band, situated immediately behind the choroid plexus. It is the thin lateral edge of the posterior pillar of the fornix, and is attached along the inner border of

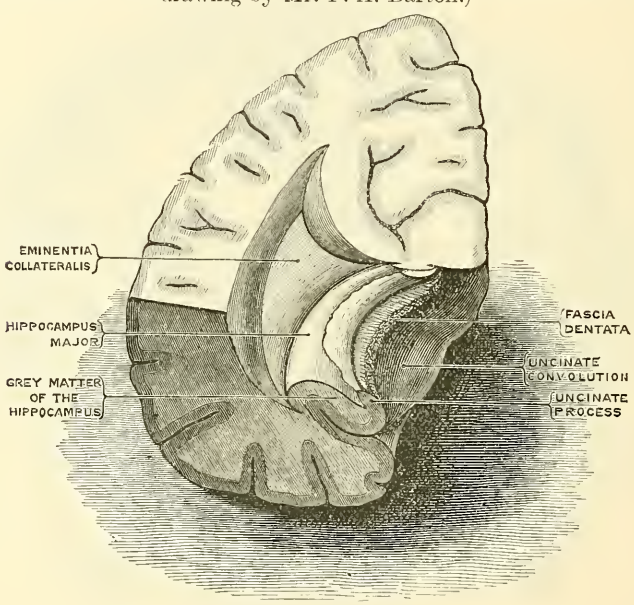
the hippocampus major as it descends into the middle horn of the lateral ventricle. It may be traced as far as the crochet or hook of the uncinate convolution.

The *optic thalamus* and *fornix* will be described on a subsequent page.

The middle cornu should now be exposed, throughout its entire extent, by introducing the little finger gently into it, and cutting outwards along the finger through the substance of the hemisphere, which should be removed, to an extent sufficient to expose the entire cavity.

The **hippocampus major,** or **cornu Ammonis** (fig. 471), is a white eminence, of a curved elongated form, extending throughout the entire length of the floor of the middle horn of the lateral ventricle. At its lower extremity it becomes enlarged, and presents a number of rounded elevations with intervening depressions, which, from presenting some resemblance to the paw of an animal, is called the *pes hippocampi*. If a transverse section is made through the hippocampus major it will be seen that this eminence is produced by the

Fig. 471.—Transverse section of the middle horn of the lateral ventricle. (From a drawing by Mr. F. A. Barton.)



extension inwards of the dentate (hippocampal) sulcus on the exterior of the brain. This sulcus is filled with grey substance, which projects along the free margin of the hippocampus major, forming a notched ridge, the *fascia dentata*. The hippocampus is covered on its ventricular surface by a thin lamina of grey matter, which is continuous with the corpus fimbriatum of the fornix.

The **eminentia collateralis,** or **pes accessorius,** has already been mentioned, as a white eminence, varying in size, placed between the hippocampus major and hippocampus minor, at the junction of the posterior with the descending cornu. It is formed by the protrusion inwards of the collateral fissure.

Fascia dentata.—On separating the inner border of the corpus fimbriatum from the choroid plexus, and raising the edge of the former, a serrated band of grey substance, the edge of the grey substance in the dentate fissure, will be seen beneath it: this is the *fascia dentata*. Correctly speaking, it is placed external to the cavity of the descending cornu.

The **transverse fissure** is of a horseshoe shape, extending from the end of the descending cornu on one side to the same point on the opposite side. Its horizontal portion (which extends from the commencement of the descending

cornu on one side to the same point on the opposite side) is bounded, above, by the splenium, or rounded posterior extremity of the corpus callosum, and the fornix; below, by the corpora quadrigemina, pineal gland, and the posterior extremity of the optic thalamus. Its lateral portions curve downwards, forwards, and inwards, and are bounded above by the crura cerebri and optic thalamus, below by the hippocampus major and the corpus fimbriatum of the fornix. Through this fissure the pia mater passes from the exterior of the brain into the ventricles, to form the velum interpositum and the choroid plexuses. Where the pia mater projects into the lateral ventricle, beneath the edge of the fornix, it pushes the lining membrane of these cavities before it so as to exclude all communication with the exterior of the brain.

The **septum lucidum** (fig. 474, 6) forms the internal boundary of the lateral ventricles. It is a thin, semi-transparent septum, attached, above, to the under surface of the corpus callosum; below, to the anterior part of the fornix; and, in front of this, to the reflected portion of the corpus callosum. It is triangular in form, broad in front, and narrow behind, its surfaces looking towards the cavities of the ventricles. The septum consists of two laminæ, separated by a narrow interval, the *fifth ventricle*.

Fifth Ventricle.—The fifth ventricle was originally a part of the great longitudinal fissure, which has become shut off by the union of the hemispheres in the formation of the corpus callosum above, and the fornix below. Its walls are therefore formed by the median wall of the hemispheres, and consist of an internal layer of grey matter, derived from the grey matter of the cortex and an external layer of white substance continuous with the white matter of the cerebral hemispheres. This is lined on its external surface by the ependyma of the lateral ventricles. The fifth ventricle is not lined by epithelium. In the fœtus, and in some animals, this space communicates, below, with the third ventricle; but in the adult, it forms a separate cavity. In cases of serous effusion into the ventricles, the septum is often found softened and partially broken down.

The fifth ventricle may be exposed by cutting through the septum and attached portion of the corpus callosum, with scissors: after its examination the corpus callosum should be cut across, towards its anterior part, and the two portions carefully dissected, the one forwards, the other backwards, when the fornix will be exposed.

The **fornix** (figs. 468, 474) is a longitudinal lamella of white fibrous matter, situated beneath the corpus callosum, with which it is continuous behind, but separated in front by the septum lucidum. It may be described as consisting of two symmetrical halves, one for either hemisphere. These two portions are joined together in the middle line, where they form the *body*, but are separated from one another in front and behind; forming the *anterior* and *posterior crura*.

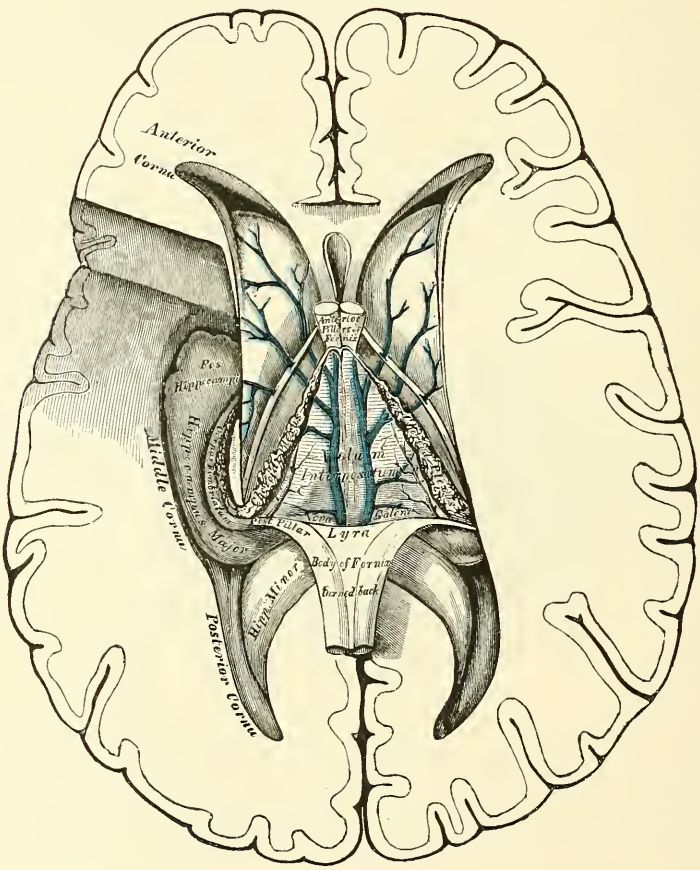
The *body of the fornix* is triangular; narrow in front, broad behind. Its upper surface is connected, in the median line, to the septum lucidum in front, and the corpus callosum behind, while laterally this surface forms part of the floor of each lateral ventricle. Its under surface rests upon the velum interpositum, which separates it from the third ventricle, and the inner portion of the optic thalami. Its outer edge, on each side, is free and is in contact with the choroid plexuses.

The *anterior crura* arch downwards towards the base of the brain, separated from each other by a narrow interval. They are composed of white fibres, which descend through a quantity of grey matter in the lateral walls of the third ventricle, and are placed immediately behind the anterior commissure. At the base of the brain, the white fibres of each crus form a sudden curve upon themselves, and spread out and form the outer part of the corresponding *corpus albicans*, from which point they may be traced upwards into the substance of the corresponding optic thalamus (fig. 474). The anterior crura of the fornix are connected in their course with the peduncle of the pineal gland and the superficial fibres of the tænia semicircularis, and receive fibres from the septum lucidum.

Between the anterior crura or pillars of the fornix and the anterior extremities of the optic thalami, an oval aperture is seen on each side : this is the *foramen of Monro* (fig. 473). The two openings descend towards the middle line, and lead into the upper part of the third ventricle. Through these openings the lateral ventricles on each side communicate with the third ventricle, and consequently with each other.

The *posterior crura*, at their commencement, are intimately connected by their upper surfaces with the corpus callosum ; diverging from one another, they pass downwards into the descending horn of the lateral ventricle, being continuous with the concave border of the hippocampus major. The lateral thin edges of the posterior crura have received the name of *corpus fimbriatum*. Upon examining the under surface of the fornix, between its diverging posterior crura, a

Fig. 472.—The fornix, velum interpositum, and middle or descending cornu of the lateral ventricle.



triangular portion of the under surface of the corpus callosum may be seen. On it are a number of lines: some transverse, others longitudinal or oblique. This portion has been termed the *lyra*, from the fancied resemblance it bears to the strings of a harp.

Divide the fornix across anteriorly, and reflect the two portions, the one forwards, the other backwards, when the velum interpositum will be exposed.

The **velum interpositum** or **tela choroidea superior** (fig. 472) is a vascular membrane, a prolongation from the pia mater into the interior of the brain through the transverse fissure, passing beneath the posterior rounded border of the corpus callosum and fornix, and above the corpora quadrigemina, pineal

gland, and optic thalami. It is of a triangular form, and separates the under surface of the body of the fornix from the cavity of the third ventricle. Its posterior border forms an almost complete investment for the pineal gland, and is continuous with the general pia mater at the back and sides of the brain. Its anterior extremity, or apex, ends just behind the anterior pillars of the fornix, where it is connected with the smaller anterior extremities of the choroid plexuses, which are united through the foramen of Monro. On its under surface are the *choroid plexuses of the third ventricle.* Its lateral margins form the choroid plexuses of the lateral ventricles. Of the arteries of the velum interpositum, some branches from the superior cerebellar and posterior cerebral enter from behind, beneath the corpus callosum; another constant branch, the anterior choroid, enters the velum interpositum at the extremity of the middle horn of the lateral ventricle, and supplies this structure and the choroid plexus. The veins of the velum interpositum, the *venæ Galeni*, two in number, run between its layers; they are formed by the venæ corporis striati and the veins of the choroid plexuses; the venæ Galeni unite posteriorly into a single trunk, which terminates in the straight sinus (fig. 426).

The velum interpositum should now be removed. This must be effected carefully, especially at its posterior part, where it invests the pineal gland; the optic thalami will then be exposed with the cavity of the third ventricle between them (fig. 473).

The **optic thalami** are two large oblong masses, placed between the diverging portions of the corpora striata; they are of a white colour superficially; internally they are composed chiefly of grey matter. Each thalamus rests upon its corresponding crus cerebri, which it embraces. *Externally*, it is separated from the corpus striatum by the tænia semicircularis. *Internally*, it forms the lateral boundary of the third ventricle; and running along its upper and inner border is the peduncle of the pineal gland. Its *upper surface* is free, being partly seen in the lateral ventricle; it is partially covered by the velum interpositum and fornix, and corresponding to the free margin of the fornix, presents a groove, which runs inwards and forwards, and terminates in front in an eminence, the *anterior tubercle.* Its *under surface* is united with the tegmentum of the crus cerebri. Its *posterior extremity* projects above the level of the corpora quadrigemina and crus cerebri, and internally forms a well-marked prominence, the *posterior tubercle* or *pulvinar*, and below and outside this it presents two small rounded eminences, the *internal* and *external geniculate bodies.* Between the pulvinar and the posterior part of the peduncle of the pineal gland is a depressed area, triangular in shape, which is called the *trigonum habenulæ.* It contains a collection of nerve cells, to which fibres pass from the peduncle of the pineal glands, and from which fibres pass to the tegmentum. Its *anterior extremity*, which is narrow, forms the posterior boundary of the foramen of Monro.

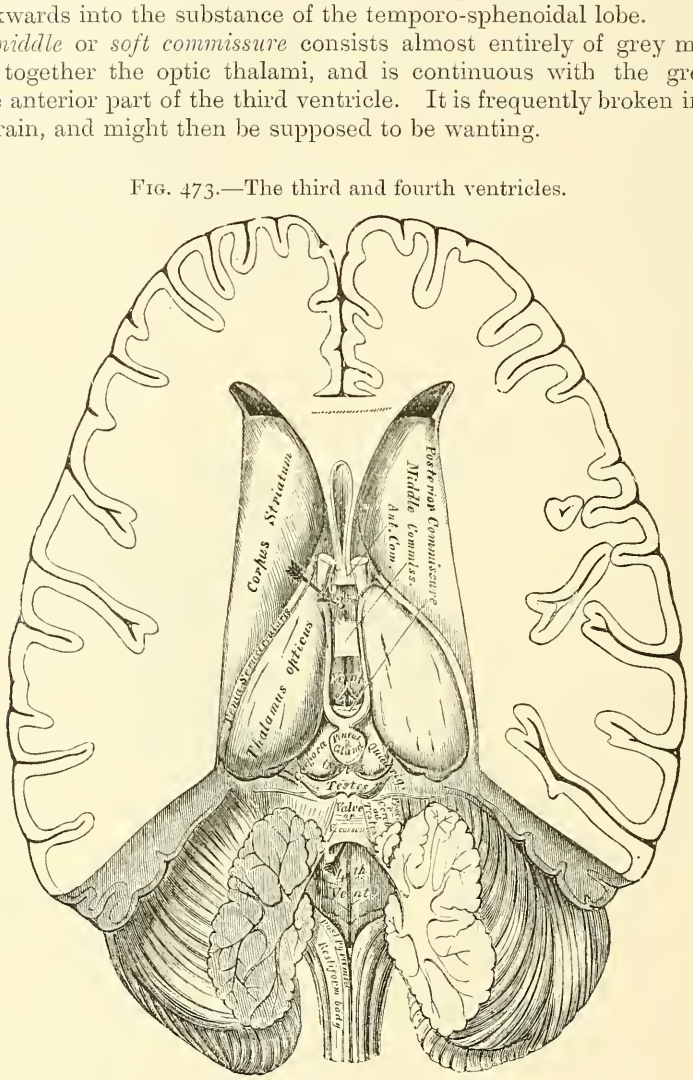
The **Third Ventricle** is the narrow oblong fissure placed between the optic thalami, and extending to the base of the brain. It is bounded, above, by the under surface of the velum interpositum, from which are suspended the choroid plexuses of the third ventricle. Its floor, somewhat oblique in its direction, is formed, from before backwards, by the parts which are contained in the interpeduncular space, viz. the lamina cinerea, the tuber cinereum and infundibulum, the corpora albicantia and the locus perforatus posticus, and behind these by the tegmenta of the crura cerebri; its sides are formed by the optic thalami, along the upper and inner border of which are two white tracts, one on each side, the *peduncles of the pineal gland.* It is bounded, in front, by the anterior crura of the fornix, and part of the anterior commissure; behind, by the posterior commissure, and the iter a tertio ad quartum ventriculum. The cavity is much deeper in front than behind, and presents a deep recess at its anterior part, which lies over the optic commissure and is therefore termed the *optic recess.* At its posterior extremity the cavity forms another smaller recess, which extends into the stalk of the pineal gland, and is termed the *pineal recess.*

The cavity of the third ventricle is crossed by three commissures, named, from their position, *anterior*, *middle*, and *posterior*.

The *anterior commissure* is a round bundle of white fibres, placed in front of the anterior crura of the fornix, and appears to connect together the corpora striati. Its fibres can be traced through the corpus striatum on each side, and then backwards into the substance of the temporo-sphenoidal lobe.

The *middle* or *soft commissure* consists almost entirely of grey matter. It connects together the optic thalami, and is continuous with the grey matter lining the anterior part of the third ventricle. It is frequently broken in examining the brain, and might then be supposed to be wanting.

Fig. 473.—The third and fourth ventricles.



An arrow has been placed in the position of the foramen of Monro.

The *posterior commissure*, smaller than the anterior, is a flattened white band of fibres, and appears to connect together the optic thalami posteriorly. It consists of decussating fibres which come from the tegmentum of the crus cerebri on one side, and pass through the optic thalami, across the back part of the third ventricle, to the white substance of the temporo-sphenoidal lobe of the other side. Some of the fibres may also serve as commissural fibres between the optic thalami. It bounds the third ventricle posteriorly, above the opening of the Sylvian aqueduct. The pineal gland is placed above it and connected to its upper surface.

The third ventricle has four openings connected with it. In front are the two oval apertures of the foramina of Monro, one on each side, through which the third communicates with the lateral ventricles. Behind is a third opening

leading into the fourth ventricle by a canal, the *aqueduct of Sylvius*, or *iter a tertio ad quartum ventriculum*. The fourth, situated in the anterior part of the floor of the ventricle, is a conical recess, which leads to the infundibulum.

The lining membrane of the lateral ventricles is continued through the foramen of Monro into the third ventricle, and extends along the iter a tertio into the fourth ventricle.

The **foramen of Monro** is a foramen by which each lateral ventricle communicates with the third ventricle. It is formed by the anterior extremity of the body of the fornix, which, dividing into its two crura, arches downwards in front of the anterior extremity of the optic thalami; the crus is not, however, in contact with the thalamus, but an interval is left between the two, which is the foramen of Monro. Its boundaries are, therefore, in front, the anterior pillar of the fornix;

19 points to the anterior commissure, indicated by an oval mark behind the number.

behind, the anterior extremity of the optic thalamus; above, the body of the fornix; and below, the groove between the anterior pillar of the fornix and the optic thalamus.

Behind the third ventricle, and in front of the cerebellum, are the corpora quadrigemina; and, resting upon these, the pineal gland.

The **pineal gland** (*epiphysis cerebri*), so named from its peculiar shape (pinus, *a fir-cone*), is a small reddish-grey body, conical in form (hence its synonym,

conarium), placed immediately behind the posterior commissure, and between the nates, upon which it rests. It is retained in its position by a duplicature of pia mater, derived from the under surface of the velum interpositum, which almost completely invests it. The pineal gland is about four lines in length, and from two to three in width, at its base, and is said to be larger in the child than in the adult, and in the female than in the male. Its base is connected to the cerebrum by a stalk on either side. This stalk consists of two flattened bands of fibre, separated from each other by the pineal recess of the third ventricle (see page 759). The lower of these bands is prolonged into the posterior commissure; the upper one (the *peduncle of the pineal gland*) passes forwards upon the upper and inner margin of the optic thalamus to the anterior crus of the fornix, with which it becomes blended. The two stalks join together at their posterior extremity, in front of the pineal gland, forming a sort of festoon, and the base of the gland is connected to their posterior margin at the point of junction.

Structure.—The pineal gland consists of a number of follicles, lined by epithelium, and connected together by ingrowths of connective tissue. The follicles contain a transparent viscid fluid, and a quantity of sabulous matter, named *acervulus cerebri*, composed of phosphate and carbonate of lime, phosphate of magnesia and ammonia, with a little animal matter. These concretions are almost constant in their existence, and are found at all periods of life. They are frequently to be found upon the surface of the body, and occasionally upon its peduncles.

On the removal of the pineal gland and adjacent portion of pia mater, the corpora quadrigemina are exposed.

The **corpora** or **tubercula quadrigemina** (*optic lobes*) are four rounded eminences placed in pairs, two in front, and two behind, and separated from one another by a crucial depression. They are situated immediately behind the third ventricle and posterior commissure, and beneath the posterior border of the corpus callosum. Below, they are separated in the middle line from the crura cerebri by the aqueduct of Sylvius, but on each side are continuous with the tegmentum of the crura. The anterior or upper pair, the *nates*, are the larger, oblong from before backwards, and of a grey colour. The posterior or lower pair, the *testes*, are hemispherical in form, and lighter in colour than the preceding. From the outer side of each of these eminences, a prominent white band, termed *brachium*, is continued forwards and outwards. Those from the nates (*brachia anteriora*) are the larger, and pass obliquely outwards, between the inner and outer geniculate bodies, into the optic tract. Those from the testes (*brachia posteriora*) pass beneath an oval prominence, the internal geniculate body, and are no longer traceable. Both pairs, in the adult, are quite solid, being composed of white matter externally, and grey matter within. These bodies are larger in the lower animals than in man. In fishes, reptiles, and birds, they are only two in number, are called the *optic lobes*, from their connection with the optic nerves, and are hollow in their interior; but in mammalia they are four in number, as in man, and quite solid. In the human fœtus they are developed at a very early period, and form a large proportion of the cerebral mass; at first they are only two in number, as in the lower vertebrata, and hollow in their interior.

These bodies are connected with the cerebellum by means of a large white cord on each side, the *processus ad testes*, or superior peduncles of the cerebellum, which is continued onwards to the optic thalami, through the tegmentum of the crus cerebri. Beneath the corpora quadrigemina, the fibres decussate with those of the opposite side across the middle line.

The **Fillet.**—Arching over these peduncles is a flattish band of white fibres which was formerly known as the fillet, but is now known as the *inferior* or *lateral fillet*, inasmuch as there are other fibres, which are more deeply placed, which are known as the *superior* or *mesial fillet*. The inferior or lateral fillet issues from beneath the transverse fibres of the pons, and arises chiefly from the superior

olivary nucleus and from a collection of nerve cells at the anterior extremity of this nucleus. If these fibres are traced upwards through the pons, they will be seen to become superficial at its upper border, to pass obliquely round the superior peduncle of the cerebellum, and become lost in the posterior quadrigeminal body. The *superior* or *mesial fillet* forms a conspicuous band of fibres seen in transverse sections of the pons, and is derived from the opposite posterior columns of the medulla. Some of its fibres pass to the anterior quadrigeminal body, and others to the cerebrum through the crusta.

The **corpora geniculata** are two small, flattened, oblong masses, placed on the under and back part of each optic thalamus, and named, from their position, *corpus geniculatum externum* and *internum*. The two bodies are separated from one another by one of the roots of the optic tract, the brachia anterior, from the nates.

Structure of the Cerebrum

The **cerebrum**, like the other parts of the great nerve-centre, is composed of grey and white matter. In order to give some general idea of its construction, at all events in part, it may be compared, for the sake of illustration, to a tree, the trunk of which divides into two main branches, and these break up into smaller branches, which finally end in twigs to which are attached the leaves, forming an investment to the branches and covering the whole tree. The trunk is represented by the medulla oblongata as it passes through the foramen magnum; the two main branches by the crura cerebri, which break up into smaller branches, which diverge from each other, dividing and subdividing, until they reach the surface of the hemispheres, where they terminate in single nerve-fibres, to which are attached the basal axial cylinder processes of the nerve cells, represented by the leaves. These cells are arranged on the surface, resembling a cap covering the hemispheres, and constitute the cerebral cortex. But here the analogy ends, for in the cerebrum we have, in addition to this cortex, other masses of grey matter situated in the middle of the brain, and other white fibres beside these diverging ones which have been mentioned, and which serve either to connect the two hemispheres, of which the cerebrum consists, or else serve to connect different structures in the same hemisphere.

The **white matter of the cerebrum** consists of medullated fibres, varying in size and arranged in bundles, separated by neuroglia. They may be divided into three distinct systems, according to the course which they take. 1. Diverging or peduncular fibres, which connect the hemispheres with the medulla oblongata and cord. 2. Transverse commissural fibres, which connect together the two hemispheres. 3. Commissural fibres, which connect different structures in the same hemisphere.

1. The **diverging** or **peduncular fibres** consist of a main body, which originates in the cord and medulla oblongata, forms the longitudinal fibres of the pons, and divides into two main branches, which, diverging from each other, constitute the *crura cerebri* or *cerebral peduncles*. In the crura cerebri, as has been before described, the diverging fibres derived from the longitudinal fibres of the pons Varolii are arranged in two strata, which are separated by the locus niger; the anterior or superficial stratum forming the *crusta* of these bodies, and the posterior or deeper stratum, the *tegmentum*. The fibres derived from these two sources take a different course, and will have to be separately considered.

The fibres of the *crusta* are derived from the pyramid of the medulla, which fibres are continued upwards through the pons to form the crusta; they are reinforced in their passage through the crus by accessory fibres derived from the central grey matter around the Sylvian aqueduct and from the locus niger. When they emerge from the crus, (1) some of the fibres pass directly upwards as radiating fibres to the grey matter of the cerebral hemisphere, forming the corona radiata; (2) some of the fibres pass to the internal capsule, between the nucleus caudatus and lenticularis, where they give off fibres to these ganglia and receive

others from them, and then, issuing from the capsule, diverge to form a part of the corona radiata, passing to the cerebral cortex. The fibres which arise from the ganglia are more numerous than those which terminate in the ganglia, so that more fibres pass out of the ganglia than pass into them.

The fibres of the *tegmentum* are continuous with those longitudinal fibres of the pons which are derived from the formatio reticularis of the medulla, which is formed by fibres (1) from the anterior column of the cord; (2) from the olivary body; (3) from the lateral column of the cord; and (4) from the funiculus cuneatus and funiculus gracilis. They are reinforced by fibres from the corpora quadrigemina and corpora geniculata, and from the superior peduncle of the cerebellum, and enter the optic thalamus. Some of these fibres pass through the optic thalamus, and, being augmented by other fibres arising within this body, pass out of it and spread out to form part of the corona radiata, especially joining the ganglion-cells of the cortex of the temporo-sphenoidal and occipital lobes; other fibres terminate in the optic thalamus.

2. The **transverse commissural fibres** connect the two hemispheres. They include: (*a*) the transverse fibres of the corpus callosum; (*b*) the anterior commissure; (*c*) the posterior commissure.

The *corpus callosum*, which has already been described, connects the two hemispheres of the brain, forming their great transverse commissure, penetrating into the substance of the convolutions and intersecting the fibres of the corona radiata.

The *anterior commissure* is a round bundle of white fibres, which is placed in front of the anterior crura of the fornix, and appears to connect the corpora striata. It passes outwards through the corpus striatum on each side, and then curves backwards into the substance of the temporo-sphenoidal lobe.

The *posterior commissure*, smaller than the anterior, is a flattened white band of fibres, which appears to connect the optic thalami posteriorly. It consists of decussating fibres which come from the tegmentum of the crus cerebri on one side, and pass through the optic thalamus, across the back part of the third ventricle, to the white substance of the temporo-sphenoidal lobe of the other. Some of the fibres may also serve as commissural fibres between the optic thalami.

3. **Commissural fibres connecting different structures in the same hemisphere.** These fibres are of two kinds: (1) those which connect adjacent convolutions, and which are termed *arcuate* or *association fibres*; (2) those which connect more distant parts in the same hemisphere—the *longitudinal* or *collateral fibres*.

The *arcuate* or *association fibres* are situated immediately beneath the grey substance of the cortex of the hemispheres, and connect together adjacent convolutions.

The *longitudinal* or *collateral fibres* include the following: (*a*) the uncinate fasciculus; (*b*) the fillet of the gyrus fornicatus; (*c*) the longitudinal fibres of the corpus callosum; (*d*) the tænia semicircularis; (*e*) the fornix; (*f*) the inferior longitudinal fasciculus.

(*a*) The *uncinate fasciculus* connects the convolutions of the frontal and temporo-sphenoidal lobes. It passes across the bottom of the Sylvian fissure and traverses the claustrum.

(*b*) The *fillet of the gyrus fornicatus* (*Cingulum*) is a band of white matter, which encircles the hemisphere in an antero-posterior direction, lying in the substance of the convolution of the corpus callosum. Commencing in front at the anterior perforated space, it passes forwards and upwards parallel with the rostrum, winds round the genu, runs in the convolution from before backwards, immediately above the corpus callosum, turns round its posterior extremity, and passes into the hippocampus major, through which it courses to its anterior extremity. In its course it is connected with the secondary convolutions of the gyrus fornicatus by short arcuate fibres.

(*c*) The *longitudinal fibres of the corpus callosum* or *nerves of Lancisi* connect

the anterior and posterior extremities of the gyrus fornicatus or convolution of the corpus callosum.

(*d*) The *tænia semicircularis* is a narrow whitish semitransparent band of medullary substance, situated in the depression between the nucleus caudatus and the optic thalamus. Anteriorly, its connections are somewhat obscure, but probably most of its fibres, if not all, are continued into the anterior pillar of the fornix; behind, it is continued into the roof of the middle or descending horn of the lateral ventricle, at the extremity of which it enters a mass of grey matter, the nucleus amygdalæ.

(*e*) The *fornix* connects the optic thalamus with the hippocampus major and uncinate convolution. It has already been described as arising from the grey matter of the optic thalamus; it then emerges from the under surface of this body, forms the corpus albicans, where the fibres are arranged in loops, between which nerve-cells are to be found; it then passes upwards into the third ventricle and joins with the fibres of the other side forming the body of the fornix; from this the posterior pillars diverge, and, entering the middle cornu of the lateral ventricle, part of its fibres are distributed to the hippocampus major, and the remainder end as the tænia hippocampi or fimbria, which is continued as a distinct piece to the *crochet* or *uncus* of the uncinate convolution.

(*f*) The *inferior longitudinal fasciculus* is a collection of fibres which connects the temporo-sphenoidal and occipital lobes, running along the outer wall of the middle and posterior cornu.

The **grey matter of the cerebrum** is disposed in three great groups: 1. The grey matter of the cerebral cortex. 2. The grey matter of the basal ganglia, that is, the great ganglia of the base of the cerebrum. 3. The grey matter which lines the internal surface of the upper part of the cerebro-spinal tube, that is, the remains of the cavity in the original vesicles from which the brain was formed, and which constitutes the central cavities of the organ.

1. The **grey matter of the cortex** (fig. 475) invests the surface of the hemispheres and gives them external form. When vertical sections are made through it, and examined microscopically, it is found to consist of five separate layers, but to this there are some exceptions. According to Meynert these exceptions are to be found: (1) in the posterior portion of the occipital lobe; (2) in the grey cortex of the hippocampus major; (3) in the wall of the fissure of Sylvius; and (4) in the olfactory bulb. The five layers in the common type are as follows: (1) The first layer is principally composed of a matrix or neuroglia, through which a few small ganglion-cells are irregularly distributed, and a nerve-fibre network. (2) The second layer consists of numerous small pyramidal cells, which have their long axes vertical to the surface of the convolutions, and are closely aggregated together so as to completely fill the layer with a number of closely compressed cells. (3) The third layer is named by

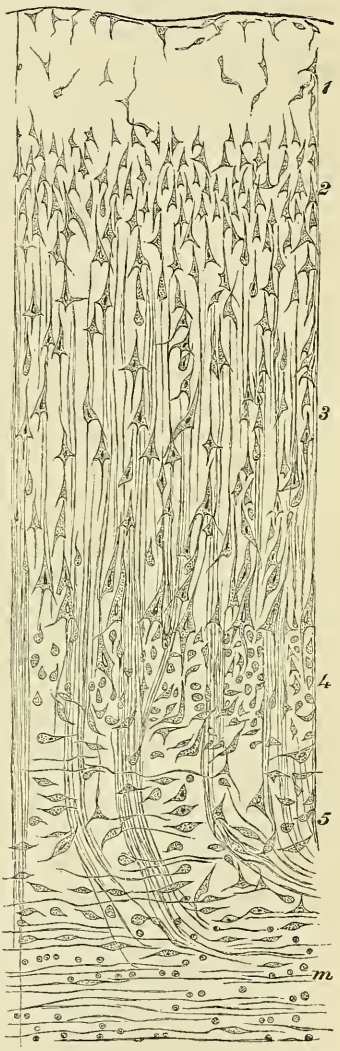

Fig. 475.—Grey matter of the cerebral cortex. (Meynert.)

Meynert the *formation of the cornu Ammonis*, as it is made up of cells, which are the only morphological element found in this part. It consists of the same sort of pyramidal cells, arranged vertically to the surface, as was found in the preceding layer, but they are of very much larger size, and increase progressively towards the deeper parts of the layer, and they are much more widely separated from each other. This layer is the principal and broadest one of the series, and is at least twice as deep as the preceding layer. (4) The fourth layer is termed the *granular formation* by Meynert, and consists of numerous small, irregular, rarely triangular or elongated, cells, which resemble the nerve-corpuscles found in the internal granule layer of the retina, and which are closely aggregated together. (5) The fifth layer is termed the *claustral formation*, and consists of a very large proportion of spindle-shaped cells, which are the peculiar elements of this layer. They are especially numerous in the inner half, and are arranged horizontally, extending parallel to the surface. They have received their name from the fact that the claustrum is made up almost entirely of an accumulation of these cells. It will be seen, therefore, that the differences in these layers depend upon the varying form and size of the cells and the closeness of their arrangement, and that the typical form of cell, and the only one which is admitted by some observers, is the pyramidal cell or nerve-corpuscle.

Character of the pyramidal cell or nerve-corpuscle.—These nerve-corpuscles are destitute of a cell wall; they present a nucleus, sometimes round or oval, sometimes angular, and give off many processes. One of these, which, in the cells arranged vertically to the surface, projects outwards and is named the *process of the apex*, is strong and branched, and according to Cleland is continuous with the nerve-fibre network in the first or superficial layer of the cortex. Another process projects inwards towards the white matter of the hemisphere and from the opposite extremity of the cell. It is termed the *process of the centre of the base*. It is more slender than the preceding and remains unbranched. It is an axis-cylinder process, and, becoming invested with a medullary sheath, constitutes a nerve-fibre, extending into the central white matter. In addition to these, lateral processes are given off, forming the *processes of the basal angle*, which can be traced for a longer or shorter distance, and break up into a network of extremely minute nerve-fibres.

Special types of the grey matter of the cortex.—The special types of grey matter of the cortex are the following: (1) On the posterior portion of the occipital lobe the grey matter consists of eight layers. This is produced by the intercalation of intermediate granule layers, similar to those forming the fourth layer of the typical cortex. (2) In the grey matter of the cortex of the hippocampus major or cornu Ammonis, pyramidal cells are alone found, such as have been described in the third layer of the typical cortex. This constitutes the greater part of the structure in this situation, the fourth and fifth layers being absent, and the second layer containing no cells. (3) In the wall of the Sylvian fissure the grey matter is termed the *claustrum*; it separates the white matter of the convolutions of the island of Reil from the external capsule of the corpus striatum. This presents peculiarities of structure, consisting mainly of spindle-shaped cells, such as constitute the fifth layer. (4) In the olfactory bulb, which may be regarded as a portion of the cerebral hemispheres, forming 'a cap superimposed upon a conical process of the cerebrum,' is another variety of structure, differing from the type of the cortex of the hemispheres. The bulb consists of both grey and white matter, and sometimes retains a central cavity lined by epithelium. The lower part is grey matter, and consists of the following layers from below upwards. (1) The *olfactory nerve-layer*, consisting of a layer of non-medullated nerve-fibres derived from the nerves which supply the olfactory region. (2) The *stratum glomerulosum*, consisting of nodulated masses, containing small nuclear cells, and a convoluted olfactory nerve-fibre amongst the cells. (3) The *stratum gelatinosum*, consisting of pyramidal or spindle-shaped nerve-cells and a fine network of nerve-fibre. (4) The *granular layer*, consisting

of small irregular nerve-cells resembling the fourth layer of the cerebrum or the granular layer of the retina.

2. The **grey matter of the basal ganglia**.—The great ganglia of the base of the brain are, the corpus striatum, the optic thalamus, the corpora quadrigemina, the corpora geniculata, and the locus niger. Only a part, however, of the grey matter of the corpora quadrigemina—that found on the periphery of this body—belongs to this group; the remainder, that contained in its centre around the Sylvian aqueduct, belongs properly to the third group, which will be discussed immediately.

The *corpus striatum* presents two distinct and separate masses, the *nucleus caudatus*, which is the intraventricular portion of the corpus striatum, and the *nucleus lenticularis*, which is the extraventricular portion. The two are separated from each other by a distinct lamina of white matter, the *internal capsule*, which also separates the nucleus lenticularis from the outer part of the optic thalamus. The grey matter of the corpus striatum is permeated by tracts of medullated nerve-fibres, some of which probably originate in it, though the actual connection of the nerve-fibres with the cells has not been demonstrated. The nerve-cells are multipolar, both large and small, the larger being principally found in the lenticular nucleus.

The *optic thalamus* is chiefly formed of grey matter, covered over by a superficial layer of white, which on the outer side separates it from the internal capsule. The grey matter is arranged in two masses, the outer and inner nuclei, partially divided by a vertical white septum. It is traversed by numerous nerve-fibres, which for the most part have no definite direction; some, however, converge and form a bundle which passes downwards to form the anterior root of the fornix. It contains comparatively large nerve-cells, both multipolar and fusiform. The inner nucleus is connected across the middle line with the inner nucleus of the opposite side by the middle commissure of the third ventricle, which, however, belongs to the third group of grey matter.

The *corpora quadrigemina* consist of two distinct and separate collections of grey matter, one at or near the surface, which belongs to the basal ganglia, and one in the centre around the aqueduct of Sylvius. The former will only be considered at present. The *peripheral grey matter of the corpora quadrigemina* differs somewhat in the posterior and anterior lobes. The posterior lobes or testes are composed almost entirely of grey matter, covered over by a thin stratum of white matter, and separated from the *central grey matter* by tracts of transverse white fibres derived from, and forming part of, the fillet. The anterior lobes or nates are covered superficially by a thin stratun of white matter; beneath this is a layer of grey matter, termed the *stratum cinereum*, and consisting, as well as the grey matter of the posterior lobes, of small multipolar cells embedded in a fine network of nerves. Beneath this again is a characteristic mass of grey matter, termed the *stratum opticum*, which is made up of fine nerve-fibres, coursing in a longitudinal direction, and containing between them small masses of grey substance, consisting of small multipolar nerve-cells embedded in grey matter. Lastly, between this body and the central grey matter around the Sylvian aqueduct is a thin lamina of white matter, derived from the fillet.

The *geniculate bodies* are continuous with the grey substance of the optic thalamus, and the external one (*corpus geniculatum externum*) is peculiar on account of its dark colour, due to its cells containing pigment. It presents a laminated arrangement, and consists of alternate thick layers of grey matter and thin layers of white matter. Its cells are multipolar. The internal body (*corpus geniculatum internum*) is of lighter colour, does not present a laminated arrangement, and its cells are smaller in size and fusiform in shape.

The *locus niger*, or grey matter of the crus cerebri, like the external geniculate body, is peculiar from the large amount of dark pigment-granules which are contained in its ganglion-cells, and which give to it its dark colour, from which it has derived its name. Its cells are small and multipolar.

3. The **central grey matter of the cerebrum** lines the upper part of the cerebro-spinal tube, which is the remains of the cavity in the original vesicles from which the brain was formed, and is continuous with the grey matter of the floor of the fourth ventricle, and through it with the grey matter of the cord. This central grey matter is found lining the aqueduct of Sylvius, by which the third communicates with the fourth ventricle; it covers the inner wall of each optic thalamus, forming the middle or grey commissure of the third ventricle; it also lines the floor of the third ventricle; it covers behind the upper surface of the tegmentum of the crus, and in front it approaches the surface of the brain, forming the posterior perforated space and the lamina cinerea. It forms also the tuber cinereum and the infundibulum, and in the lower vertebrata, especially fishes, the posterior lobe of the pituitary body. In the higher vertebrates this lobe does not present any nervous structure, being encroached upon and obliterated by an ingrowth of connective tissue and vessels.

The grey matter surrounding the Sylvian aqueduct, which has been before mentioned as the central grey matter of the corpora quadrigemina, presents some features requiring especial mention. It forms a tolerably thick layer surrounding the canal, but is thicker on the lower wall; that is, below the canal, than above. The cells, which are multipolar, are here collected into groups, and form nuclei for the origin of the third and fourth cranial nerves. The nucleus for the third and fourth consists of a column of cells of large size on either side of, and close to, the median line. In addition to these cells there are found at the periphery of the zone of grey matter surrounding the aqueduct, some other, and larger, cells: sometimes single, sometimes grouped in twos or threes, or even more. They are globular, and lie in the midst of well-marked nerve-fibres, with which their processes appear to be continuous.

The Cerebellum

The **Cerebellum,** or little brain, is that portion of the encephalon which is contained in the inferior occipital fossæ. It is situated beneath the occipital lobes of the cerebrum, from which it is separated by the tentorium. In form, the cerebellum is oblong, and flattened from above downwards, its great diameter being from side to side. It measures from three and a half to four inches transversely, and from two to two and a half inches from before backwards, being about two inches thick in the centre, and about six lines at the circumference, which is the thinnest part. It consists of grey and white matter: the former, darker than that of the cerebrum, occupies the surface; the latter, the interior. The surface of the cerebellum is not convoluted like the cerebrum, but traversed by numerous curved furrows or sulci, which vary in depth at different parts, and separate the laminæ of which its exterior is composed.

Weight of the Cerebellum.—Its average weight in the male is 5 oz. 4 drs. It attains its maximum weight between the twenty-fifth and fortieth year; its increase in weight after the fourteenth year being relatively greater in the female than in the male. The proportion between the cerebellum and cerebrum is, in the male, as 1 to $8\frac{1}{7}$; and in the female, as 1 to $8\frac{1}{4}$. In the infant, the cerebellum is proportionately much smaller than in the adult, the relation between it and the cerebrum being, according to Chaussier, between 1 to 13, and 1 to 26; by Cruveilhier the proportion was found to be 1 to 20.

Lobes of the Cerebellum.—The cerebellum consists of two lateral portions, or hemispheres, joined together by a median narrower part, the vermiform process. This central portion on the upper surface of the cerebellum forms a slight elevation, which is termed the *superior vermiform process*; whilst on the under surface it forms a well-marked projection, the *inferior vermiform process*, at the bottom of a deep recess between the two hemispheres. This recess or fossa is known as the *valley* or *vallecula*, and in it is lodged the medulla; it terminates in front at the fourth ventricle and behind in a deep notch, the *incisura cerebelli posterior*

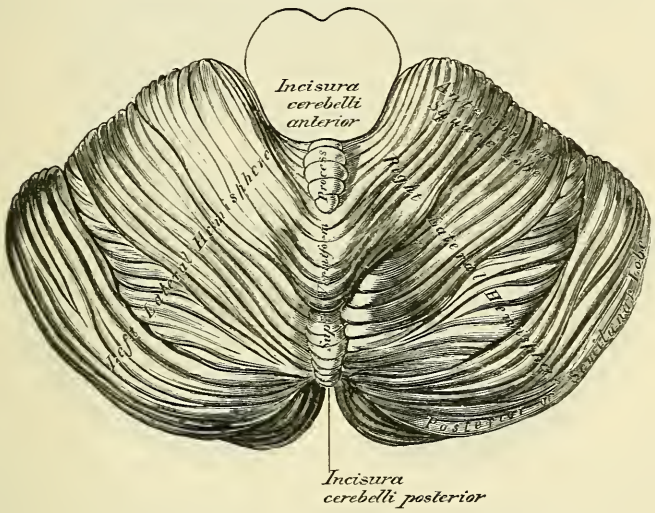
(*incisura marsupialis*), which separates the posterior part of the two hemispheres from each other, and is occupied by the falx cerebelli. The two hemispheres are also separated in front and above by a broader, shallower notch, the *incisura cerebelli anterior* (*incisura semi-lunaris*), which encircles the posterior part of the corpora quadrigemina.

The cerebellum is connected to the rest of the encephalon by three pairs of peduncles, which will be described in the sequel: a *superior* pair, which connect it with the cerebrum; a *middle* pair, which connect it with the pons; and an *inferior* pair, which connect it with the medulla.

The cerebellum is divided into an upper and a lower portion by a great horizontal fissure, which commences in front at the pons and passes horizontally round the free margin of the hemisphere to the middle line behind. From this primary fissure numerous secondary fissures proceed, which separate the cerebellum into lobes, and in these lobes are curved furrows or sulci, which separate individual folia or laminæ from each other.

The *superior surface of the cerebellum* (fig. 476) is somewhat elevated in the middle line and sloped towards its circumference; it consists of the two lateral hemispheres connected together by an elevated median portion or lobe, the

Fig. 476.—Upper surface of the cerebellum.



superior vermiform process. The principal fissure on the lateral parts of this surface starts from the great horizontal fissure near its commencement, passes backwards and inwards in a curved direction, with its convexity backwards and outwards, to the back part of the superior vermiform process. It divides the upper surface of the hemisphere into two lobes, an *anterior* or *square* lobe and a *posterior* or *semi-lunar* lobe. The anterior or square lobe is subdivided by another fissure into an *anterior* and *posterior crescentic portions*. A small part of the anterior crescentic portion is by some differentiated off from the rest by another fissure, which is situated near the anterior border of this surface. This small part is known as the *ala lobuli centralis*, because it is continuous internally with the central lobe of the superior vermiform process.

The *superior vermiform process* is the elevated median portion which connects the two lateral hemispheres. It begins at the valve of Vieussens, between the two superior peduncles of the cerebellum, and terminates at the bottom of the posterior notch. The process is divided by fissures, which are continuous with the fissures on the lateral hemispheres, into the following parts, enumerated in their order from before backwards: the lobulus centralis, the monticulus cerebelli and the folium cacuminis.

The *lobulus centralis* is a small, square lobe situated below and behind the testes, from which it is separated by a fold of pia mater. It rests on a tongue-shaped process of the cerebellum, the *lingula*, which separates the central lobe from the valve of Vieussens. Laterally the lobulis centralis expands and forms the anterior part of the square lobe under the name of the *ala lobuli centralis*.

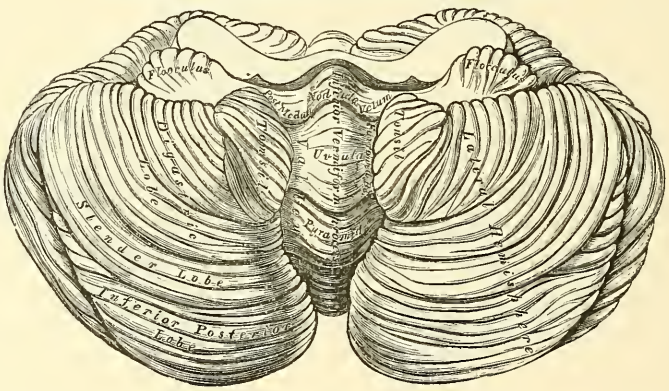
The *monticulus cerebelli* consists of two parts, the *lobus culminis* (*culmen*) and the *lobus clivi* (*clivus*), which are continuous on each side with the anterior and posterior crescentic parts of the square lobe of the lateral hemispheres; the fissure which separates the culmen from the clivus being the continuation of the fissure which separates the anterior crescentic portion from the posterior.

The *folium cacuminis* is a short and narrow concealed band, which connects the posterior superior or semi-lunar lobes of the lateral hemispheres.

The *under surface of the cerebellum* (fig. 477) is subdivided into two lateral hemispheres by a depression, the *vallecula* or *valley*, which extends from before backwards in the middle line. These lateral hemispheres are lodged in the inferior occipital fossæ; the median depression, or valley, receives the back part of the medulla oblongata, is broader in the centre than at either extremity, and has, projecting from its floor, part of the median lobe of the cerebellum, called the *inferior vermiform process*.

Upon the under surface of each hemisphere there are five lobes, separated by sulci; these are, from before backwards: (1) the *flocculus* or *subpeduncular lobe*,

Fig. 477.—Under surface of the cerebellum.



a prominent tuft, situated behind and below the middle peduncle of the cerebellum; its surface is composed of grey matter, subdivided into a few small laminæ; it is sometimes called the *pneumogastric lobule*, from being situated behind the pneumogastric nerve: (2) the *amygdala* or *tonsil*, situated on either side of the great median fissure or valley, and projecting into the fourth ventricle: (3) the *digastric* or *biventral lobe*, situated on the outside of the tonsil, and connected in part with the pyramid: (4) the *slender lobe*, behind the digastric, and connected with the back part of the pyramid and the commissura brevis: and more posteriorly (5) the *inferior posterior lobe*, which also joins the commissura brevis in the valley.

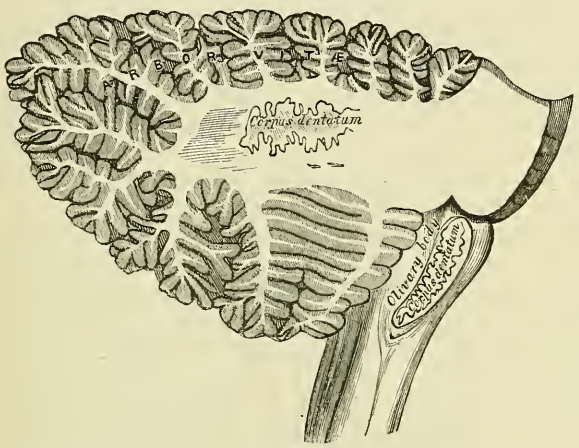
The inferior vermiform process.—The parts entering into the composition of the inferior vermiform process, from behind forwards, are: the *tuber valvulæ* or *commissura brevis*, a transverse lamina uniting the inferior posterior and slender lobes of the two sides; in front of this, a laminated conical projection, the *pyramid*, which is connected to the digastric lobe by a narrow ridge; more anteriorly, a larger eminence, the *uvula*, which is placed between two rounded lobes, the *amygdalæ* or *tonsils*, which occupy the sides of the valley, and which is connected with them by a commissure of grey matter, indented on the surface, called the *furrowed band*. In front of the uvula is the *nodule*; it is the anterior pointed termination of the inferior vermiform process, and projects into the cavity of the

fourth ventricle; it has been named by Malacarne the *laminated tubercle*. On each side of the nodule is a thin layer of white substance, attached externally to the flocculus, and internally to the nodule; these form together the *inferior medullary velum*, or commissure of the flocculus. It is usually covered in and concealed by the amygdalæ, and cannot be seen until they are drawn aside. This band is of a semi-lunar form on each side, its anterior margin being free and concave, its posterior attached just in front of the furrowed band. Between it and the nodule and uvula behind is a deep fossa, called the *swallow's nest* (*nidus hirundinis*).

Internal structure of the cerebellum.—The cerebellum consists both of white and grey matter.

If a vertical section (fig. 478) is made through either hemisphere of the cerebellum, midway between its centre and the superior vermiform process, the interior will be found to consist of a central stem of white matter, which contains in its interior a grey mass, the *corpus dentatum*. From the surface of this central stem a series of plates of medullary matter are detached, which, covered with grey matter, form the laminæ. In consequence of the main branches from the

Fig. 478.—Vertical section of the cerebellum.



central stem dividing and subdividing, the section presents a characteristic appearance which is named the *arbor vitæ*. If a vertical section is made in the median plane of the cerebellum it will be found that the central stem divides into two main branches, named respectively, from their direction, the vertical and the horizontal branch. The *vertical* branch passes upwards to the superior vermiform process, most of its secondary branches breaking up in the column, but some passing forwards and upwards to the central lobe and the lingula. The *horizontal* branch passes backwards to the folium cacuminis considerably diminished in size, in consequence of having given off two large secondary branches; one, from its upper surface, which ascends to the clivus; the other, which descends, and breaking up into branches, enters the lobes in the inferior vermiform process, the tuber valvulæ, the pyramid, the uvula and the nodule.

From the anterior part of each hemisphere arise three large processes or peduncles—superior, middle, and inferior—by which the cerebellum is connected with the rest of the encephalon.

The **white matter** includes two varieties of nerve matter: (1) the *peduncular fibres*, which are directly continuous with the fibres of the peduncles of the cerebellum; (2) the fibres (*fibræ propriæ*) proper to the cerebellum itself.

The *peduncles of the cerebellum*—superior, middle, and inferior—serve to connect it with the rest of the encephalon.

The *superior peduncles* (*processus e cerebello ad testes*) arise from the middle

of the white matter of the cerebral hemispheres; they run beneath the testes of the corpora quadrigemina and, emerging at its posterior border, pass outwards and backwards to the cerebellum. Each peduncle forms the upper part of the lateral boundary of the fourth ventricle, and is connected with its fellow of the opposite side by the *valve of Vieussens*. Beneath the corpora quadrigemina the innermost fibres of each peduncle decussate with each other, so that some fibres from the one half of the cerebrum are continued into the other half of the cerebellum. Upon entering the cerebellum the fibres of this peduncle pass to a great extent into the interior of the corpus dentatum, though some wind round it and reach the grey cortical matter, especially on its inferior surface.

The *valve of Vieussens*, or *superior medullary velum*, is a thin, translucent lamina of white matter, marked superficially by a few transverse streaks of grey substance, stretched between the two processus e cerebello ad testes; it forms part of the roof of the fourth ventricle. It is narrow in front, where it is connected with the testes; and broader behind, at its connection with the superior vermiform process of the cerebellum. A slight elevated ridge, the *frænulum*, descends upon the upper part of the valve from the corpora quadrigemina, and on either side of it may be seen the fourth nerve, which is connected with its fellow of the opposite side by a transverse band of fibres forming a partial decussation. Its lower half is streaked by three or four grey bands, with intervening furrows. These bands are prolonged from the anterior border of the cerebellum; they are called the *lingula*.

The *middle peduncles* (*processus ad pontem*) the largest of the three, connect together the two hemispheres of the cerebellum, forming their great transverse commissure. They consist of a large mass of curved fibres, which arise in the grey matter of the foliated cortex of the hemispheres of the cerebellum, and pass across the pons Varolii, forming its transverse fibres.

The *inferior peduncles* (*processus ad medullam*) connect the cerebellum with the medulla oblongata. As the restiform bodies, they pass upwards and outwards, forming part of the lateral wall of the fourth ventricle; entering the cerebellum, they end in the grey cortex of the upper surface of this organ.

The *fibræ propriæ of the cerebellum* are of two kinds: (1) *commissural fibres*, which cross the middle line to connect the opposite halves of the hemispheres, some at the anterior part, and others at the posterior part of the vermiform process; (2) *arcuate* or *association fibres*, which connect one lamina with another, arching across the fissures between the laminæ.

The **grey matter of the cerebellum** is found in two situations: (1) on the surface, forming the cortex; (2) as independent masses in the interior.

1. The *grey matter of the cortex* presents a characteristic foliated appearance, due to the series of laminæ which are given off from the central white matter; these laminæ give off secondary laminæ which are covered with grey matter. This arrangement gives to the cut surface of the organ a foliated appearance, to which the name *arbor vitæ* has been applied (fig. 478). Externally the cortex is covered by pia mater, and internally is the medullary centre, consisting mainly of nerve-fibres.

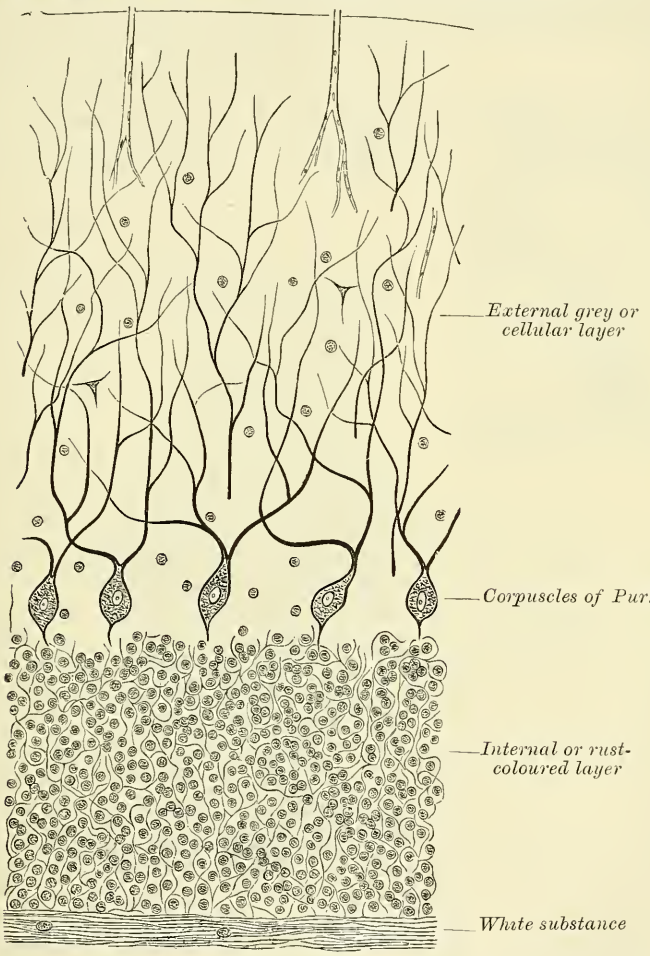
Microscopical appearance of the cortex.—The cortex presents a remarkable structure, consisting of two distinct layers, viz. an external grey or cellular layer and an internal rust-coloured granular layer. Between the two layers, or rather situated in the deepest part of the grey or cellular layer, is an incomplete stratum of the characteristic cells of the cerebellum, the *corpuscles of Purkinje*.

The *external grey* or *cellular layer* (fig. 479) consists of a transparent tissue-like neuroglia, containing fibres and cells. The fibres are delicate fibrillæ running at right angles to the surface, and many of them connected with the processes of the large nerve-cells immediately below; others are delicate supporting connective tissue-like fibres, which spread out into a broad base against the inner surface of the pia mater.

The cells are granular bodies, some very small, and probably belonging to the neuroglia; others, according to Lockhart Clarke, connected with the processes of the corpuscles of Purkinje which lie immediately beneath.

The *corpuscles of Purkinje* (fig. 479) are flask-shaped cells, in the deepest part of the external grey or cellular layer, resting against the internal rust-coloured layer. From their under service a slight slender process arises, which passes through the internal layer, and becomes continuous with the axial cylinder of a medullated nerve-fibre in the medullary substance beneath. From the other

Fig. 479.—Vertical section through the grey matter of the human cerebellum. Magnified about 100 diameters. (Klein and Noble Smith.)



extremity two peripheral processes are given off, which branch in an antler-like manner in the external layer, some of the finer processes becoming connected with the cells in this layer.

The *internal* or *rust-coloured layer* (fig. 479) is characterised by containing multitudes of granular-looking bodies embedded in a gelatinous matrix. They are minute stellate cells, consisting of a well-defined nucleus with a thin protoplasmic envelope. Between the cells is a fine nerve-network, with which the processes of the cells are supposed to be continuous.

2. The *independent centres of grey matter in the cerebellum* are four in number: one, situated in each hemisphere, is of large size, and is known as the corpus dentatum; the other three, much smaller, are situated near the middle of

the cerebellum, and are known as the nucleus emboliformis, nucleus globosus, and nucleus fastigii.

The *corpus dentatum* or *ganglion of the cerebellum* is situated a little to the inner side of the centre of the stem of white matter. It consists of an open bag or capsule of grey matter, the section of which presents a grey dentated outline, open at its anterior part. It is surrounded by white fibres; white fibres are also contained in its interior which issue from it to join the superior peduncles.

The *nucleus emboliformis* is a mass of grey matter placed on the inner side of the corpus dentatum, and partly covering the opening at its anterior part. The *nucleus globosus* is an elongated clump of grey matter placed to the inner side of the preceding. The *nucleus fastigii* is somewhat larger than the other two, and is situated close to the middle line at the anterior end of the superior vermiform process, and immediately over the roof of the fourth ventricle, from which it is separated by a thin layer of white matter. It was formerly known as the roof nucleus of Stilling.

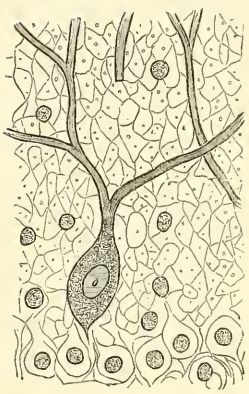


Fig. 480.—A corpuscle of Purkinje, with its dichotomously branched processes.

Fourth Ventricle (figs. 455, 473)

The **Fourth Ventricle**, or *ventricle of the cerebellum*, is the space between the posterior surface of the medulla oblongata and pons in front and the cerebellum behind. It is lozenge- or diamond-shaped; that is to say, it is composed of two triangles, with their bases opposed to each other. The lower triangle is formed by the divergence of the funiculi graciles and cuneati of the medulla oblongata on either side. These columns, as they pass upwards in the medulla, about the middle of its length, bend outwards, and, diverging from each other, form a triangular space, which is the lower half of the fourth ventricle. In like manner the upper triangle is formed by the divergence of the superior peduncles (processus e cerebello ad testes) of the cerebellum. These crura as they emerge from the corpora quadrigemina are in contact by their lateral margins, but they gradually diverge, passing downwards, backwards, and outwards, to reach the cerebellum, thus enclosing a triangular space, which forms the upper half of the fourth ventricle. This cavity is therefore bounded laterally by the processus e cerebello ad testes in its upper half, and by the funiculi graciles, the funiculi cuneati, and the restiform bodies in its lower half. It presents four angles. The upper angle reaches as high as the upper border of the pons; it presents the lower opening of the aqueduct of Sylvius, by which this ventricle communicates with the third ventricle. The lower angle is on a level with the lower border of the olivary body. From the resemblance that it bears to the nib of a writing pen it has been named the *calamus scriptorius*. In the point of the angle is a somewhat cleft-like space, the *ventricle of Arantius*, which opens by a minute hole into the central canal of the spinal cord. At its lateral angles the fourth ventricle is extended for a short distance between the side of the medulla and the cerebellum, where these two structures come in contact, forming a pointed *lateral recess*.

The roof is formed from above downwards by the following structures: a part of the superior peduncles of the cerebellum, the superior medullary velum, the inferior medullary vela, the tela choroidea inferior, the obex, and the ligula.

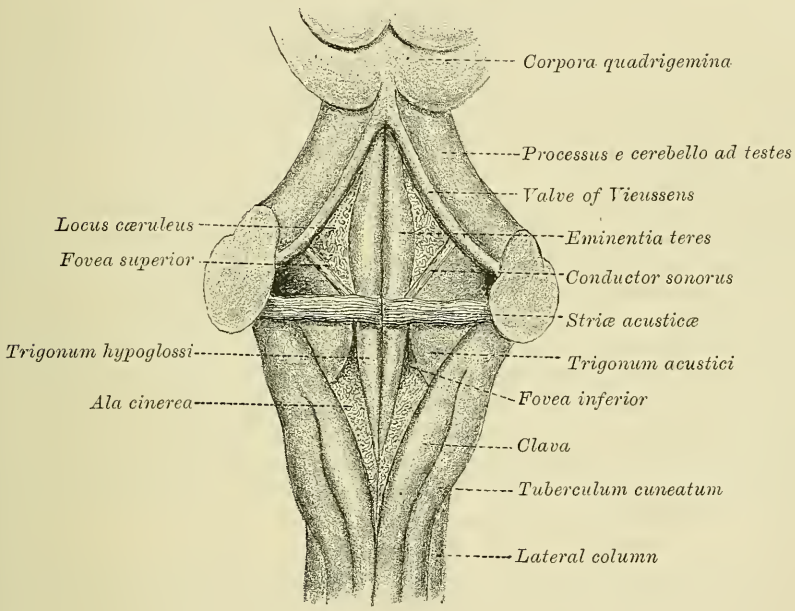
The *superior peduncles of the cerebellum*, when they emerge from the medullary substance of its hemispheres, pass upwards and forwards, forming the lateral boundaries of the upper half of the fourth ventricle, but as they approach the corpora quadrigemina the mesial portion of the peduncle forms a

part of the roof of the cavity, in consequence of the ventricle extending to a slight extent underneath the peduncle.

The superior medullary velum (*Valve of Vieussens*).—In the angular interval left between the two superior peduncles is a thin lamina of white matter, which bridges across from one peduncle to the other, and so completes the roof of the superior part of the ventricle. This is the superior medullary velum (see p. 772). It is marked on its upper surface by three or four transverse grey bands, separated by sulci. These bands are continued laterally into the grey matter of the cerebellar hemispheres, and are termed the *ligula*. The *inferior medullary vela* are thin layers of white substance, attached on either side externally to the flocculus, and internally to the nodule, which assist in forming a part of the roof of the fourth ventricle (see p. 771). They are attached to the cerebellum by thin convex edges, and by thin concave margins are apparently free, but are connected with the epithelium of the ventricle.

The *tela choroidea inferior* is a layer of pia mater which covers in the lower part of the fourth ventricle below the inferior medullary vela. It extends from the choroid plexuses of the fourth ventricle in front to the lower and posterior

Fig. 481.—Floor of the fourth ventricle. Diagrammatic.



part of the cavity, where it becomes continuous with the pia mater, covering the posterior surface of the lower part of the medulla. It does not form a complete membrane, for there are contained in it three openings, one in the middle line at the inferior angle of the ventricle, just above the position of the opening of the central canal of the cord; this is the *foramen of Majendie*; the other two are at the extremities of the lateral recesses of the ventricle, and are named the *foramina of Key and Retzius* (see p. 726). The *obex* is a thin, triangular lamina of white matter which fills in the angle between the two diverging funiculi graciles for a short distance, and covers over the ventricle of Arantius. The *ligula* (*tænia*) are narrow bands of white matter which project from the internal border of the funiculi graciles. They at first run upwards and forwards, and then turn outwards over the restiform bodies. Their inner borders are continuous with the epithelial roof of the ventricle.

The *floor of the fourth ventricle* (fig. 481) is rhomboidal in shape, and is

traversed in its longer diameter by a median fissure, the *sulcus longitudinalis medianus*. At its widest part, at the level of the lateral recesses, it is marked by some transverse white lines, the *striæ medullaris* or *striæ acusticæ*. These consist of white fibres, which arise on the under surface of the medulla, emerge from the longitudinal sulcus, and pass to the flocculus of the cerebellum. They were formerly described as passing into the root of the auditory nerve, hence their name.

These striæ divide the floor of the ventricle into two triangles, inferior and superior. The inferior triangle, or lower half of the floor, presents above a triangular depression, the *fovea inferior*, the apex of which is at the striæ. As this depression widens out it cuts off two triangular areas, one to the inner side and one to the outer. The one to the inner side is bounded internally by the median sulcus, and outside by the groove which forms the inner boundary of the fovea inferior; its base is directed upwards and limited by the striæ medullaris. It is termed the *trigonum hypoglossi*, because it corresponds in position to the tract of nerve-cells from which the hypoglossal nerve takes origin. The triangular area to the outer side of the fovea inferior is named the *trigonum acustici*. It lies between the groove forming the outer boundary of the fovea inferior and the lateral wall of the ventricle, and, like the trigonum hypoglossi, has its base directed upwards. Here it is continuous with a prominence, the *tuberculum acusticum*, which extends into the anterior part of the floor of the ventricle, and from which the greater part of the auditory nerve arises. As the fovea inferior widens out it marks off a triangular depression, with its base directed downwards. This is of a darker colour than the rest of the floor of the ventricle, and is therefore named the *ala cinerea*, and from the fact that it contains the nuclei of the vagus and glosso-pharyngeal nerves it is sometimes called the *trigonum vagi*.

The *superior half* of the floor of the fourth ventricle, i.e. the part above the striæ medullaris, presents in the middle line the continuation of the median longitudinal sulcus. On either side of this is a spindle-shaped longitudinal eminence, prominent in its centre, but less so above and below. This is the *eminentia teres*, and is produced by an underlying bundle of white fibres, the *funiculus teres*, formed, at all events in part, by the fibres of the facial nerve. Outside the *eminentia teres* is an angular depression, the *fovea superior*, which is sometimes crossed by a whitish band of fibres, the *conductor sonorus*, which below is connected with the striæ medullaris. Above the fovea is a bluish depressed area, the *locus cæruleus*. Its colour is due to some pigmented nerve-cells, showing through the white covering of the floor. These pigmented cells are named the *substantia ferruginea*.

The *lining membrane of the fourth ventricle* is continuous with that of the third, through the aqueduct of Sylvius, and its cavity communicates below with the subarachnoidean space of the brain and cord through an aperture in the layer of pia mater extending between the cerebellum and medulla oblongata. Laterally, this membrane is reflected outwards a short distance between the cerebellum and medulla.

The *choroid plexuses* of the fourth ventricle are two in number: they are delicate vascular fringes, which project into the ventricle on each side, though excluded from the ventricular cavity by a layer of epithelium. They pass from the inferior vermiform process, where they lie close together on each side of the middle line, in a direction outwards to the apertures in the pia mater of the lateral recesses of the ventricle.

CRANIAL NERVES

The cranial nerves arise from some part of the cerebro-spinal centre, and are transmitted through foramina in the base of the cranium. They have been named numerically, according to the order in which they pass through the dura

mater lining the base of the skull. Other names are also given to them derived from the parts to which they are distributed, or from their functions. Taken in their order, from before backwards, they are as follows:—

1st. Olfactory.
2nd. Optic.
3rd. Motor oculi.
4th. Trochlear (Pathetic).
5th. Trifacial (Trigeminus).
6th. Abducent.
7th. Facial (Portio dura).
8th. Auditory (Portio mollis).
9th. Glosso-pharyngeal.
10th. Pneumogastric (Par vagum).
11th. Spinal accessory.
12th. Hypoglossal.

All the cranial nerves are connected to some part of the surface of the brain. This is termed their *superficial* or *apparent origin*. But their fibres may, in all cases, be traced deeply into the substance of the brain to some special centre of grey matter, termed a *nucleus*. This is called their *deep* or *real origin*. The nerves, after emerging from the brain at their apparent origin, pass through foramina or tubular prolongations in the dura mater, leave the skull through foramina in its base, and pass to their final distribution.

First Nerve (fig. 466, page 747)

The **First Cranial** or **Olfactory Nerves**, the special nerves of the sense of smell, are about twenty in number. They are given off from the under surface of the olfactory bulb, an oval mass of a greyish colour, which rests on the cribriform plate of the ethmoid bone, and forms the anterior expanded extremity of a slender process of brain-substance, named the *olfactory tract* (see page 738). The olfactory tract is the remains of a hollow projection of the fore-brain of the fœtus, in which the cavity becomes obliterated in man, though persistent in many mammals and other vertebrates. It is an elongated body, triangular in section, and capped at its extremity by a layer of grey matter, forming the olfactory bulb. It contains in its centre a core of neuroglia, which is the remains of the obliterated cavity; above this the tract consists of grey matter, which is continuous with the cerebral cortex; below, it consists of white matter, which divides posteriorly into two roots. Of these, the external, which is the larger, passes outwards round the anterior perforated space, across the fissure of Sylvius, to the temporo-sphenoidal lobe. The other, or internal root, passes inwards and joins the lower end of the corpus callosum. Between these two diverging roots a triangular interval is left, in which is seen an elevation, which is sometimes described as the middle or grey root of the tract. It passes backwards into the anterior commissure.

As the olfactory tract passes forwards, it is contained in a deep sulcus, the *olfactory sulcus*, between two convolutions, lying on the under surface of the frontal lobe, on either side of the longitudinal fissure, and is retained in position by the arachnoid membrane which covers it. On reaching the cribriform plate of the ethmoid bone, it forms the *olfactory bulb*. From the under part of this bulb are given off the olfactory nerves, which pass through the cribriform foramina, and are distributed to the mucous membrane of the nose. Each nerve is surrounded by a tubular prolongation from the dura mater and pia mater; the former being lost on the periosteum lining the nose; the latter, in the neurilemma of the nerve. The nerves, as they enter the nares, are divisible into two groups: an inner group, larger than those on the outer wall, spread out over the upper third of the septum; and an outer set, which are distributed over the superior turbinated bone, and the surface of the ethmoid in front of it. As the filaments descend, they unite in a plexiform network, and are believed by most observers to terminate in the *cells of Schultze*.

The olfactory differs in structure from other nerves, in being composed exclusively of non-medullated fibres. They are deficient in the white substance

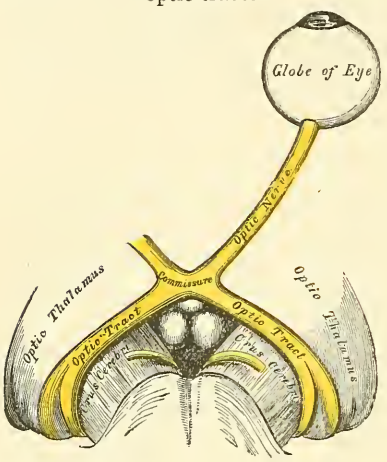
of Schwann, and consist of axis-cylinders, with a distinct nucleated sheath, in which there are, however, fewer nuclei than in ordinary non-medullated fibres.

Surgical Anatomy.—In severe injuries to the head, the olfactory bulb may become separated from the olfactory nerves, thus producing loss of the sense of smelling (*anosmia*), and with this a considerable loss in the sense of taste, as much of the perfection of the sense of taste is due to the sapid substances being also odorous, and simultaneously exciting the sense of smell.

Second Nerve (fig. 482)

The **Second** or **Optic Nerve**, the special nerve of the sense of sight, is distributed exclusively to the eyeball. The nerves of opposite sides are connected together at the commissure, and from the back of the commissure they may be traced to the brain, under the name of the *optic tracts*.

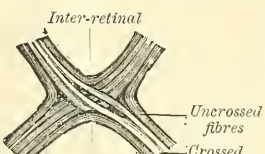
Fig. 482.—The left optic nerve and optic tracts.



The *optic tract*, at its connection with the brain, is divided into two bands. One of these arises from a greyish white layer (*stratum opticum*) in the interior of the anterior or upper lobes of the corpora quadrigemina, and emerges from the nates of this body as the anterior brachium, and passes obliquely outwards between the inner and outer geniculate bodies; the second arises from the pulvinar of the optic thalamus, and passes through the inner geniculate body, from which it derives fibres, and joins with the other band to form the optic tract. From this origin the tract winds obliquely across the under surface of the crus cerebri, in the form of a flattened band, destitute of neurilemma, and is attached to the crus by its anterior margin. It then assumes a cylindrical form, and, as it passes forwards, is connected with the tuber cinereum and lamina cinerea, with both of which it is connected. It finally joins with the tract of the opposite side to form the *optic commissure*.

The *commissure* or *chiasma*, somewhat quadrilateral in form, rest upon the optic groove of the sphenoid bone, being bounded, above, by the lamina cinerea; behind, by the tuber cinereum; on either side, by the anterior perforated space.

Fig. 483.—Course of the fibres in the optic commissure.



Within the commissure, the optic nerves of the two sides undergo a partial decussation. The fibres which form the inner margin of each tract and posterior part of the commissure have no connection with the optic nerves. They simply pass across from one side of the brain to the other, and connect the internal geniculated bodies of the two sides. They are known as the *commissure of Gudden*. Some fibres are continued across the anterior border of the chiasma, and connect the optic nerves of the two sides, having no relation with the optic tracts.* They may be regarded as commissural fibres between the two retinæ (*inter-retinal fibres*). The remainder and principal part of the commissure consists of two sets of fibres, crossed and uncrossed. The *crossed*, which are the more numerous, occupy the mesial part of the chiasma, and pass from the optic tract of one side to the optic nerve of the other, decussating in the commissure with similar fibres of the opposite tract.

* The presence of these fibres has been doubted by some observers, but they have been recently asserted to exist by Stilling.

The uncrossed fibres occupy the outer part of the chiasma, and pass from the tract of one side to the nerve of the same side.*

The *optic nerves* arise from the fore part of the commissure, and, diverging from one another, become rounded in form and firm in texture, and are enclosed in a sheath derived from the arachnoid. As each nerve passes through the corresponding optic foramen, it receives a sheath from the dura mater; and as it enters the orbit this sheath divides into two layers, one of which becomes continuous with the periosteum of the orbit; the other forms the proper sheath of the nerve, and surrounds it as far as the sclerotic. The nerve passes through the cavity of the orbit, pierces the sclerotic and choroid coats at the back part of the eyeball, a little to the nasal side of its centre, and expands into the retina. Arnold describes a communication between the optic nerve in the orbit and the ascending branches of Meckel's ganglion. A small artery, the *arteria centralis retinæ*, perforates the optic nerve a little behind the globe, and runs along its interior in a tubular canal of fibrous tissue. It supplies the inner surface of the retina, and is accompanied by corresponding veins.

Surgical Anatomy.—The optic nerve is peculiarly liable to become the seat of neuritis or undergo atrophy in affections of the central nervous system, and as a rule the pathological relationship between the two affections is exceedingly difficult to trace. There are, however, certain points in connection with the anatomy of this nerve which tend to throw light upon the frequent association of these affections with intracranial disease: (1) From its mode of development (see page 97), and from its structure, the optic nerve must be regarded as a prolongation of the brain-substance, rather than as an ordinary cerebro-spinal nerve. (2) As it passes from the brain, it receives sheaths from the three cerebral membranes, a perineural sheath from the pia mater; an intermediate sheath from the arachnoid, and an outer sheath from the dura mater, which is also connected with the periosteum, as it passes through the optic foramen. These sheaths are separated from each other by spaces, which communicate with the subdural and subarachnoid spaces respectively. The innermost or perineural sheath sends a process around the arteria centralis retinæ into the interior of the nerve, and enters intimately into the structure of the nerve. Thus inflammatory affection of the meninges or of the brain may readily extend themselves along these spaces, or along the interstitial connective tissue in the nerve.

The course of the fibres in the optic commissure has an important pathological bearing, and has been the subject of much controversy. Microscopic examination, experiments, and pathology all seem to point to the fact that there is a partial decussation of the fibres, each tract supplying the corresponding half of each eye, so that the right tract supplies the right half of each eye, and the left tract the left half of each eye. At the same time Charcot believes, and his view has met with general acceptation, that the fibres which do not decussate at the optic commissure have already decussated in the corpora quadrigemina, so that lesion of the cerebral centre of one side causes complete blindness of the opposite eye, because both sets of decussating fibres are destroyed. Whereas should one tract, say the right, be destroyed by disease, there will be blindness of the right half of both retinæ.

An antero-posterior section through the commissure would divide the decussating fibres, and would therefore produce blindness of the inner half of each eye; while a section at the margin of the side of the optic commissure would produce blindness of the external half of the retina of the same side.

The optic nerve may also be affected in injuries or diseases involving the orbit; in fractures of the anterior fossa of the base of the skull; in tumours of the orbit itself, or those invading this cavity from neighbouring parts.

Third Nerve (figs. 484, 485, 486)

The **Third** or **Motor Oculi Nerve** supplies all the muscles of the orbit, except the Superior oblique and External rectus; it also supplies, through its connection with the ciliary ganglion, the sphincter muscle of the iris and the ciliary muscle. It is a rather large nerve, of rounded form and firm texture.

Its apparent origin is from the inner surface of the crus cerebri, immediately in front of the pons Varolii. The *deep origin* may be traced through the locus

* A specimen of congenital absence of the optic commissure is to be found in the Museum of the Westminster Hospital. See also Henle, *Nervenlehre*, p. 393, ed. 2.

niger and tegmentum of the crus to a nucleus situated on either side of the median line beneath the floor of the aqueduct of Sylvius.

On emerging from the brain, the nerve is invested with a sheath of pia mater, and enclosed in a prolongation from the arachnoid. It passes between the superior cerebellar and posterior cerebral arteries, and then pierces the dura mater in front of and external to the posterior clinoid process, passing between the two processes from the free and attached borders of the tentorium, which are prolonged forwards to be connected with the anterior and posterior clinoid processes of the sphenoid bone. It passes along the outer wall of the cavernous sinus, above the other orbital nerves, receiving in its course one or two filaments from the cavernous plexus of the sympathetic, and a communicating branch from the first division of the fifth. It then divides into two branches, which enter the orbit through the sphenoidal fissure, between the two heads of the External rectus muscle. On passing through the fissure, the nerve is placed below the fourth and the frontal and lachrymal branches of the ophthalmic nerve, and has passing between its two divisions the nasal nerve.

Fig. 484.—Nerves of the orbit. Seen from above.

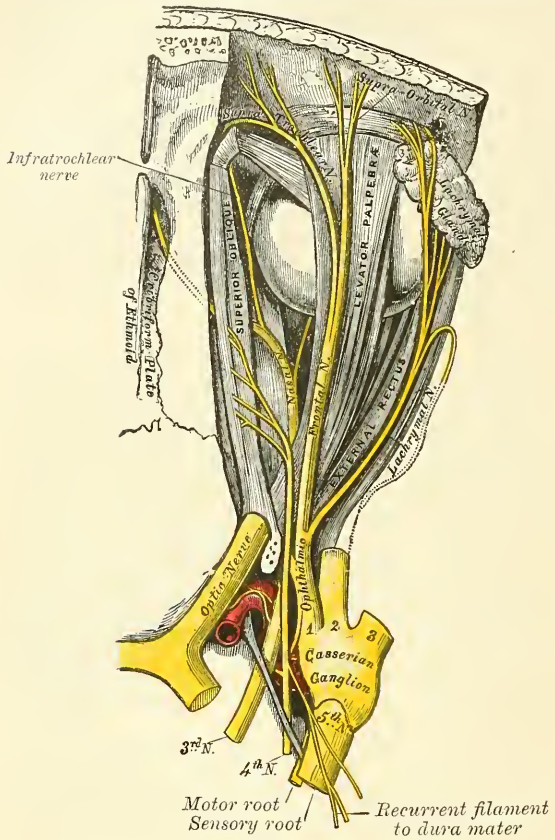


Fig. 485.—Plan of the motor oculi nerve. (After Flower.)

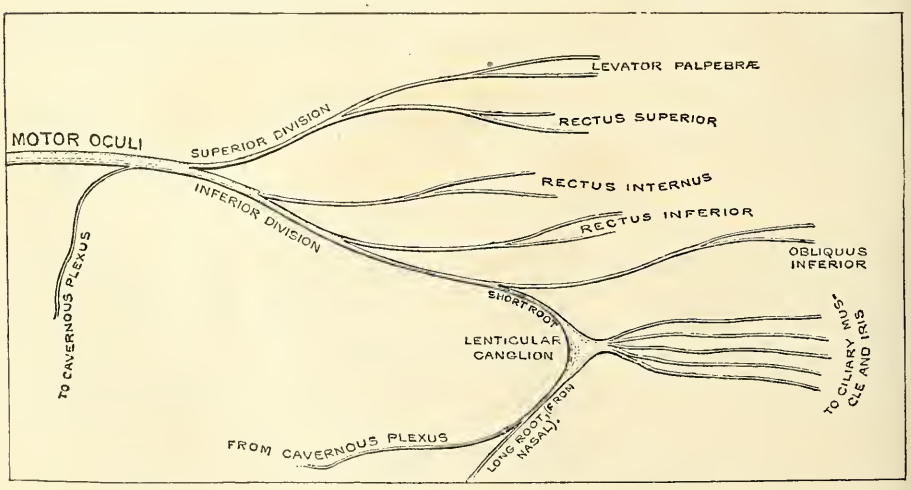


The *superior division*, the smaller, passes inwards over the optic nerve, and supplies the Superior rectus and Levator palpebræ. The *inferior division*, the larger, divides into three branches. One passes beneath the optic nerve to the Internal rectus; another, to the Inferior rectus; and the third, the longest of the three, passes forwards between the Inferior and External recti to the Inferior oblique. From this latter a short, thick branch is given off to the lower part of the lenticular ganglion, which forms its inferior root. It also gives off one or two filaments to the Inferior rectus. All these branches enter the muscles on their ocular surface.

Surgical Anatomy.—Paralysis of the third nerve may be the result of many causes: as cerebral disease; conditions causing pressure on the cavernous sinus; periostitis of the bones entering into the formation of the sphenoidal fissure. It results, when complete, in (1) ptosis, or drooping of the upper eyelid, in consequence of the Levator palpebræ being paralysed; (2) external strabismus, on account of the unopposed action of the External rectus muscle, which is not supplied by the third nerve, and is not therefore paralysed; (3) dilatation of the pupil, because the sphincter fibres of the iris are paralysed; (4) loss of power of accommodation, as the sphincter pupillæ, the ciliary muscle, and the Internal rectus are paralysed; (5) slight prominence of the eyeball, from the compressing action of the Superior oblique, which is not paralysed. Occasionally paralysis may affect only a part of the nerve, that is to say, there may be, for example, a dilated and fixed pupil, with ptosis, but no other signs. Irritation of the nerve causes spasm of one or other of the muscles supplied by it; thus, there may be internal strabismus from spasm of the Internal rectus; accommodation for near objects only from spasm of the ciliary muscle; or myosis, contraction of the pupil, from irritation of the sphincter of the pupil.

Fourth Nerve (fig. 484)

The **Fourth** or **Trochlear Nerve** (*pathetic*), the smallest of the cranial nerves, supplies the Superior oblique muscle.

Its *apparent origin*, at the base of the brain, is on the outer side of the crus cerebri, just in front of the pons Varolii, but the fibres can be traced backwards behind the corpora quadrigemina to the valve of Vieussens, on the upper surface of which the two nerves decussate. Its *deep origin* may be traced to a nucleus in the floor of the aqueduct of Sylvius immediately below that of the third nerve, with which it is continuous.

The nerve winds round the outer side of the crus cerebri, immediately above the pons Varolii, pierces the dura mater in the free border of the tentorium cerebelli, just behind, and external to, the posterior clinoid process, and passes forwards in the outer wall of the cavernous sinus, between the third nerve and the ophthalmic division of the fifth. It crosses the third nerve and enters the orbit, through the sphenoidal fissure. It now becomes the highest of all the nerves, lying at the inner extremity of the fissure internal to the frontal nerve. In the orbit it passes inwards, above the origin of the Levator palpebræ, and finally enters the orbital surface of the Superior oblique muscle.

In the outer wall of the cavernous sinus this nerve is not unfrequently blended with the ophthalmic division of the fifth. *Branches of communication.*—In the outer wall of the cavernous sinus it receives some filaments from the cavernous plexus of the sympathetic. In the sphenoidal fissure it occasionally gives off a branch to assist in the formation of the lachrymal nerve. *Branches of distribution.*—It gives off a recurrent branch, which passes backwards between the layers of the tentorium, dividing into two or three filaments which may be traced as far back as the wall of the lateral sinus.

Surgical Anatomy.—The fourth nerve when paralysed causes loss of function in the Superior oblique, so that the patient is unable to turn his eye downwards and outwards. Should the patient attempt to do this, the eye on the affected side is twisted inwards, producing diplopia or double vision. Accordingly, it is said that the first symptom of loss of function in this muscle is giddiness when going down hill or in descending stairs, owing to the double vision induced by the patient looking at his steps whilst descending.

Fifth Nerve

The **Fifth** or **Trifacial Nerve** (*trigeminus*) is the largest cranial nerve. It resembles a spinal nerve: (1) in arising by two roots; (2) in having a ganglion developed on its posterior root; and (3) in its function, since it is a compound nerve. It is the great sensory nerve of the head and face, and the motor nerve of the muscles of mastication. Its upper two divisions are entirely sensory, the third division is partly sensory and partly motor.

It arises by two roots: of these the anterior is the smaller, and is the motor root; the posterior, the larger and sensory. Its *superficial origin* is from the side of the pons Varolii, nearer to the upper than the lower border. The smaller root consists of three or four bundles; the larger root consists of numerous bundles of fibres, varying in number from seventy to a hundred. The two roots are separated from one another by a few of the transverse fibres of the pons. The *deep origin* of the larger or sensory root is chiefly from a long tract in the medulla, the so-called *ascending root*; the fibres from which pass upwards through the pons and join with those derived from a nucleus in the floor of the fourth ventricle, placed deeper and to the outer side of the nucleus from which the small or motor root is derived. The *deep origin* of the smaller or motor root is derived partly from a nucleus embedded in the grey matter of the floor of the fourth ventricle and partly from a collection of nerve-cells situated at the side of the aqueduct of Sylvius, which pass downwards to join the nerve, and are known as the descending root.

The two roots of the nerve pass forwards through an oval opening in the dura mater, on the superior border of the petrous portion of the temporal bone, above the internal auditory meatus: they then run between the bone and the dura mater to the apex of the petrous portion of the temporal bone, where the fibres of the sensory root form a large semilunar ganglion (*Gasserian*), while the motor root passes beneath the ganglion without having any connection with it, and joins outside the cranium with one of the trunks derived from it.

The **Gasserian** or **semilunar ganglion*** is lodged in a depression near the apex of the petrous portion of the temporal bone. It is of somewhat crescentic form, with its convexity turned forwards. Its upper surface is intimately adherent to the dura mater. Besides the small or motor root, the large superficial petrosal nerve lies underneath the ganglion.

Branches of communication.—This ganglion receives, on its *inner side*, filaments from the carotid plexus of the sympathetic. *Branches of distribution.*—It gives off minute branches to the tentorium cerebelli and the dura mater, in the middle fossa of the cranium. From its *anterior border*, which is directed forwards and outwards, three large branches proceed: the *ophthalmic*, *superior maxillary*, and *inferior maxillary*. The ophthalmic and superior maxillary consist exclusively of fibres derived from the larger root and ganglion, and are solely nerves of common sensation. The third division, or inferior maxillary, is joined outside the cranium by the motor root. This, therefore, strictly speaking, is the only portion of the fifth nerve which can be said to resemble a spinal nerve.

Ophthalmic Nerve (figs. 484, 486, 487)

The **Ophthalmic**, or first division of the fifth, is a sensory nerve. It supplies the eyeball, the lachrymal gland, the mucous lining of the eye and nasal fossæ, and the integument of the eyebrow, forehead, and nose. It is the smallest of the three divisions of the fifth, rising from the upper part of the Gasserian ganglion.

* A Viennese anatomist, Raimund Balthasar Hirsch (1765), was the first who recognised the ganglionic nature of the swelling on the sensory root of the fifth nerve, and called it, in honour of his otherwise unknown teacher, Jon. Laur. Gasser, the 'Ganglion Gasseri.' Julius Casserius, whose name is given to the musculo-cutaneous nerve of the arm, was Professor at Padua, 1545–1605. See Hyrtl, *Lehrbuch der Anatomie*, p. 895 and p. 55.

It is a short, flattened band, about an inch in length, which passes forwards along the outer wall of the cavernous sinus, below the other nerves, and just before entering the orbit, through the sphenoidal fissure, divides into three branches, *lachrymal*, *frontal* and *nasal*.

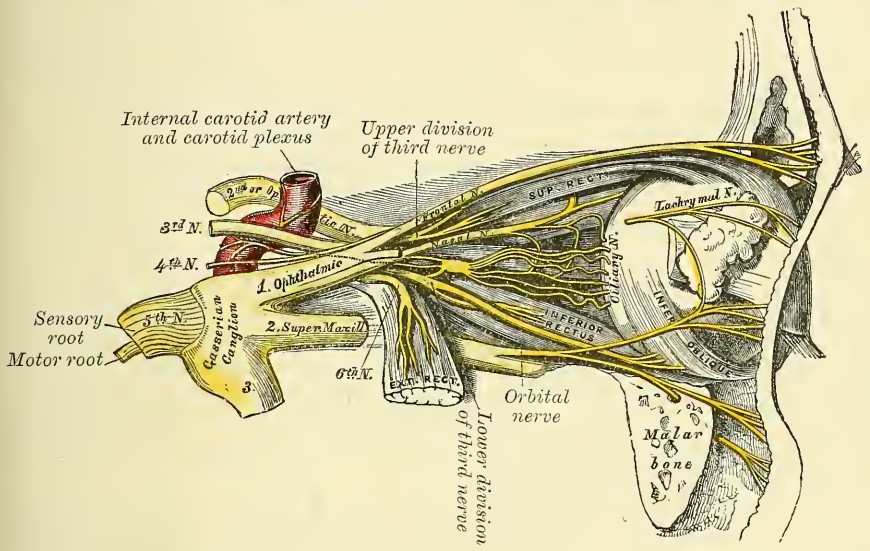
Branches of communication.—The ophthalmic nerve is joined by filaments from the cavernous plexus of the sympathetic, communicates with the third and sixth nerves, and is not unfrequently joined with the fourth.

Branches of distribution.—It gives off recurrent filaments which pass between the layers of the tentorium along with a branch from the fourth nerve, and then divides into

Lachrymal. Frontal. Nasal.

The **Lachrymal** is the smallest of the three branches of the ophthalmic. Not unfrequently it arises by two filaments, one from the ophthalmic, the other from the fourth. It passes forwards in a separate tube of dura mater, and enters the orbit through the narrowest part of the sphenoidal fissure. In the orbit it runs

Fig. 486.—Nerves of the orbit and ophthalmic ganglion. Side view.



along the upper border of the External rectus muscle, with the lachrymal artery, and sends off a recurrent branch which joins the orbital branch of the superior maxillary nerve, and occasionally takes the place of the temporal branch of this nerve, which is then absent. Within the lachrymal gland it gives off several filaments, which supply the gland and the conjunctiva. Finally, it pierces the tarsal ligaments, and terminates in the integument of the upper eyelid, joining with filaments of the facial nerve.

The **Frontal** is the largest division of the ophthalmic, and may be regarded, both from its size and direction, as the continuation of the nerve. It enters the orbit above the muscles, through the highest and broadest part of the sphenoidal fissure, and runs forwards along the middle line, between the Levator palpebræ and the periosteum. Midway between the apex and base of the orbit it divides into two branches, supratrochlear and supra-orbital.

The *supratrochlear branch*, the smaller of the two, passes inwards, above the pulley of the Superior oblique muscle, and gives off a descending filament, which joins with the infratrochlear branch of the nasal nerve. It then escapes from the orbit between the pulley of the Superior oblique and the supra-orbital foramen, curves up on to the forehead close to the bone, and descends beneath the Corrugator supercilii and Occipito-frontalis muscles, and dividing into branches,

which pierce these muscles, it supplies the integument of the lower part of the forehead on either side of the middle line.

The *supra-orbital branch* passes forwards through the supra-orbital foramen, and gives off, in this situation, palpebral filaments to the upper eyelid. It then ascends upon the forehead, and terminates in cutaneous and pericranial branches. The *cutaneous branches*, two in number, an inner and an outer, supply the integument of the cranium as far back as the occiput. They are at first situated beneath the Occipito-frontalis, the inner branch perforating the frontal portion of the muscle, the outer branch its tendinous aponeurosis. The *pericranial branches* are distributed to the pericranium over the frontal and parietal bones.

The **Nasal nerve** is intermediate in size between the frontal and lachrymal, and more deeply placed than the other branches of the ophthalmic. It enters the orbit between the two heads of the External rectus, and passes obliquely inwards across the optic nerve, beneath the Levator palpebræ and Superior rectus muscles, to the inner wall of the orbit, where it enters the anterior ethmoidal foramen, immediately below the Superior oblique. It then enters the cavity of the cranium, traverses a shallow groove on the front of the cribriform plate of the ethmoid bone, and passes down, through the slit by the side of the crista galli, into the nose, where it divides into two branches, an internal and an external. The *internal branch* supplies the mucous membrane near the fore part of the septum of the nose. The *external branch* descends in a groove on the inner surface of the nasal bone, and supplies a few filaments to the mucous membrane covering the fore part of the outer wall of the nares as far as the inferior spongy bone; it then leaves the cavity of the nose, between the lower border of the nasal bone and the upper lateral cartilage of the nose, and, passing down beneath the Compressor nasi, supplies the integument of the ala and the tip of the nose, joining with the facial nerve.

The branches of the nasal nerve are, the *ganglionic*, *ciliary*, and *infra-trochlear*.

The *ganglionic* is a slender branch, about half an inch in length, which usually arises from the nasal, between the two heads of the External rectus. It passes forwards on the outer side of the optic nerve, and enters the superior and posterior angle of the ciliary ganglion, forming its superior or long root. It is sometimes joined by a filament from the cavernous plexus of the sympathetic, or from the superior division of the third nerve.

The *long ciliary nerves*, two or three in number, are given off from the nasal as it crosses the optic nerve. They join the short ciliary nerves from the ciliary ganglion, pierce the posterior part of the sclerotic, and, running forwards between it and the choroid, are distributed to the ciliary muscle, iris, and cornea.

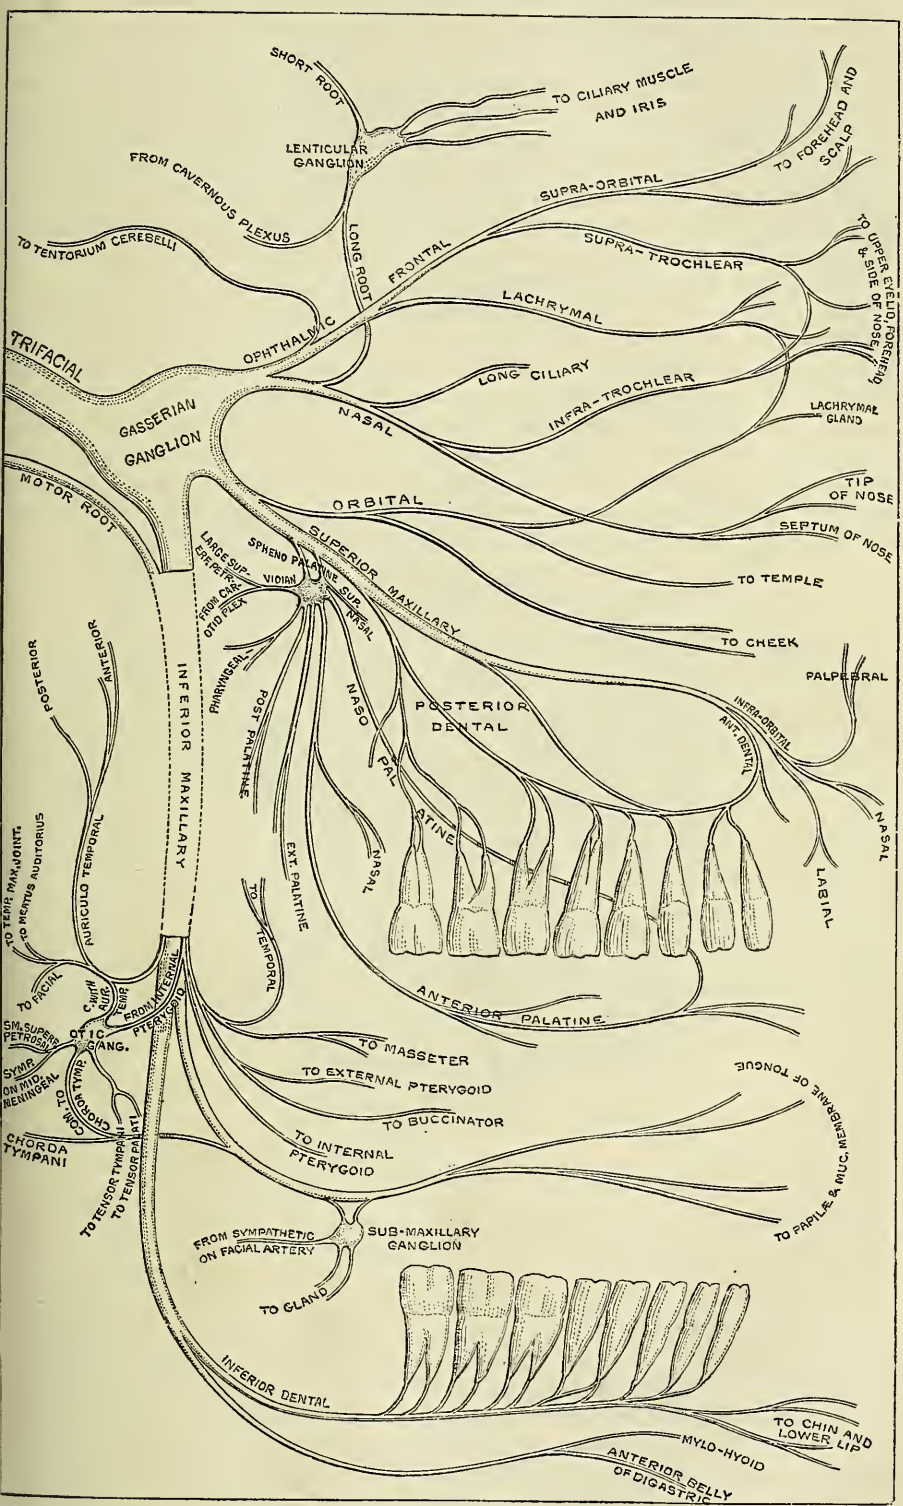
The *infratrochlear branch* is given off just before the nasal nerve passes through the anterior ethmoidal foramen. It runs forwards along the upper border of the Internal rectus, and is joined, beneath the pulley of the Superior oblique, by a filament from the supratrochlear nerve. It then passes to the inner angle of the eye, and supplies the integument of the eyelids and side of the nose, the conjunctiva, lachrymal sac, and caruncula lachrymalis.

Ophthalmic Ganglion (figs. 486, 487)

Connected with the three divisions of the fifth nerve are four small ganglia. With the first division is connected the *ophthalmic ganglion*; with the second division, the *spheno-palatine* or *Meckel's ganglion*; and with the third, the *otic* and *submaxillary ganglia*. All the four receive sensory filaments from the fifth, and motor and sympathetic filaments from various sources; these filaments are called the *roots of the ganglia*.

The **Ophthalmic**, **Lenticular**, or **Ciliary Ganglion** is a small, quadrangular, flattened ganglion, of a reddish-grey colour, and about the size of a pin's head, situated at the back part of the orbit between the optic nerve and the External

Fig. 487.—Plan of the fifth cranial nerve. (After Flower.)



rectus muscle, lying generally on the outer side of the ophthalmic artery. It is enclosed in a quantity of loose fat, which makes its dissection somewhat difficult.

Its *branches of communication*, or *roots*, are three, all of which enter its posterior border. One, the long or sensory root, is derived from the nasal branch of the ophthalmic, and joins its superior angle. The second, the short or motor root, is a short, thick nerve, occasionally divided into two parts, which is derived from the branch of the third nerve to the Inferior oblique muscle, and is connected with the inferior angle of the ganglion. The third, the sympathetic root, is a slender filament from the cavernous plexus of the sympathetic. This is frequently blended with the long root, though it sometimes passes to the ganglion separately. According to Tiedemann, this ganglion receives a filament of communication from the spheno-palatine ganglion.

Its *branches of distribution* are the short ciliary nerves. These are delicate filaments, from six to ten in number, which arise from the fore part of the ganglion in two bundles, connected with its superior and inferior angles; the lower bundle is the larger. They run forwards with the ciliary arteries in a wavy course, one set above and the other below the optic nerve, and are joined by the long ciliary nerves from the nasal. They pierce the sclerotic at the back part of the globe, pass forwards in delicate grooves on its inner surface, and are distributed to the ciliary muscle, iris, and cornea. Tiedemann has described one small branch as penetrating the optic nerve with the arteria centralis retinæ.

Superior Maxillary Nerve (fig. 488)

The **Superior Maxillary**, or second division of the fifth, is a sensory nerve. It is intermediate, both in position and size, between the ophthalmic and inferior maxillary. It commences at the middle of the Gasserian ganglion as a flattened plexiform band, and passing horizontally forwards, it leaves the skull through the foramen rotundum, where it becomes more cylindrical in form, and firmer in texture. It then crosses the spheno-maxillary fossa, enters the orbit through the spheno-maxillary fissure, traverses the infra-orbital canal in the floor of the orbit, and appears upon the face at the infra-orbital foramen.* At its termination, the nerve lies beneath the Levator labii superioris muscle, and divides into a leash of branches, which spread out upon the side of the nose, the lower eyelid, and upper lip, joining with filaments of the facial nerve.

Branches of distribution.—The branches of this nerve may be divided into four groups: 1. Those given off in the cranium. 2. Those given off in the spheno-maxillary fossa. 3. Those in the infra-orbital canal. 4. Those on the face.

In the cranium . . .	Meningeal
Spheno-maxillary fossa	Orbital or temporo-malar.
	Spheno-palatine.
	Posterior superior dental.
Infra-orbital canal .	Middle superior dental.
	Anterior superior dental.
On the face	Palpebral.
	Nasal.
	Labial.

The **meningeal branch** is given off directly after its origin from the Gasserian ganglion, and supplies the dura mater, communicating with a meningeal branch from the inferior maxillary nerve.

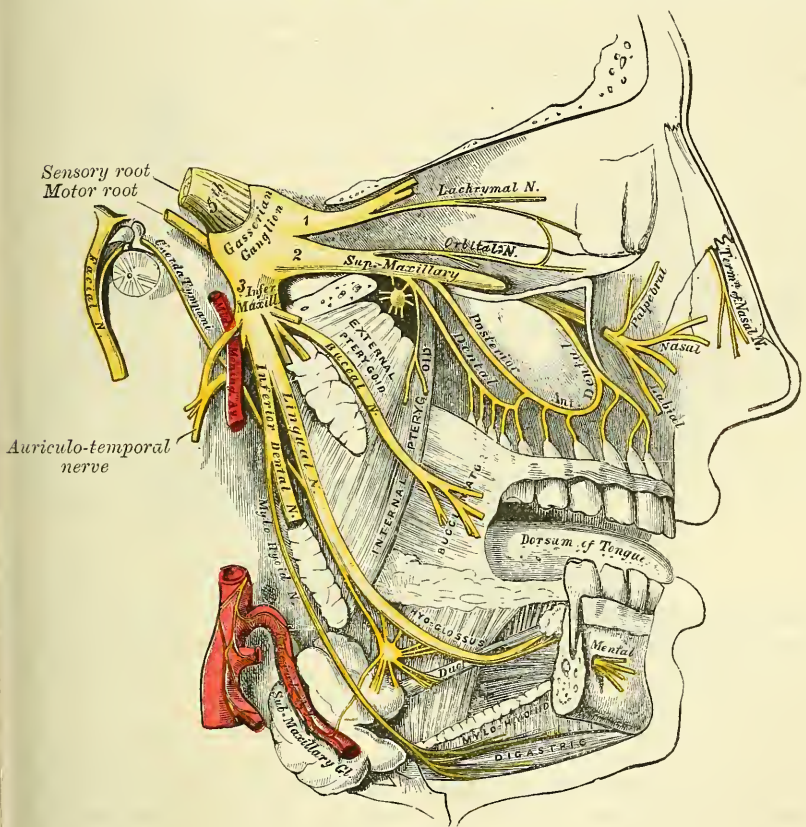
The **orbital** or **temporo-malar branch** arises in the spheno-maxillary fossa, enters the orbit by the spheno-maxillary fissure, and divides at the back of that cavity into two branches, temporal and malar.

* After it enters the infra-orbital canal, the nerve is frequently called the *infra-orbital*.

The *temporal branch* runs in a groove along the outer wall of the orbit (in the malar bone), receives a branch of communication from the lachrymal, and, passing through a foramen in the malar bone, enters the temporal fossa. It ascends between the bone and substance of the Temporal muscle, pierces this muscle and the temporal fascia about an inch above the zygoma, and is distributed to the integument covering the temple and side of the forehead, communicating with the facial and auriculo-temporal branch of the inferior maxillary nerve. As it pierces the temporal fascia, it gives off a slender twig, which runs between the two layers of the fascia to the outer angle of the orbit.

The *malar branch* passes along the external inferior angle of the orbit, emerges upon the face through a foramen in the malar bone, and, perforating

Fig. 488.—Distribution of the second and third divisions of the fifth nerve and submaxillary ganglion.



e Orbicularis palpebrarum muscle, supplies the skin on the prominence of the eek, and is named *subcutaneus malæ*. It joins with the facial and the palpebral anches of the superior maxillary.

The **spheno-palatine branches**, two in number, descend to the spheno-palatine nglion.

The **posterior superior dental branches** arise from the trunk of the nerve just it is about to enter the infra-orbital canal; they are generally two in number, t sometimes arise by a single trunk, and immediately divide and pass down- rds on the tuberosity of the superior maxillary bone. They give off several igs to the gums and neighbouring parts of the mucous membrane of the cheek *perior gingival branches*). They then enter the posterior dental canals on the gomatic surface of the superior maxillary bone, and, passing from behind

forwards in the substance of the bone, communicate with the middle dental nerve, and give off branches to the lining membrane of the antrum and three twigs to each of the molar teeth. These twigs enter the foramina at the apices of the fangs, and supply the pulp.

The **middle superior dental branch** is given off from the superior maxillary nerve in the back part of the infra-orbital canal, and runs downwards and forwards in a special canal in the outer wall of the antrum to supply the two bicuspid teeth. It communicates with the posterior and anterior dental branches. At its point of communication with the posterior branch is a slight thickening which has received the name of the *ganglion of Valentin*; and at its point of communication with the anterior branch is a second enlargement, which is called the *ganglion of Bochdalek*. Neither of these is probably a true ganglion.

The **anterior superior dental branch**, of large size, is given off from the superior maxillary nerve just before its exit from the infra-orbital foramen; it enters a special canal in the anterior wall of the antrum, and, coursing from before backwards, divides into a series of branches which supply the incisor and canine teeth. It communicates with the middle dental branch and gives off a *nasal branch*, which passes through a minute canal into the nasal fossa, and supplies the mucous membrane of the fore part of the inferior meatus and the floor of this cavity, communicating with the naso-palatine nerve from Meckel's ganglion.

The **palpebral branches** pass upwards beneath the Orbicularis palpebrarum. They supply the integument and conjunctiva of the lower eyelid with sensation, joining at the outer angle of the orbit with the facial nerve and malar branch of the orbital.

The **nasal branches** pass inwards; they supply the integument of the side of the nose, and join with the nasal branch of the ophthalmic.

The **labial branches**, the largest and most numerous, descend beneath the Levator labii superioris, and are distributed to the integument of the upper lip, the mucous membrane of the mouth, and labial glands.

All these branches are joined, immediately beneath the orbit, by filaments from the facial nerve, forming an intricate plexus, the *infra-orbital*.

Spheno-palatine Ganglion (fig. 489)

The **spheno-palatine ganglion** (*Meckel's*), the largest of the cranial ganglia, is deeply placed in the spheno-maxillary fossa, close to the spheno-palatine foramen. It is triangular or heart-shaped, of a reddish-grey colour, and is situated just below the superior maxillary nerve as it crosses the fossa.

Its branches of communication.—Like the other ganglia of the fifth nerve, it possesses a motor, a sensory, and a sympathetic root. Its *sensory root* is derived from the superior maxillary nerve through its two spheno-palatine branches. These branches of the nerve, given off in the spheno-maxillary fossa, descend to the ganglion. Their fibres, for the most part, pass in front of the ganglion, as they proceed to their destination, in the palate and nasal fossa, and are not incorporated in the ganglionic mass; some few of the fibres, however, enter the ganglion, constituting its sensory root. Its *motor root* is derived from the facial nerve through the large superficial petrosal nerve; and its *sympathetic root*, from the carotid plexus, through the large deep petrosal nerve. These two nerves join together to form a single nerve, the *Vidian*, before their entrance into the ganglion.

The *large superficial petrosal branch* (*nervus petrosus superficialis major*) is given off from the intumescentia ganglioformis in the aqueductus Fallopii; it passes through the hiatus Fallopii; enters the cranial cavity, and runs forwards contained in a groove on the anterior surface of the petrous portion of the temporal bone, lying beneath the dura mater and the Gasserian ganglion. It then enters the cartilaginous substance which fills in the foramen lacerum

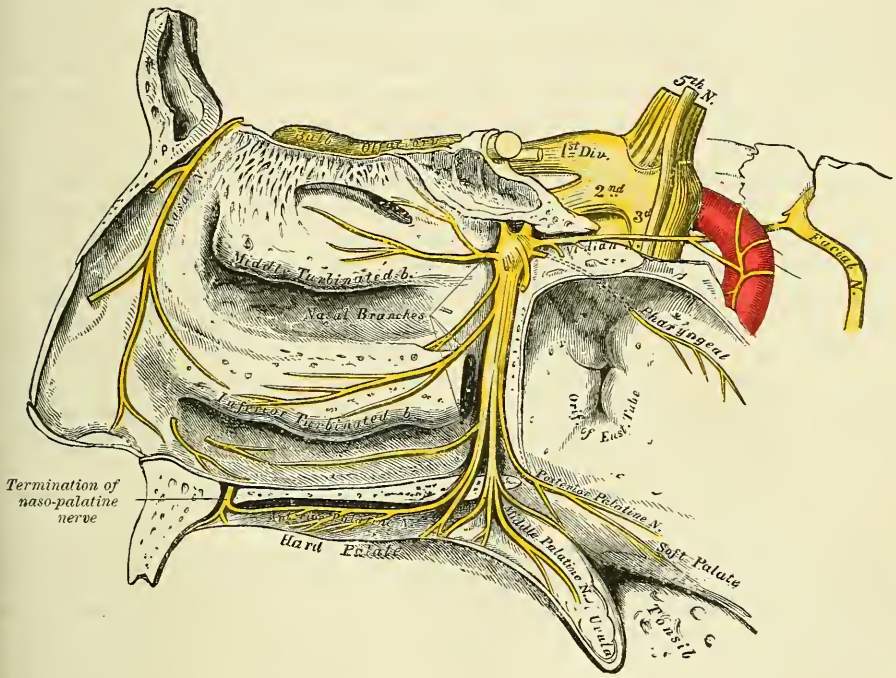
medium basis cranii, and joining with the large deep petrosal branch forms the Vidian nerve.

The *large deep petrosal branch* (*nervus petrosus profundus*) is given off from the carotid plexus, and runs through the carotid canal on the outer side of the internal carotid artery. It then enters the cartilaginous substance which fills in the foramen lacerum medium, and joins with the large superficial petrosal nerve to form the Vidian.

The *Vidian nerve*, formed in the cartilaginous substance which fills in the middle lacerated foramen by the junction of the two preceding nerves, passes forwards, through the Vidian canal, with the artery of the same name, and, entering the spheno-maxillary fossa, joins the posterior angle of Meckel's ganglion.

Its *branches of distribution* are divisible into four groups: *ascending*, which pass to the orbit; *descending*, to the palate; *internal*, to the nose; and *posterior branches*, to the pharynx and nasal fossæ.

Fig. 489.—The spheno-palatine ganglion and its branches.



The *ascending branches* are two or three delicate filaments, which enter the orbit by the spheno-maxillary fissure, and supply the periosteum. According to Luschka, some filaments pass through foramina in the suture between the os planum of the ethmoid and frontal bones to supply the mucous membrane of the posterior ethmoidal and sphenoidal sinuses.

The *descending* or *palatine branches* are distributed to the roof of the mouth, the soft palate, tonsil, and lining membrane of the nose. They are almost a direct continuation of the spheno-palatine branches of the superior maxillary nerve, and are three in number: anterior, middle, and posterior.

The *anterior* or *large palatine nerve* descends through the posterior palatine canal, emerges upon the hard palate, at the posterior palatine foramen, and passes forwards through a groove in the hard palate, nearly as far as the incisor teeth. It supplies the gums, the mucous membrane and glands of the hard palate, and communicates in front with the termination of the naso-palatine nerve. While in the posterior palatine canal, it gives off *inferior nasal branches*, which enter the nose through openings in the palate bone, and ramify over the

middle meatus and the middle and inferior spongy bones; and, at its exit from the canal, a palatine branch is distributed to both surfaces of the soft palate.

The *middle* or *external palatine nerve* descends, through one of the accessory palatine canals, distributing branches to the uvula, tonsil, and soft palate. It is occasionally wanting.

The *posterior* or *small palatine nerve* descends with a small artery through the small posterior palatine canal, emerging by a separate opening behind the posterior palatine foramen. It supplies the Levator palati and Azygos uvulæ muscles,* the soft palate, tonsil, and uvula. The middle and posterior palatine join with the tonsillar branches of the glosso-pharyngeal to form the plexus around the tonsil (*circulus tonsillaris*).

The *internal branches* are distributed to the septum and outer wall of the nasal fossæ. They are the superior nasal (anterior) and the naso-palatine.

The *superior nasal branches* (*anterior*), four or five in number, enter the back part of the nasal fossa by the spheno-palatine foramen. They supply the mucous membrane covering the superior and middle spongy bones, and that lining the posterior ethmoidal cells, a few being prolonged to the upper and back part of the septum. One branch is continued on to the inner surface of the anterior wall of the antrum, and there forms a communication with the anterior dental nerve. At the point of communication a swelling exists, denominated 'the ganglion of Bochdalek,' the nature of which seems to be, however, uncertain.

The *naso-palatine nerve* (*Cotunnius*) also enters the nasal fossa through the spheno-palatine foramen, and passes inwards across the roof of the nose, below the orifice of the sphenoidal sinus, to reach the septum; it then runs obliquely downwards and forwards along the lower part of the septum, to the anterior palatine foramen, lying between the periosteum and mucous membrane. It descends to the roof of the mouth through the anterior palatine canal. The two nerves are here contained in separate and distinct canals, situated in the intermaxillary suture, and termed the foramina of Scarpa, the left nerve being usually anterior to the right one. In the mouth, they become united, supply the mucous membrane behind the incisor teeth, and join with the anterior palatine nerve. The naso-palatine nerve occasionally furnishes a few small filaments to the mucous membrane of the septum.

The *posterior branches* are, the pharyngeal (pterygo-palatine), and the upper posterior nasal branches.

The *pharyngeal nerve* (*pterygo-palatine*) is a small branch arising from the back part of the ganglion, being generally blended with the Vidian nerve. It passes through the pterygo-palatine canal with the pterygo-palatine artery, and is distributed to the mucous membrane of the upper part of the pharynx, behind the Eustachian tube.

The *upper posterior nasal branches* are a few twigs given off from the posterior part of the ganglion, which run backwards in the sheath of the Vidian nerve to the mucous membrane at the back part of the roof, septum, and superior meatus of the nose and that covering the end of the Eustachian tube.

Inferior Maxillary Nerve (fig. 488)

The **Inferior Maxillary Nerve** distributes branches to the teeth and gums of the lower jaw, the integument of the temple and external ear, the lower part of the face and lower lip, and the muscles of mastication: it also supplies the tongue with a large branch. It is the largest of the three divisions of the fifth, and is made up of two roots: a large or sensory root proceeding from the inferior angle of the Gasserian ganglion; and a small or motor root, which passes beneath the ganglion, and unites with the sensory root, just after its exit from the skull through the foramen ovale. Immediately beneath the base of the skull, this

* It is probable that this is not the true motor supply to these muscles, but that they are supplied by the spinal accessory through the pharyngeal plexus.

nerve divides into two trunks, anterior and posterior. Previous to its division, the primary trunk gives off from its inner side a recurrent (meningeal) branch, and the nerve to the Internal pterygoid muscle.

The **recurrent branch** is given off directly after its exit from the foramen ovale. It passes backwards into the skull through the foramen spinosum with the middle meningeal artery. It divides into two branches, anterior and posterior, which accompany the main divisions of the artery and supply the dura mater. The posterior branch also supplies the mucous lining of the mastoid cells. The anterior branch communicates with the meningeal branch of the superior maxillary nerve.

The **Internal Pterygoid Nerve**, given off from the inferior maxillary, previous to its division, is intimately connected at its origin with the otic ganglion, to which it furnishes a motor root. It is a long and slender branch, which passes inwards to enter the deep surface of the Internal pterygoid muscle.

The *anterior* and smaller division, which receives nearly the whole of the motor root, divides into branches, which supply the muscles of mastication. They are, the masseteric, deep temporal, buccal, and external pterygoid.

The **masseteric branch** passes outwards, above the External pterygoid muscle, in front of the temporo-maxillary articulation, and crosses the sigmoid notch with the masseteric artery, to the Masseter muscle, in which it ramifies nearly as far as its anterior border. It occasionally gives a branch to the Temporal muscle, and a filament to the articulation of the jaw.

The **deep temporal branches**, two in number, anterior and posterior, supply the deep surface of the Temporal muscle. The *posterior branch*, of small size, is placed at the back of the temporal fossa. It is sometimes joined with the masseteric branch. The *anterior branch* is frequently given off from the buccal nerve, it is reflected upwards, at the pterygoid ridge of the sphenoid, to the front of the temporal fossa. Sometimes there are three deep temporal branches, the third branch (*middle deep temporal*) passing outwards over the External pterygoid muscle to enter the deep surface of the Temporal muscle.

The **buccal branch** passes forwards between the two heads of the External pterygoid, and downwards beneath the inner surface of the coronoid process of the lower jaw, or through the fibres of the Temporal muscle, to reach the surface of the Buccinator, upon which it divides into a superior and an inferior branch. It gives a branch to the External pterygoid during its passage through that muscle, and a few ascending filaments to the Temporal muscle, one of which occasionally joins with the anterior branch of the deep temporal nerve. The *upper branch* supplies the integument and upper part of the Buccinator muscle, joining with the facial nerve round the facial vein. The *lower branch* passes forwards to the angle of the mouth; it supplies the integument and Buccinator muscle, as well as the mucous membrane lining the inner surface of that muscle, and joins the facial nerve.*

The **External Pterygoid Nerve** is most frequently derived from the buccal, but it may be given off separately from the anterior trunk of the nerve. It enters the muscle on its inner surface.

The *posterior* and larger division of the inferior maxillary nerve is for the most part sensory, but receives a few filaments from the motor root. It divides into three branches: auriculo-temporal, lingual (gustatory), and inferior dental.

The **Auriculo-temporal Nerve** generally arises by two roots, between which the middle meningeal artery passes. It runs backwards beneath the External pterygoid muscle to the inner side of the neck of the lower jaw. It then turns upwards with the temporal artery, between the external ear and condyle of the jaw, under cover of the parotid gland, and, escaping from beneath this structure, ascends over the zygoma, and divides into two temporal branches.

* There seems to be no reason to doubt that the branch supplying the Buccinator muscle is entirely a nerve of ordinary sensation, and that the true motor supply of this muscle is from the facial.

The *branches of communication* are with the facial and with the otic ganglion. The branches of communication with the facial, usually two in number, pass forwards, from behind the neck of the condyle of the jaw, to join this nerve at the posterior border of the Masseter muscle. They form one of the principal branches of communication between the facial and the fifth nerve. The filaments of communication with the otic ganglion are derived from the commencement of the auriculo-temporal nerve.

The *branches of distribution* are :—

Anterior auricular.	Articular.
Branches to the meatus auditorius.	Parotid.
Superficial temporal.	

The *anterior auricular branches* are usually two in number. They supply the front of the upper part of the pinna, being distributed principally to the skin covering the front of the helix and tragus.

Branches to the meatus auditorius, two in number, enter the canal between the bony and cartilaginous portion of the meatus. They supply the skin lining the meatus ; the upper one sending a filament to the membrana tympani.

A *branch to the temporo-maxillary articulation* is usually derived from the auriculo-temporal nerve.

The *parotid branches* supply the parotid gland.

The *superficial temporal* accompanies the temporal artery to the vertex of the skull, and supplies the integument of the temporal region, communicating with the facial nerve, and the temporal branch of the temporo-malar, from the superior maxillary.

The **Lingual Nerve** (**gustatory**) supplies the papillæ and mucous membrane of the tongue. It is deeply placed throughout the whole of its course. It lies at first beneath the External pterygoid muscle, together with the inferior dental nerve, being placed to the inner side of the latter nerve, and is occasionally joined to it by a branch which crosses the internal maxillary artery. The chorda tympani also joins it at an acute angle in this situation. The nerve then passes between the Internal pterygoid muscle and the inner side of the ramus of the jaw, and crosses obliquely to the side of the tongue over the Stylo-glossus muscle, and then between the Hyo-glossus muscle and deep part of the submaxillary gland ; the nerve lastly runs across Wharton's duct, and along the side of the tongue to its apex, lying immediately beneath the mucous membrane.

The *branches of communication* are with the facial through the chorda tympani, the inferior dental and hypoglossal nerves, and the submaxillary ganglion. The branches to the submaxillary ganglion are two or three in number ; those connected with the hypoglossal nerve form a plexus at the anterior margin of the Hyo-glossus muscle.

The *branches of distribution* are few in number. They supply the mucous membrane of the mouth, the gums, the sublingual gland, the filiform and fungiform papillæ and mucous membrane of the tongue ; the terminal filaments communicate, at the tip of the tongue, with the hypoglossal nerve.

The **Inferior Dental** is the largest of the three branches of the inferior maxillary nerve. It passes downwards with the inferior dental artery, at first beneath the External pterygoid muscle, and then between the internal lateral ligament and the ramus of the jaw to the dental foramen. It then passes forwards in the dental canal of the inferior maxillary bone, lying beneath the teeth, as far as the mental foramen, where it divides into two terminal branches, incisor and mental.

The branches of the inferior dental are, the mylo-hyoid, dental, incisive and mental.

The *mylo-hyoid* is derived from the inferior dental just as that nerve is about to enter the dental foramen. It descends in a groove on the inner surface of the ramus of the jaw, in which it is retained by a process of fibrous membrane. It reaches the under surface of the Mylo-hyoid muscle, and supplies it and the anterior

belly of the Digastric, occasionally sending one or two filaments to the submaxillary gland.

The *dental branches* supply the molar and bicuspid teeth. They correspond in number to the fangs of those teeth : each nerve entering the orifice at the point of the fang, and supplying the pulp of the tooth.

The *incisive branch* is continued onwards within the bone to the middle line, and supplies the canine and incisor teeth.

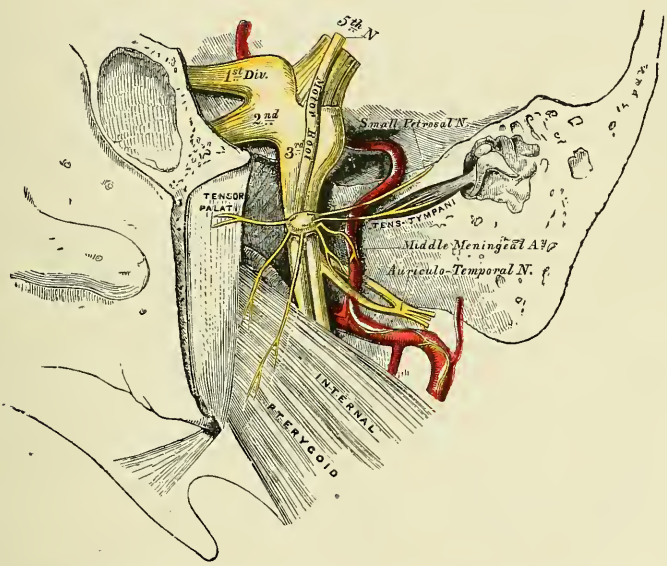
The *mental branch* emerges from the bone at the mental foramen, and divides beneath the Depressor anguli oris into two or three branches ; one descends to supply the skin of the chin, and another (sometimes two) ascends to supply the skin and mucous membrane of the lower lip. These branches communicate freely with the facial nerve.

Two small ganglia are connected with the inferior maxillary nerve : the otic with the trunk of the nerve ; and the submaxillary with its lingual branch.

Otic Ganglion (fig. 490)

The **Otic Ganglion** (*Arnold's*) is a small, oval-shaped, flattened ganglion of a reddish-grey colour, situated immediately below the foramen ovale, on the inner

Fig. 490.—The otic ganglion and its branches.



surface of the inferior maxillary nerve, surrounding the origin of the internal pterygoid nerve. It is in relation, *externally*, with the trunk of the inferior maxillary nerve, at the point where the motor root joins the sensory portion ; *internally*, with the cartilaginous part of the Eustachian tube, and the origin of the Tensor palati muscle ; *behind* it is the middle meningeal artery.

Branches of communication.—This ganglion is connected with the internal pterygoid branch of the inferior maxillary nerve, by two or three short, delicate filaments. From this it may obtain a motor root, and possibly also a sensory root, as these filaments from the nerve to the Internal pterygoid may contain sensory fibres. It communicates with the glosso-pharyngeal and facial nerves, through the small superficial petrosal nerve continued from the tympanic plexus, and through this communication it probably receives its sensory root from the glosso-pharyngeal and its motor root from the facial ; its communication with the sympathetic is effected by a filament from the plexus surrounding the middle meningeal artery. The ganglion also communicates with the auriculo-temporal

nerve. This is probably a branch from the glosso-pharyngeal which passes to the ganglion, and through it and the auriculo-temporal nerve to the parotid gland.

Its *branches of distribution* are, a filament to the Tensor tympani, and one to the Tensor palati. The former passes backwards, on the outer side of the Eustachian tube; the latter arises from the ganglion, near the origin of the internal pterygoid nerve, and passes forwards. The fibres of these nerves are, however, mainly derived from the nerve to the Internal pterygoid muscle. It also gives off a small communicating branch to the chorda tympani.

Submaxillary Ganglion (fig. 488)

The **submaxillary ganglion** is of small size, fusiform in shape, and situated above the deep portion of the submaxillary gland, near the posterior border of the Mylo-hyoid muscle, being connected by filaments with the lower border of the lingual (gustatory) nerve.

Branches of communication.—This ganglion is connected with the lingual (gustatory) nerve by a few filaments which join it separately, at its fore and back part. It also receives a branch from the chorda tympani, by which it communicates with the facial; and communicates with the sympathetic by filaments from the sympathetic plexus around the facial artery.

Branches of distribution.—These are five or six in number; they arise from the lower part of the ganglion, and supply the mucous membrane of the mouth and Wharton's duct, some being lost in the submaxillary gland. The branch of communication from the lingual to the fore part of the ganglion is by some regarded as a branch of distribution, by which filaments of the chorda tympani pass from the ganglion to the nerve, and by it are conveyed to the sublingual gland and the tongue.

Surface Marking.—It will be seen from the above description that the three terminal branches of the three divisions of the fifth nerve emerge from foramina in the bones of the skull and face on to the face: the terminal branch of the first division emerging through the supra-orbital foramen; that of the second through the infra-orbital foramen; and the third through the mental foramen. The supra-orbital foramen is situated at the junction of the internal and middle third of the supra-orbital arch between the internal and external angular processes. If a straight line is drawn from this point to the lower border of the inferior maxillary bone, so that it passes between the two bicuspid teeth of the lower jaw, it will pass over the infra-orbital and mental foramina; the former being situated about one centimetre ($\frac{2}{5}$ of an inch) below the margin of the orbit, and the latter varying in position according to the age of the individual. In the adult it is midway between the upper and lower borders of the inferior maxillary bone; in the child it is nearer the lower border, and in the edentulous jaw of old age it is close to the upper margin.

Surgical Anatomy.—The fifth nerve may be affected in its entirety; or its sensory or motor root may be affected; or one of its primary main divisions. In injury to the sensory root there is anæsthesia of the whole of the side of the face on the side of the lesion, with the exception of the skin over the parotid gland; insensibility of the conjunctiva, followed by destructive inflammation of the cornea, partly from loss of trophic influence, and partly from the irritation produced by the presence of foreign bodies on it, which are not perceived by the patient, and therefore not expelled by the act of winking; dryness of the nose, loss to a considerable extent of the sense of taste, and diminished secretion of the lachrymal and salivary glands. In injury to the motor root, there is impaired action of the lower jaw, from paralysis of the muscles of mastication on the affected side.

The fifth nerve is often the seat of neuralgia, and each of the three divisions has been divided, or a portion of the nerve excised, for this affection. The supra-orbital nerve may be exposed by making an incision an inch and a half in length along the supra-orbital margin below the eyebrow, which is to be drawn upwards, the centre of the incision corresponding to the supra-orbital notch. The skin and Orbicularis palpebrarum having been divided, the nerve can be easily found emerging from the notch, and lying in some loose cellular tissue. It should be drawn up by a blunt hook and divided, or, what is better, a portion of it removed. The infra-orbital nerve has been divided at its exit by an incision on the cheek; or the floor of the orbit has been exposed, the infra-orbital canal opened up, and the anterior part of the nerve resected; or the whole nerve, together with Meckel's ganglion as far back as the foramen rotundum, has been removed. This latter

operation, though undoubtedly a severe proceeding, appears to have been followed by the best results. The operation is performed as follows: the superior maxillary bone is first exposed by a T-shaped incision, one limb passing along the lower margin of the orbit, the other from the centre of this vertically down the cheek to the angle of the mouth. The nerve is then found, divided, and a piece of silk tied to it as a guide. A small trephine ($\frac{1}{2}$-inch) is then applied to the bone, below, but including the infra-orbital foramen, and the antrum opened. The trephine is now applied to the posterior wall of the antrum, and the spheno-maxillary fossa exposed. The infra-orbital canal is opened up from below by fine cutting-pliers or a chisel, and the nerve drawn down into the trephine hole, it being held on the stretch by means of the piece of silk; it is severed with fine curved scissors as near the foramen rotundum as possible, any branches coming off from the ganglion being also divided.* The inferior dental nerve has been divided at its exit from the foramen by an incision made through the mucous membrane where it is reflected from the alveolar process on to the lower lip; or a portion of the nerve has been resected by an incision on the cheek through the Masseter muscle, exposing the outer surface of the ramus of the jaw. A trephine was then applied over the position of the inferior dental foramen and the outer table removed, so as to expose the inferior dental canal. The nerve was dissected out of the portion of the canal exposed, and, having been divided after its exit from the mental foramen, it was by traction on the end exposed in the trephine hole, drawn out entire, and cut off as high up as possible.† The inferior dental nerve has also been divided by an incision within the mouth, the bony point guarding the inferior dental foramen forming the guide to the nerve. The buccal nerve may be divided by an incision through the mucous membrane of the mouth and the Buccinator just in front of the anterior border of the ramus of the lower jaw (Stimson).

The lingual (gustatory) nerve is occasionally divided with the view of relieving the pain in cancerous disease of the tongue. This may be done in that part of its course where it lies below and behind the last molar tooth. If a line is drawn from the middle of the crown of the last molar tooth to the angle of the jaw it will cross the nerve, which lies about half an inch behind the tooth, parallel to the bulging alveolar ridge on the inner side of the body of the bone. If the knife is entered three-quarters of an inch behind and below the last molar tooth, and carried down to the bone, the nerve will be divided. Hilton divided it opposite the second molar tooth, where it is covered only by the mucous membrane, and Lucas pulls the tongue forwards and over to the opposite side, when the nerve can be seen standing out as a firm cord under the mucous membrane by the side of the tongue, and can be easily seized with a sharp hook and divided, or a portion excised. This is a simple enough operation on the cadaver, but when the disease is extensive and has extended to the floor of the mouth, as is generally the case when division of the nerve is required, the operation is not practicable.

Sixth Nerve (fig. 486)

The **Sixth** or **Abducent Nerve** supplies the External rectus muscle.

Its *superficial origin* is by several filaments from the constricted part of the pyramid, close to the pons, or from the lower border of the pons itself, in the groove between this body and the medulla. Its *deep origin* is from the floor of the fourth ventricle, close to the median line, beneath the eminentia teres.

The nerve pierces the dura mater on the basilar surface of the sphenoid bone, runs through a notch immediately below the posterior clinoid process, and enters the cavernous sinus. It passes forwards through the sinus, lying on the outer side of the internal carotid artery. It enters the orbit through the sphenoidal fissure, and lies above the ophthalmic vein, from which it is separated by a lamina of dura mater. It then passes between the two heads of the External rectus, and is distributed to that muscle on its ocular surface.

Branches of communication.—It is joined by several filaments from the carotid and cavernous plexus, and by one from the ophthalmic nerve.

The above-mentioned nerve, as well as the third, fourth, and the ophthalmic division of the fifth, as they pass to the orbit, bear a certain relation to each other in the cavernous sinus, at the sphenoidal fissure, and in the cavity of the orbit, which will now be described.

In the *cavernous sinus* (fig. 427), the third, fourth, and ophthalmic division of the fifth are placed on the outer wall of the sinus, in their numerical order, both from above downwards, and from within outwards. The sixth nerve lies at the outer side of the internal carotid artery. As these nerves pass forwards to the

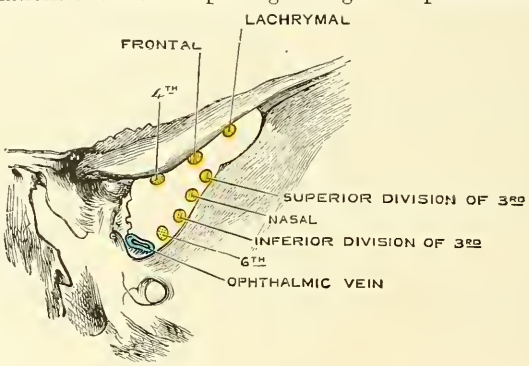
* Camochan, *Amer. Journ. Med. Science*, 1858, p. 136.
† Mears, *Trans. Amer. Surg. Assoc.*, vol. ii. p. 469.

sphenoidal fissure, the third and fifth nerves become divided into branches, and the sixth approaches the rest; so that their relative position becomes considerably changed.

In the *sphenoidal fissure* (fig. 491), the fourth, and the frontal and lachrymal divisions of the ophthalmic lie upon the same plane, the former being most internal, the latter external; and they enter the cavity of the orbit above the muscles. The remaining nerves enter the orbit between the two heads of the External rectus. The superior division of the third is the highest of these; beneath this lies the nasal branch of the ophthalmic; then the inferior division of the third; and the sixth lowest of all.

In the *orbit*, the fourth, and the frontal and lachrymal divisions of the ophthalmic, lie on the same plane immediately beneath the periosteum, the fourth nerve being internal and resting on the Superior oblique, the frontal resting on the Levator palpebræ, and the lachrymal on the External rectus. Next in order comes the superior division of the third nerve lying immediately beneath the Superior rectus, and then the nasal branch of the ophthalmic, crossing the optic nerve from the outer to the inner side of the orbit. Beneath these is found the

Fig. 491.—Relations of structures passing through the sphenoidal fissure.



optic nerve, surrounded in front by the ciliary nerves, and having the lenticular ganglion on its outer side, between it and the External rectus. Below the optic is the inferior division of the third, and the sixth, which lies on the outer side of the orbit.

Surgical Anatomy.—The sixth nerve is more frequently involved in fractures of the base of the skull than any other of the cranial nerves. The result of paralysis of this nerve is internal or convergent squint. When injured so that its function is destroyed, there is, in addition to the paralysis of the External rectus muscle, often a certain amount of contraction of the pupil, because some of the sympathetic fibres to the radiating muscle of the iris pass along with this nerve.

Seventh Nerve (figs. 492, 493, 494)

The **Seventh** or **Facial Nerve** (*portio dura*) is the motor nerve of all the muscles of expression in the face, and of the Platysma and Buccinator; the muscles of the External ear; the posterior belly of the Digastric, and the Stylohyoid. Through its chorda tympani it supplies the Lingualis; by its tympanic branch, the Stapedius.

Its *superficial origin* is from the lateral tract of the medulla oblongata, in the groove between the olivary and restiform bodies. Its *deep origin* is from a nucleus situated in the reticular formation of the lower part of the pons. From this origin the fibres pursue a tortuous course in the substance of the pons. They first pass backwards and inwards, and then turn upwards and forwards forming the funiculus teres, which produces an eminence (eminentia teres) on the floor of the fourth ventricle, and finally bend sharply downwards and outwards

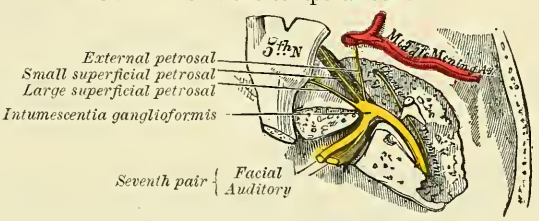
round the upper end of the nucleus of origin of the sixth nerve, to reach their superficial origin between the olivary and restiform bodies.

The auditory nerve (*portio mollis*) lies to its outer side; and between the two is a small fasciculus (*portio inter duram et mollem* of Wrisberg, or *pars intermedia*), which arises from the medulla and joins the facial nerve in the internal auditory meatus. It arises from the upper end of the nucleus of the glosso-pharyngeal nerve, and at its emergence it is frequently connected with both the nerves, between which it lies.

The facial nerve, firmer, rounder, and smaller than the auditory, passes forwards and outwards upon the middle peduncle of the cerebellum, and enters the internal auditory meatus with the auditory nerve. Within the meatus, the facial nerve lies first to the inner side of the auditory, and then in a groove upon that nerve. The pars intermedia is placed between the facial and auditory nerves in the internal auditory meatus, and at the commencement of the geniculate ganglion it joins the facial nerve. Occasionally a few of its fibres pass into the auditory nerve.

At the bottom of the meatus, the facial nerve enters the aqueductus Fallopii, and follows the serpentine course of that canal through the petrous portion of the temporal bone, from its commencement at the internal meatus, to its termination at the stylo-mastoid foramen. It is at first directed backwards and outwards between the cochlea and vestibule towards the inner wall of the tympanum; it then bends suddenly backwards and forms a reddish gangliform swelling (*intumescentia ganglioformis*, or *geniculate ganglion*), and from this arches downwards behind the tympanum to the stylo-mastoid foramen. On emerging from this aperture, it runs forwards in the substance of the parotid gland, crosses the external carotid artery, and divides behind the ramus of the lower jaw into two primary branches, *temporo-facial* and *cervico-facial*, from which numerous offsets are distributed over the side of the head, face, and upper part of the neck supplying the superficial muscles in these regions. As the primary branches and their offsets diverge from each other, they present somewhat the appearance of a bird's claw; hence the name of *pes anserinus* is given to the divisions of the facial nerve in and near the parotid gland.

Fig. 492.—The course and connections of the facial nerve in the temporal bone.



The communications of the facial nerve may be thus arranged:—

In the internal auditory meatus .	With the auditory nerve.
In the aqueductus Fallopii . .	With Meckel's ganglion by the large superficial petrosal nerve. With the otic ganglion by the small superficial petrosal nerve. With the sympathetic on the middle meningeal by the external superficial petrosal nerve.
At its exit from the stylo-mastoid foramen	With the glossal-pharyngeal. ,, pneumogastric. ,, carotid plexus. ,, auricularis magnus. ,, auriculo-temporal.
On the face	With the three divisions of the fifth.

In the internal auditory meatus some minute filaments pass between the facial and auditory nerves.

Opposite the hiatus Fallopii, the gangliform enlargement on the facial nerve

communicates with Meckel's ganglion by means of the large superficial petrosal nerve, which forms its motor root; with the otic ganglion, by the small superficial petrosal nerve: and with the sympathetic filaments accompanying the middle meningeal artery, by the external petrosal (Bidder). From the gangliform enlargement, according to Arnold, a twig is sent back to the auditory nerve.

At its exit from the stylo-mastoid foramen, it sends a twig to the glosso-pharyngeal, another to the pneumogastric nerve, and communicates with the carotid plexus of the sympathetic, with the great auricular branch of the cervical plexus, with the auriculo-temporal branch of the inferior maxillary nerve in the parotid gland, and on the face with the terminal branches of the three divisions of the fifth.

Branches of Distribution

- Within the aqueductus Fallopii
  - Tympanic.
  - Chorda Tympani.
- At its exit from the stylo-mastoid foramen
  - Posterior Auricular.
  - Digastric.
  - Stylo-hyoid.
- On the face
  - Temporo-facial
    - Temporal.
    - Malar.
    - Infra-orbital.
  - Cervico-facial
    - Buccal.
    - Supramaxillary.
    - Inframaxillary.

The **tympanic branch** arises from the nerve opposite the pyramid; it passes through a small canal in the pyramid, and supplies the Stapedius muscle.

The **chorda tympani** is given off from the facial as it passes vertically downwards at the back of the tympanum, about a quarter of an inch before its exit from the stylo-mastoid foramen. It passes from below upwards and forwards in a distinct canal, and enters the cavity of the tympanum, through an aperture (*iter chordæ posterius*) on its posterior wall between the opening of the mastoid cells and the attachment of the membrana tympani, and becomes invested with mucous membrane. It passes forwards through the cavity of the tympanum, between the fibrous and mucous layers of the membrana tympani, to its anterior inferior angle, and emerges from that cavity through a foramen at the inner end of the Glaserian fissure, which is called the *iter chordæ anterius*, or *canal of Huguier*. It then descends between the two Pterygoid muscles, meets the lingual nerve at an acute angle, and accompanies it to the submaxillary gland; part of it then joins the submaxillary ganglion; the rest is continued onwards into the tongue. A few of its fibres probably pass through the submaxillary ganglion to the sublingual gland. Before joining the lingual nerve it receives a small communicating branch from the otic ganglion.

The **Posterior auricular nerve** arises close to the stylo-mastoid foramen, and passes upwards in front of the mastoid process, where it is joined by a filament from the auricular branch of the pneumogastric, and communicates with the mastoid branch of the auricularis magnus and with the small occipital. As it ascends between the meatus and mastoid process it divides into two branches. The *auricular branch* supplies the Retrahens aurem and the small muscles on the cranial surface of the pinna. The *occipital branch*, the larger, passes backwards along the superior curved line of the occipital bone, and supplies the occipital portion of the Occipito-frontalis.

The **digastric branch** usually arises by a common trunk with the Stylo-hyoid branch; it divides into several filaments, which supply the posterior belly of the Digastric; one of these perforates that muscle to join the glosso-pharyngeal nerve.

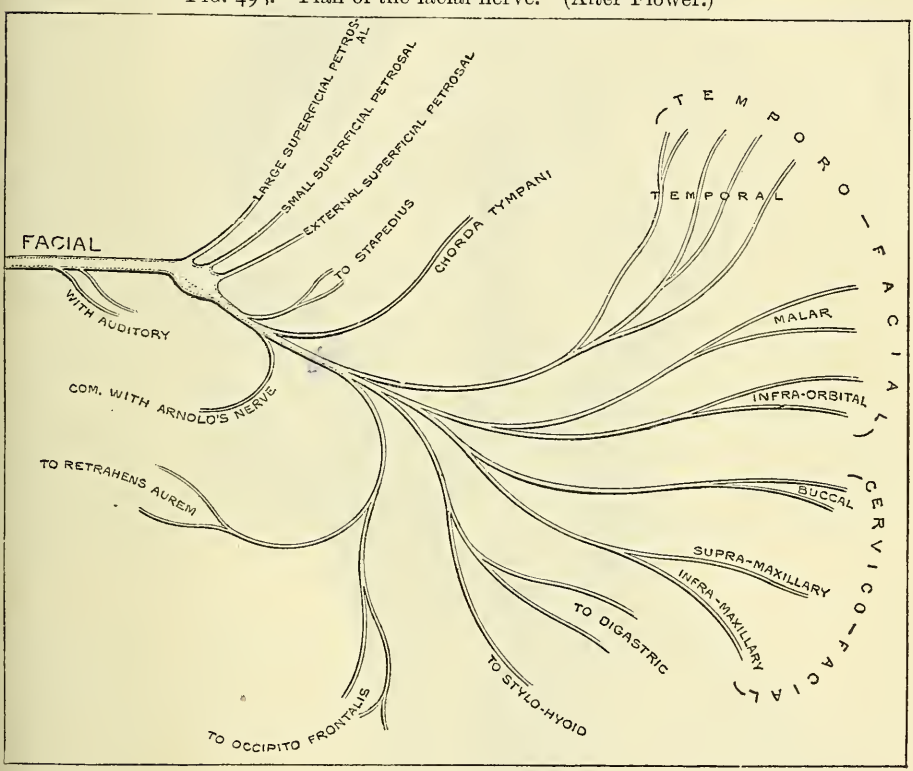
The **stylo-hyoid** is a long slender branch, which passes inwards, entering the

Stylo-hyoid muscle about its middle; it communicates with the sympathetic filaments on the external carotid artery.

The **Temporo-facial**, the larger of the two terminal branches, passes upwards and forwards through the parotid gland, crosses the external carotid artery and temporo-maxillary vein, and passes over the neck of the condyle of the jaw, being connected in this situation with the auriculo-temporal branch of the inferior maxillary nerve, and divides into branches, which are distributed over the temple and upper part of the face; these are divided into three sets: temporal, malar, and infra-orbital.

The *temporal branches* cross the zygoma to the temporal region, supplying the Attrahens and Attollens aurem muscles, and join with the temporal branch of the temporo-maxillary, a branch of the superior maxillary, and with the auriculo-temporal branch of the inferior maxillary. The more anterior branches supply the

Fig. 493.—Plan of the facial nerve. (After Flower.)



frontal portion of the Occipito-frontalis, the Orbicularis palpebrarum, and Corrugator supercilii muscles, joining with the supra-orbital and lachrymal branches of the ophthalmic.

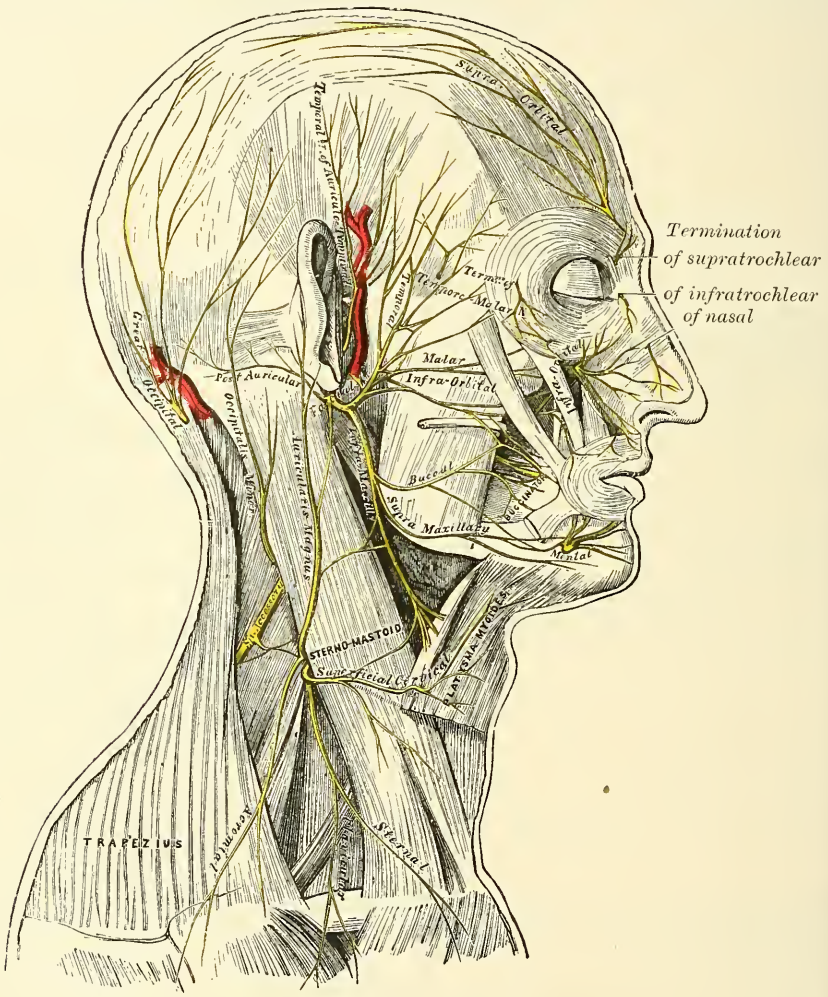
The *malar branches* pass across the malar bone to the outer angle of the orbit, where they supply the Orbicularis palpebrarum muscle, joining with filaments from the lachrymal nerve; others supply the lower eyelid, joining with filaments of the malar branch (*subcutaneous malæ*) of the superior maxillary nerve.

The *infra-orbital*, of larger size than the rest, pass horizontally forwards to be distributed between the lower margin of the orbit and the mouth. The *superficial branches* run beneath the skin and above the superficial muscles of the face which they supply: some branches are distributed to the Pyramidalis nasi, joining at the inner angle of the orbit with the infratrochlear and nasal branches of the ophthalmic. The *deep branches* pass beneath the Zygomatici and the Levator labii superioris, supplying them and the Levator anguli oris, and form a plexus (*infra-*

orbital) by joining with the infra-orbital branch of the superior maxillary nerve and the buccal branches of the cervico-facial. This branch also supplies the Levator labii superioris alæque nasi and the small muscles of the nose.

The **Cervico-facial division of the facial nerve** passes obliquely downwards and forwards through the parotid gland, crossing the external carotid artery. In this situation it is joined by branches from the great auricular nerve. Opposite the angle of the lower jaw it divides into branches which are distributed on the lower half of the face and upper part of the neck. These may be divided into three sets: buccal, supramaxillary, and inframaxillary.

Fig. 494.—The nerves of the scalp, face, and side of the neck.



The *buccal branches* cross the Masseter muscle. They supply the Buccinator and Orbicularis oris, and join with the infra-orbital branches of the temporo-facial division of the nerve, and with filaments of the buccal branch of the inferior maxillary nerve.

The *supramaxillary* (*mandibular*) *branches* pass forwards beneath the Platysma and Depressor anguli oris, supplying the muscles of the lower lip and chin, and communicating with the mental branch of the inferior dental nerve.

The *inframaxillary* (*cervical*) *branches* run forward beneath the Platysma, and form a series of arches across the side of the neck over the suprahyoid region.

One of these branches descends vertically to join with the superficialis colli nerve from the cervical plexus; others supply the Platysma.

Surgical Anatomy.—The facial nerve is more frequently paralysed than any of the other of the cranial nerves. The paralysis may depend either upon (1) central causes, i.e. blood clots or intracranial tumours pressing on the nerve before its entrance into the internal auditory meatus. It is also one of the nerves involved in 'bulbar paralysis.' Or (2) it may be paralysed in its passage through the petrous bone, by damage due to middle ear disease, or by fractures of the base. Or (3) it may be affected at or after its exit from the stylo-mastoid foramen. This is commonly known as 'Bell's paralysis.' It may be due to exposure to cold or to injury of the nerve, either from accidental wounds of the face, or during some surgical operation, as removal of parotid tumours, opening of abscesses, or operations on the lower jaw.

When the cause is central, the sixth nerve is usually also paralysed, and there is hemiplegia on the opposite side. In these cases the electrical reactions are the same as in health; whereas, when the paralysis is in the course of the nerve, the reaction is usually lost. When the nerve is paralysed in the petrous bone, in addition to the paralysis of the muscles of expression, there is loss of taste in the anterior part of the tongue, and the patient is unable to recognise the difference between bitters and sweets, acids and salines, from involvement of the chorda tympani. The mouth is dry, because the salivary glands are not secreting; and the sense of hearing is affected from paralysis of the Stapedius. When the cause of the paralysis is from fracture of the base of the skull, the auditory nerve and the petrosal nerves, which are connected with the intumescentia ganglioformis, are also involved. When the injury is after the exit of the nerve from the stylo-mastoid foramen, all the muscles of expression, except the Levator palpebræ, together with the posterior belly of the Digastric and Stylo-hyoid, are paralysed. There is smoothness of the forehead, and the patient is unable to frown; the eyelids cannot be closed and the lower lid droops, so that the punctum is no longer in contact with the globe, and the tears run down the cheek; there is smoothness of the cheek and loss of the naso-labial furrow; the nostril cannot be dilated; the mouth is drawn to the sound side, and there is inability to whistle; food collects between the cheek and gum from paralysis of the Buccinator. The facial nerve is at fault in cases of so-called 'histrionic spasm,' which consists in an almost constant and uncontrollable twitching of the muscles of the face. This twitching is sometimes so severe as to cause great discomfort and annoyance to the patient, and to interfere with sleep, and for its relief the facial nerve has been stretched. The operation is performed by making an incision behind the ear, from the root of the mastoid process to the angle of the jaw. The parotid is turned forwards and the dissection carried along the anterior border of the Sterno-mastoid muscle and mastoid process, until the upper border of the posterior belly of the Digastric is found. The nerve is parallel to this on about a level of the middle of the mastoid process. When found, the nerve must be stretched by passing a blunt hook beneath it and pulling it forwards and outwards. Too great force must not be used, for fear of permanent injury to the nerve.

Eighth Nerve

The **Eighth** or **Auditory Nerve** (*portio mollis*) is the special nerve of the sense of hearing, being distributed exclusively to the internal ear.

Its *superficial origin* is from the groove between the olivary and restiform bodies at the lower border of the pons. It lies external to the facial nerve. Its *deep origin* is by two roots, mesial and lateral, which embrace the restiform body. The lateral or posterior root arises partly from the tuberculum acusticum on the floor of the fourth ventricle, is partly continued into the striæ medullaris, and partly also arises from the accessory auditory nucleus, a group of cells placed in front of the restiform body in the angular interspace between the two roots. This root is believed to be connected with the cochlear nerve, and is the true nerve of hearing. The mesial or anterior root arises from a collection of cells, the dorsal auditory nucleus, corresponding to the trigonum acustici in the floor of the fourth ventricle to the inner side of the restiform body. This root is supposed to be connected with the vestibular nerve, and to be concerned in the maintenance of equilibrium.

The auditory nerve after leaving the medulla passes forwards across the posterior border of the middle peduncle of the cerebellum, in company with the facial nerve, from which it is partially separated by a small artery (auditory). It then enters the internal auditory meatus with the facial nerve. At the bottom of the meatus it receives one or two filaments from the facial nerve, and then divides

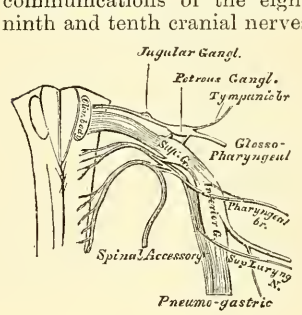
into two branches, *cochlear* and *vestibular*, which are distributed, the former to the cochlear, the latter to the vestibule and semicircular canals. The auditory nerve is soft in texture (hence the name *portio mollis*), and is destitute of neurilemma. The distribution of the auditory nerve in the internal ear will be found described along with the anatomy of that organ in a subsequent page.

Surgical Anatomy.—The auditory nerve is frequently injured, together with the facial nerve, in fractures of the middle fossa of the base of the skull implicating the internal auditory meatus. The nerve may be either torn across, producing permanent deafness, or it may be bruised or pressed upon by extravasated blood or inflammatory exudation, when the deafness will in all probability be temporary. The nerve may also be injured by violent blows on the head without fracture, and deafness may arise from loud explosions from dynamite, etc., probably from some lesion of this nerve, which is more liable to be injured than the other cranial nerves on account of its structure. The test that the nerve is destroyed, and that the deafness is not due to some lesion of the auditory apparatus, is obtained by placing a vibrating tuning-fork on the head. The vibrations will be heard in cases where the auditory apparatus is at fault, but not in cases of destruction of the auditory nerve.

Ninth Pair (figs. 495, 496, 497)

The **Ninth** or **Glosso-pharyngeal Nerve** (figs. 495, 496, 497) is distributed, as its name implies, to the tongue and pharynx, being the nerve of sensation to the mucous membrane of the pharynx, fauces, and tonsil; and a special nerve of taste to all the parts of the tongue to which it is distributed.

Fig. 495.—Origin, ganglia, and communications of the eighth, ninth and tenth cranial nerves.



Its *superficial origin* is by three or four filaments closely connected together, from the upper part of the medulla oblongata, in the groove between the olivary and the restiform body.

Its *deep origin* may be traced through the fasciculi of the lateral tract, to three different sources, (1) some of the fibres may be traced to a nucleus of grey matter at the lower part of the floor of the fourth ventricle beneath the inferior fovea; these are regarded as the fibres conducting the special sense of taste. (2) Others may be traced downwards into the *funiculus solitarius*, a rounded bundle of fibres in the lower part of the medulla, commencing immediately above the decussation of the pyramids. These fibres have not yet been distinctly traced to cells: they are probably efferent. (3) A third set of fibres pass forward to a collection of cells, the *nucleus ambiguus*, which is directly continuous with the nucleus of the vagus.

From its superficial origin, it passes outwards across the flocculus, and leaves the skull at the central part of the jugular foramen, in a separate sheath of the dura mater, in front of the pneumogastric and spinal accessory nerves (fig. 429). In its passage through the jugular foramen, it grooves the lower border of the petrous portion of the temporal bone; and, at its exit from the skull, passes forwards between the jugular vein and internal carotid artery, and descends in front of the latter vessel, and beneath the styloid process and the muscles connected with it, to the lower border of the Stylo-pharyngeus. The nerve now curves inwards, forming an arch on the side of the neck and lying upon the Stylo-pharyngeus and Middle constrictor of the pharynx, above the superior laryngeal nerve. It then passes beneath the Hyo-glossus, and is finally distributed to the mucous membrane of the fauces and base of the tongue, and the mucous glands of the mouth and tonsil.

In passing through the jugular foramen, the nerve presents, in succession, two gangliform enlargements. The superior, the smaller, is called the *jugular ganglion*; the inferior and larger, the *petrous ganglion*, or the *ganglion of Andersch*.

The **superior, or jugular, ganglion** is situated in the upper part of the groove in which the nerve is lodged during its passage through the jugular foramen. It is of very small size, and involves only the lower part of the trunk of the nerve. It is usually regarded as a segmentation from the lower ganglion.

The **inferior, or petrous, ganglion** is situated in a depression in the lower border of the petrous portion of the temporal bone; it is larger than the former, and involves the whole of the fibres of the nerve. From this ganglion arise those filaments which connect the glosso-pharyngeal with the pneumogastric and sympathetic nerves.

The *branches of communication* are with the pneumogastric, sympathetic and facial.

The branches to the pneumogastric are two filaments, arising from the petrous ganglion, one to its auricular branch, and one to the upper ganglion of the pneumogastric.

The branch to the sympathetic, also arising from the petrous ganglion, is connected with the superior cervical ganglion.

The branch of communication with the facial perforates the posterior belly of the Digastric. It rises from the trunk of the nerve below the petrous ganglion, and joins the facial just after its exit from the stylo-mastoid foramen.

The *branches of distribution* are, the tympanic, carotid, pharyngeal, muscular, tonsillar, and lingual.

The **tympanic branch** (*Jacobson's nerve*) arises from the petrous ganglion, and enters a small bony canal in the lower surface of the petrous portion of the temporal bone; the lower opening of which is situated on the bony ridge which separates the carotid canal from the jugular fossa. It ascends to the tympanum, enters that cavity by an aperture in its floor close to the inner wall, and divides into branches, which are contained in grooves upon the surface of the promontory, forming the tympanic plexus. This will be described in connection with the anatomy of the ear.

The **carotid branches** descend along the trunk of the internal carotid artery as far as its commencement, communicating with the pharyngeal branch of the pneumogastric, and with branches of the sympathetic.

The **pharyngeal branches** are three or four filaments which unite opposite the Middle constrictor of the pharynx with the pharyngeal branches of the pneumogastric, the external laryngeal, and sympathetic nerves, to form the pharyngeal plexus, branches from which perforate the muscular coat of the pharynx to supply the muscles and mucous membrane.

The **muscular branch** is distributed to the Stylo-pharyngeus.

The **tonsillar branches** supply the tonsil, forming a plexus (*circulus tonsillaris*) around this body, from which branches are distributed to the soft palate and fauces, where they communicate with the palatine nerves.

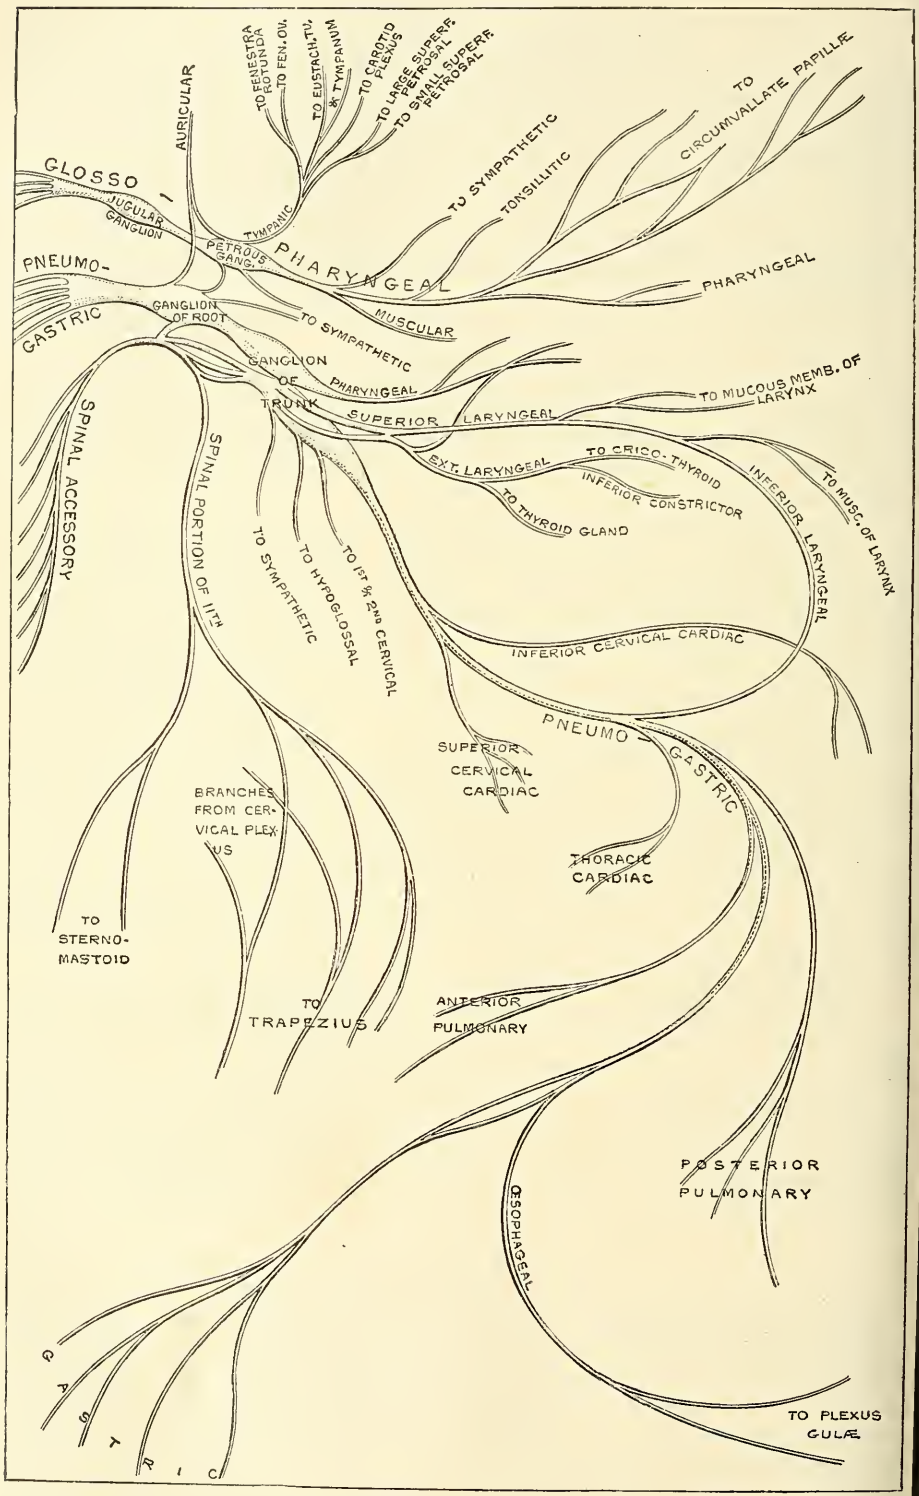
The **lingual branches** are two in number: one supplies the circumvallate papillæ and the mucous membrane covering the surface of the base of the tongue; the other perforates its substance, and supplies the mucous membrane and follicular glands of the tongue and anterior surface of the epiglottis.

Tenth Pair (figs. 496, 497)

The **Tenth** or **Pneumogastric Nerve** (*nervus vagus* or *par vagum*) has a more extensive distribution than any of the other cranial nerves, passing through the neck and thorax to the upper part of the abdomen. It is composed of both motor and sensory fibres. It supplies the organs of voice and respiration with motor and sensory fibres; and the pharynx, œsophagus, stomach, and heart with motor fibres.

Its *superficial origin* is by eight or ten filaments from the groove between the olivary and the restiform body below the glosso-pharyngeal; its *deep origin* may

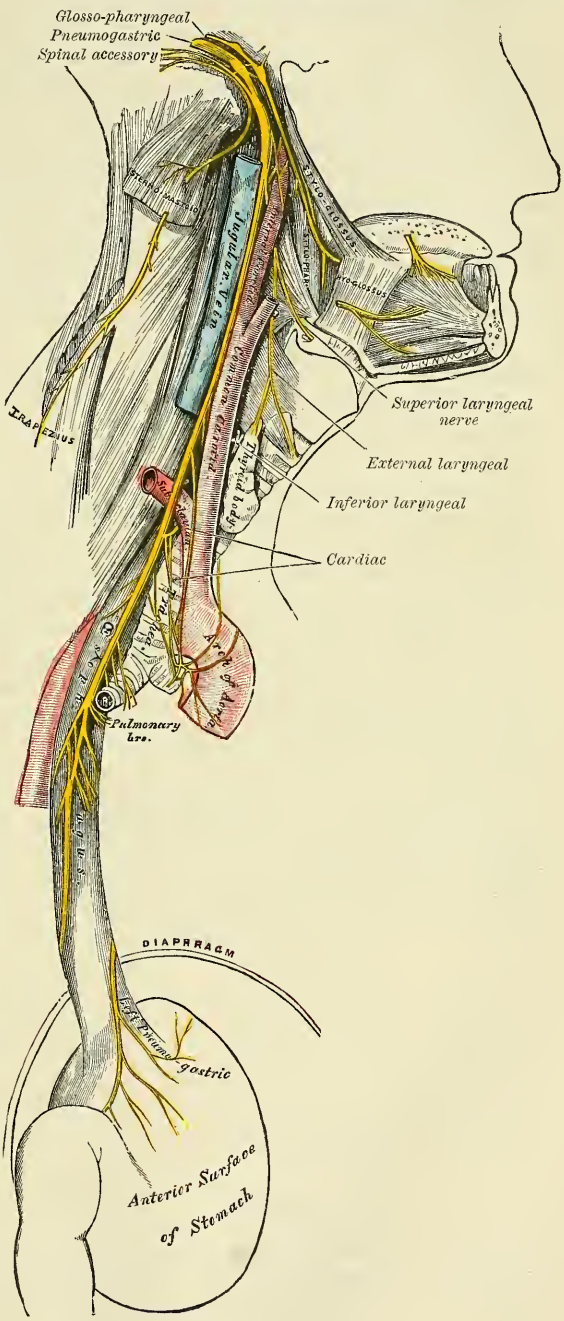
Fig. 496.—Plan of the glosso-pharyngeal, pneumogastric, and spinal accessory nerves. (After Flower.)



be traced through the fasciculi of the medulla, to terminate in a nucleus of grey matter, the nucleus vagus, at the lower part of the floor of the fourth ventricle, beneath the ala cinerea, below and continuous with the nucleus of origin of the glosso-pharyngeal. In addition to this a few fibres pass into the funiculus solitarius, and others into the nucleus ambiguus or accessory vagal nucleus.

The filaments become united, and form a flat cord, which passes outwards beneath the flocculus to the jugular foramen, through which it emerges from the cranium. In passing through this opening, the pneumogastric accompanies the spinal accessory, being contained in the same sheath of dura mater with it, a membranous septum separating it from the glosso-pharyngeal, which lies in front (fig. 429). The nerve in this situation presents a well-marked ganglionic enlargement, which is called *jugular ganglion*, or the *ganglion of the root of the pneumogastric*: to it the accessory part of the spinal accessory nerve is connected by one or two filaments. After the exit of the nerve from the jugular foramen, the nerve is joined by the accessory portion of the spinal accessory, and enlarges into a second gangliform swelling, called the *ganglion inferius* or the *ganglion of the trunk of the nerve*; through which the fibres of the spinal accessory pass unchanged, being principally distributed to the pharyngeal and superior laryngeal branches of the vagus, but some of the filaments from it are continued into the trunk of the vagus below the ganglion, to be distributed with the recurrent laryngeal nerve and probably also with the cardiac nerves. The nerve passes vertically down the neck within the sheath of the carotid vessels lying between the internal carotid artery and internal jugular vein as far as the thyroid cartilage, and then between the same vein and the common carotid to

Fig. 497.—Course and distribution of the eighth, ninth and tenth cranial nerves.



the root of the neck. Here the course of the nerve becomes different on the two sides of the body.

On the *right side*, the nerve passes across the subclavian artery between it and the right innominate vein, and descends by the side of the trachea to the back part of the root of the lung, where it spreads out in a plexiform network (*posterior pulmonary*), from the lower part of which two cords descend upon the œsophagus, on which they divide, forming, with branches from the opposite nerve, the œsophageal plexus (*plexus gulæ*); below, these branches are collected into a single cord, which runs along the back part of the œsophagus, enters the abdomen, and is distributed to the posterior surface of the stomach, joining the left side of the solar plexus, and sending filaments to the splenic plexus and a considerable branch to the cœliac plexus.

On the *left side*, the pneumogastric nerve enters the chest between the left carotid and subclavian arteries, behind the left innominate vein. It crosses the arch of the aorta, and descends behind the root of the left lung, forming the *posterior pulmonary plexus*, and along the anterior surface of the œsophagus, where it unites with the nerve of the right side in forming the plexus gulæ, to the stomach, distributing branches over its anterior surface, some extending over the great *cul-de-sac*, and others along the lesser curvature. Filaments from these branches enter the gastro-hepatic omentum, and join the hepatic plexus.

The *ganglion of the root* is of a greyish colour, circular in form, about two lines in diameter, and resembles the ganglion on the large root of the fifth nerve.

Connecting branches.—To this ganglion the accessory portion of the spinal accessory nerve is connected by several delicate filaments; it also has a communicating twig with the petrous ganglion of the glosso-pharyngeal, with the facial nerve by means of its auricular branch, and with the sympathetic by means of an ascending filament from the superior cervical ganglion.

The *ganglion of the trunk* (inferior) is a plexiform cord, cylindrical in form, of a reddish colour, and about an inch in length; it involves the whole of the fibres of the nerve, and passing through it is the accessory portion of the spinal accessory nerve, which blends with the pneumogastric below the ganglion, and is then principally continued into its pharyngeal and superior laryngeal branches.

Connecting branches.—This ganglion is connected with the hypoglossal, the superior cervical ganglion of the sympathetic, and the loop between the first and second cervical nerves.

The *branches of the pneumogastric* are—

In the jugular fossa	Meningeal. Auricular.
In the neck	Pharyngeal. Superior laryngeal. Recurrent laryngeal. Cervical cardiac.
In the thorax	Thoracic cardiac. Anterior pulmonary. Posterior pulmonary. Œsophageal.
In the abdomen	Gastric.

The **meningeal branch** is a recurrent branch given off from the ganglion of the root in the jugular foramen. It passes backwards, and is distributed to the dura mater covering the posterior fossa of the base of the skull.

The **auricular branch** (*Arnold's*) arises from the ganglion of the root, and is joined soon after its origin by a filament from the petrous ganglion of the glosso-pharyngeal; it passes outwards behind the jugular vein, and enters a small

canal on the outer wall of the jugular fossa. Traversing the substance of the temporal bone, it crosses the aqueductus Fallopii about two lines above its termination at the stylo-mastoid foramen; here it gives off an ascending branch, which joins the facial: the continuation of the nerve reaches the surface by passing through the auricular fissure between the mastoid process and the external auditory meatus, and divides into two branches, one of which communicates with the posterior auricular nerve, while the other supplies the integument at the back part of the pinna and the posterior part of the external auditory meatus.

The **pharyngeal branch**, the principal motor nerve of the pharynx, arises from the upper part of the inferior ganglion of the pneumogastric. It consists principally of filaments from the accessory portion of the spinal accessory; it passes across the internal carotid artery (in front or behind), to the upper border of the Middle constrictor, where it divides into numerous filaments, which join with those from the glosso-pharyngeal, superior laryngeal (its external branch), and sympathetic, to form the pharyngeal plexus, from which branches are distributed to the muscles and mucous membrane of the pharynx and the muscles of the soft palate. From the pharyngeal plexus a minute filament is given off, which descends and joins the hypoglossal nerve as it winds round the occipital artery.

The **superior laryngeal** is the nerve of sensation to the larynx. It is larger than the preceding, and arises from the middle of the inferior ganglion of the pneumogastric. It consists principally of filaments from the accessory portion of the spinal accessory. In its course it receives a branch from the superior cervical ganglion of the sympathetic. It descends, by the side of the pharynx, behind the internal carotid, where it divides into two branches, the external and internal laryngeal.

The *external laryngeal branch*, the smaller, descends by the side of the larynx, beneath the Sterno-thyroid, to supply the Crico-thyroid muscle. It gives branches to the pharyngeal plexus and the Inferior constrictor, and communicates with the superior cardiac nerve, behind the common carotid.

The *internal laryngeal branch* descends to the opening in the thyro-hyoid membrane, through which it passes with the superior laryngeal artery, and is distributed to the mucous membrane of the larynx. A small branch communicates with the recurrent laryngeal nerve. The branches to the mucous membrane are distributed, some in front to the epiglottis, the base of the tongue, and the epiglottidean glands; while others pass backwards, in the aryteno-epiglottidean fold, to supply the mucous membrane surrounding the superior orifice of the larynx, as well as the membrane which lines the cavity of the larynx as low down as the vocal cord. The filament which joins with the recurrent laryngeal descends beneath the mucous membrane on the inner surface of the thyroid cartilage, where the two nerves become united.

The **inferior** or **recurrent laryngeal**, so called from its reflected course, is the motor nerve of the larynx. It arises on the right side, in front of the subclavian artery; winds from before backwards round that vessel, and ascends obliquely to the side of the trachea, behind the common carotid and inferior thyroid arteries. On the left side, it arises in front of the arch of the aorta, and winds from before backwards round the aorta at the point where the remains of the ductus arteriosus are connected with it, and then ascends to the side of the trachea. The nerves on both sides ascend in the groove between the trachea and œsophagus, and, passing under the lower border of the Inferior constrictor muscle, enter the larynx behind the articulation of the inferior cornu of the thyroid cartilage with the cricoid, being distributed to all the muscles of the larynx, excepting the Crico-thyroid. It communicates with the superior laryngeal nerve.

The recurrent laryngeal, as it winds round the subclavian artery and aorta, gives off several cardiac filaments, which unite with the cardiac branches from the pneumogastric and sympathetic. As it ascends in the neck it gives off œsophageal

branches, more numerous on the left than on the right side, which supply the mucous membrane and muscular coat of the œsophagus; tracheal branches to the mucous membrane and muscular fibres of the trachea; and some pharyngeal filaments to the Inferior constrictor of the pharynx.

The **cervical cardiac branches**, two or three in number, arise from the pneumogastric, at the upper and lower part of the neck.

The *superior branches* are small, and communicate with the cardiac branches of the sympathetic. They can be traced to the great or deep cardiac plexus.

The *inferior branches*, one on each side, arise at the lower part of the neck, just above the first rib. On the right side, this branch passes in front or by the side of the arteria innominata, and communicates with one of the cardiac nerves proceeding to the great or deep cardiac plexus. On the left side, it passes in front of the arch of the aorta, and joins the superficial cardiac plexus.

The **thoracic cardiac branches**, on the right side, arise from the trunk of the pneumogastric, as it lies by the side of the trachea, and from its recurrent laryngeal branch; but on the left side from the recurrent nerve only; passing inwards, they terminate in the deep cardiac plexus.

The **anterior pulmonary branches**, two or three in number, and of small size, are distributed on the anterior aspect of the root of the lungs. They join with filaments from the sympathetic, and form the *anterior pulmonary plexus*.

The **posterior pulmonary branches**, more numerous and larger than the anterior, are distributed on the posterior aspect of the root of the lung: they are joined by filaments from the third and fourth (sometimes also first and second) thoracic ganglia of the sympathetic, and form the *posterior pulmonary plexus*. Branches from both plexuses accompany the ramifications of the air-tubes through the substance of the lungs.

The **œsophageal branches** are given off from the pneumogastric both above and below the pulmonary branches. The lower are more numerous and larger than the upper. They form, together with branches from the opposite nerve, the *œsophageal plexus* or *plexus gulæ*. From this plexus branches are distributed to the back of the pericardium.

The **gastric branches** are the terminal filaments of the pneumogastric nerve. The nerve on the right side is distributed to the posterior surface of the stomach, and joins the left side of the cœliac plexus and the splenic plexus. The nerve on the left side is distributed over the anterior surface of the stomach, some filaments passing across the great *cul-de-sac*, and others along the lesser curvature. They unite with branches of the right nerve and with the sympathetic, some filaments passing through the lesser omentum to the hepatic plexus.

Surgical Anatomy.—The laryngeal nerves are of considerable importance in considering some of the morbid conditions of the larynx. When the peripheral terminations of the superior laryngeal nerve are irritated by some foreign body passing over them, reflex spasm of the glottis is the result. When the trunk of this same nerve is pressed upon, by, for instance, a goitre or an aneurism of the upper part of the carotid, we have a peculiar dry, brassy cough. When the nerve is paralysed, we have anæsthesia of the mucous membrane of the larynx, so that foreign bodies can readily enter the cavity, and, in consequence of its supplying the Crico-thyroid muscle, the vocal cords cannot be made tense, and the voice is deep and hoarse. Paralysis of the superior laryngeal nerves may be the result of bulbar paralysis; may be a sequel to diphtheria when both nerves are usually involved; or it may, though less commonly, be caused by the pressure of tumours or aneurisms, when the paralysis is generally unilateral. Irritation of the inferior laryngeal nerves produces spasm of the muscles of the larynx. When both these recurrent nerves are paralysed, the vocal cords are motionless, in the so-called 'cadaveric position'—that is to say, in the position in which they are found in ordinary tranquil respiration; neither closed as in phonation, nor open as in deep inspiratory efforts. When one recurrent nerve is paralysed, the cord of the same side is motionless, while the opposite one crosses the middle line to accommodate itself to the affected one; hence phonation is present, but the voice is altered and weak in timbre. The recurrent laryngeal nerves may be paralysed in bulbar paralysis or after diphtheria, when it usually affects both sides; or they may be affected by the pressure of aneurisms of the aorta, innominate or subclavian arteries; by mediastinal tumours; by bronchocele; or by cancer of the upper part of the œsophagus, when the paralysis is often unilateral.

Eleventh Pair (figs. 496, 497)

The **Eleventh** or **Spinal Accessory Nerve** consists of two parts: one, the accessory part to the vagus, and the other the spinal portion.

The **bulbar** or **accessory part** is the smaller of the two. Its *superficial origin* is by four or five delicate filaments from the side of the medulla, below the roots of the vagus. Its *deep origin* may be traced to a nucleus of grey matter at the back of the medulla, extending from the level of the top of the calamus scriptorius as far down as the intermedio-lateral tract of the spinal cord. It passes outwards to the jugular foramen, where it joins with the spinal portion and with the upper ganglion of the vagus by one or two filaments: and is then continued over the surface of this ganglion to join the trunk of the vagus, after its exit from the jugular foramen. The fibres of the accessory part then pass unchanged through the inferior ganglion, or ganglion of the trunk of the vagus, to be distributed principally to the pharyngeal and superior laryngeal branches of the pneumogastric. Through the pharyngeal branch it probably supplies the muscles of the soft palate (see page 422). Some few filaments from it are continued into the trunk of the vagus below the ganglion, to be distributed with the recurrent laryngeal nerve and probably also with the cardiac nerves.

The **spinal portion** is firm in texture. Its *superficial origin* is by several filaments from the lateral tract of the cord, as low down as the sixth cervical nerve. Its *deep origin* may be traced to the intermedio-lateral tract of the grey matter of the cord. This portion of the nerve ascends between the ligamentum denticulatum and the posterior roots of the spinal nerves, enters the skull through the foramen magnum, and is then directed outwards to the jugular foramen, through which it passes, lying in the same sheath as the pneumogastric, but separated from it by a fold of the arachnoid. In the jugular foramen, it receives one or two filaments from the accessory portion. At its exit from the jugular foramen, it passes backwards, either in front of or behind the internal jugular vein, and descends obliquely behind the Digastric and Stylo-hyoid muscles to the upper part of the Sterno-mastoid. It pierces that muscle, and passes obliquely across the occipital triangle, to terminate in the deep surface of the Trapezius. This nerve gives several branches to the Sterno-mastoid during its passage through it, and joins in its substance with branches from the second cervical, which supply the muscle. In the occipital triangle it joins with the second and third cervical nerves and assists in the formation of the cervical plexus. Beneath the Trapezius it joins with the third and fourth cervical nerves to form a sort of plexus, from which fibres are distributed to the muscle.

Surgical Anatomy.—In cases of spasmodic torticollis in which all previous palliative treatment has failed, and the spasms are so severe as to undermine the patient's health, division or excision of a portion of the spinal accessory nerve has been resorted to. This may be done either along the anterior or posterior border of the Sterno-mastoid muscle. The former operation is performed by making an incision from the apex of the mastoid process, three inches in length, along the anterior border of the Sterno-mastoid muscle. The anterior border of the muscle is defined and pulled backwards, so as to stretch the nerve, which is then to be sought for, beneath the Digastric muscle, about two inches below the apex of the mastoid process. The other operation consists in making an incision along the posterior border of the muscle, so that the centre of the incision corresponds to the middle of this border of the muscle. The superficial structures having been divided and the border of the muscle defined, the nerve is to be sought for as it emerges from the muscle to cross the occipital triangle. When found, it is to be traced upwards through the muscle, and a portion of it excised above the point where it gives off its branches to the Sterno-mastoid. In this operation one of the descending branches of the superficial cervical plexus is liable to be mistaken for the nerve.

Twelfth Pair (figs. 497, 498)

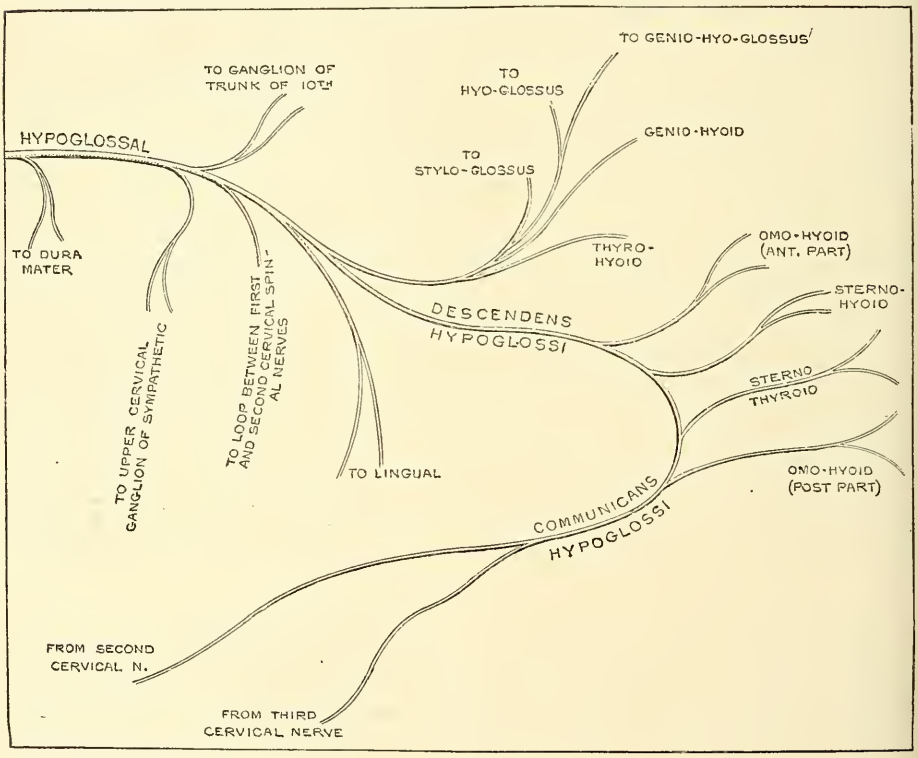
The **Twelfth** or **Hypoglossal Nerve** is the motor nerve of the tongue.

Its *superficial origin* is by several filaments, from ten to fifteen in number,

from the groove between the pyramidal and olivary bodies, in a continuous line with the anterior roots of the spinal nerves. Its *deep origin* can be traced to a nucleus of grey matter on the floor of the fourth ventricle, on either side of the median line, extending from the level of the auditory striæ to the lowest point of the ventricle of Arantius.

The filaments of this nerve are collected into two bundles, which perforate the dura mater separately, opposite the anterior condyloid foramen, and unite together after their passage through it. In those cases in which the anterior condyloid foramen in the occipital bone is double, these two portions of the nerve are separated by the small piece of bone which divides the foramen. The nerve descends almost vertically to a point corresponding with the angle of the jaw. It is at first deeply seated beneath the internal carotid artery and internal jugular vein, and intimately connected with the pneumogastric nerve; it then passes forwards between the vein and artery, and lower down in the neck becomes superficial below the Digastric muscle. The nerve then loops round the occipital

Fig. 498.—Plan of the hypoglossal nerve. (After Flower.)



artery, and crosses the external carotid below the tendon of the Digastric muscle. It passes beneath the Mylo-hyoid muscle, lying between it and the Hyo-glossus, and communicates at the anterior border of the latter muscle with the lingual (gustatory) nerve; it is then continued forwards in the fibres of the Genio-hyo-glossus muscle as far as the tip of the tongue, distributing branches to its substance.

The branches of communication are, with the

Pneumogastric.	First and second cervical nerves.
Sympathetic.	Lingual (gustatory).

The communication with the pneumogastric takes place close to the exit of the nerve from the skull, numerous filaments passing between the hypoglossal

and lower ganglion of the pneumogastric; sometimes the two nerves are united so as to form one mass. It also communicates with the pharyngeal plexus by a minute filament as it winds round the occipital artery.

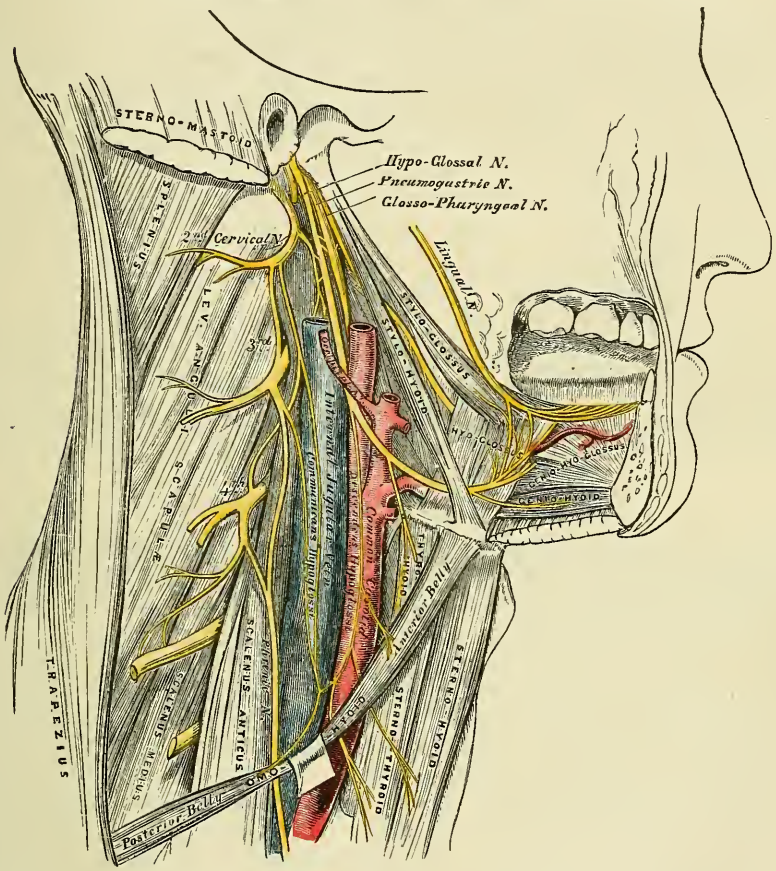
The communication with the sympathetic takes place opposite the atlas by branches derived from the superior cervical ganglion, and in the same situation the nerve is joined by a filament derived from the loop connecting the first two cervical nerves.

The communication with the lingual (gustatory) takes place near the anterior border of the Hyo-glossus muscle by numerous filaments which ascend upon it.

The *branches of distribution* are, the

Meningeal.	Thyro-hyoid.
Descendens hypoglossi.	Muscular.

Fig. 499.—Hypoglossal nerve, cervical plexus, and their branches.



Meningeal branches.—As the hypoglossal nerve passes through the anterior condyloid foramen it gives off, according to Luschka, several filaments to the dura mater in the posterior fossa of the base of the skull.

The **descendens hypoglossi** is a long slender branch, which quits the hypoglossal where it turns round the occipital artery. It descends obliquely across the sheath of the carotid vessels, and joins the communicating branches from the second and third cervical nerves, just below the middle of the neck, to form a loop. From the convexity of this loop branches pass forwards to supply the Sterno-hyoid, Sterno-thyroid, and both bellies of the Omo-hyoid. According to Arnold, another filament descends in front of the vessels into the chest, and joins the cardiac and phrenic nerves. The descendens hypoglossi is occasionally

contained in the sheath of the carotid vessels, being sometimes placed over, and sometimes beneath the internal jugular vein.

The **thyro-hyoid** is a small branch, arising from the hypoglossal near the posterior border of the Hyo-glossus; it passes obliquely across the great cornu of the hyoid bone, and supplies the Thyro-hyoid muscle.

The **muscular branches** are distributed to the Stylo-glossus, Hyo-glossus, Genio-hyoid, and Genio-hyo-glossus muscles. At the under surface of the tongue numerous slender branches pass upwards into the substance of the organ to supply its muscular structure.

Surgical Anatomy.—The hypoglossal nerve is an important guide in the operation of ligature of the lingual artery (see page 562). It runs forwards just above the great cornu of the hyoid bone, and forms the upper boundary of the triangular space in which the artery is to be sought for.

THE SPINAL NERVES

The **spinal nerves** are so called because they take their origin from the spinal cord, and are transmitted through the intervertebral foramina on either side of the spinal column. There are thirty-one pairs of spinal nerves, which are arranged into the following groups, corresponding to the region of the spine through which they pass:

Cervical	8 pairs
Dorsal	12 ,,
Lumbar	5 ,,
Sacral	5 ,,
Coccygeal	1 pair

It will be observed that each group of nerves corresponds in number with the vertebræ in that region, except the cervical and coccygeal.

Each spinal nerve arises by two roots, an anterior or motor root, and a posterior or sensory root.

Roots of the Spinal Nerves

The Anterior Roots.—The *superficial origin* is from a longitudinal area upon the antero-lateral column of the cord, opposite to the anterior cornu of grey matter, by an almost continuous series of filaments; each nerve root being comprised of from four to eight filaments.

The *deep origin* can be traced to the anterior part of the antero-lateral column; the roots, after penetrating horizontally through the longitudinal fibres of this tract, enter the grey substance, where their fibrils diverge in several directions: some, passing *inwards,* are continued across the anterior commissure in front of the central canal, to become continuous with the axis-cylinder processes of the large cells of the anterior cornu of the opposite side; others terminate in the mesial group of cells of the anterior column of the same side; other fibrils pass *outwards*, some to become continuous with the axis-cylinder processes of the group of cells in the lateral part of the anterior column; and others enter the lateral column of the same side, where, turning upwards, they pursue their course as longitudinal fibres. The remaining fibrils pass *backwards* to the posterior horn, where they are continuous with the axis-cylinders of the cells at the base of the posterior cornu.

The Posterior Roots.—The *superficial origin* is from the postero-lateral fissure of the cord. The *deep origin* is from the grey substance of the posterior cornu, either directly through the substantia gelatinosa, or indirectly, by first passing through the white matter of the posterior column and winding round in front of the caput cornu. Those which enter the grey matter at once, for the most part turn upwards and downwards, and become continuous with the fine nerve-plexus in the central portion of the grey matter; some few fibres pass transversely

through the posterior commissure to the opposite side, and others into the anterior cornu of the same side. Those fibres which enter the grey matter in front of the caput cornu reach the posterior vesicular column (Clarke's column) and blend with it; a few fibres passing through it, to become longitudinal in the posterior column of the cord.

The *anterior roots* are smaller than the posterior, devoid of ganglionic enlargement, and their component fibrils are collected into two bundles, near the intervertebral foramina.

The *posterior roots* of the nerves are larger, but the individual filaments are finer and more delicate than those of the anterior. As their component fibrils pass outwards, towards the aperture in the dura mater, they coalesce into two bundles, receive a tubular sheath from that membrane, and enter the ganglion which is developed upon each root.

The posterior root of the first cervical nerve forms an exception to these characters. It is smaller than the anterior, has frequently no ganglion developed upon it, and when the ganglion exists it is often situated within the dura mater.

Ganglia of the Spinal Nerves

A **ganglion** is developed upon the posterior root of each of the spinal nerves. These ganglia are of an oval form, and of a reddish colour; they bear a proportion in size to the nerves upon which they are formed, and are placed in the intervertebral foramina, external to the point where the nerves perforate the dura mater. Each ganglion is bifid internally, where it is joined by the two bundles of the posterior root, the two portions being united into a single mass externally. The ganglion upon the first and second cervical nerves forms an exception to these characters, being placed on the arches of the vertebræ over which the nerves pass. The ganglia, also, of the sacral nerves are placed within the spinal canal; and that on the coccygeal nerve, also in the canal, about the middle of its posterior root.

Distribution of the Spinal Nerves

Immediately beyond the ganglion the two roots coalesce, their fibres intermingle, and the trunk thus formed passes out of the intervertebral foramen, and divides into a posterior division for the supply of the posterior part of the body, and an anterior division for the supply of the anterior part of the body; each containing fibres from both roots.

The **posterior divisions of the spinal nerves** are generally smaller than the anterior; they arise from the trunk resulting from the union of the roots, in the intervertebral foramina; and, passing backwards, divide into internal and external branches, which are distributed to the muscles and integument behind the spine. The first cervical, the fourth and fifth sacral, and the coccygeal, do not divide into external and internal branches.

The **anterior divisions of the spinal nerves** supply the parts of the body in front of the spine, including the limbs. They are for the most part larger than the posterior divisions; this increase of size being proportioned to the larger extent of structures they are required to supply. Each division is connected by slender filaments with the sympathetic. In the dorsal region the anterior divisions of the spinal nerves are completely separate from each other, and are uniform in their distribution; but in the cervical, lumbar, and sacral regions they form intricate plexuses previous to their distribution.

Points of Emergence of the Spinal Nerves

The roots of the spinal nerves from their origin in the cord run obliquely downwards to their point of exit from the intervertebral foramina: the amount of

obliquity varying in different regions of the spine, and being greater in the lower than the upper part. The level of their emergence from the cord is within certain limits variable, and of course does not correspond to the point of emergence of the nerve from the intervertebral foramina. The accompanying table, from Macalister, shows as accurately as can be shown the relation of these points of origin from the spinal cord to the bodies and spinous processes of the vertebræ.

Level of Body of	No. of Nerve	Level of tip of Spine of	Level of Body of	No. of Nerve	Level of tip of Spine of

CERVICAL NERVES

The **roots of the cervical nerves** increase in size from the first to the fifth, and then remain the same size to the eighth. The posterior roots bear a proportion to the anterior as 3 to 1, which is much greater than in any other region, the individual filaments being also much larger than those of the anterior roots. In direction, the roots of the cervical are less oblique than those of the other spinal nerves. The first cervical nerve is directed a little upwards and outwards; the second is horizontal; the others are directed obliquely downwards and outwards, the lowest being the most oblique, and consequently longer than the upper, the distance between their place of origin and their point of exit from the spinal canal never exceeding the depth of one vertebra.

The *trunk of the first cervical nerve* (*suboccipital*) leaves the spinal canal, between the occipital bone and the posterior arch of the atlas; the second, between the posterior arch of the atlas and the lamina of the axis; and the eighth (the last), between the last cervical and first dorsal vertebræ.

Each nerve, at its exit from the intervertebral foramen, divides into a posterior and an anterior division. The anterior divisions of the four upper cervical nerves form the cervical plexus. The anterior divisions of the four lower cervical nerves, together with the first dorsal, form the brachial plexus.

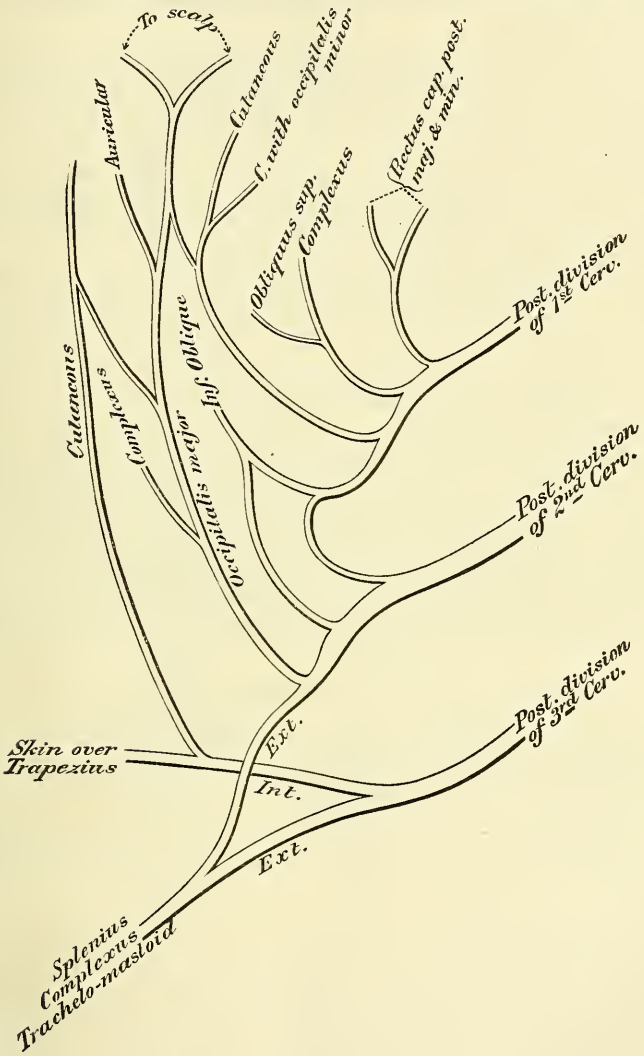
Posterior Divisions of the Cervical Nerves (fig. 500)

The **posterior division of the first cervical** (*suboccipital*) **nerve** differs from the posterior divisions of the other cervical nerves in not dividing into an internal and external branch. It is larger than the anterior division, and escapes from the spinal canal between the occipital bone and the posterior arch of the atlas, lying behind the vertebral artery. It enters the suboccipital triangle formed by the Rectus capitis posticus major, the Obliquus superior, and Obliquus inferior, and supplies the Recti and Obliqui muscles, and the Complexus. From the branch which supplies the Inferior oblique a filament is given off which joins the second cervical nerve. This nerve also occasionally gives off a cutaneous

filament, which accompanies the occipital artery, and communicates with the occipitalis major and minor nerves.

The **posterior division of the second cervical nerve** is three or four times greater than the anterior division, and the largest of all the posterior cervical divisions. It emerges from the spinal canal between the posterior arch of the atlas and lamina of the axis, below the Inferior oblique. It supplies this muscle, and receives a communicating filament from the first cervical. It then divides into an internal and an external branch.

Fig. 500.—Posterior divisions of the upper cervical nerves.



The *internal branch*, called, from its size and distribution, the *occipitalis major*, ascends obliquely inwards between the Obliquus inferior and Complexus, and pierces the latter muscle and the Trapezius near their attachments to the cranium It is now joined by a filament from the posterior division of the third cervical nerve, and, ascending on the back part of the head with the occipital artery, divides into two branches, which supply the integument of the scalp as far forwards as the vertex, communicating with the occipitalis minor. It gives off an auricular branch to the back part of the ear, and muscular branches to the

Complexus. The *external branch* is often joined by the external branch of the posterior division of the third, and supplies the Splenius, Trachelo-mastoid, and Complexus.

The **posterior division of the third cervical** is smaller than the preceding, but larger than the fourth; it differs from the posterior divisions of the remaining cervical nerves in its supplying an additional filament, the third occipital nerve, to the integument of the occiput. The posterior division of the third nerve, like the others, divides into an internal and external branch. The *internal branch* passes between the Complexus and Semispinalis, and, piercing the Splenius and Trapezius, supplies the skin over the latter muscle; the *external branch* joins with that of the posterior division of the second to supply the Splenius, Trachelo-mastoid, and Complexus.

The *third occipital nerve* arises from the internal or cutaneous branch beneath the Trapezius; it then pierces that muscle, and supplies the skin on the lower and back part of the head. It lies to the inner side of the occipitalis major, with which it is connected.

The posterior division of the suboccipital nerve and the internal branches of the posterior divisions of the second and third cervical nerves are occasionally joined beneath the Complexus by communicating branches. This communication is described by Cruveilhier as the *posterior cervical plexus*.

The **posterior divisions of the fourth, fifth, sixth, seventh, and eighth cervical nerves** (fig. 507) pass backwards, and divide, behind the Intertransversales muscles, into internal and external branches. The *internal branches*, the larger, are distributed differently in the upper and lower part of the neck. Those derived from the fourth and fifth nerves pass between the Complexus and Semispinalis muscles, and, having reached the spinous processes, perforate the aponeurosis of the Splenius and Trapezius, and are continued outwards to the integument over the Trapezius, whilst those derived from the three lowest cervical nerves are the smallest, and are placed beneath the Semispinalis colli, which they supply, and then pass into the Interspinales, Multifidus spinæ and Complexus, and send twigs through this latter muscle to supply the integument near the spinous processes (Hirschfeld). The *external branches* supply the muscles at the side of the neck, viz. the Cervicalis ascendens, Transversalis colli, and Trachelo-mastoid.

Anterior Divisions of the Cervical Nerves

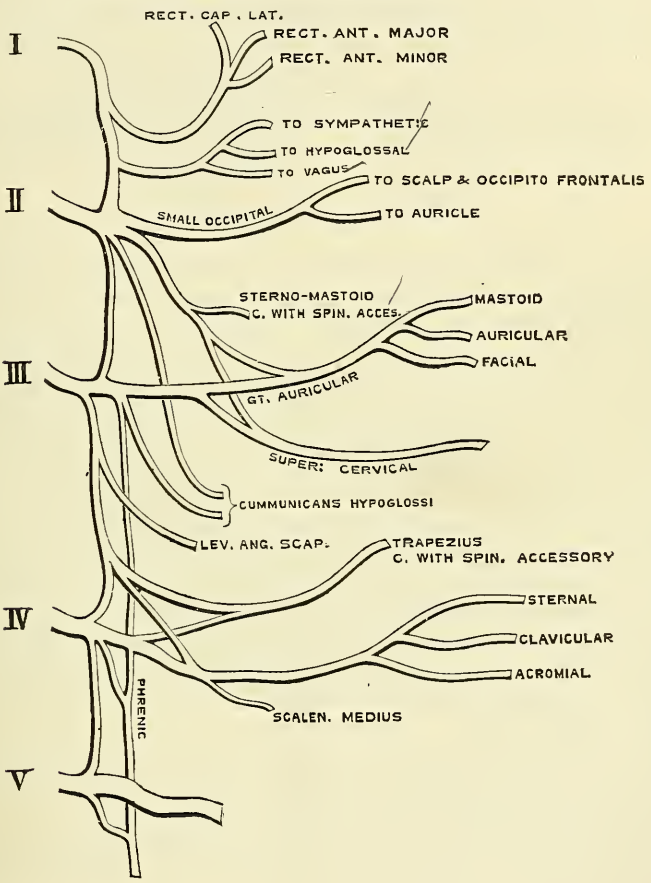
The **anterior division of the first** or **suboccipital nerve** is of small size. It escapes from the spinal canal through a groove upon the posterior arch of the atlas. In this groove it lies beneath the vertebral artery, to the inner side of the Rectus capitis lateralis. As it crosses the foramen in the transverse process of the atlas, it receives a filament from the sympathetic. It then descends, in front of this process, to communicate with an ascending branch from the second cervical nerve.

Communicating filaments from this nerve join the pneumogastric, the hypoglossal, and sympathetic, and some branches are distributed to the Rectus lateralis and the two Anterior recti. According to Valentin, the anterior division of the suboccipital also distributes filaments to the occipito-atlantal articulation, and mastoid process of the temporal bone.

The **anterior division of the second cervical nerve** escapes from the spinal canal, between the posterior arch of the atlas and the lamina of the axis, and, passing forwards on the outer side of the vertebral artery, divides in front of the Intertransverse muscle, into an ascending branch, which joins the first cervical; and one or two descending branches which join the third. It gives off the small occipital; a branch to assist in forming the great auricular; another to assist in forming the superficial cervical; one of the communicantes hypoglossi, and a filament to the Sterno-mastoid, which communicates in the substance of the muscle with the spinal accessory.

The **anterior division of the third cervical nerve** is double the size of the preceding. At its exit from the intervertebral foramen, it passes downwards and outwards beneath the Sterno-mastoid, and divides into two branches. The ascending branch joins the anterior division of the second cervical; the descending branch passes down in front of the Scalenus anticus, and communicates with the fourth. It gives off the greater part of the great auricular and superficial cervical nerves; one of the communicantes hypoglossi; a branch to the supraclavicular nerves; a filament to assist in forming the phrenic; and muscular branches to the Levator anguli scapulæ and Trapezius; this latter nerve communicates beneath the muscle with the spinal accessory. Sometimes the nerve to the Scalenus medius is derived from this source.

Fig. 501.—Plan of the cervical plexus.



The **anterior division of the fourth cervical** is of the same size as the preceding. It receives a branch from the third, sends a communicating branch to the fifth cervical, and, passing downwards and outwards, divides into numerous filaments, which cross the posterior triangle of the neck, forming the supraclavicular nerves. It gives a branch to the phrenic nerve, whilst it is contained in the intertransverse space, and sometimes a branch to the Scalenus medius muscle. It also gives a branch to the Levator anguli scapulæ and to the Trapezius, which unites with the branch given off from the third nerve, and communicates beneath the muscle with the spinal accessory.

The **anterior divisions of the fifth, sixth, seventh, and eighth cervical nerves** are remarkable for their large size. They are much larger than the preceding

nerves, and are all of equal size. They assist in the formation of the brachial plexus.

Cervical Plexus

The cervical plexus (fig. 501) is formed by the anterior divisions of the four upper cervical nerves. It is situated opposite the four upper cervical vertebræ, resting upon the Levator anguli scapulæ and Scalenus medius muscles, and covered in by the Sterno-mastoid.

Its branches may be divided into two groups, *superficial* and *deep*, which may be thus arranged :—

- *Superficial*
  - Ascending
    - Occipitalis minor.
    - Auricularis magnus.
    - Superficialis colli.
  - Descending — Supraclavicular
    - Suprasternal.
    - Supraclavicular.
    - Supra-acromial.
- *Deep*
  - Internal
    - Communicating.
    - Muscular.
    - Communicans hypoglossi.
    - Phrenic.
  - External
    - Communicating.
    - Muscular.

Superficial Branches of the Cervical Plexus

The **Occipitalis minor** (fig. 507, page 833) arises from the second cervical nerve ; it curves round the posterior border of the Sterno-mastoid, and ascends, running parallel to the posterior border of the muscle, to the back part of the side of the head. Near the cranium it perforates the deep fascia, and is continued upwards along the side of the head behind the ear, supplying the integument, and communicating with the occipitalis major, the auricularis magnus, and with the posterior auricular branch of the facial.

This nerve gives off an *auricular branch*, which supplies the integument of the upper and back part of the auricle, communicating with the mastoid branch of the auricularis magnus. This branch is occasionally derived from the great occipital nerve. The occipitalis minor varies in size ; it is occasionally double.

The **Auricularis Magnus** is the largest of the ascending branches. It arises from the second and third cervical nerves, winds round the posterior border of the Sterno-mastoid, and, after perforating the deep fascia, ascends upon that muscle beneath the Platysma to the parotid gland, where it divides into facial, auricular, and mastoid branches.

The *facial branches* pass across the parotid, and are distributed to the integument of the face over the parotid gland ; others penetrate the substance of the gland, and communicate with the facial nerve.

The *auricular branches* ascend to supply the integument of the back part of the pinna, except at its upper part, communicating with the auricular branches of the facial and pneumogastric nerves.

The *mastoid branch* communicates with the occipitalis minor and the posterior auricular branch of the facial, and is distributed to the integument behind the ear.

The **Superficialis Colli** arises from the second and third cervical nerves, turns round the posterior border of the Sterno-mastoid about its middle, and, passing obliquely forwards beneath the external jugular vein to the anterior border of that muscle, perforates the deep cervical fascia, and divides beneath the Platysma into two branches, which are distributed to the antero-lateral parts of the neck.

The *ascending branch* gives a filament which accompanies the external jugular vein ; it then passes upwards to the submaxillary region, and divides into branches, some of which form a plexus with the cervical branches of the facial

nerve beneath the Platysma; others pierce that muscle, supply it, and are distributed to the integument of the upper half of the neck, at its fore part, as high as the chin.

The *descending branch* (occasionally represented by two or more filaments) pierces the Platysma, and is distributed to the integument of the side and front of the neck, as low as the sternum.

The **Descendnig** or **supraclavicular** branches arise from the third and fourth cervical nerves: emerging beneath the posterior border of the Sterno-mastoid, they descend in the interval between that muscle and the Trapezius, and divide into branches, which are arranged, according to their position, into three groups.

The *inner* or *suprasternal branches* cross obliquely over the clavicular and sternal attachments of the Sterno-mastoid, and supply the integument as far as the median line.

The *middle* or *supraclavicular branches* cross the clavicle, and supply the integument over the Pectoral and Deltoid muscles, communicating with the cutaneous branches of the upper intercostal nerves.

The *external* or *supra-acromial branches* pass obliquely across the outer surface of the Trapezius and the acromion, and supply the integument of the upper and back part of the shoulder.

Deep Branches of the Cervical Plexus. Internal Series

The **communicating branches** consist of several filaments, which pass from the loop between the first and second cervical nerves in front of the atlas to the pneumogastric, hypoglossal, and sympathetic; and a communicating branch between the fourth and fifth cervical.

Muscular branches supply the Anterior recti and Rectus lateralis muscles; they proceed from the first cervical nerve, and from the loop formed between it and the second.

The **Communicans Hypoglossi** (fig. 499) consists usually of two filaments, one being derived from the second, and the other from the third cervical. These filaments pass downwards on the outer side of the internal jugular vein, cross in front of the vein a little below the middle of the neck, and form a loop with the descendens hypoglossi in front of the sheath of the carotid vessels (see page 811). Occasionally, the junction of these nerves takes place within the sheath.

The **Phrenic Nerve** (*internal respiratory of Bell*) arises chiefly from the fourth cervical nerve with a few filaments from the third and a communicating branch from the fifth. It descends to the root of the neck, running obliquely across the front of the Scalenus anticus, passes over the first part of the subclavian artery, between it and the subclavian vein, and, as it enters the chest, crosses the internal mammary artery near its origin. Within the chest, it descends nearly vertically in front of the root of the lung, and by the side of the pericardium, between it and the mediastinal portion of the pleura, to the Diaphragm, where it divides into branches, which separately pierce that muscle, and are distributed to its under surface.

The two phrenic nerves differ in their length, and also in their relations at the upper part of the thorax.

The *right nerve* is situated more deeply, and is shorter and more vertical in direction than the left; it lies on the outer side of the right vena innominata and superior vena cava.

The *left nerve* is rather longer than the right, from the inclination of the heart to the left side, and from the Diaphragm being lower on this than on the opposite side. At the upper part of the thorax, it crosses in front of the arch of the aorta to the root of the lung.

Each nerve supplies filaments to the pericardium and pleura, and near the chest is joined by a filament from the sympathetic, and, occasionally, by one from

the union of the descendens hypoglossi with the spinal nerves: this filament is found, according to Swan, only on the left side. It is also usually connected by a filament with the nerve to the Subclavius muscle. Branches have been described as passing to the peritoneum.

From the *right nerve*, one or two filaments pass to join in a small ganglion with phrenic branches of the solar plexus: and branches from this ganglion are distributed to the hepatic plexus, the suprarenal capsule, and inferior vena cava. From the *left nerve*, filaments pass to join the phrenic plexus of the sympathetic, but without any ganglionic enlargement.

Deep Branches of the Cervical Plexus. External Series

Communicating branches.—The deep branches of the external series of the cervical plexus communicate with the spinal accessory nerve, in the substance of the Sterno-mastoid muscle, in the occipital triangle, and beneath the Trapezius.

Muscular branches are distributed to the Sterno-mastoid, Trapezius, Levator anguli scapulæ, and Scalenus medius.

The branch for the Sterno-mastoid is derived from the second cervical, the Trapezius and Levator anguli scapulæ receive branches from the third and fourth. The Scalenus medius is supplied sometimes from the third, sometimes the fourth, and occasionally from both nerves.

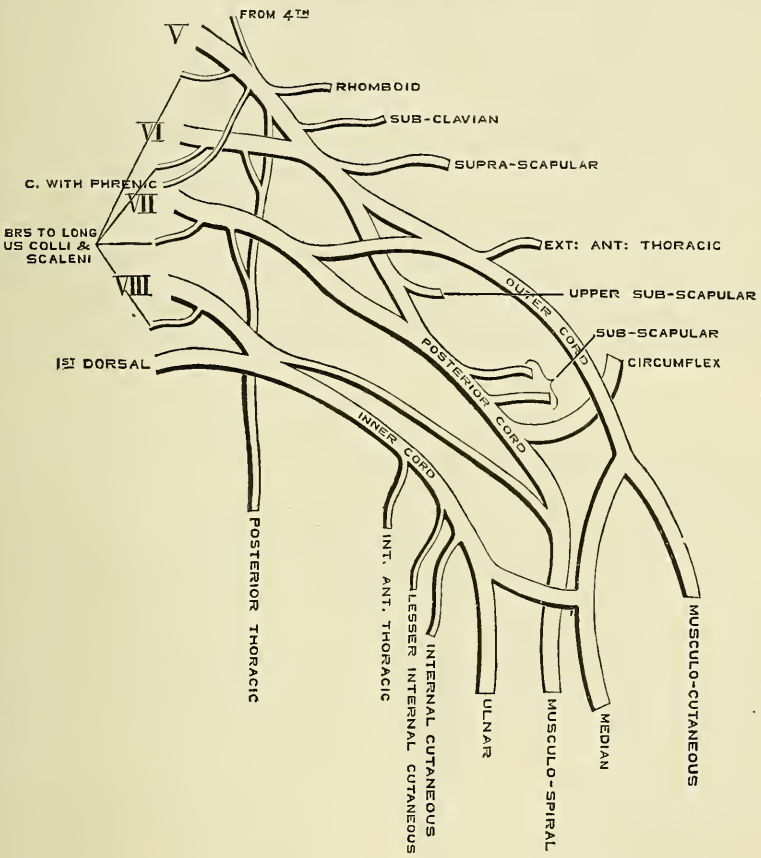
The Brachial Plexus (fig. 502)

The **Brachial Plexus** is formed by the union of the anterior branches of the four lower cervical and the greater part of the first dorsal nerves, receiving also a fasciculus from the fourth cervical nerve. It extends from the lower part of the side of the neck to the axilla. It is very broad, and presents little of a plexiform arrangement at its commencement. It is narrow opposite the clavicle, becomes broad, and forms a more dense interlacement in the axilla, and divides opposite the coracoid process into numerous branches for the supply of the upper limb. The nerves which form the plexus are all similar in size, and their mode of communication is subject to considerable variation, so that no one plan can be given as applying to every case. The following appears, however, to be the most constant arrangement. The fifth and sixth cervical unite together soon after their exit from the intervertebral foramina to form a common trunk. The eighth cervical and first dorsal also unite to form one trunk. So that the nerves forming the plexus, as they lie on the Scalenus medius, external to the outer border of the Scalenus anticus, are blended into three trunks: an outer one formed by the junction of the fifth and sixth cervical nerves; a middle one, consisting of the seventh cervical nerve; and an inner one formed by the junction of the eighth cervical and first dorsal nerves. As they pass beneath the clavicle, each of these three trunks divides into two branches, an *anterior* and a *posterior*. The anterior divisions of the outer and middle trunks then unite to form a common cord, which is situated on the outer side of the middle part of the axillary artery, and is called the *outer cord* of the brachial plexus. The anterior division of the inner trunk, formed by the union of the eighth cervical and first dorsal, passes down on the inner side of the axillary artery in the middle of the axilla, and forms the *inner cord* of the brachial plexus. The posterior divisions of the outer trunk (formed by the junction of the fifth and sixth nerves) and of the middle trunk (the seventh nerve) unite together to form the *posterior cord* of the brachial plexus, which is situated behind the second portion of the axillary artery. From this posterior cord are given off the two lower subscapular nerves; the upper subscapular nerve being given off from the posterior division of the outer trunk prior to its junction with the posterior division of the middle trunk. The posterior cord divides into the circumflex and musculo-spiral nerves. The musculo-spiral nerve is subsequently joined by the posterior division of the inner trunk, formed by the union of the eighth cervical and first dorsal.

The brachial plexus communicates with the cervical plexus by a branch from the fourth to the fifth nerve, and with the phrenic nerve by a branch from the fifth cervical, which joins that nerve on the Anterior scalenus muscle: the cervical and first dorsal nerves are also joined by filaments from the middle and inferior cervical ganglia of the sympathetic, close to their exit from the intervertebral foramina.

Relations.—*In the neck*, the brachial plexus lies at first between the Anterior and Middle scaleni muscles, and then above and to the outer side of the subclavian artery: it then passes behind the clavicle and Subclavius muscle, lying upon the first serration of the Serratus magnus, and the Subscapularis muscles. *In the axilla* it is placed on the outer side of the first portion of the axillary artery; it surrounds the artery in the second part of its course, one cord lying

Fig. 502.—Plan of the brachial plexus.



upon the outer side of that vessel, one on the inner side, and one behind it; and at the lower part of the axillary space gives off its terminal branches to the upper extremity.

Branches.—The branches of the brachial plexus are arranged into two groups, viz. those given off above the clavicle, and those below that bone.

Branches above the Clavicle

Communicating.	Posterior thoracic.
Muscular.	Suprascapular.

The **communicating branch** with the phrenic is derived from the fifth cervical nerve or from the loop between the fifth and sixth; it joins the phrenic on the Anterior scalenus muscle.

The **muscular branches** supply the Longus colli, Scaleni, Rhomboidei, and Subclavius muscles. Those for the Longus colli and Scaleni arise from the lower cervical nerves at their exit from the intervertebral foramina. The rhomboid branch arises from the fifth cervical, pierces the Scalenus medius, and passes beneath the Levator anguli scapulæ, which it occasionally supplies, to the Rhomboid muscles. The nerve to the Subclavius is a small filament, which arises from the fifth cervical at its point of junction with the sixth nerve; it descends in front of the subclavian artery to the Subclavius muscle, and is usually connected by a filament with the phrenic nerve.

The **posterior thoracic nerve** (*long thoracic, external respiratory of Bell*) (fig. 505) supplies the Serratus magnus, and is remarkable for the length of its course. It sometimes arises by two roots, from the fifth and sixth cervical nerves immediately after their exit from the intervertebral foramina, but generally by three roots from the fifth, sixth, and seventh nerves. These unite in the substance of the Middle scalenus muscle, and, after emerging from it, the nerve passes down behind the brachial plexus and the axillary vessels, resting on the outer surface of the Serratus magnus. It extends along the side of the chest to the lower border of that muscle, supplying filaments to each of its digitations.

The **suprascapular nerve** (fig. 506) arises from the cord formed by the fifth and sixth cervical nerves; passing obliquely outwards beneath the Trapezius, it enters the supraspinous fossa, through the notch in the upper border of the scapula; and, passing beneath the Supraspinatus muscle, curves in front of the spine of the scapular to the infraspinous fossa. In the supraspinous fossa it gives off two branches to the Supraspinatus muscle, and an articular filament to the shoulder-joint; and in the infraspinous fossa it gives off two branches to the Infraspinatus muscle, besides some filaments to the shoulder-joint and scapula.

Branches below the Clavicle

The branches given off below the clavicle are derived from the three cords of the brachial plexus, in the following manner:

From the outer cord arise the external of the two anterior thoracic nerves, the musculo-cutaneous nerve, and the outer head of the median.

From the inner cord arise the internal of the two anterior thoracic nerves, the internal cutaneous, the lesser internal cutaneous (nerve of Wrisberg), the ulnar and inner head of the median.

From the posterior cord arise two of the three subscapular nerves, the third arising from the posterior division of the trunk formed by the fifth and sixth cervical nerves; the cord then divides into the musculo-spiral and circumflex nerves.

These may be arranged according to the parts they supply:

To the chest	Anterior thoracic.
To the shoulder	Subscapular. Circumflex.
To the arm, forearm, and hand .	Musculo-cutaneous. Internal cutaneous. Lesser internal cutaneous. Median. Ulnar. Musculo-spiral.

The fasciculi of which these nerves are composed may be traced through the plexus to the spinal nerves from which they originate. They are as follows:

External anterior thoracic	from	5th, 6th, and 7th cervical.
Internal anterior thoracic	,,	8th cervical and 1st dorsal.
Subscapular	,,	5th, 6th, 7th, and 8th cervical.

Circumflex	from 5th, 6th, 7th, and 8th cervical.
Musculo-cutaneous	,, 5th, 6th, and 7th cervical.
Internal cutaneous	,, 8th cervical and 1st dorsal.
Lesser internal cutaneous	,, 1st dorsal.
Median	,, 6th, 7th, and 8th cervical, and 1st dorsal.
Ulnar	,, 8th cervical and 1st dorsal.
Musculo-spiral	,, 6th, 7th, and 8th cervical; sometimes also from the 5th.

The **Anterior Thoracic Nerves** (fig. 505), two in number, supply the Pectoral muscles.

The *external* or superficial nerve, the larger of the two, arises from the outer cord of the brachial plexus, through which its fibres may be traced to the fifth, sixth, and seventh cervical nerves. It passes inwards, across the axillary artery and vein, pierces the costo-coracoid membrane, and is distributed to the under surface of the Pectoralis major. It sends down a communicating filament to join the internal nerve, which forms a loop round the inner side of the axillary artery.

The *internal* or deep nerve arises from the inner cord, and through it from the eighth cervical and first dorsal. It passes upwards between the axillary artery and vein, and joins with the filament from the superficial nerve. It then passes to the under surface of the Pectoralis minor muscle, where it divides into a number of branches, which supply the muscle on its under surface. Some of the branches pass through the muscle; others wind round its upper border and pierce the costo-coracoid membrane to supply the Pectoralis major.

The **Subscapular Nerves**, three in number, supply the Subscapularis, Teres major, and Latissimus dorsi muscles. The fasciculi of which they are composed may be traced to the fifth, sixth, seventh, and eighth cervical nerves.

The *upper subscapular nerve*, the smallest, enters the upper part of the Subscapularis muscle.

The *lower subscapular nerve* enters the axillary border of the Subscapularis, and terminates in the Teres major. The latter muscle is sometimes supplied by a separate branch.

The *middle* or *long subscapular*, the largest of the three, follows the course of the subscapular artery, along the posterior wall of the axilla to the Latissimus dorsi, through which it may be traced as far as its lower border.

The **Circumflex Nerve** (fig. 506) supplies some of the muscles, and the integument of the shoulder, and the shoulder-joint. It arises from the posterior cord of the brachial plexus, in common with the musculo-spiral nerve, and its fibres may be traced through the posterior cord to the fifth, sixth, seventh, and eighth cervical nerves. It is at first placed behind the axillary artery, between it and the Subscapularis muscle, and passes downwards and outwards to the lower border of that muscle. It then winds backwards, in company with the posterior circumflex artery, through a quadrilateral space, bounded above by the Teres minor, below by the Teres major, internally by the long head of the Triceps, and externally by the neck of the humerus, and divides into two branches.

The *upper branch* winds round the surgical neck of the humerus, beneath the Deltoid, with the posterior circumflex vessels, as far as the anterior border of that muscle, supplying it, and giving off cutaneous branches, which pierce the muscle and ramify in the integument covering its lower part.

The *lower branch*, at its origin, distributes filaments to the Teres minor and back part of the Deltoid muscles. Upon the filament to the former muscle a gangliform enlargement usually exists. The nerve then pierces the deep fascia, and supplies the integument over the lower two-thirds of the posterior surface of the Deltoid, as well as that covering the long head of the Triceps.

The circumflex nerve, before its division, gives off an articular filament, which enters the shoulder-joint below the Subscapularis.

The **Musculo-cutaneous Nerve** (fig. 505) (*external cutaneous* or *perforans*

Casserii)* supplies some of the muscles of the arm, and the integument of the forearm. It arises from the outer cord of the brachial plexus, opposite the lower border of the Pectoralis minor, receiving filaments from the fifth, sixth, and seventh cervical nerves. It perforates the Coraco-brachialis muscle, passes obliquely between the Biceps and Brachialis anticus, to the outer side of the

Fig. 503.—Cutaneous nerves of right upper extremity. Anterior view.

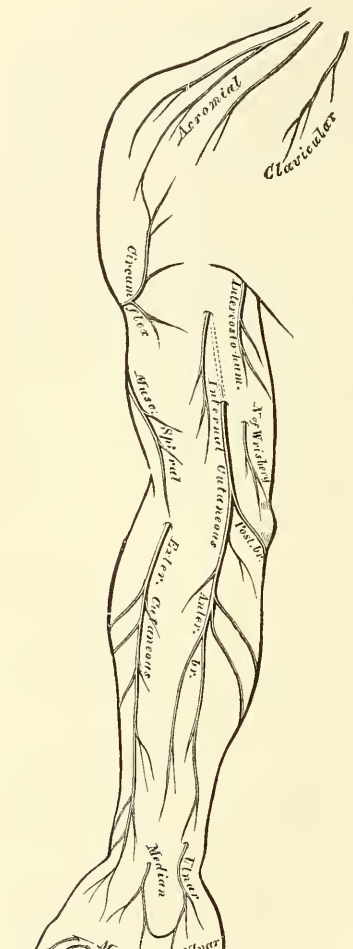


Fig. 504.—Cutaneous nerves of right upper extremity. Posterior view.

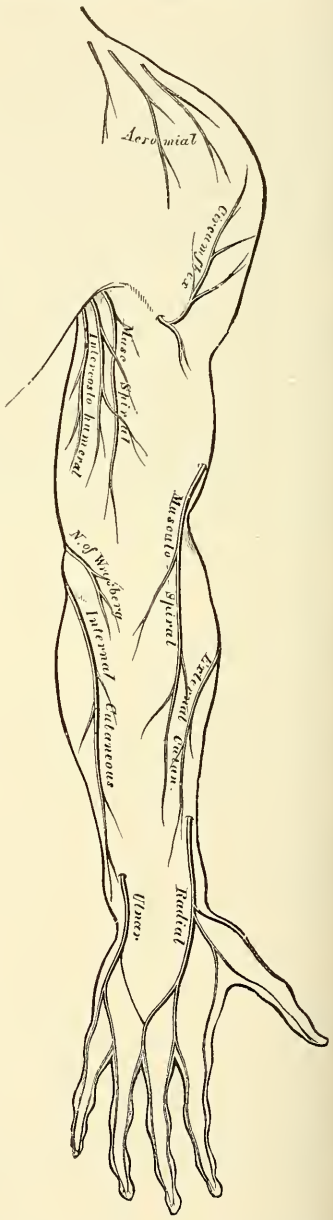
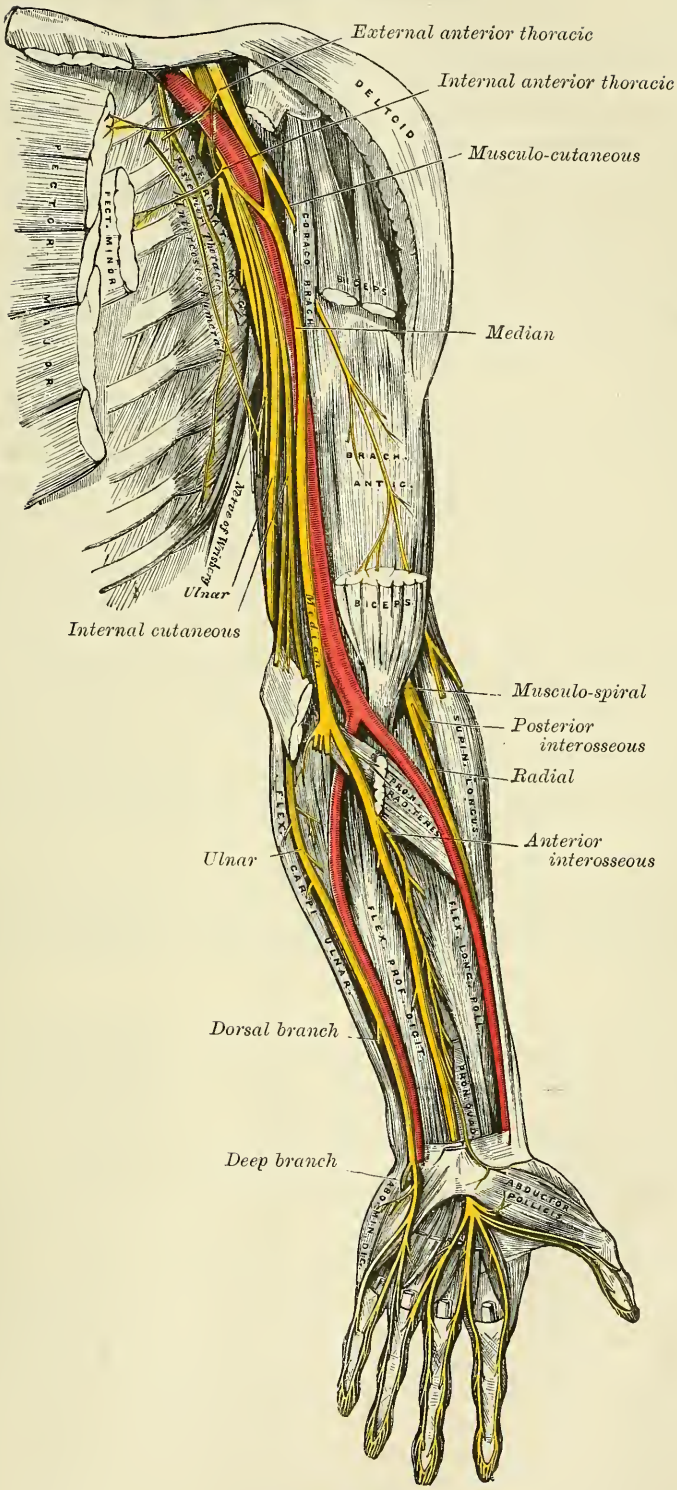


arm, and, a little above the elbow, winds round the outer border of the tendon of the Biceps, and, perforating the deep fascia, becomes cutaneous. This nerve, in its course through the arm, supplies the Coraco-brachialis, Biceps, and part of the Brachialis anticus muscles. The branch to the Coraco-brachialis is given

* See foot-note, p. 782.

Fig. 505.—Nerves of the left upper extremity.



off from the nerve close to its origin, and in some instances as a separate filament from the outer cord of the plexus. The branches to the Biceps and Brachialis anticus are given off after the nerve has pierced the Coraco-brachialis. The nerve also sends a small branch to the bone, which enters the nutrient foramen with the accompanying artery, and a filament, from the branch supplying the Brachialis anticus, to the elbow-joint.

The cutaneous portion of the nerve passes behind the median cephalic vein, and divides, opposite the elbow-joint, into an anterior and a posterior branch.

The *anterior branch* descends along the radial border of the forearm to the wrist, and supplies the integument over the outer half of the anterior surface. At the wrist-joint it is placed in front of the radial artery, and some filaments, piercing the deep fascia, accompany that vessel to the back of the wrist, supplying the carpus. The nerve then passes downwards to the ball of the thumb, where it terminates in cutaneous filaments. It communicates with a branch from the radial nerve, and the palmar cutaneous branch of the median.

The *posterior branch* passes downwards, along the back part of the radial side of the forearm, to the wrist. It supplies the integument of the lower third of the forearm, communicating with the radial nerve and the external cutaneous branch of the musculo-spiral.

The **Internal Cutaneous Nerve** (fig. 505) is one of the smallest branches of the brachial plexus. It arises from the inner cord in common with the ulnar and internal head of the median, and, at its commencement, is placed on the inner side of the axillary, and afterwards of the brachial artery. It derives its fibres from the eighth cervical and first dorsal nerves. It passes down the inner side of the arm, pierces the deep fascia with the basilic vein, about the middle of the limb, and, becoming cutaneous, divides into two branches, anterior and posterior.

This nerve gives off, near the axilla, a cutaneous filament, which pierces the fascia and supplies the integument covering the Biceps muscle, nearly as far as the elbow. This filament lies a little external to the common trunk, from which it arises.

The *anterior branch*, the larger of the two, passes usually in front of, but occasionally behind, the median basilic vein. It then descends on the anterior surface of the ulnar side of the forearm, distributing filaments to the integument as far as the wrist, and communicating with a cutaneous branch of the ulnar nerve.

The *posterior branch* passes obliquely downwards on the inner side of the basilic vein, passes in front of, or over, the internal condyle of the humerus to the back of the forearm, and descends on the posterior surface of its ulnar side as far as the wrist, distributing filaments to the integument. It communicates, above the elbow, with the lesser internal cutaneous, and above the wrist with the dorsal cutaneous branch of the ulnar nerve (Swan).

The **Lesser Internal Cutaneous Nerve** (*nerve of Wrisberg*) is distributed to the integument on the inner side of the arm (fig. 505). It is the smallest of the branches of the brachial plexus, and arising from the inner cord, with the internal cutaneous and ulnar nerves, receives its fibres from the first dorsal nerve. It passes through the axillary space, at first lying behind, and then on the inner side of the axillary vein, and communicates with the intercosto-humeral nerve. It descends along the inner side of the brachial artery to the middle of the arm, where it pierces the deep fascia, and is distributed to the integument of the back part of the lower third of the arm, extending as far as the elbow, where some filaments are lost in the integument in front of the inner condyle, and others over the olecranon. It communicates with the posterior branch of the internal cutaneous nerve.

In some cases the nerve of Wrisberg and intercosto-humeral are connected

by two or three filaments, which form a plexus at the back part of the axilla. In other cases, the intercosto-humeral is of large size, and takes the place of the nerve of Wrisberg, receiving merely a filament of communication from the brachial plexus, which represents the latter nerve. In other cases, this filament is wanting, the place of the nerve of Wrisberg being supplied entirely from the intercosto-humeral.

The **Median Nerve** (fig. 505) has received its name from the course it takes along the middle of the arm and forearm to the hand, lying between the ulnar and the musculo-spiral and radial nerves. It arises by two roots, one from the outer, and one from the inner cord of the brachial plexus; these embrace the lower part of the axillary artery, uniting either in front or on the outer side of that vessel. It receives filaments from the sixth, seventh, and eighth cervical and the first dorsal. As it descends through the arm, it lies at first on the outer side of the brachial artery, crosses that vessel in the middle of its course, usually in front, but occasionally behind it, and lies on its inner side to the bend of the elbow, where it is placed beneath the bicipital fascia, and is separated from the elbow-joint by the Brachialis anticus. *In the forearm* it passes between the two heads of the Pronator radii teres, and descends beneath the Flexor sublimis, lying on the Flexor profundus, to within two inches above the annular ligament, where it becomes more superficial, lying between the tendons of the Flexor sublimis and Flexor carpi radialis, beneath, and rather to the radial side of, the tendon of the Palmaris longus, covered by the integument and fascia. It then passes beneath the annular ligament into the hand. In its course through the forearm it is accompanied by a small artery.

Branches.—No branches are given off from the median nerve in the arm. *In the forearm* its branches are, muscular, anterior interosseous, and palmar cutaneous, and, according to Rüdinger and Macalister, two articular twigs to the elbow-joint.

The *muscular branches* supply all the superficial muscles on the front of the forearm, except the Flexor carpi ulnaris. These branches are derived from the nerve near the elbow. The branch furnished to the Pronator radii teres often arises above the joint.

The *anterior interosseous* supplies the deep muscles on the front of the forearm, except the inner half of the Flexor profundus digitorum. It accompanies the anterior interosseous artery along the interosseous membrane, in the interval between the Flexor longus pollicis and Flexor profundus digitorum muscles, both of which it supplies, and terminates below in the Pronator quadratus.

The *palmar cutaneous branch* arises from the median nerve at the lower part of the forearm. It pierces the fascia above the annular ligament, and descending over that ligament, divides into two branches: of which the *outer* supplies the skin over the ball of the thumb, and communicates with the anterior cutaneous branch of the musculo-cutaneous nerve; and the *inner* supplies the integument of the palm of the hand, communicating with the cutaneous branch of the ulnar.

In the palm of the hand, the median nerve is covered by the integument and palmar fascia, and crossed by the superficial palmar arch. It rests upon the tendons of the flexor muscles. In this situation it becomes enlarged, somewhat flattened, of a reddish colour, and divides into two branches. Of these, the *external* supplies a muscular branch to some of the muscles of the thumb, and digital branches to the thumb and index finger; the *internal* supplies digital branches to the contiguous sides of the index and middle, and of the middle and ring fingers.

The *branch to the muscles of the thumb* is a short nerve, which divides to supply the Abductor, Opponens, and outer head of the Flexor brevis pollicis muscles; the remaining muscles of this group being supplied by the ulnar nerve.

The *digital branches* are five in number. The *first* and *second* pass along the borders of the thumb, the external branch communicating with branches of the radial nerve. The *third* passes along the radial side of the index finger, and supplies the First lumbrical muscle. The *fourth* subdivides to supply the adjacent sides of the index and middle fingers, and sends a branch to the Second lumbrical muscle. The *fifth* supplies the adjacent sides of the middle and ring fingers, and communicates with a branch from the ulnar nerve.

Each digital nerve, opposite the base of the first phalanx, gives off a dorsal branch, which joins the dorsal digital nerve from the radial, and runs along the side of the dorsum of the finger, to end in the integument over the last phalanx. At the end of the finger, the digital nerve divides into a palmar and a dorsal branch: the former of which supplies the extremity of the finger, and the latter ramifies round and beneath the nail. The digital nerves, as they run along the fingers, are placed superficial to the digital arteries.

The **Ulnar Nerve** (fig. 505) is placed along the inner or ulnar side of the upper limb, and is distributed to the muscles and integument of the forearm and hand. It is smaller than the median, behind which it is placed, diverging from it in its course down the arm. It arises from the inner cord of the brachial plexus, in common with the inner head of the median and the internal cutaneous nerve, and derives its fibres from the eighth cervical and first dorsal nerves. At its commencement it lies at the inner side of the axillary artery, and holds the same relation with the brachial artery to the middle of the arm. From this point it runs obliquely across the internal head of the Triceps, pierces the internal intermuscular septum, and descends to the groove between the internal condyle and the olecranon, accompanied by the inferior profunda artery. *At the elbow*, it rests upon the back of the inner condyle, and passes into the forearm between the two heads of the Flexor carpi ulnaris. *In the forearm*, it descends in a perfectly straight course along its ulnar side, lying upon the Flexor profundus digitorum, its upper half being covered by the Flexor carpi ulnaris, its lower half lying on the outer side of the muscle, covered by the integument and fascia. The ulnar artery, in the upper third of its course, is separated from the ulnar nerve by a considerable interval; but in the rest of its extent the nerve lies to its inner side. *At the wrist* the ulnar nerve crosses the annular ligament on the outer side of the pisiform bone, to the inner side, and a little behind the ulnar artery, and immediately beyond this bone divides into two branches, superficial and deep palmar.

The branches of the ulnar nerve are:

In the forearm: Articular (elbow). Muscular. Cutaneous. Dorsal cutaneous. Articular (wrist).

In the hand: Superficial palmar. Deep palmar.

The *articular branches* distributed to the elbow-joint consist of several small filaments. They arise from the nerve as it lies in the groove between the inner condyle and olecranon.

The *muscular branches* are two in number: one supplying the Flexor carpi ulnaris; the other, the inner half of the Flexor profundus digitorum. They arise from the trunk of the nerve near the elbow.

The *cutaneous branch* arises from the ulnar nerve about the middle of the forearm, and divides into two branches.

One branch (frequently absent) pierces the deep fascia near the wrist, and is distributed to the integument, communicating with a branch of the internal cutaneous nerve.

The second branch (*palmar cutaneous*) lies on the ulnar artery, which it accompanies to the hand, some filaments entwining round the vessel; it ends in the integument of the palm, communicating with branches of the median nerve.

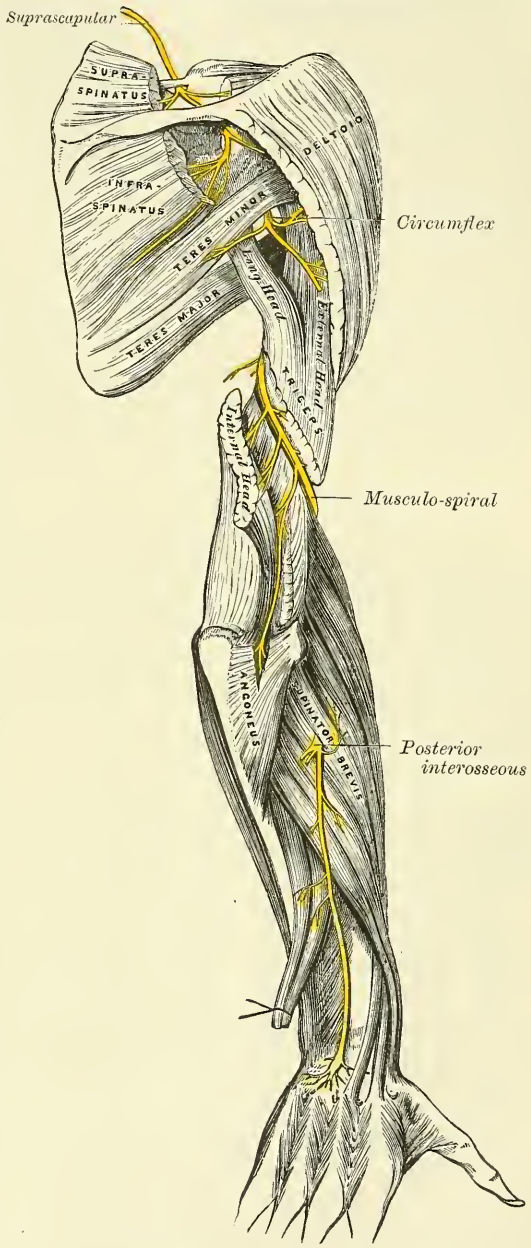
The *dorsal cutaneous branch* arises about two inches above the wrist; it passes backwards beneath the Flexor carpi ulnaris, perforates the deep fascia, and, running along the ulnar side of the back of the wrist and hand, divides into branches; one of these supplies the inner side of the little finger; a second supplies the adjoining sides of the little and ring fingers; a third joins the branch of the radial nerve which supplies the adjoining sides of the middle and ring fingers, and assists in supplying them; a fourth is distributed to the metacarpal region of the hand, communicating with a branch of the radial nerve.

The *articular filaments to the wrist* are also supplied by the ulnar nerve.

The *superficial palmar branch* supplies the Palmaris brevis, and the integument on the inner side of the hand, and terminates in two digital branches, which are distributed, one to the ulnar side of the little finger, the other to the adjoining sides of the little and ring fingers, the latter communicating with a branch from the median. The digital branches are distributed to the fingers in the same manner as the digital branches of the median.

The *deep palmar branch* passes between the Abductor and Flexor brevis minimi digiti muscles, and follows the course of the deep palmar arch beneath the flexor tendons. At its origin it supplies the muscles of the little finger. As it crosses the deep part of the hand, it sends two branches to each interosseous space, one for the Dorsal and one for the Palmar interosseous muscle, the branches to the Second and Third palmar interossei supplying filaments to the two inner Lumbrical muscles. At its termination between the thumb and index finger, it supplies the Adductores transversus et obliquus pollicis and the inner head of the Flexor brevis pollicis.

Fig. 506.—The suprascapular, circumflex, and musculo-spiral nerves.



It will be remembered that the inner part of the Flexor profundus digitorum

is supplied by the ulnar nerve; the two inner Lumbricales, which are connected with the tendons of this part of the muscle, are therefore supplied by the same nerve. The outer part of the Flexor profundus is supplied by the median nerve: the two outer Lumbricales, which are connected with the tendons of this part of the muscle, are therefore supplied by the same nerve. Brooks states that in twelve instances out of twenty-one he found that the third lumbrical received a twig from the median nerve, in addition to its branch from the ulnar.

The **Musculo-spiral Nerve** (fig. 506), the largest branch of the brachial plexus, supplies the muscles of the back part of the arm and forearm, and the integument of the same parts, as well as that of the back of the hand. It arises from the posterior cord of the brachial plexus by a common trunk with the circumflex nerve, and is afterwards joined by the posterior division of the trunk formed by the junction of the eighth cervical and first dorsal nerves. It receives filaments from the sixth, seventh, and eighth, and sometimes also from the fifth cervical nerves. At its commencement it is placed behind the axillary and upper part of the brachial arteries, passing down in front of the tendons of the Latissimus dorsi and Teres major. It winds round the humerus in the musculo-spiral groove with the superior profunda artery, passing from the inner to the outer side of the bone, between the internal and external heads of the Triceps muscle. It pierces the external intermuscular septum, and descends between the Brachialis anticus and Supinator longus to the front of the external condyle, where it divides into the radial and posterior interosseous nerves.

The branches of the musculo-spiral nerve are:

Muscular.	Radial.
Cutaneous.	Posterior interosseous.

The *muscular branches* are divided into internal, posterior, and external; they supply the Triceps, Anconeus, Supinator longus, Extensor carpi radialis longior, and Brachialis anticus. These branches are derived from the nerve, at the inner side, back part, and outer side of the arm.

The internal muscular branches supply the inner and middle heads of the Triceps muscle. That to the inner head of the Triceps is a long, slender filament, which lies close to the ulnar nerve, as far as the lower third of the arm, and is often intimately connected with it.

The posterior muscular branch, of large size, arises from the nerve in the groove between the Triceps and the humerus. It divides into branches, which supply the outer head of the Triceps and Anconeus muscles. The branch for the latter muscle is a long, slender filament, which descends in the substance of the Triceps to the Anconeus.

The external muscular branches supply the Supinator longus, Extensor carpi radialis longior, and (usually) the outer part of the Brachialis anticus.

The *cutaneous branches* are three in number, one internal and two external.

The internal cutaneous branch arises in the axillary space, with the inner muscular branch. It is of small size, and passes through the axilla to the inner side of the arm, supplying the integument on its posterior aspect nearly as far as the olecranon. In its course it crosses beneath the intercosto-humeral, with which it communicates.

The two external cutaneous branches perforate the outer head of the Triceps, at its attachment to the humerus. The upper and smaller one passes to the front of the elbow, lying close to the cephalic vein, and supplies the integument of the lower half of the arm on its anterior aspect. The lower branch pierces the deep fascia below the insertion of the Deltoid, and passes down along the outer side of the arm and elbow, and then along the back part of the radial side of the forearm to the wrist, supplying the integument in its course, and joining, near its termination, with the posterior cutaneous branch of the musculo-cutaneous nerve.

The **radial nerve** passes along the front of the radial side of the forearm to

the commencement of its lower third. It lies at first a little to the outer side of the radial artery, concealed beneath the Supinator longus. In the middle third of the forearm, it lies beneath the same muscle, in close relation with the outer side of the artery. It quits the artery about three inches above the wrist, passes beneath the tendon of the Supinator longus, and, piercing the deep fascia at the outer border of the forearm, divides into two branches.

The external branch, the smaller of the two, supplies the integument of the radial side and ball of the thumb, joining with the anterior branch of the musculo-cutaneous nerve.

The internal branch communicates, above the wrist, with the posterior cutaneous branch from the musculo-cutaneous, and, on the back of the hand, forms an arch with the dorsal cutaneous branch of the ulnar nerve. It then divides into three digital nerves, which are distributed as follows: the first supplies the ulnar side of the thumb and the radial side of the index finger; the second, the adjoining sides of the index and middle fingers; and the third, the adjacent borders of the middle and ring fingers.* The latter nerve communicates with a filament from the dorsal branch of the ulnar nerve.

The **Posterior Interosseous Nerve** winds to the back of the forearm round the outer side of the radius, passes between the two planes of fibres of the Supinator brevis, and is prolonged downwards between the superficial and deep layer of muscles, to the middle of the forearm. Considerably diminished in size, it descends on the interosseous membrane, beneath the Extensor longus pollicis, to the back of the carpus, where it presents a gangliform enlargement from which filaments are distributed to the ligaments and articulations of the carpus. It supplies all the muscles of the radial and posterior brachial regions, excepting the Anconeus, Supinator longus, and Extensor carpi radialis longior.

Surgical Anatomy.—The brachial plexus may be ruptured by traction on the limb, leading to complete paralysis. In these cases the lesion would appear to be rather a tearing away of the nerves from the spinal cord, than a solution of continuity of the nerve-fibres themselves. In the axilla, any of the nerves forming the brachial plexus may be injured in a wound of this part, the median being the one which is most frequently damaged from its exposed position; and the musculo-spiral, on account of its sheltered and deep position, being the least often wounded. The brachial plexus in the axilla is often damaged from the pressure of a crutch, producing the condition known as 'crutch paralysis.' In these cases the musculo-spiral appears to be the nerve which is most frequently implicated to the greatest extent; the ulnar nerve being the one that appears to suffer next in frequency.

The *circumflex nerve* is of particular surgical interest. On account of its course round the joint, it is liable to be torn in fractures of the surgical neck of the humerus and in dislocations of the shoulder-joint. leading to paralysis of the deltoid, and, according to Erb, inflammation of the shoulder-joint is liable to be followed by a neuritis of this nerve from extension of the inflammation to it.

Mr. Hilton takes the circumflex nerve as an illustration of a law which he lays down, that 'the same trunks of nerves whose branches supply the groups of muscles moving a joint, furnish also a distribution of nerves to the skin over the insertions of the same muscles, and the interior of the joint receives its nerves from the same source.' In this way he explains the fact that an inflamed joint becomes rigid, because the same nerves which supply the interior of the joint supply the muscles also which move that joint.

The *median nerve* is liable to injury in wounds of the forearm. When paralysed, there is loss of flexion of the second phalanges of all the fingers, and of the terminal phalanges of the index and middle fingers. Flexion of the terminal phalanges of the ring and middle fingers is effected by that portion of the Flexor profundus digitorum which is supplied by the ulnar nerve. There is power to flex the proximal phalanges through the Interossei. The thumb cannot be flexed or opposed, and is maintained in a position of extension and adduction. All power of pronation is lost. The wrist can be flexed, if the hand is first adducted, by the action of the Flexor carpi ulnaris. There is loss or impairment of sensation on the palmar surface of the thumb, index, middle, and outer half of ring fingers, and on the dorsal surface of the same fingers over the last two phalanges; except in the thumb, where the loss of sensation would be limited to the back of the last

* According to Hutchinson, the digital nerve to the thumb reaches only as high as the root of the nail: the one to the forefinger as high as the middle of the second phalanx: and the one to the middle and ring fingers not higher than the first phalangeal joint.—*London Hos. Gaz.* vol. iii. p. 319.

phalanx. In order to expose the median nerve, for the purpose of stretching, an incision should be made along the radial side of the tendon of the Palmaris longus, which serves as a guide to the nerve.

The *ulnar nerve* is also liable to be injured in wounds of the forearm. When paralysed, there is loss of power of flexion in the ring and little fingers; there is impaired power of ulnar flexion and adduction; there is inability to spread out the fingers from paralysis of the Interossei; and there is inability to adduct the thumb. Sensation is lost, or impaired, in the skin supplied by the nerve. In order to expose the nerve in the lower part of the forearm, an incision should be made along the outer border of the tendon of the Flexor carpi ulnaris, and the nerve will be found lying on the ulnar side of the ulnar artery.

The *musculo-spiral nerve* is probably more frequently injured than any other nerve of the upper extremity. In consequence of its close relationship to the humerus, as it lies in the musculo-spiral groove, it is frequently torn or injured in fractures of this bone, or subsequently involved in the callus that may be thrown out around a fracture and thus pressed upon and its functions interfered with. It is also liable to be contused against the bone by kicks or blows, or to be divided by wounds of the arm. When paralysed, the hand is flexed at the wrist and lies flaccid. This is known as 'drop wrist.' The fingers are also flexed, and on an attempt being made to extend them, the last two phalanges only will be extended, through the action of the Interossei; the first phalanges remaining flexed. There is no power of extending the wrist. Supination is completely lost when the forearm is extended on the arm, but is possible to a certain extent if the forearm is flexed so as to allow of the action of the Biceps. The power of extension of the forearm is lost on account of paralysis of the Triceps. The best position in which to expose the nerve, for the purpose of stretching, is to make an incision along the inner border of the Supinator longus, just above the level of the elbow-joint. The skin and superficial structures are to be divided and the deep fascia exposed. The white line in this structure indicating the border of the muscle is to be defined, and the deep fascia divided in this line. By now raising the Supinator longus, the nerve will be found lying beneath it, on the Brachialis anticus.

DORSAL NERVES (fig. 507)

The **dorsal nerves** are twelve in number on each side. The first appears between the first and second dorsal vertebræ, and the last between the last dorsal and first lumbar.

The *roots of the dorsal nerves* are of small size, and vary but slightly from the second to the last. Both roots are very slender; the posterior roots only slightly exceeding the anterior in thickness. They gradually increase in length from above downwards, and pass down in contact with the spinal cord for a distance equal to the height of, at least, two vertebræ, in the lower part of the dorsal region, before they emerge from the spinal canal. They then join in the intervertebral foramen, and, at their exit, divide into two primary divisions, a posterior (dorsal) and an anterior (intercostal).

The first and last dorsal nerves are peculiar in some respects.

Posterior Divisions of the Dorsal Nerves

The **posterior divisions of the dorsal nerves**, which are smaller than the anterior, pass backwards between the transverse processes, and divide into internal and external branches.

The *internal branches of the six upper nerves* pass inwards between the Semispinalis dorsi and Multifidus spinæ muscles, which they supply; and then, piercing the origins of the Rhomboidei and Trapezius muscles, become cutaneous by the side of the spinous processes and ramify in the integument. The internal branches of the six lower nerves are distributed to the Multifidus spinæ, without giving off any cutaneous filaments.

The *external branches* increase in size from above downwards. They pass through the Longissimus dorsi, to the cellular interval between it and the Iliocostalis, and supply those muscles, as well as their continuations upwards to the head, and the Levatores costarum; the five or six lower nerves also give off cutaneous filaments, which pierce the Serratus posticus inferior and Latissimus dorsi, in a line with the angles of the ribs, and then ramify in the integument.

The *cutaneous branches of the dorsal nerves* are twelve in number. The six

FIG. 507.—Superficial and deep distribution of the posterior branches of the spinal nerves (after Hirschfeld and Leveillé). On the left side the cutaneous branches are represented lying on the superficial layer of muscles. On the right side the superficial muscles have been removed, the Splenius capitis and Complexus divided in the neck, and the Erector spinæ divided and partly removed in the back, so as to expose the posterior divisions of the spinal nerves near their origin.

Some of those distributed to the skin on the left side.

upper cutaneous nerves are derived from the internal branches of the posterior divisions of the dorsal nerves. They pierce the origins of the Rhomboidei and Trapezius muscles, and become cutaneous by the side of the spinous processes, and then ramify in the integument. They are frequently furnished with ganglifform enlargements. The six lower cutaneous nerves are derived from the external branches of the posterior divisions of the dorsal nerves. They pierce the Serratus posticus inferior and Latissimus dorsi, in a line with the angles of the ribs, and then ramify in the integument.

Anterior Divisions of the Dorsal Nerves

The **anterior divisions of the dorsal nerves** (*intercostal nerves*) are twelve in number on each side. They are, for the most part, distributed to the parietes of the thorax and abdomen, separately from each other, without being joined in a plexus; in which respect they differ from the other spinal nerves. Each nerve is connected with the adjoining ganglia of the sympathetic by one or two filaments. The intercostal nerves may be divided into two sets, from the difference they present in their distribution. The six upper, with the exception of the first and the intercosto-humeral branch of the second, are limited in their distribution to the parietes of the chest. The six lower supply the parietes of the chest and abdomen, the last one sending a cutaneous filament to the hip.

The first dorsal nerve.—The anterior division of the first dorsal nerve divides into two branches: one, the larger, leaves the thorax in front of the neck of the first rib, and enters into the formation of the brachial plexus; the other and smaller branch runs along the first intercostal space, forming the *first intercostal nerve*, and terminates on the front of the chest, by forming the first anterior cutaneous nerve of the thorax. Occasionally this anterior cutaneous branch is wanting. The first intercostal nerve as a rule gives off no lateral cutaneous branch; but sometimes a small branch is given off, which communicates with the intercosto-humeral. It frequently receives a connecting twig from the second dorsal nerve, which passes upwards over the neck of the second rib.

The upper dorsal nerves.—The anterior divisions of the second, third, fourth, fifth, and sixth dorsal nerves and the small branch from the first dorsal are confined to the parietes of the thorax, and are named *upper* or *pectoral intercostal nerves*. They pass forwards in the intercostal spaces with the intercostal vessels, being situated below them. At the back of the chest they lie between the pleura and the External intercostal muscles, but are soon placed between the two planes of Intercostal muscles as far as the middle of the rib. They then enter the substance of the Internal intercostal muscles, and, running amidst their fibres as far as the costal cartilages, they gain the inner surface of the muscles and lie between them and the pleura. Near the sternum, they cross the internal mammary artery and Triangularis sterni muscle, pierce the Internal intercostal and Pectoralis major muscles, and supply the integument of the front of the chest and over the mammary gland, forming the anterior cutaneous nerves of the thorax; the branch from the second nerve becoming joined with the supraclavicular nerves of the cervical plexus.

Branches.—Numerous slender muscular filaments supply the Intercostals, the Infracostales, the Levatores costarum, Serratus posticus superior, and Triangularis sterni muscles. Some of these branches, at the front of the chest, cross the costal cartilages from one to another intercostal space.

Lateral cutaneous nerves.—These are derived from the intercostal nerves, midway between the vertebræ and sternum; they pierce the External intercostal and Serratus magnus muscles, and divide into two branches, anterior and posterior.

The *anterior branches* are reflected forwards to the side and the fore part of the chest, supplying the integument of the chest and mamma, and the upper digitations of the External oblique.

The *posterior branches* are reflected backwards, to supply the integument over the scapula and over the Latissimus dorsi.

The lateral cutaneous branch of the second intercostal nerve is of large size, and does not divide, like the other nerves, into an anterior and posterior branch. It is named, from its origin and distribution, the *intercosto-humeral nerve* (fig. 505). It pierces the External intercostal muscle, crosses the axilla to the inner side of the arm, and joins with a filament from the nerve of Wrisberg. It then pierces the fascia, and supplies the skin of the upper half of the inner and back part of the arm, communicating with the internal cutaneous branch of the musculo-spiral nerve. The size of this nerve is in inverse proportion to the size of the other cutaneous nerves, especially the nerve of Wrisberg. A second intercosto-humeral nerve is frequently given off from the third intercostal. It supplies filaments to the armpit and inner side of the arm.

The lower dorsal nerves.—The anterior divisions of the seventh, eighth, ninth, tenth, and eleventh dorsal nerves are continued anteriorly from the intercostal spaces into the abdominal wall, and the twelfth dorsal is continued throughout its whole course in the abdominal wall, since it is placed below the last rib; hence these nerves are named *lower* or *abdominal intercostal nerves*. They have (with the exception of the last) the same arrangement as the upper ones as far as the anterior extremities of the intercostal spaces, where they pass behind the costal cartilages, and between the Internal oblique and Transversalis muscles, to the sheath of the Rectus, which they perforate. They supply the Rectus muscle, and terminate in branches which become subcutaneous near the linea alba. These branches are named the anterior cutaneous nerves of the abdomen. They are directed outwards as far as the lateral cutaneous nerves, supplying the integument of the front of the belly. The lower intercostal nerves supply the Intercostals, Serratus posticus inferior, and Abdominal muscles, and, about the middle of their course, give off lateral cutaneous branches, which pierce the External intercostal and External oblique muscles, in the same line as the lateral cutaneous nerves of the thorax, and divide into anterior and posterior branches, which are distributed to the integument of the abdomen and back, the anterior branches passing nearly as far forwards as the margin of the Rectus: the posterior branches passing backwards to supply the skin over the Latissimus dorsi, where they join the dorsal cutaneous nerves.

The **last dorsal** is larger than the other dorsal nerves. Its anterior division runs along the lower border of the last rib in front of the Quadratus lumborum, perforates the Transversalis, and passes forwards between it and the Internal oblique, to be distributed in the same manner as the lower intercostal nerves. It communicates with the ilio-hypogastric branch of the lumbar plexus, and is frequently connected with the first lumbar nerve by a slender branch, the *dorsi-lumbar nerve*, which descends in the substance of the Quadratus lumborum.

The *lateral cutaneous branch of the last dorsal* is remarkable for its large size; it perforates the Internal and External oblique muscles, passes downwards over the crest of the ilium in front of the iliac branch of the ilio-hypogastric (fig. 514), and is distributed to the integument of the front of the hip, some of its filaments extending as low down as the trochanter major. It does not divide into an anterior and posterior branch like the other lateral cutaneous branches of the intercostal nerves.

Surgical Anatomy.—The lower seven intercostal nerves and the ilio-hypogastric from the first lumbar nerve, supply the skin of the abdominal wall. They run downwards and inwards fairly equidistant from each other. The sixth and seventh supply the skin over the 'pit of the stomach'; the eighth corresponds to about the position of the middle linea transversa; the tenth to the umbilicus; and the ilio-hypogastric supplies the skin over the pubes and external abdominal ring. There are several points of surgical importance about the distribution of these nerves, and it is important to remember their origin and course, for in many diseases affecting the nerve-trunks at or near the origin, the pain is referred to their peripheral terminations. Thus, in Pott's disease of the spine, children will often be brought to the surgeon suffering from pain in the belly. This is due to the

fact that the nerves are irritated at the seat of disease as they issue from the spinal canal. When the irritation is confined to a single pair of nerves, the sensation complained of is often a feeling of constriction, as if a cord were tied round the abdomen, and in these cases the situation of the sense of constriction may serve to localise the disease in the spinal column. In other cases where the bone disease is more extensive, and two or more nerves are involved, a more general diffused pain in the abdomen is complained of. A similar condition is sometimes present in affections of the cord itself, as in tabes dorsalis.

Again, it must be borne in mind that the same nerves which supply the skin of the abdomen supply also the planes of muscle, which constitute the greater part of the abdominal wall. Hence it follows that any irritation applied to the peripheral terminations of the cutaneous branches in the skin of the abdomen is immediately followed by reflex contraction of the abdominal muscles. A good practical illustration of this may sometimes be seen in watching two surgeons examine the abdomen of the same patient. One, whose hand is cold, causes the muscles of the abdominal wall to at once contract and the belly to become rigid, and thus not nearly so suitable for examination; the other, who has taken the precaution to warm his hand, examines the abdomen without exciting any reflex contraction. The supply of both muscles and skin from the same source is of importance in protecting the abdominal viscera from injury. A blow on the abdomen, even of a severe character, will do no injury to the viscera if the muscles are in a condition of firm contraction; whereas in cases where the muscles have been taken unawares, and the blow has been struck while they were in a state of rest, an injury insufficient to produce any lesion of the abdominal wall has been attended with rupture of some of the abdominal contents. The importance therefore of immediate reflex contraction upon the receipt of an injury cannot be over estimated, and the intimate association of the cutaneous and muscular fibres in the same nerve produces a much more immediate response on the part of the muscles to any peripheral stimulation of the cutaneous filaments than would be the case if the two sets of fibres were derived from independent sources.

Again, the nerves supplying the abdominal muscles and skin derived from the lower intercostal nerves are intimately connected with the sympathetic supplying the abdominal viscera, through the lower thoracic ganglia from which the splanchnic nerves are derived. In consequence of this, in laceration of the abdominal viscera and in acute peritonitis, the muscles of the belly wall become firmly contracted, and thus as far as possible preserve the abdominal contents in a condition of rest.

LUMBAR NERVES

The **lumbar nerves** are five in number on each side. The first appears between the first and second lumbar vertebræ, and the last between the last lumbar and the base of the sacrum.

The **roots of the lumbar nerves** are the largest, and their filaments the most numerous, of all the spinal nerves, and they are closely aggregated together upon the lower end of the cord. The anterior roots are the smaller; but there is not the same disproportion between them and the posterior roots as in the cervical nerves. The roots of these nerves have a vertical direction, and are of considerable length, more especially the lower ones, since the spinal cord does not extend beyond the first lumbar vertebra. The roots become joined in the intervertebral foramina; and the nerves, so formed, divide at their exit into two divisions, posterior and anterior.

Posterior Divisions of the Lumbar Nerves

The **posterior divisions of the lumbar nerves** (fig. 507) diminish in size from above downwards; they pass backwards between the transverse processes, and divide into internal and external branches.

The *internal branches*, the smaller, pass inwards close to the articular processes of the vertebræ, and supply the Multifidus spinæ and Interspinales muscles.

The *external branches* supply the Erector spinæ and Intertransverse muscles. From the three upper branches, cutaneous nerves are derived which pierce the aponeurosis of the Latissimus dorsi muscle, and descend over the back part of the crest of the ilium, to be distributed to the integument of the gluteal region; some of the filaments passing as far as the trochanter major.

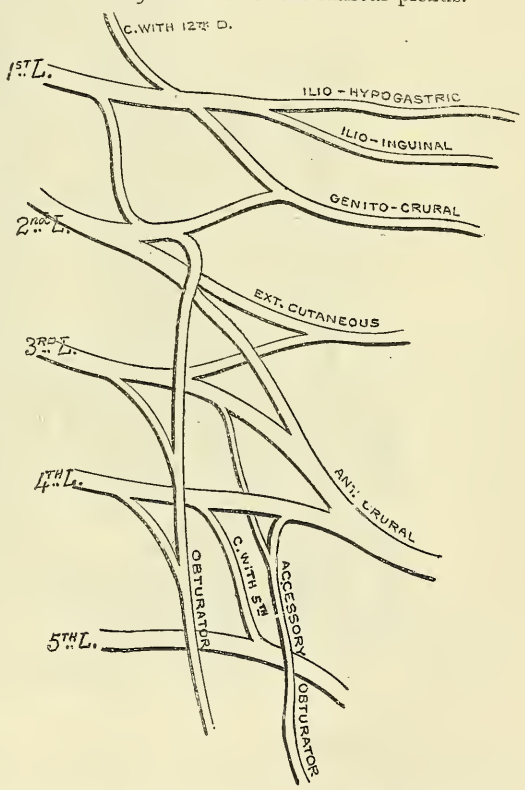
Anterior Divisions of the Lumbar Nerves

The **anterior divisions of the lumbar nerves** increase in size from above downwards. At their origin, they communicate with the lumbar ganglia of the sympathetic by long, slender filaments, which accompany the lumbar arteries round the sides of the bodies of the vertebræ, beneath the Psoas muscle. The nerves pass obliquely outwards behind the Psoas magnus, or between its fasciculi, distributing filaments to it and the Quadratus lumborum. The anterior divisions of the four upper nerves are connected together in this situation by anastomotic loops, and form the *lumbar plexus*. The anterior division of the fifth lumbar, joined with a branch from the fourth, descends across the base of the sacrum to join the anterior division of the first sacral nerve, and assist in the formation of the sacral plexus. The cord resulting from the union of the fifth lumbar and the branch from the fourth is called the *lumbo-sacral nerve*.

Lumbar Plexus

The lumbar plexus is formed by the loops of communication between the anterior divisions of the four upper lumbar nerves. The plexus is narrow above, and often connected with the last dorsal by a slender branch, the *dorsi-lumbar nerve*; it is broad below, where it is joined to the sacral plexus by the lumbo-sacral cord. It is situated in the substance of the Psoas muscle near its posterior part, in front of the transverse processes of the lumbar vertebræ.

Fig. 508.—Plan of the lumbar plexus.



The mode in which the plexus is formed is the following:—The first lumbar nerve receives a branch from the last dorsal, and gives off a larger branch, which subdivides into the ilio-hypogastric and ilio-inguinal; a communicating branch which passes down to the second lumbar nerve; and a third branch which unites with a branch of the second lumbar to form the genito-crural nerve. The second, third, and fourth lumbar nerves divide into an anterior and posterior division. The anterior division of the second divides into two branches, one of which joins with the above-mentioned branch of the first nerve to form the genito-crural; the other unites with the anterior division of the third nerve, and a part of the anterior division of the fourth nerve to form the obturator nerve. The remainder of the anterior division of the fourth nerve passes down to communicate with the fifth lumbar nerve. The posterior divisions of the second and third nerve divide into two branches, a smaller branch from each uniting to form the external cutaneous nerve, and a larger branch from each, which join with the whole of the posterior division of the fourth lumbar nerve to form the anterior crural. The accessory obturator, when it exists, is formed

by a small branch from the third nerve joining with a small branch from the fourth.

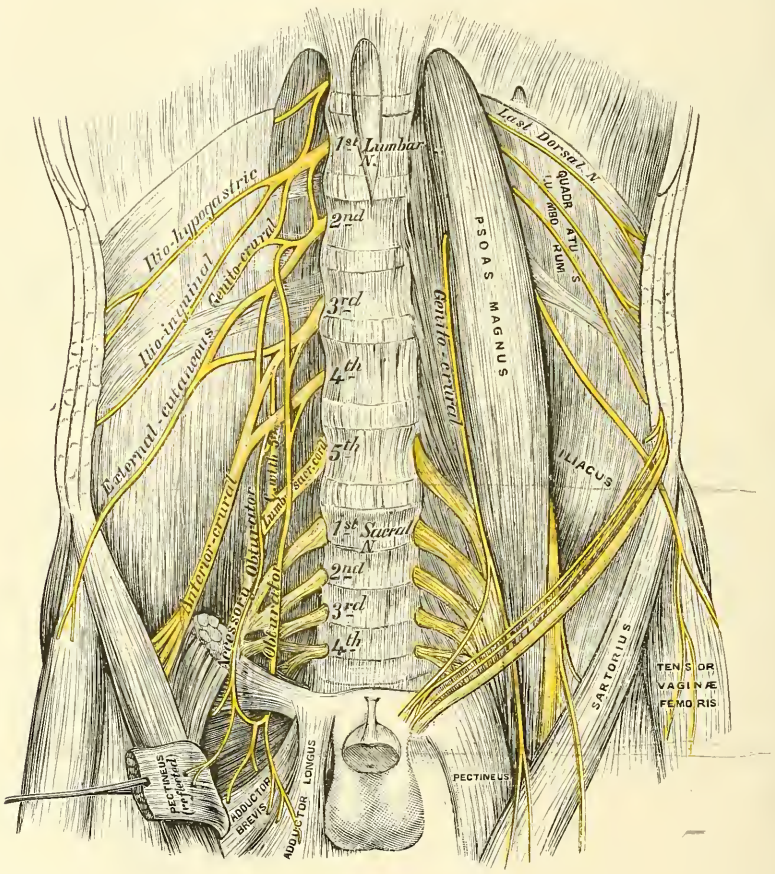
From this arrangement it follows that the ilio-hypogastric and ilio-inguinal are derived entirely from the first lumbar nerve. The genito-crural from the first and second nerves. The external cutaneous from the second and third. The anterior crural and obturator by fibres derived from the second, third, and fourth. And the accessory obturator, when it exists, from the third and fourth.

The branches of the lumbar plexus are, the

Ilio-hypogastric.	External cutaneous.
Ilio-inguinal.	Anterior crural.
Genito-crural.	Obturator.

Accessory obturator.

Fig. 509.—The lumbar plexus and its branches.



The **Ilio-hypogastric Nerve** (*superior musculo-cutaneous*) arises from the first lumbar nerve. It emerges from the outer border of the Psoas muscle at its upper part, and crosses obliquely in front of the Quadratus lumborum to the crest of the ilium. It then perforates the Transversalis muscle at its posterior part, near the crest of the ilium, and divides between it and the Internal oblique into two branches, iliac and hypogastric.

The *iliac branch* pierces the Internal and External oblique muscles immediately above the crest of the ilium, and is distributed to the integument of the gluteal region, behind the lateral cutaneous branch of the last dorsal nerve (fig. 514). The size of this nerve bears an inverse proportion to that of the cutaneous branch of the last dorsal nerve.

The *hypogastric branch* (fig. 510) continues onwards between the Internal oblique and Transversalis muscles. It then pierces the Internal oblique, and near the middle line perforates the aponeurosis of the External oblique, about an inch above, and a little to the outer side of the external abdominal ring, and is distributed to the integument of the hypogastric region.

The ilio-hypogastric nerve communicates with the last dorsal and ilio-inguinal nerves.

The **Ilio-inguinal Nerve** (*inferior musculo-cutaneous*), smaller than the preceding, arises with it from the first lumbar nerve. It emerges from the outer border of the Psoas just below the ilio-hypogastric, and, passing obliquely across the Quadratus lumborum and Iliacus muscles, perforates the Transversalis, near the fore part of the crest of the ilium, and communicates with the ilio-hypogastric nerve between that muscle and the Internal oblique. The nerve then pierces the Internal oblique, distributing filaments to it, and accompanying the spermatic cord through the inguinal canal, it escapes at the external abdominal ring, and is distributed to the integument of the upper and inner part of the thigh; and to the scrotum in the male, and to the labium in the female. The size of this nerve is in inverse proportion to that of the ilio-hypogastric. Occasionally it is very small, and ends by joining the ilio-hypogastric; in such cases, a branch from the ilio-hypogastric takes the place of the ilio-inguinal, or the latter nerve may be altogether absent.

The **Genito-crural Nerve** arises from the first and second lumbar nerves. It passes obliquely through the substance of the Psoas, and emerges from its inner border, close to the vertebral column, opposite the disc between the third and fourth lumbar vertebræ; it then descends on the surface of the Psoas muscle, under cover of the peritoneum, and divides into a genital and crural branch.

The *genital branch* passes outwards on the Psoas magnus, and pierces the fascia transversalis, or passes through the internal abdominal ring; it then descends along the back part of the spermatic cord to the scrotum, and supplies, in the male, the Cremaster muscle. In the female, it accompanies the round ligament, and is lost upon it.

The *crural branch* descends on the external iliac artery, sending a few filaments round it, and, passing beneath Poupart's ligament to the thigh, enters the sheath of the femoral vessels, lying superficial and a little external to the femoral artery. It pierces the anterior layer of the sheath of the vessels, and, becoming superficial by passing through the fascia lata, it supplies the skin of the anterior aspect of the thigh as far as midway between the pelvis and knee. On the front of the thigh it communicates with the outer branch of the middle cutaneous nerve, derived from the anterior crural.

A few filaments from this nerve may be traced on to the femoral artery; they are derived from the nerve as it passes beneath Poupart's ligament.

The **External Cutaneous Nerve** arises from the second and third lumbar nerves. It emerges from the outer border of the Psoas muscle about its middle, and crosses the Iliacus muscle obliquely, to the notch immediately beneath the anterior superior spine of the ilium, where it passes under Poupart's ligament into the thigh, and divides into two branches, anterior and posterior.

The *anterior branch* descends in an aponeurotic canal formed in the fascia lata, becomes superficial about four inches below Poupart's ligament, and divides into branches which are distributed to the integument along the anterior and outer part of the thigh, as far down as the knee. This nerve occasionally communicates with a branch of the long saphenous nerve in front of the knee-joint.

The *posterior branch* pierces the fascia lata, and subdivides into branches which pass backwards across the outer and posterior surface of the thigh, supplying the integument from the crest of the ilium as far as the middle of the thigh.

The **Obturator Nerve** supplies the Obturator externus and Adductor muscles of the thigh, the articulations of the hip and knee, and occasionally the integument of the thigh and leg. It arises by three branches: from the second, the

Fig. 510.—Cutaneous nerves of lower extremity. Front view.

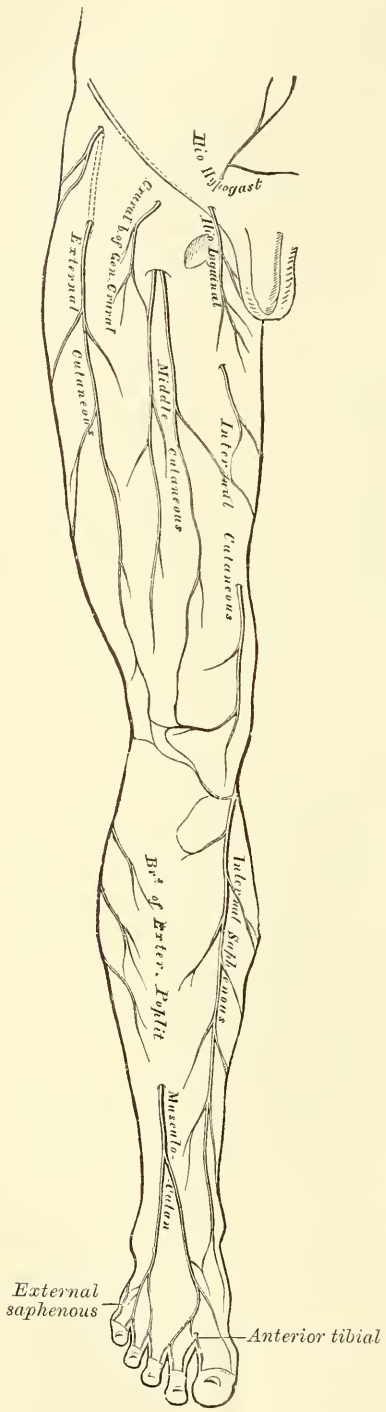


Fig. 511.—Nerves of the lower extremity. Front view.

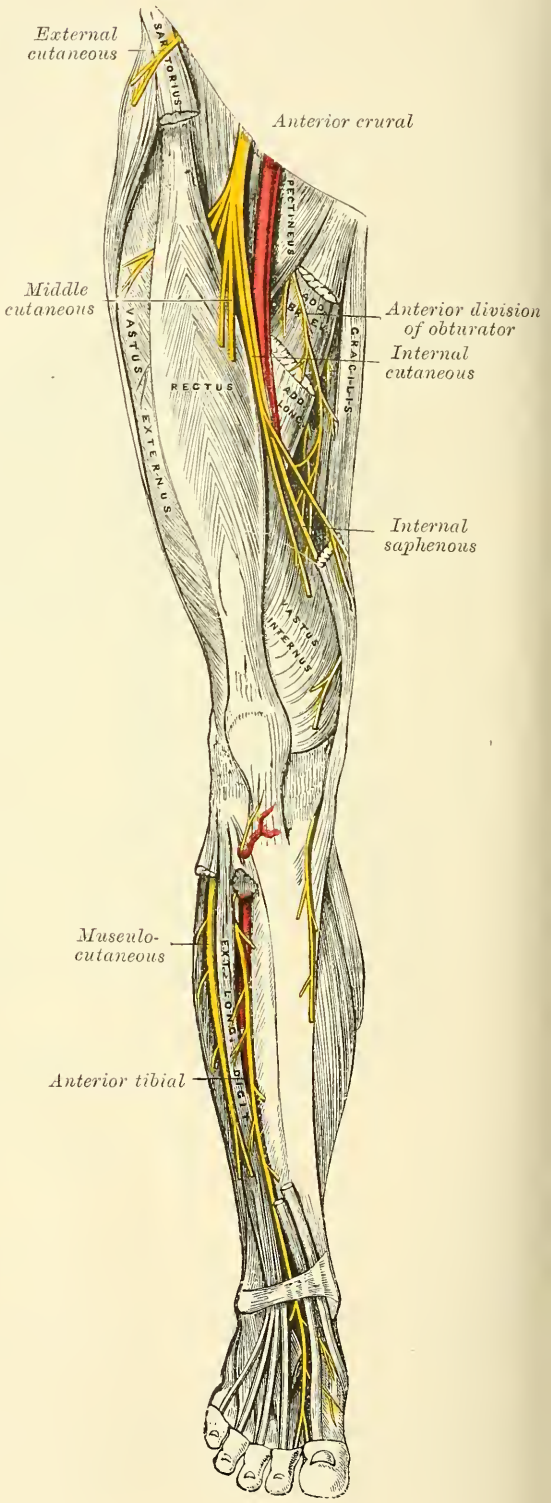


third, and the fourth lumbar nerves. Of these the branch from the third is the largest, whilst that from the second is often very small. It descends through the inner fibres of the Psoas muscle, and emerges from its inner border near the brim of the pelvis; it then runs along the lateral wall of the pelvis, above the obturator vessels, to the upper part of the obturator foramen, where it enters the thigh, and divides into an anterior and a posterior branch, separated by some of the fibres of the Obturator externus (fig. 368), and lower down by the Adductor brevis muscle.

The *anterior branch* (fig. 511) passes down in front of the Adductor brevis, being covered by the Pectineus and Adductor longus; and at the lower border of the latter muscle communicates with the internal cutaneous and internal saphenous nerves, forming a kind of plexus. It then descends upon the femoral artery, upon which it is finally distributed. The nerve, near the obturator foramen, gives off an articular branch to the hip-joint. Behind the Pectineus, it distributes muscular branches to the Adductor longus and Gracilis, and occasionally to the Adductor brevis, and in rare cases to the Pectineus, and receives a communicating branch from the accessory obturator nerve.

Occasionally the communicating branch to the internal cutaneous and internal saphenous nerves is continued down, as a cutaneous branch, to the thigh and leg. When this is so, this occasional cutaneous branch emerges from beneath the lower border of the Adductor longus, descends along the posterior margin of the Sartorius to the inner side of the knee, where it pierces the deep fascia, communicates with the long saphenous nerve, and is distributed to the integument of the inner side of the leg as low down as its middle. When this communicating branch is small, its place is supplied by the internal cutaneous nerve.

The *posterior branch of the obturator nerve* pierces the Obturator externus, sending branches to supply it, and passes behind the Adductor brevis on the front of the Adductor magnus, where it divides into numerous muscular branches, which supply the Adductor magnus, and occasionally the Adductor brevis. One of the branches gives off a filament to the knee-joint.

The *articular branch for the knee-joint* perforates the lower part of the Adductor magnus, and enters the popliteal space; it then descends upon the popliteal artery, as far as the back part of the knee-joint, where it perforates the posterior ligament, and is distributed to the synovial membrane. It gives filaments to the artery in its course.

Accessory Obturator Nerve (fig. 509) is not constantly present. It is of small size, and arises by separate filaments from the third and fourth lumbar nerves. It descends along the inner border of the Psoas muscle, crosses the ascending ramus of the os pubis, and passes under the outer border of the Pectineus muscle, where it divides into numerous branches. One of these supplies the Pectineus, penetrating its under surface; another is distributed to the hip-joint; while a third communicates with the anterior branch of the obturator nerve. When this nerve is absent, the hip-joint receives two branches from the obturator nerve. Occasionally it is very small and becomes lost in the capsule of the hip-joint.

The **Anterior Crural Nerve** (figs. 509, 511) is the largest branch of the lumbar plexus. It supplies muscular branches to the Iliacus, Pectineus, and all the muscles on the front of the thigh, excepting the Tensor vaginæ femoris; cutaneous filaments to the front and inner side of the thigh, and to the leg and foot: and articular branches to the hip and knee. It arises from the second, third, and fourth lumbar nerves. It descends through the fibres of the Psoas muscle, emerging from it at the lower part of its outer border; and passes down between it and the Iliacus, and beneath Poupart's ligament, into the thigh, where it becomes somewhat flattened, and divides into an anterior part, which passes superficial to the external circumflex vessels, and a posterior part which passes beneath these vessels. Under Poupart's ligament, it is separated from the femoral artery by the Psoas muscle, and lies beneath the iliac fascia.

Within the pelvis the anterior crural nerve gives off from its outer side some

small branches to the Iliacus, and a branch to the femoral artery, which is distributed upon the upper part of that vessel. The origin of this branch varies: it occasionally arises higher than usual, or it may arise lower down in the thigh.

External to the pelvis the following branches are given off:

From the Anterior Division	*From the Posterior Division*
Middle cutaneous.	Long saphenous.
Internal cutaneous.	Muscular.
	Articular.

The *middle cutaneous nerve* (fig. 510) pierces the fascia lata (generally the Sartorius also) about three inches below Poupart's ligament, and divides into two branches, which descend in immediate proximity along the fore part of the thigh, distributing numerous branches to the integument as low as the front of the knee, where it communicates with the *nervus cutaneus patellæ*, a branch of the internal saphenous nerve, helping to form the patellar plexus. Its outer branch communicates, above, with the crural branch of the genito-crural nerve; and the inner branch with the internal cutaneous nerve below. The Sartorius muscle is supplied by this or the following nerve.

The *internal cutaneous nerve* passes obliquely across the upper part of the sheath of the femoral artery, and divides in front, or at the inner side of that vessel, into two branches, anterior and posterior or internal.

The *anterior branch* runs downwards on the Sartorius, perforates the fascia lata at the lower third of the thigh, and divides into two branches: one of which supplies the integument as low down as the inner side of the knee; the other crosses to the outer side of the patella, communicating in its course with the nervus cutaneus patellæ, a branch of the internal saphenous nerve.

The *posterior* or *internal branch* descends along the inner border of the Sartorius muscle to the knee, where it pierces the fascia lata, communicates with the long saphenous nerve, and gives off several cutaneous branches. The nerve then passes down the inner side of the leg, to the integument of which it is distributed. This nerve, beneath the fascia lata, at the lower border of the Adductor longus, joins in a plexiform network by uniting with branches of the long saphenous and obturator nerves (fig. 511). When the communicating branch from the obturator nerve is large and continued to the integument of the leg, the inner branch of the internal cutaneous is small, and terminates at the plexus, occasionally giving off a few cutaneous filaments.

The internal cutaneous nerve, before dividing, gives off a few filaments, which pierce the fascia lata, to supply the integument of the inner side of the thigh, accompanying the long saphenous vein. One of these filaments passes through the saphenous opening; a second becomes subcutaneous about the middle of the thigh; and a third pierces the fascia at its lower third.

The *long* or *internal saphenous nerve* is the largest of the cutaneous branches of the anterior crural. It approaches the femoral artery where this vessel passes beneath the Sartorius, and lies on its outer side, beneath the aponeurotic covering of Hunter's canal, as far as the opening in the lower part of the Adductor magnus. It then quits the artery, and descends vertically along the inner side of the knee, beneath the Sartorius, pierces the fascia lata, opposite the interval between the tendons of the Sartorius and Gracilis, and becomes subcutaneous. The nerve then passes along the inner side of the leg, accompanied by the internal saphenous vein, descends behind the internal border of the tibia, and, at the lower third of the leg, divides into two branches: one continues its course along the margin of the tibia, terminating at the inner ankle; the other passes in front of the ankle, and is distributed to the integument along the inner side of the foot, as far as the great toe, communicating with the internal branch of the musculo-cutaneous nerve.

Branches.—The long saphenous nerve about the middle of the thigh gives off

a communicating branch, which joins the plexus formed by the obturator and internal cutaneous nerves.

At the inner side of the knee it gives off a large branch (*nervus cutaneus patellæ*) which pierces the Sartorius and fascia lata, and is distributed to the integument in front of the patella. This nerve communicates above the knee with the anterior branch of the internal cutaneous and with the middle cutaneous; below the knee, with other branches of the long saphenous; and, on the outer side of the joint, with branches of the external cutaneous nerve, forming a plexiform network, the *plexus patellæ*. The cutaneous nerve of the patella is occasionally small, and terminates by joining the internal cutaneous, which supplies its place in front of the knee.

Below the knee, the branches of the long saphenous nerve are distributed to the integument of the front and inner side of the leg, communicating with the cutaneous branches from the internal cutaneous, or from the obturator nerve.

The *muscular branches* supply the Pectineus and all the muscles on the front of the thigh, except the Tensor vaginæ femoris which is supplied from the superior gluteal nerve, and the Sartorius which is supplied by filaments from the middle or internal cutaneous nerves.

The *branches to the Pectineus*, usually two in number, pass inwards behind the femoral vessels, and enter the muscle on its anterior surface. Sometimes one of these nerves is given off in the pelvis, and is then often united with the accessory obturator.

The *branch to the Rectus muscle* enters its under surface high up, sending off a small filament to the hip-joint.

The *branch to the Vastus externus*, of large size, follows the course of the descending branch of the external circumflex artery to the lower part of the muscle. It gives off an articular filament to the knee-joint.

The *branch to the Vastus internus* is a long branch which runs down on the outer side of the femoral vessels in company with the internal saphenous nerve for its upper part. It enters the muscle about its middle, and gives off a filament, which can usually be traced downwards on the surface of the muscle to the knee-joint.

The *branch to the Crureus* enters the muscle on its anterior surface about the middle of the thigh, and sends a filament through the muscle to the Subcrureus.

The *articular branch to the hip-joint* is derived from the nerve to the Rectus.

The *articular branches to the knee-joint* are two in number. One, a long, slender filament, is derived from the nerve to the Vastus externus. It penetrates the capsular ligament of the joint on its anterior aspect. The other is derived from the nerve to the Vastus internus. It can usually be traced downwards on the surface of this muscle to near the joint; it then penetrates the muscular fibres, and accompanies the deep branch of the anastomotica magna artery, pierces the capsular ligament of the joint on its inner side, and supplies the synovial membrane.

THE SACRAL AND COCCYGEAL NERVES

The *sacral nerves* are five in number on each side. The four upper ones pass from the sacral canal, through the sacral foramina; the fifth through the foramen between the sacrum and coccyx.

The *roots of the upper sacral (and lumbar) nerves* are the largest of all the spinal nerves; whilst those of the lowest sacral and coccygeal nerve are the smallest. They are of very considerable length, being longer than those of any of the other spinal nerves, on account of the spinal cord not extending beyond the first lumbar vertebra. From their great length, and the appearance they

present in connection with the spinal cord, the roots of origin of these nerves are called collectively the *cauda equina*.

Each sacral and coccygeal nerve separates into two divisions, posterior and anterior.

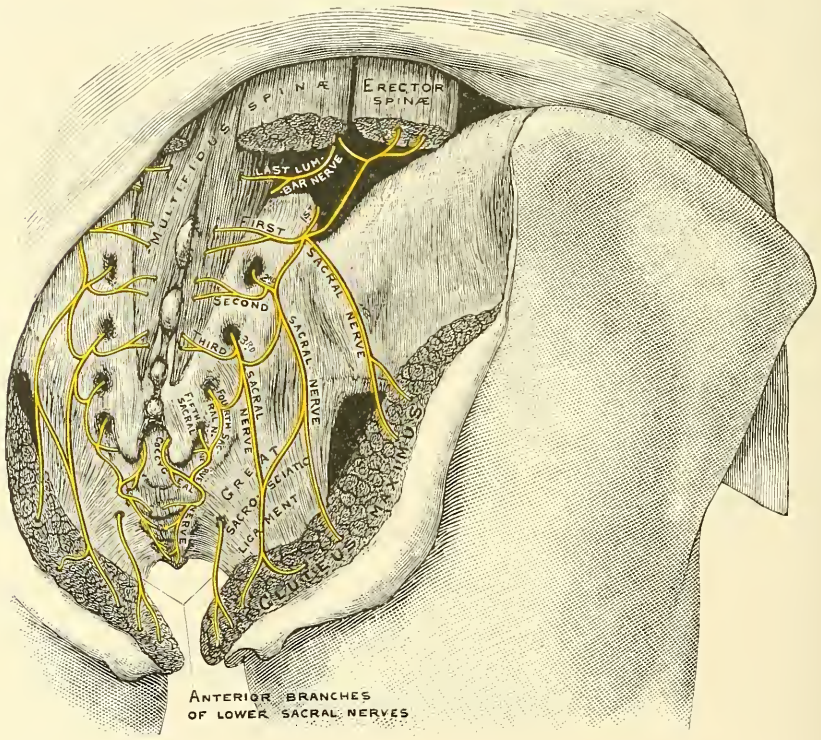
The **posterior divisions of the sacral nerves** (fig. 512) are small, diminish in size from above downwards, and emerge, except the last, from the sacral canal by the posterior sacral foramina.

The *three upper ones* are covered, at their exit from the sacral canal, by the Multifidus spinæ, and divide into internal and external branches.

The *internal branches* are small, and supply the Multifidus spinæ.

The *external branches* join with one another, and with the last lumbar and fourth sacral nerves, by means of communicating loops. These branches pass outwards to the outer surface of the great sacro-sciatic ligament, where they form a second series of loops beneath the Gluteus maximus. Cutaneous branches from

Fig. 512.—The posterior sacral nerves.



this second series of loops, usually three in number, pierce the Gluteus maximus: one near the posterior inferior spine of the ilium; another opposite the end of the sacrum; and the third midway between the other two. They supply the integument over the posterior part of the gluteal region.

The *posterior divisions of the two lower sacral nerves* are situated below the Multifidus spinæ. They are of small size, and do not divide into internal and external branches, but join with each other, and with the coccygeal nerve, so as to form loops on the back of the sacrum, filaments from which supply the Extensor coccygis and the integument over the coccyx.

The **coccygeal nerve** divides into its anterior and posterior division in the spinal canal. The *posterior division* is the smaller. It does not divide, but receives, as already mentioned, a communicating branch from the last sacral, and is lost in the integument over the back of the coccyx.

The **anterior divisions of the sacral nerves** diminish in size from above down-

wards. The four upper ones emerge from the anterior sacral foramina: the anterior division of the fifth, after emerging from the spinal canal through its terminal opening, curves forwards between the sacrum and the coccyx. All the anterior sacral nerves communicate with the sacral ganglia of the sympathetic, at their exit from the sacral foramina. The *first nerve*, of large size, unites with the lumbo-sacral cord, formed by the fifth lumbar, and a branch from the fourth. The *second*, equal in size to the preceding, and a *third*, about one-fourth the size of the second, unite with this trunk, and form, with a small fasciculus from the fourth, the *sacral plexus*, a visceral branch being given off from the third nerve to the bladder.

The **fourth anterior sacral nerve** sends a branch to join the sacral plexus. The remaining portion of the nerve divides into visceral and muscular branches; and a communicating filament descends to join the fifth sacral nerve. The *visceral branches* are distributed to the viscera of the pelvis, communicating with the sympathetic nerve. These branches ascend upon the rectum and bladder, and in the female upon the vagina, communicating with branches of the sympathetic from the pelvic plexus. The *muscular branches* are distributed to the Levator ani, Coccygeus, and Sphincter ani. The branch to the Sphincter ani pierces the Levator ani, so as to reach the ischio-rectal fossa, where it is found lying in front of the coccyx. Cutaneous filaments arise from the latter branch, which supply the integument between the anus and coccyx. Another cutaneous branch is frequently given off from this nerve, though sometimes from the pudic (Schwalbe). It perforates the great sacro-sciatic ligament, and, winding round the lower border of the Gluteus maximus, supplies the skin over the lower and inner part of this muscle.

The **fifth anterior sacral nerve**, after passing from the lower end of the sacral canal, curves forwards through the fifth sacral foramen, formed between the lower part of the sacrum and the transverse process of the first piece of the coccyx. It pierces the Coccygeus muscle, and descends upon its anterior surface to near the tip of the coccyx, where it again perforates the muscle, to be distributed to the integument over the back part and side of the coccyx. This nerve communicates above with the fourth sacral, and below with the coccygeal nerve, and supplies the Coccygeus muscle.

The **anterior division of the coccygeal nerve** is a delicate filament which escapes at the termination of the sacral canal; it passes downwards behind the rudimentary transverse process of the first piece of the coccyx, and curves forwards, through the notch between the first and second pieces, piercing the Coccygeus muscle and descending on its anterior surface to near the tip of the coccyx, where it again pierces the muscle, to be distributed to the integument over the back part and side of the coccyx. It is joined by a branch from the fifth anterior sacral as it descends on the surface of the Coccygeus muscle.

Sacral Plexus (fig. 513)

The **sacral plexus** is formed by the lumbo-sacral cord, the anterior divisions of the three upper sacral nerves, and part of that of the fourth. These nerves proceed in different directions: the upper ones obliquely downwards and outwards, the lower one nearly horizontally, and they all unite into two cords: an *upper* and larger which is formed by the lumbo-sacral cord with the first, second, and the greater part of the third sacral nerves; and a *lower* and smaller formed by the remainder of the third, with a portion of the fourth sacral nerve. The upper cord is prolonged into the great sciatic nerve and the lower into the pudic. Frequently a small filament is given off from the second sacral nerve to join the lower cord.

The sacral plexus is triangular in form, its base corresponding with the exit of the nerves from the sacrum, its apex with the lower part of the great sacro-sciatic foramen. It rests upon the anterior surface of the Pyriformis, and is

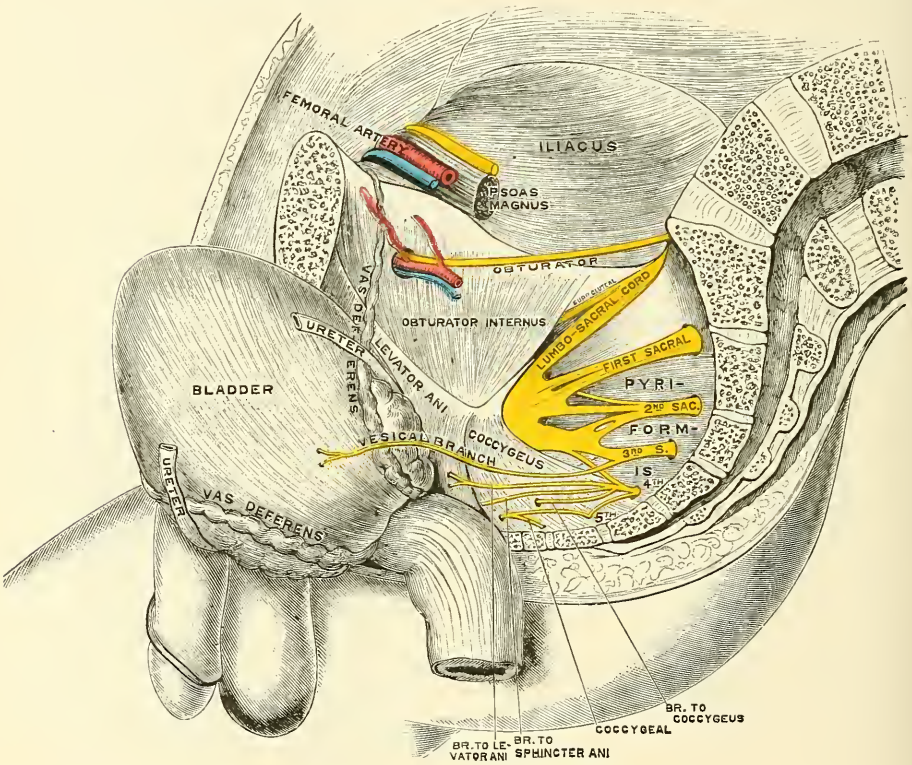
covered in front by the pelvic fascia, which separates it from the sciatic and pudic branches of the internal iliac artery, and from the viscera of the pelvis.

The branches of the sacral plexus are:

Collateral branches	Muscular
	Superior Gluteal
	Inferior Gluteal
	Small Sciatic
Terminal branches	Pudic
	Great Sciatic

The **muscular branches** supply the Pyriformis, Obturator internus, the two Gemelli, and the Quadratus femoris. The branch to the Pyriformis arises from

Fig. 513.—Side view of pelvis, showing sacral nerves.



the upper two sacral nerves before they enter the plexus; the branch to the Obturator internus arises at the junction of the lumbo-sacral and first sacral nerves: it passes out of the pelvis through the great sacro-sciatic foramen, crosses the spine of the ischium, and re-enters the pelvis through the lesser sacro-sciatic foramen to enter the inner surface of the Obturator internus; the branch to the Gemellus superior arises in common with the nerve to the Obturator internus: it enters the muscle at the upper part of its posterior surface; the small branch to the Gemellus inferior and Quadratus femoris also arises from the upper part of the plexus: it passes through the great sacro-sciatic foramen, and courses down beneath the Gemelli and tendon of the Obturator internus, and supplies the muscles on their deep or anterior surface. It gives off an articular branch to the hip-joint. A second articular branch is occasionally derived from the upper part of the sacral plexus.

The **Superior Gluteal Nerve** (fig. 515) arises from the back part of the lumbo-sacral cord, with some filaments from the first sacral nerve; it passes from the

pelvis through the great sacro-sciatic foramen above the Pyriformis muscle, accompanied by the gluteal vessels, and divides into a superior and an inferior branch.

The *superior branch* follows the line of origin of the Gluteus minimus, and supplies the Gluteus medius.

The *inferior branch* crosses obliquely between the Gluteus minimus and medius, distributing filaments to both these muscles, and terminates in the Tensor vaginæ femoris, extending nearly to its lower end.

The **Inferior Gluteal** arises from the lumbo-sacral cord, and first and second sacral nerves, and is intimately connected with the small sciatic at its origin. It passes out of the pelvis through the great sciatic notch, beneath the Pyriformis muscle, and dividing into a number of branches enters the Gluteus maximus muscle, on its under surface. It gives off a cutaneous branch, which winds round the lower border of the Gluteus maximus muscle to supply the skin of the buttock. This cutaneous filament frequently comes off as a separate branch from the sacral plexus, and is termed the perforating cutaneous nerve.

The **Small Sciatic Nerve** (fig. 515) supplies the integument of the perinæum and back part of the thigh and leg. It is usually formed by the union of two branches, which arise from the second and third nerves of the sacral plexus. It issues from the pelvis through the great sacro-sciatic foramen below the Pyriformis muscle, descends beneath the Gluteus maximus with the sciatic artery, and at the lower border of that muscle passes along the back part of the thigh, beneath the fascia lata, to the lower part of the popliteal region, where it pierces the fascia and becomes cutaneous. It then accompanies the external saphenous vein to about the middle of the leg, its terminal filaments communicating with the external saphenous nerve.

The branches of the small sciatic nerve are all cutaneous, and consist of four groups : internal, external, ascending, and descending.

The *internal cutaneous branches* are distributed to the skin at the upper and inner side of the thigh, on its posterior aspect. One branch, longer than the rest, the *inferior pudendal*, curves forward below the tuber ischii, pierces the fascia lata, and passes forwards beneath the superficial fascia of the perinæum to be distributed to the integument of the scrotum in the male and the labium in the female, communicating with the superficial perineal and inferior hæmorrhoidal nerves.

The *external cutaneous branches* consist of two or three filaments, which are distributed to the skin at the upper and outer side of the thigh on its posterior aspect, as far down as the middle of that region.

The *ascending cutaneous branches* consist of two or three filaments, which turn upwards round the lower border of the Gluteus maximus, to supply the integument covering its surface.

The *descending cutaneous branches* are given off from the lesser sciatic nerve as it descends beneath the fascia of the thigh ; they supply the integument of the back part of the thigh, popliteal region, and upper part of the leg.

The **Pudic nerve** is the direct continuation of the lower cord of the sacral plexus, and derives its fibres from the third and fourth sacral nerves and frequently from the second also. It leaves the pelvis, through the great sacro-sciatic foramen, below the Pyriformis. It then crosses the spine of the ischium, and reenters the pelvis through the lesser sacro-sciatic foramen. It accompanies the pudic vessels upwards and forwards along the outer wall of the ischio-rectal fossa, being contained in a sheath of the obturator fascia, and divides into two terminal branches, the perineal nerve, and the dorsal nerve of the penis or clitoris. Before its division, it gives off the inferior hæmorrhoidal nerve.

The *inferior hæmorrhoidal nerve* is occasionally derived separately from the sacral plexus. It passes across the ischio-rectal fossa, with its accompanying vessels, towards the lower end of the rectum, and is distributed to the integument round the anus. Branches of this nerve communicate with the inferior pudendal and superficial perineal nerves at the fore part of the perinæum.

FIG. 514.—Cutaneous nerves of lower extremity. Posterior view.

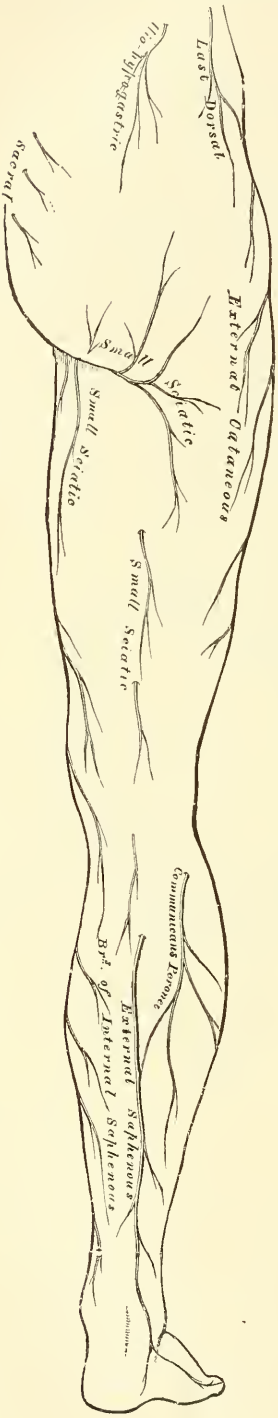


FIG. 515.—Nerves of the lower extremity.* Posterior view.

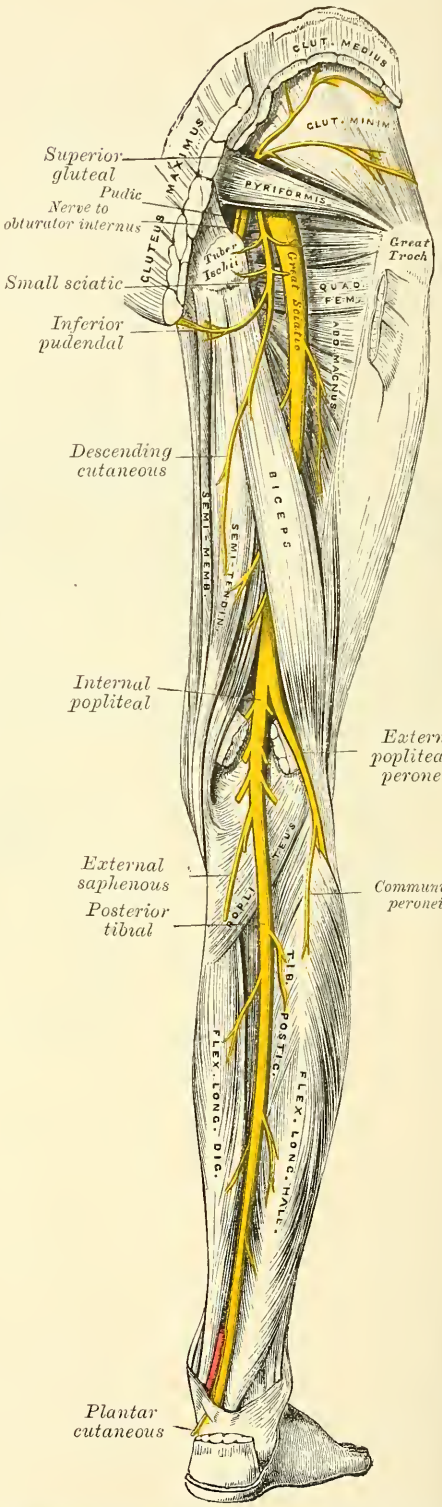


* N.B.—In this diagram the external saphenous and communicans peronei are not in their normal position. They have been displaced by the removal of the superficial muscles.

The *perineal nerve*, the inferior and larger of the two terminal branches of the pudic, is situated below the pudic artery. It accompanies the superficial perineal artery in the perinæum, dividing into cutaneous and muscular branches.

The cutaneous branches (superficial perineal) are two in number, posterior and anterior. The *posterior* or *external branch* passes forwards along the outer side of the perineal space parallel to the inferior pudendal nerve, and is distributed to the skin of the scrotum. It communicates with the inferior hæmorrhoidal, the inferior pudendal, and the other superficial perineal nerve. The *anterior* or *internal branch* passes forwards nearer to the middle line, to be distributed to the inner and back part of the scrotum. Both these nerves supply the labia majora in the female.

The muscular branches are distributed to the Transversus perinæi, Accelerator urinæ, Erector penis, and Compressor urethræ. A distinct branch is given off from the nerve to the Accelerator urinæ, which pierces this muscle, and supplies the corpus spongiosum, ending in the mucous membrane of the urethra. This is the nerve to the bulb.

The *dorsal nerve of the penis* is the deepest division of the pudic nerve; it accompanies the pudic artery along the ramus of the ischium; piercing the superior layer of the deep perineal fascia, it runs forward along the inner margin of the ramus of the os pubis, between the two layers of the deep fascia. It then pierces the inferior layer, and, in company with the dorsal artery of the penis, passes through the suspensory ligament, and, running forwards, is distributed to the glans. On the penis, this nerve gives off a cutaneous branch, which runs along the side of the organ; it is joined with branches of the sympathetic, and supplies the integument of the upper surface and sides of the penis and prepuce, giving a large branch to the corpus cavernosum.

In the female the dorsal nerve is very small, and supplies the clitoris.

The **Great Sciatic Nerve** (fig. 515) supplies nearly the whole of the integument of the leg, the muscles of the back of the thigh, and those of the leg and foot. It is the largest nervous cord in the body, measuring three-quarters of an inch in breadth, and is the continuation of the upper division of the sacral plexus. It passes out of the pelvis through the great sacro-sciatic foramen, below the Pyriformis muscle. It descends between the trochanter major and tuberosity of the ischium, along the back part of the thigh to about its lower third, where it divides into two large branches, the *internal* and *external popliteal nerves*.

This division may take place at any point between the sacral plexus and the lower third of the thigh. When the division occurs at the plexus, the two nerves descend together, side by side; or they may be separated, at their commencement, by the interposition of part or the whole of the Pyriformis muscle. As the nerve descends along the back of the thigh, it rests at first upon the External rotator muscles, in company with the small sciatic nerve and artery, being covered by the Gluteus maximus; lower down, it lies upon the Adductor magnus, and is covered by the long head of the Biceps.

The *branches* of the nerve, before its division, are articular and muscular.

The *articular branches* arise from the upper part of the nerve; they supply the hip-joint, perforating its fibrous capsule posteriorly. These branches are sometimes derived from the sacral plexus.

The *muscular branches* are distributed to the Flexors of the leg: viz. the Biceps, Semitendinosus, and Semimembranosus, and a branch to the Adductor magnus. These branches are given off beneath the Biceps muscle.

The **Internal Popliteal Nerve**, the larger of the two terminal branches of the great sciatic, descends along the back part of the thigh, through the middle of the popliteal space to the lower part of the Popliteus muscle, where it passes with the artery beneath the arch of the Soleus, and becomes the posterior tibial. It is overlapped by the hamstring muscles above, and then becomes more superficial, and lies to the outer side of, and some distance from, the popliteal vessels;

opposite the knee-joint, it is in close relation with the vessels, and crosses to the inner side of the artery. Below, it is overlapped by the Gastrocnemius.

The *branches* of this nerve are, articular, muscular, and a cutaneous branch the *communicans poplitei nerve*.

The *articular branches*, usually three in number, supply the knee-joint; two of these branches accompany the superior and inferior internal articular arteries; and a third, the azygos articular artery.

The *muscular branches*, four or five in number, arise from the nerve as it lies between the two heads of the Gastrocnemius muscle; they supply that muscle, the Plantaris, Soleus, and Popliteus. The filaments which supply the Popliteus turn round its lower border and are distributed to its deep surface.

The *communicans poplitei* descends between the two heads of the Gastrocnemius muscle, and, about the middle of the back of the leg, pierces the deep fascia, and joins a communicating branch (*communicans peronei*) from the external popliteal nerve to form the external, or short, saphenous (fig. 514).

The *external saphenous nerve*, formed by the cutaneous branches of the internal and external popliteal nerves, passes downwards and outwards near the outer margin of the tendo Achillis, lying close to the external saphenous vein, to the interval between the external malleolus and the os calcis. It winds round the outer malleolus, and is distributed to the integument along the outer side of the foot and little toe, communicating on the dorsum of the foot with the musculocutaneous nerve. In the leg, its branches communicate with those of the small sciatic.

The **Posterior Tibial Nerve** (fig. 515) commences at the lower border of the Popliteus muscle, and passes along the back part of the leg with the posterior tibial vessels to the interval between the inner malleolus and the heel, where it divides into the *external* and *internal plantar nerves*. It lies upon the deep muscles of the leg, and is covered in the upper part by the muscles of the calf, lower down by the skin and fascia. In the upper part of its course, it lies to the inner side of the posterior tibial artery; but it soon crosses that vessel, and lies to its outer side as far as the ankle. In the lower third of the leg, it is placed parallel with the inner margin of the tendo Achillis.

The *branches of the posterior tibial nerve* are muscular, plantar cutaneous, and articular.

The *muscular branches* arise either separately or by a common trunk from the upper part of the nerve. They supply the Tibialis posticus, Flexor longus digitorum, and Flexor longus hallucis muscles; the branch to the latter muscle accompanying the peroneal artery.

The *plantar cutaneous branch* perforates the internal annular ligament, and supplies the integument of the heel and inner side of the sole of the foot.

The *articular branch* is given off just above the bifurcation of the nerve, and supplies the ankle-joint.

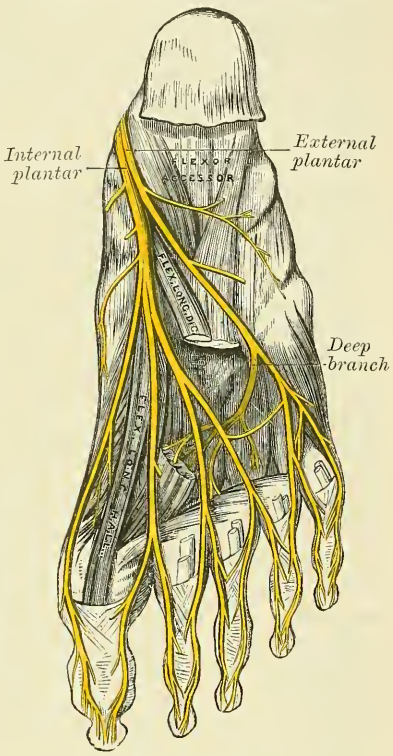
The **internal plantar nerve** (fig. 516), the larger of the two terminal branches of the posterior tibial, accompanies the internal plantar artery along the inner side of the foot. From its origin at the inner ankle it passes beneath the Abductor hallucis, and then forwards between this muscle and the Flexor brevis digitorum, divides opposite the bases of the metatarsal bones into four digital branches, and communicates with the external plantar nerve.

Branches.—In its course, the internal plantar nerve gives off *cutaneous branches*, which pierce the plantar fascia, and supply the integument of the sole of the foot; *muscular branches*, which supply the Abductor hallucis and Flexor brevis digitorum; *articular branches* to the articulations of the tarsus and metatarsus; and *four digital branches*. These pass between the divisions of the plantar fascia in the clefts between the toes, and are distributed in the following manner: The *first* supplies the inner border of the great toe, and sends a filament to the Flexor brevis hallucis muscle; the *second* bifurcates, to supply the adjacent sides of the great and second toes, sending a filament to the First

lumbrical muscle; the *third digital branch* supplies the adjacent sides of the second and third toes*; the *fourth* supplies the corresponding sides of the third and fourth toes, and receives a communicating branch from the external plantar nerve. Each digital nerve gives off cutaneous and articular filaments; and opposite the last phalanx sends a dorsal branch, which supplies the structure round the nail, the continuation of the nerve being distributed to the ball of the toe. It will be observed, that the distribution of these branches is precisely similar to that of the median nerve in the hand.

The **external plantar nerve**, the smaller of the two, completes the nervous supply to the structures of the sole of the foot, being distributed to the little toe and one-half of the fourth, as well as to most of the deep muscles, its distribution being similar to that of the ulnar in the hand. It passes obliquely forwards with the external plantar artery to the outer side of the foot, lying between the Flexor brevis digitorum and Flexor accessorius; and, in the interval between the former muscle and Abductor minimi digiti, divides into a superficial and a deep branch. Before its division, it supplies the Flexor accessorius and Abductor minimi digiti.

Fig. 516.—The plantar nerves.



The *superficial branch* separates into two digital nerves: one, the smaller of the two, supplies the outer side of the little toe, the Flexor brevis minimi digiti, and the two Interosseous muscles of the fourth metatarsal space; the other and larger digital branch supplies the adjoining sides of the fourth and fifth toes, and communicates with the internal plantar nerve.

The *deep* or *muscular branch* accompanies the external plantar artery into the deep part of the sole of the foot, beneath the tendons of the Flexor muscles and Adductor transversus hallucis, and supplies all the Interossei (except those in the fourth metatarsal space), the three outer Lumbricales, the Adductor obliquus hallucis, and the Adductor transversus hallucis.

The **External Popliteal** or **Peroneal Nerve** (fig. 515), about one-half the size of the internal popliteal, descends obliquely along the outer side of the popliteal space to the head of the fibula, close to the inner margin of the Biceps muscle. It is easily felt beneath the skin behind the head of the fibula, at the inner side of the tendon of the Biceps. It passes between the tendon of the Biceps and outer head of the Gastrocnemius muscle, winds round the neck of the fibula, between the Peroneus longus and the bone, and divides beneath the muscle into the anterior tibial and musculo-cutaneous nerves.

The *branches of the peroneal nerve*, previous to its division, are articular and cutaneous.

The *articular branches* are three in number; two of these accompany the superior and inferior external articular arteries to the outer side of the knee. The upper one occasionally arises from the great sciatic nerve before its bifurcation. The third (*recurrent*) articular nerve is given off at the point of division of the peroneal nerve; it ascends with the anterior recurrent tibial artery through the Tibialis anticus muscle to the front of the knee, which it supplies.

The *cutaneous branches*, two or three in number, supply the integument along

* See footnote, p. 541.

the back part and outer side of the leg, as far as its middle or lower part; one of these, larger than the rest, the *communicans peronei*, arises near the head of the fibula, crosses the external head of the Gastrocnemius to the middle of the leg, and joins with the communicans poplitei to form the external saphenous. This nerve occasionally exists as a separate branch, which is continued down as far as the heel.

The **Anterior Tibial Nerve** (fig. 511) commences at the bifurcation of the peroneal nerve, between the fibula and upper part of the Peroneus longus, passes obliquely forwards beneath the Extensor longus digitorum to the fore part of the interosseous membrane, and reaches the other side of the anterior tibial artery above the middle of the leg; it then descends with the artery to the front of the ankle-joint, where it divides into an external and an internal branch. This nerve lies at first on the outer side of the anterior tibial artery, then in front of it, and again at its outer side at the ankle-joint.

The *branches of the anterior tibial nerve*, in its course through the leg, are the muscular branches to the Tibialis anticus, Extensor longus digitorum, Peroneus tertius, and Extensor proprius hallucis muscles, and an *articular branch* to the ankle-joint.

The *external* or *tarsal branch of the anterior tibial* passes outwards across the tarsus, beneath the Extensor brevis digitorum, and, having become ganglionic like the posterior interosseous nerve at the wrist, supplies the Extensor brevis digitorum. From the ganglion are given off three minute *interosseous branches* which supply the tarsal joints and the metatarso-phalangeal joints of the second, third, and fourth toes. The first of these sends a filament to the second dorsal interosseous muscle.

The *internal branch*, the continuation of the nerve, accompanies the dorsalis pedis artery along the inner side of the dorsum of the foot, and, at the first interosseous space, divides into two branches, which supply the adjacent sides of the great and second toes, communicating with the internal branch of the musculo-cutaneous nerve. Before it divides it gives off an *interosseous branch* to the first space, which supplies the metatarso-phalangeal joint of the great toe and sends a filament to the First dorsal interosseous muscle.

The **Musculo-cutaneous Nerve** (fig. 511) supplies the muscles on the fibular side of the leg, and the integument of the dorsum of the foot. It passes forwards between the Peronei muscles and the Extensor longus digitorum, pierces the deep fascia at the lower third of the leg, on its front and outer side, and divides into two branches. This nerve, in its course between the muscles, gives off muscular branches to the Peroneus longus and brevis, and cutaneous filaments to the integument of the lower part of the leg.

The *internal branch of the musculo-cutaneous nerve* passes in front of the ankle-joint, and along the dorsum of the foot, supplying the inner side of the great toe, and the adjoining sides of the second and third toes. It also supplies the integument of the inner ankle and inner side of the foot, communicating with the internal saphenous nerve, and joins with the anterior tibial nerve, between the great and second toes.

The *external branch*, the larger, passes along the outer side of the dorsum of the foot, to be distributed to the adjoining sides of the third, fourth, and fifth toes. It also supplies the integument of the outer ankle and outer side of the foot, communicating with the short saphenous nerve.

The distribution of these branches of the musculo-cutaneous nerve will be found to vary; together, they supply all the toes excepting the outer side of the little toe, and the adjoining sides of the great and second toes, the former being supplied by the external saphenous, and the latter by the internal branch of the anterior tibial.

Surgical Anatomy.—The lumbar plexus passes through the Psoas muscle, and, therefore, in psoas abscess, any or all of its branches may be irritated, causing severe pain in the

part to which the irritated nerves are distributed. The genito-crural nerve is the one which is most frequently implicated. This nerve is also of importance as it is concerned in one of the principal reflexes employed in the investigation of diseases of the spine. If the skin over the inner side of the thigh just below Poupart's ligament, the part supplied by the crural branch of the genito-crural nerve, be gently tickled in a male child, the testicle will be noticed to be drawn upwards, through the action of the Cremaster muscle, supplied by the genital branch of the same nerve. The same result may sometimes be noticed in adults, and can almost always be produced by severe stimulation. This reflex, when present, shows that the portion of the cord from which the first and second lumbar nerves are derived is in a normal condition.

The anterior crural nerve is in danger of being injured in fractures of the true pelvis, since the fracture most commonly takes place through the ascending ramus of the os pubis, at or near the point where this nerve crosses the bone. It is also liable to be injured in fractures and dislocations of the femur, and is likely to be pressed upon, and its functions impaired, in some tumours growing in the pelvis. Moreover, on account of its superficial position, it is exposed to injury in wounds and stabs in the groin. When this nerve is paralysed, the patient is unable to flex his hip completely, on account of the loss of motion in the Iliacus; or to extend the knee on the thigh, on account of paralysis of the Quadriceps extensor cruris; there is complete paralysis of the Sartorius, and partial paralysis of the Pectineus. There is loss of sensation down the front and inner side of the thigh, except in that part supplied by the crural branch of the genito-crural, and by the ilio-inguinal. There is also loss of sensation down the inner side of the leg and foot as far as the ball of the great toe.

The obturator nerve is of special surgical interest. It is rarely paralysed alone, but occasionally in association with the anterior crural. The principal interest attached to it is in connection with its supply to the knee; pain in the knee being symptomatic of many diseases in which the trunk of this nerve, or one of its branches, is irritated. Thus it is well known that in the earlier stages of hip-joint disease the patient does not complain of pain in that articulation, but on the inner side of the knee, or in the knee-joint itself, both these articulations being supplied by the obturator nerve, the final distribution of the nerve being to the knee-joint. Again, the same thing occurs in sacro-iliac disease: pain is complained of in the knee-joint, or on its inner side. The obturator nerve is in close relationship with the sacro-iliac articulation, passing over it, and, according to some anatomists, distributing filaments to it. Again, in cancer of the sigmoid flexure, and even in cases where masses of hardened fæces are impacted in this portion of the gut, pain is complained of in the knee. The obturator nerve lies beneath the sigmoid flexure, and is readily pressed upon and irritated when disease exists in this part of the intestine. Finally, pain in the knee forms an important diagnostic sign in obturator hernia. The hernial protrusion as it passes out through the opening in the obturator membrane presses upon the nerve and causes pain in the parts supplied by its peripheral filaments. When the obturator nerve is paralysed, the patient is unable to press his knees together or to cross one leg over the other, on account of paralysis of the Adductor muscles. Rotation outwards of the thigh is impaired from paralysis of the Obturator externus. Sometimes there is loss of sensation in the upper half of the inner side of the leg.

The great sciatic nerve is liable to be pressed upon by various forms of pelvic tumours, giving rise to pain along its trunk, to which the term sciatica is applied. Tumours growing from the pelvic viscera, or bones, aneurisms of some of the branches of the internal iliac artery, calculus in the bladder when of large size, accumulation of fæces in the rectum, may all cause pressure on the nerve inside the pelvis, and give rise to sciatica. Outside the pelvis exposure to cold, violent movements of the hip-joint, exostoses or other tumours growing from the margin of the sacro-sciatic foramen, may also give rise to the same condition. When paralysed there is loss of motion in all the muscles below the knee, and loss of sensation in the same situation, except the upper half of the back of the leg, supplied by the small sciatic and the upper half of the inner side of the leg, when the communicating branch of the obturator is large (see page 841).

The sciatic nerve has been frequently cut down upon and stretched, or has been acupunctured for the relief of sciatica. The nerve has also been stretched in cases of locomotor ataxy, the anæsthesia of leprosy, etc. In order to define it on the surface, a point is taken at the junction of the middle and lower third of a line stretching from the posterior superior spine of the ilium to the outer part of the tuber ischii, and a line drawn from this to the middle of the upper part of the popliteal space. The line must be slightly curved with its convexity outwards, and as it passes downwards to the lower border of the Gluteus maximus is slightly nearer the tuber ischii than the great trochanter, as it crosses a line drawn between these two points. The operation of stretching the sciatic nerve is performed by making an incision over the course of the nerve about the centre of the thigh. The skin, superficial structures, and deep fascia having been divided, the interval between the inner and outer hamstrings is to be defined, and these muscles pulled inwards and outwards with retractors. The nerve will be found a little to the inner side of the Biceps. It is to be separated from the surrounding structures, hooked up with the finger, and stretched by steady and continuous traction for two or three minutes. The sciatic nerve may also be stretched by what is known as the 'dry' plan. The patient is laid on

his back, the foot is extended, the leg flexed on the thigh, and the thigh strongly flexed on the abdomen. While the thigh is maintained in this position, the leg is forcibly extended to its full extent, and the foot as fully flexed on the leg.

The position of the external popliteal, close behind the tendon of the Biceps on the outer side of the ham, should be remembered in subcutaneous division of the tendon. After it is divided, a cord often rises up close beside it, which might be mistaken for a small undivided portion of the tendon, and the surgeon might be tempted to reintroduce his knife and divide it. This must never be done, as the cord is the external popliteal nerve, which becomes prominent as soon as the tendon is divided.

THE SYMPATHETIC NERVE

The **Sympathetic Nervous System** consists of (1) a series of ganglia, connected together by intervening cords, extending from the base of the skull to the coccyx, one on each side of the middle line of the body, partly in front and partly on each side of the vertebral column; (2) of three great gangliated plexuses, or aggregations of nerves and ganglia, situated in front of the spine in the thoracic, abdominal, and pelvic cavities respectively; (3) of smaller ganglia situated in relation with the abdominal viscera; and (4) of numerous nerve-fibres. These latter are of two kinds: *communicating*, by which the ganglia communicate with each other and with the cerebro-spinal nerves; and *distributory*, supplying, in general, all the internal viscera and the coats of the blood-vessels.

Each **gangliated cord** may be traced upwards from the base of the skull into its cavity by an ascending branch, which passes through the carotid canal, forms a plexus on the internal carotid artery, and communicates with the ganglia on the first and second divisions of the fifth nerve. According to some anatomists, the two cords are joined, at their cephalic extremities, by these ascending branches communicating in a small ganglion (the *ganglion of Ribes*), situated upon the anterior communicating artery. The ganglia of these cords are distinguished as cervical, dorsal, lumbar, and sacral, and except in the neck they correspond pretty nearly in number to the vertebræ against which they lie. They may be thus arranged:

Cervical portion	. .	3 pairs of ganglia.
Dorsal ,,	. .	12 ,, ,,
Lumbar ,,	. .	4 ,, ,,
Sacral ,,	. .	4 or 5 ,, ,,

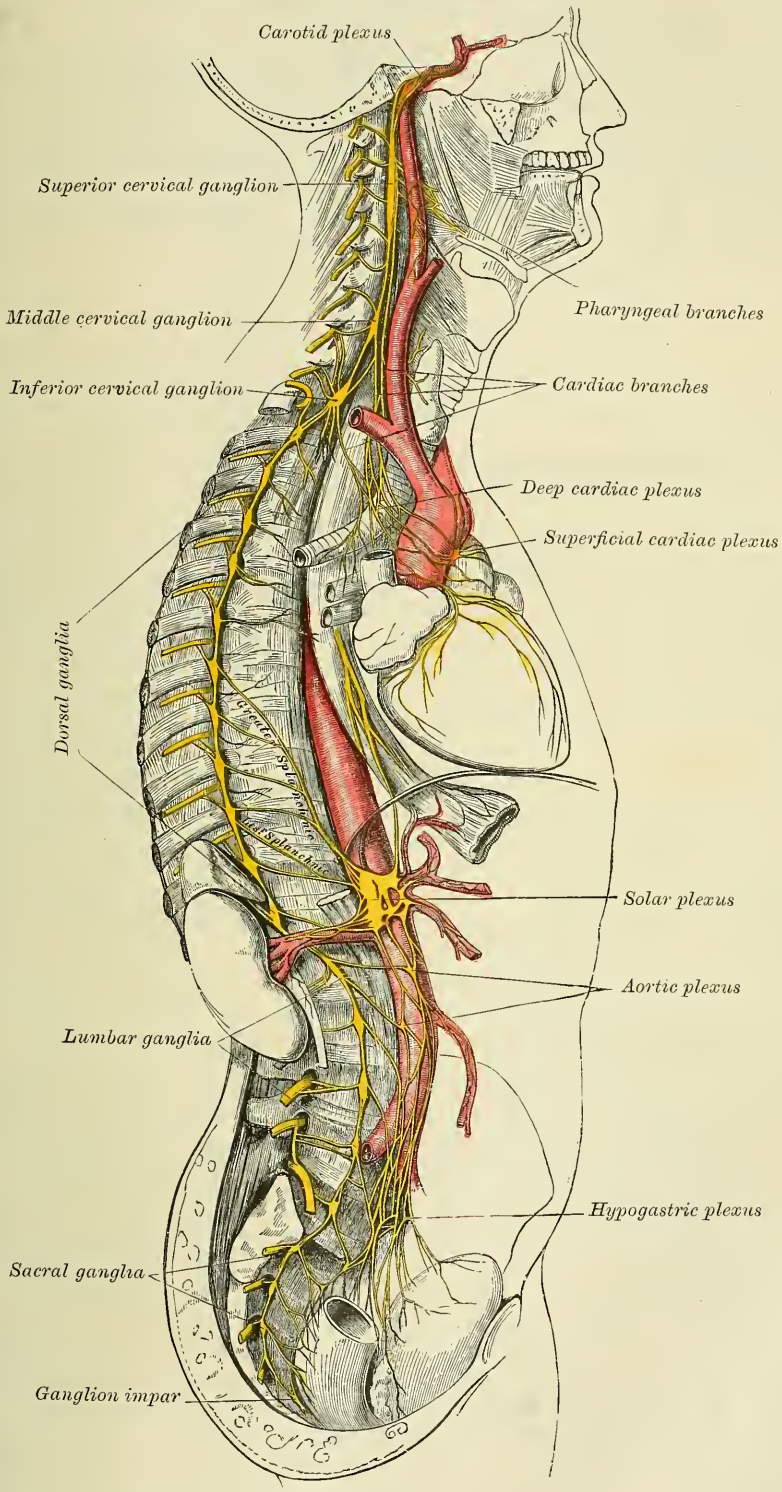
In the neck they are situated in front of the transverse processes of the vertebræ; in the dorsal region, in front of the heads of the ribs; in the lumbar region, on the sides of the bodies of the vertebræ; and in the sacral region, in front of the sacrum. As the two cords pass into the pelvis, they converge and unite together in a single ganglion (*ganglion impar*), placed in front of the coccyx. Each ganglion may be regarded as a distinct centre, and, in addition to its branches of distribution, possesses also branches of communication, which communicate with other ganglia and with the cerebro-spinal nerves.

The branches of communication between the ganglia are composed of grey and white nerve-fibres, the latter being continuous with those fibres of the spinal nerves which pass to the ganglia.

The branches of communication between the ganglia and the cerebro-spinal nerves also consist of a white and grey portion; the former proceeding from the spinal nerve *to* the ganglion, the latter passing *from* the ganglion to the spinal nerve, so that a double interchange takes place between the two systems.

The **three great gangliated plexuses** are situated in front of the spine in the thoracic, abdominal, and pelvic regions, and are named respectively, the *cardiac*, the *solar* or *epigastric*, and the *hypogastric plexus*. They consist of collections of nerves and ganglia; the nerves being derived from the gangliated cords, and from the cerebro-spinal nerves. They distribute branches to the viscera.

FIG. 517.—The sympathetic nerve.



Smaller ganglia are also found lying amidst the nerves, some of them of microscopic size, in certain viscera—as, for instance, in the heart, the stomach, and the uterus. They serve as additional centres for the origin of nerve-fibres.

The **branches of distribution** derived from the gangliated cords, from the prevertebral plexuses, and also from the smaller ganglia, are principally destined for the blood-vessels and thoracic and abdominal viscera, supplying the involuntary muscular fibre of the coats of the vessels and the hollow viscera, and the secreting cells, as well as the muscular coats of the vessels in the glandular viscera.

In addition to these various divisions of the sympathetic, the ganglia connected with the three branches of the fifth cranial nerve are believed by some to constitute a part of the sympathetic system. These ganglia have already been described (page 784 *et seq.*).

Cervical Portion of the Gangliated Cord

The cervical portion of the gangliated cord consists of three ganglia on each side, which are distinguished, according to their position, as the superior, middle, and inferior cervical.

The **Superior Cervical Ganglion**, the largest of the three, is placed opposite the second and third cervical vertebræ, and sometimes as low as the fourth or fifth. It is of a reddish-grey colour, and usually fusiform in shape; sometimes broad, and occasionally constricted at intervals, so as to give rise to the opinion that it consists of the coalescence of several smaller ganglia; and it is usually believed that it is formed by the coalescence of the four ganglia, corresponding to the four upper cervical nerves. It is in relation, in front, with the sheath of the internal carotid artery, and internal jugular vein; behind, it lies on the Rectus capitis anticus major muscle.

Its branches may be divided into superior, inferior, external, internal, and anterior.

The *superior branch* appears to be a direct prolongation of the ganglion. It is soft in texture, and of a reddish colour. It ascends by the side of the internal carotid artery, and, entering the carotid canal in the temporal bone, divides into two branches, which lie, one on the outer, and the other on the inner side of that vessel.

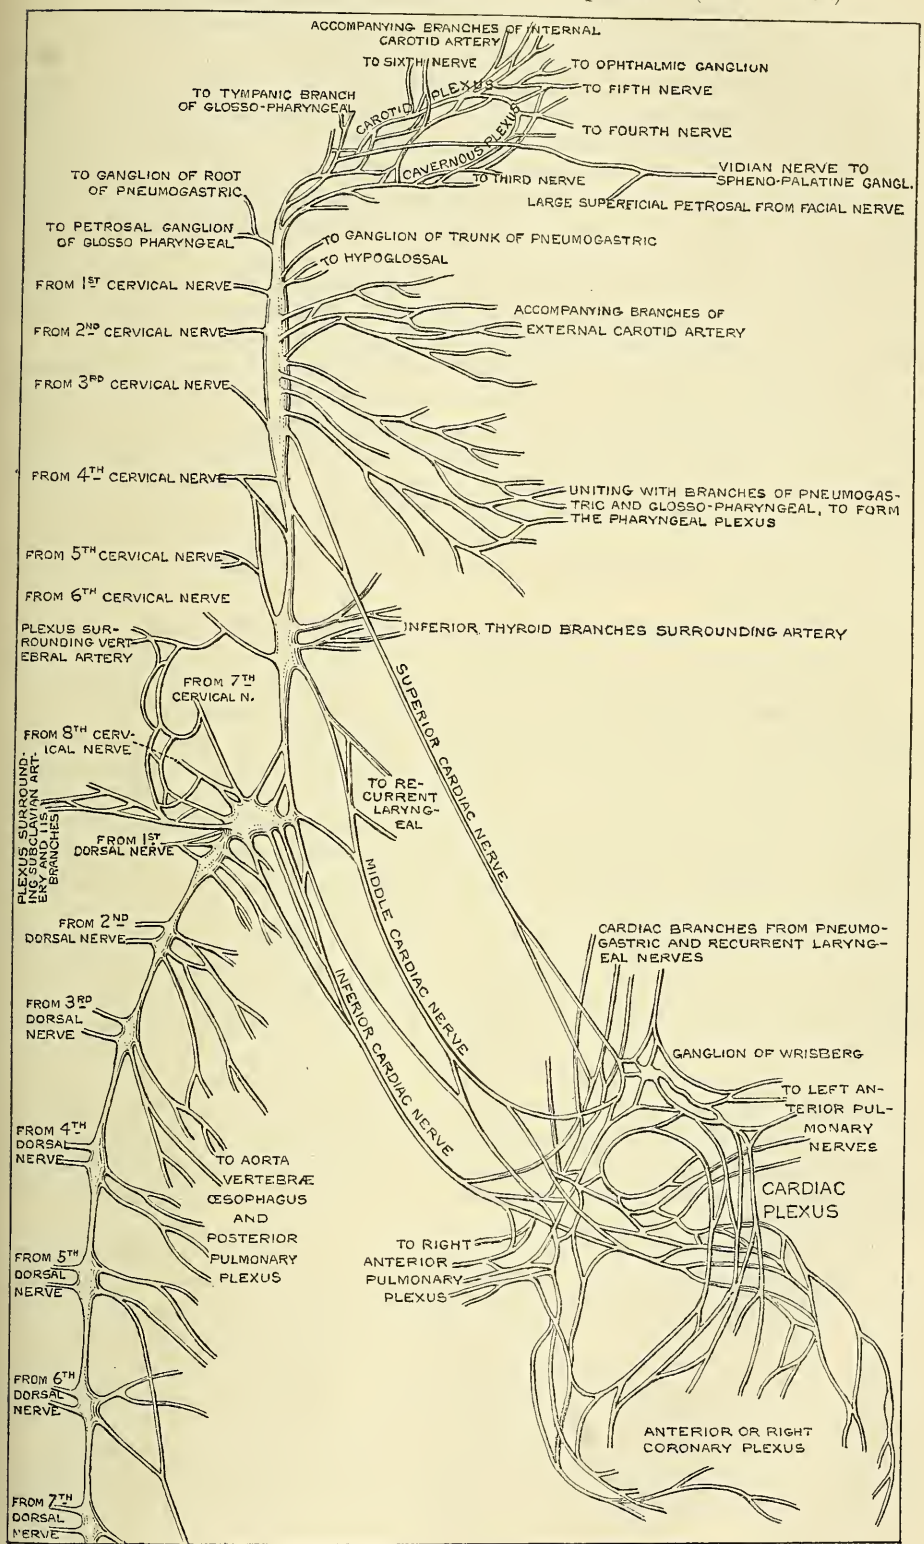
The *outer branch*, the larger of the two, distributes filaments to the internal carotid artery, and forms the *carotid plexus*.

The *inner branch* also distributes filaments to the internal carotid, and, continuing onwards, forms the *cavernous plexus*.

The **carotid plexus** is situated on the outer side of the internal carotid. Filaments from this plexus occasionally form a small gangliform swelling on the under surface of the artery, which is called the carotid ganglion. The carotid plexus communicates with the Gasserian ganglion, with the sixth nerve, and the spheno-palatine ganglion, and distributes filaments to the wall of the carotid artery, and to the dura mater (Valentin); while in the carotid canal it communicates with Jacobson's nerve, the tympanic branch of the glosso-pharyngeal.

The *communicating branches with the sixth nerve* consist of one or two filaments which join that nerve as it lies upon the outer side of the internal carotid. Other filaments are also connected with the Gasserian ganglion. The communication with the spheno-palatine ganglion is effected by a branch, the *large deep petrosal*, which is given off from the plexus on the outer side of the artery, and which passes through the cartilage filling up the foramen lacerum medium, and joins the great superficial petrosal to form the Vidian nerve. The Vidian nerve then proceeds along the pterygoid or Vidian canal to the spheno-palatine ganglion. The communication with Jacobson's nerve is effected by two branches, one of which is called the *small deep petrosal nerve*, and the other the *long petrosal*.

Fig. 518.—Plan of the cervical portion of the sympathetic. (After Flower.)



The **cavernous plexus** is situated below, and internal to that part of the internal carotid which is placed by the side of the sella Turcica, in the cavernous sinus, and is formed chiefly by the internal division of the ascending branch from the superior cervical ganglion. It communicates with the third, the fourth, the ophthalmic division of the fifth, and the sixth nerves, and with the ophthalmic ganglion, and distributes filaments to the wall of the internal carotid. The branch of communication with the third nerve joins it at its point of division; the branch to the fourth nerve joins it as it lies on the outer wall of the cavernous sinus; other filaments are connected with the under surface of the trunk of the ophthalmic nerve; and a second filament of communication joins the sixth nerve.

The filament of connection with the ophthalmic ganglion arises from the anterior part of the cavernous plexus; it accompanies the nasal nerve, or continues forwards as a separate branch.

The terminal filaments from the carotid and cavernous plexuses are prolonged along the internal carotid, forming plexuses which entwine round the cerebral and ophthalmic arteries; along the former vessel they may be traced on to the pia mater; along the latter, into the orbit, where they accompany each of the subdivisions of the vessel, a separate plexus passing, with the arteria centralis retinæ, into the interior of the eyeball. The filaments prolonged on to the anterior communicating artery form a small ganglion, the *ganglion of Ribes*,* which serves, as mentioned above, to connect the sympathetic nerves of the right and left sides.

The **inferior** or **descending branch of the superior cervical ganglion** communicates with the middle cervical ganglion.

The **external branches** are numerous, and communicate with the cranial nerves, and with the four upper spinal nerves. Sometimes the branch to the fourth spinal nerve may come from the cord connecting the upper and middle cervical ganglia. The branches of communication with the cranial nerves consist of delicate filaments, which pass from the superior cervical ganglion to the ganglion of the trunk of the pneumogastric, and to the hypoglossal nerve. A separate filament from the cervical ganglion subdivides and joins the petrosal ganglion of the glosso-pharyngeal, and the ganglion of the root of the pneumogastric in the jugular foramen.

The **internal branches** are three in number: the *pharyngeal*, *laryngeal*, and *superior cardiac nerve*. The *pharyngeal branches* pass inwards to the side of the pharynx, where they join with branches from the glosso-pharyngeal, pneumogastric, and external laryngeal nerves to form the *pharyngeal plexus*. The *laryngeal branches* unite with the superior laryngeal nerve and its branches.

The *superior cardiac nerve* (*nervus superficialis cordis*) arises by two or more branches from the superior cervical ganglion, and occasionally receives a filament from the cord of communication between the first and second cervical ganglia. It runs down the neck behind the common carotid artery, lying upon the Longus colli muscle; and crosses in front of the inferior thyroid artery, and recurrent laryngeal nerve.

The *right superior cardiac nerve*, at the root of the neck, passes either in front of or behind the subclavian artery, and along the arteria innominata, to the back part of the arch of the aorta, where it joins the deep cardiac plexus. This nerve, in its course, is connected with other branches of the sympathetic; about the middle of the neck it receives filaments from the external laryngeal nerve; lower down, one or two twigs from the pneumogastric; and as it enters the thorax it is joined by a filament from the recurrent laryngeal. Filaments from this nerve communicate with the thyroid branches from the middle cervical ganglion.

The *left superior cardiac nerve*, in the chest, runs by the side of the left common carotid artery, and in front of the arch of the aorta, to the superficial

* The existence of this ganglion is doubted by some observers.

cardiac plexus ; but occasionally it passes behind the aorta, and terminates in the deep cardiac plexus.

The **anterior branches** ramify upon the external carotid artery and its branches, forming round each a delicate plexus, on the nerves composing which small ganglia are occasionally found. These ganglia have been named, according to their position, intercarotid* (placed at the angle of bifurcation of the common carotid), lingual, temporal, and pharyngeal. The plexuses accompanying some of these arteries have important communications with other nerves. That surrounding the external carotid is connected with the branch of the facial nerve to the stylo-hyoid muscle; that surrounding the facial communicates with the submaxillary ganglion by one or two filaments ; and that accompanying the middle meningeal artery sends offsets which pass to the otic ganglion and to the intumescentia ganglioformis of the facial nerve (external petrosal).

The **Middle Cervical Ganglion** (*thyroid ganglion*) is the smallest of the three cervical ganglia, and is occasionally altogether wanting. It is placed opposite the sixth cervical vertebra, usually upon, or close to, the inferior thyroid artery ; hence the name 'thyroid ganglion,' assigned to it by Haller. It is probably formed by the coalescence of two ganglia corresponding to the fifth and sixth cervical nerves.

Its *superior branches* ascend to communicate with the superior cervical ganglion.

Its *inferior branches* descend to communicate with the inferior cervical ganglion.

Its *external branches* pass outwards to join the fifth and sixth spinal nerves. These branches are not constantly found.

Its *internal branches* are the thyroid and the middle cardiac nerve.

The *thyroid branches* are small filaments, which accompany the inferior thyroid artery to the thyroid gland ; they communicate, on the artery, with the superior cardiac nerve, and, in the gland, with branches from the recurrent and external laryngeal nerves.

The *middle cardiac nerve* (*nervus cardiacus magnus*), the largest of the three cardiac nerves, arises from the middle cervical ganglion, or from the cord between the middle and inferior ganglia. On the right side it descends behind the common carotid artery ; and at the root of the neck passes either in front of or behind the subclavian artery ; it then descends on the trachea, receives a few filaments from the recurrent laryngeal nerve, and joins the right side of the deep cardiac plexus. In the neck, it communicates with the superior cardiac and recurrent laryngeal nerves. On the left side, the middle cardiac nerve enters the chest between the left carotid and subclavian arteries, and joins the left side of the deep cardiac plexus.

The **Inferior Cervical Ganglion** is situated between the base of the transverse process of the last cervical vertebra and the neck of the first rib, on the inner side of the superior intercostal artery. Its form is irregular ; it is larger in size than the preceding, and frequently joined with the first thoracic ganglion. It is probably formed by the coalescence of two ganglia which correspond to the two last cervical nerves.

Its *superior branches* communicate with the middle cervical ganglion.

Its *inferior branches* descend, some in front of, others behind the subclavian artery, to join the first thoracic ganglion.

Its *internal branch* is the inferior cardiac nerve.

The *inferior cardiac nerve* (*nervus cardiacus minor*) arises from the inferior cervical or first thoracic ganglion. It passes down behind the subclavian artery and along the front of the trachea, to join the deep cardiac plexus. It communicates freely behind the subclavian artery with the recurrent laryngeal and middle cardiac nerves.

* This ganglion is of the same structure as the coccygeal gland (Luschka).

The *external branches* consist of several filaments, some of which communicate with the seventh and eighth spinal nerves; others accompany the vertebral artery along the vertebral canal, forming a plexus round the vessel, supplying it with filaments, which are continued up the vertebral and basilar to the cerebral arteries. The branches communicate with the cervical spinal nerves.

Thoracic Portion of the Gangliated Cord

The thoracic portion of the gangliated cord consists of a series of ganglia, which usually correspond in number to that of the vertebræ; but, from the occasional coalescence of two, their number is uncertain. These ganglia are placed on each side of the spine, resting against the heads of the ribs, and covered by the pleura costalis; the last two are, however, anterior to the rest, being placed on the side of the bodies of the eleventh and twelfth dorsal vertebræ. The ganglia are small in size, and of a greyish colour. The first, larger than the rest, is of an elongated form, and frequently blended with the last cervical. They are connected together by cord-like prolongations from their substance.

The *external branches* from each ganglion, usually two in number, communicate with each of the dorsal spinal nerves.

The *internal branches from the five or six upper ganglia* are very small; they supply filaments to the thoracic aorta and its branches, besides small branches to the bodies of the vertebræ and their ligaments. Branches from the third and fourth, and sometimes, also, from the first and second ganglia form part of the posterior pulmonary plexus.

The *internal branches from the six or seven lower ganglia* are large and white in colour; they distribute filaments to the aorta, and unite to form the three splanchnic nerves. These are named the *great*, the *lesser*, and the *smallest* or *renal splanchnic*.

The *great splanchnic nerve* is of a white colour, firm in texture, and bears a marked contrast to the ganglionic nerves. It is formed by branches from the thoracic ganglia between the fifth or sixth and the ninth or tenth, receiving filaments (according to Dr. Beck) from all the thoracic ganglia above the sixth. These roots unite to form a large round cord of considerable size. It descends obliquely inwards in front of the bodies of the vertebræ along the posterior mediastinum, perforates the crus of the Diaphragm, and terminates in the semilunar ganglion of the solar plexus, distributing filaments to the renal and suprarenal plexus.

The *lesser splanchnic nerve* is formed by filaments from the tenth and eleventh ganglia, and from the cord between them. It pierces the Diaphragm with the preceding nerve, and joins the solar plexus. It communicates in the chest with the great splanchnic nerve, and occasionally sends filaments to the renal plexus.

The *smallest*, or *renal splanchnic nerve* arises from the last ganglion, and, piercing the Diaphragm, terminates in the renal plexus and lower part of the solar plexus. It occasionally communicates with the preceding nerve.

A striking analogy appears to exist between the splanchnic and the cardiac nerves. The cardiac nerves are three in number; they arise from the three cervical ganglia, and are distributed to a large and important organ in the thoracic cavity. The splanchnic nerves, also three in number, are connected probably with all the dorsal ganglia, and are distributed to important organs in the abdominal cavity.

The Lumbar Portion of the Gangliated Cord

The lumbar portion of the gangliated cord is situated in front of the vertebral column, along the inner margin of the Psoas muscle. It consists usually of four ganglia, connected together by interganglionic cords. The ganglia are of small size, of a greyish colour, shaped like a barleycorn, and placed much nearer the median line than the thoracic ganglia.

The *superior* and *inferior branches of the lumbar ganglia* serve as communicating branches between the chain of ganglia in this region. They are usually single, and of a white colour.

The *external branches* communicate with the lumbar spinal nerves. From the situation of the lumbar ganglia, these branches are longer than in the other regions. They are usually two in number from each ganglion, but their connection with the spinal nerves is not so uniform as in other regions. They accompany the lumbar arteries around the sides of the bodies of the vertebræ, passing beneath the fibrous arches from which some of the fibres of the Psoas muscle arise.

Of the *internal branches*, some pass inwards, in front of the aorta, and help to form the aortic plexus. Other branches descend in front of the common iliac arteries, and join over the promontory of the sacrum, helping to form the hypogastric plexus. Numerous delicate filaments are also distributed to the bodies of the vertebræ, and the ligaments connecting them.

Pelvic Portion of the Gangliated Cord

The pelvic portion of the gangliated cord is situated in front of the sacrum, along the inner side of the anterior sacral foramina. It consists of four or five small ganglia on each side, connected together by interganglionic cords. Below, these cords converge and unite on the front of the coccyx, by means of a small ganglion (the *coccygeal ganglion*, or *ganglion impar*).

The *superior* and *inferior branches* are the cords of communication between the ganglia above and below.

The *external branches*, exceedingly short, communicate with the sacral nerves. They are two in number from each ganglion. The coccygeal nerve communicates either with the last sacral, or coccygeal ganglion.

The *internal branches* communicate, on the front of the sacrum, with the corresponding branches from the opposite side; some, from the first two ganglia, pass to join the pelvic plexus, and others form a plexus, which accompanies the middle sacral artery and sends filaments to the coccygeal gland.

THE GREAT PLEXUSES OF THE SYMPATHETIC

The great plexuses of the sympathetic are the large aggregations of nerves and ganglia, above alluded to, situated in the thoracic, abdominal, and pelvic cavities respectively. From them are derived the branches which supply the viscera.

The Cardiac Plexus

The cardiac plexus is situated at the base of the heart, and is divided into a *superficial part*, which lies in the concavity of the arch of the aorta, and a *deep part*, which lies between the trachea and aorta. The two plexuses are, however, closely connected.

The **great** or **deep cardiac plexus** (*plexus magnus profundus*, Scarpa) is situated in front of the trachea at its bifurcation, above the point of division of the pulmonary artery, and behind the arch of the aorta. It is formed by the cardiac nerves derived from the cervical ganglia of the sympathetic, and the cardiac branches of the recurrent laryngeal and pneumogastric. The only cardiac nerves which do not enter into the formation of this plexus are the left superior cardiac nerve, and the inferior cervical cardiac branch from the left pneumogastric.

The branches from the *right side* of this plexus pass, some in front of, and others behind, the right pulmonary artery; the former, the more numerous, transmit a few filaments to the anterior pulmonary plexus, and are then

continued onwards to form part of the anterior coronary plexus; those behind the pulmonary artery distribute a few filaments to the right auricle, and are then continued onwards to form part of the posterior coronary plexus.

The branches from the *left side* of the deep cardiac plexus distribute a few filaments to the superficial cardiac plexus, to the left auricle of the heart, and to the anterior pulmonary plexus, and then pass on to form the greater part of the posterior coronary plexus.

The **superficial (anterior) cardiac plexus** lies beneath the arch of the aorta, in front of the right pulmonary artery. It is formed by the left superior cardiac nerve, the inferior cervical cardiac branches of the left (and occasionally the right) pneumogastric, and filaments from the deep cardiac plexus. A small ganglion (*cardiac ganglion of Wrisberg*) is occasionally found connected with these nerves at their point of junction. This ganglion, when present, is situated immediately beneath the arch of the aorta, on the right side of the ductus arteriosus. The superficial cardiac plexus forms the chief part of the anterior coronary plexus, and several filaments pass along the pulmonary artery to the left anterior pulmonary plexus.

The **posterior** or **right coronary plexus** is chiefly formed by filaments prolonged from the left side of the deep cardiac plexus, and by a few from the right side. It surrounds the branches of the coronary artery at the back of the heart, and its filaments are distributed with those vessels to the muscular substance of the ventricles.

The **anterior** or **left coronary plexus** is formed chiefly from the superficial cardiac plexus, but receives filaments from the deep cardiac plexus. Passing forwards between the aorta and pulmonary artery, it accompanies the left coronary artery on the anterior surface of the heart.

Valentin has described nervous filaments ramifying under the endocardium; and Remak has found, in several mammalia, numerous small ganglia on the cardiac nerves, both on the surface of the heart and in its muscular substance.

The Epigastric or Solar Plexus (figs. 517, 519)

The **Epigastric** or **Solar plexus** supplies all the viscera in the abdominal cavity. It consists of a great network of nerves and ganglia situated behind the stomach and in front of the aorta and crura of the Diaphragm. It surrounds the cœliac axis and root of the superior mesenteric artery, extending downwards as low as the pancreas, and outwards to the suprarenal capsules. This plexus, and the ganglia connected with it, receive the great and small splanchnic nerves of both sides, and some filaments from the right pneumogastric. It distributes filaments, which accompany, under the name of plexuses, all the branches from the front of the abdominal aorta.

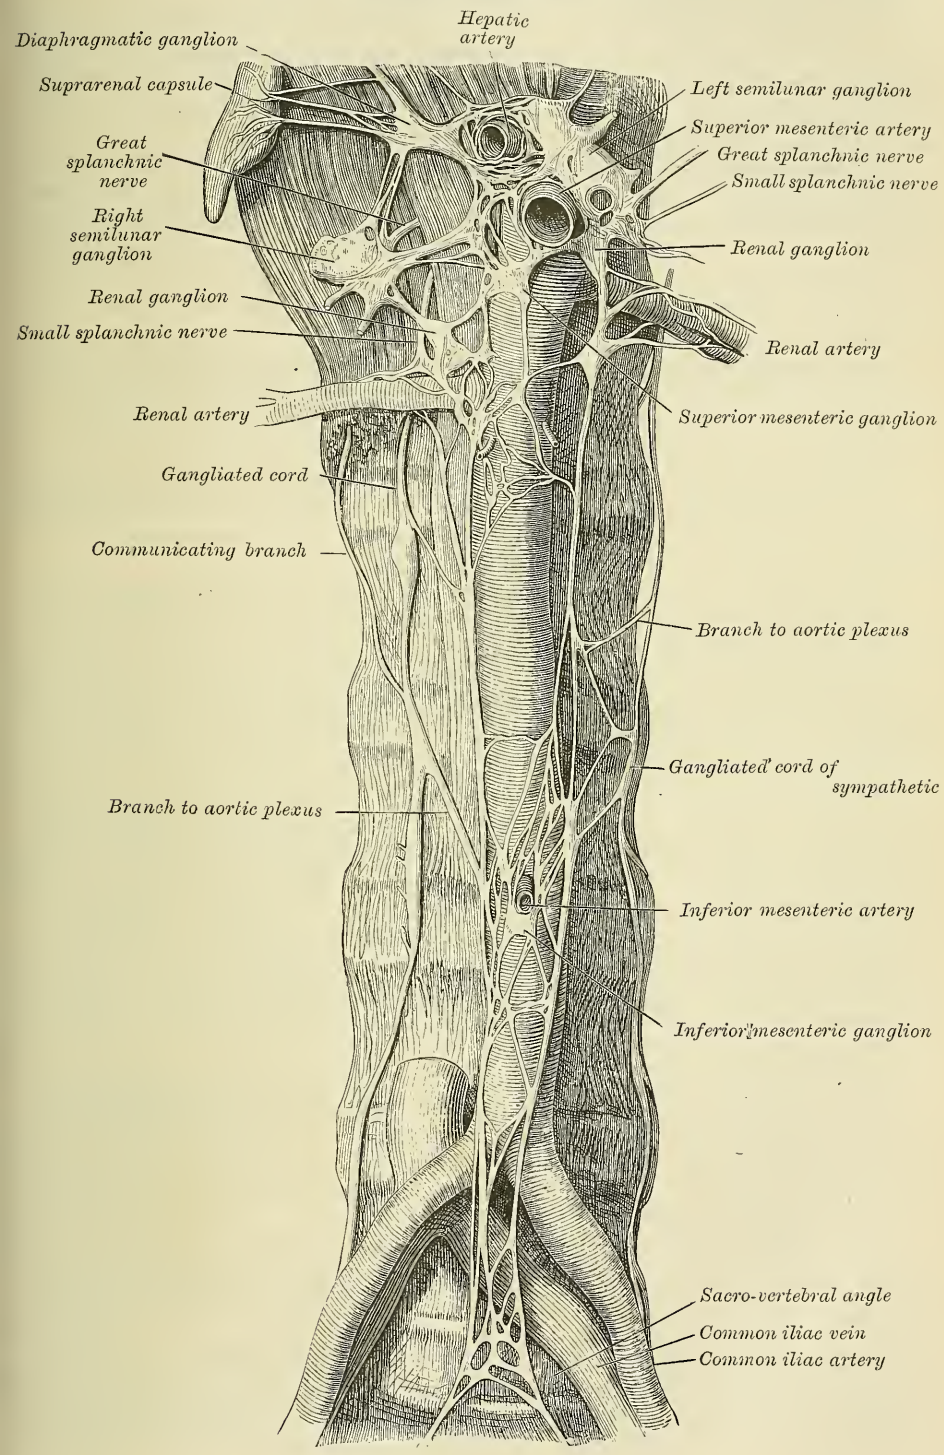
Of the ganglia of which the solar plexus is partly composed the principal are the two **semilunar ganglia**, which are situated one on each side of the plexus, and are the largest ganglia in the body. They are large irregular gangliform masses, formed by the aggregation of smaller ganglia, having interspaces between them. They are situated in front of the crura of the Diaphragm, close to the suprarenal capsules: the one on the right side lies beneath the inferior vena cava; the upper part of each ganglion is joined by the greater splanchnic nerve, and to the inner side of each the branches of the solar plexus are connected.

From the epigastric or solar plexus are derived the following:

Phrenic or Diaphragmatic plexus.
Suprarenal plexus.
Renal plexus.
Spermatic plexus.
Cœliac plexus — Gastric plexus; Splenic plexus; Hepatic plexus.
Superior mesenteric plexus.
Aortic plexus.

The **phrenic plexus** accompanies the phrenic artery to the Diaphragm, which it supplies; some filaments passing to the suprarenal capsule. It arises from the upper part of the semilunar ganglion, and is larger on the right than on the left

FIG. 519.—Lumbar portion of the gangliated cord, with the solar and hypogastric plexuses. (After Henle.)



side. It receives one or two branches from the phrenic nerve. In connection with this plexus, on the right side, at its point of junction with the phrenic nerve, is a small ganglion (*ganglion diaphragmaticum*). This ganglion is placed on the under surface of the Diaphragm, near the suprarenal capsule. Its branches are distributed to the inferior vena cava, suprarenal capsule, and the hepatic plexus. There is no ganglion on the left side.

The **suprarenal plexus** is formed by branches from the solar plexus, from the semilunar ganglion, and from the phrenic and great splanchnic nerves, a ganglion being formed at the point of junction of the latter nerve. It supplies the suprarenal capsule. The branches of this plexus are remarkable for their large size, in comparison with the size of the organ they supply.

The **renal plexus** is formed by filaments from the solar plexus, the outer part of the semilunar ganglion, and the aortic plexus. It is also joined by filaments from the lesser and smallest splanchnic nerves. The nerves from these sources, fifteen or twenty in number, have numerous ganglia developed upon them. They accompany the branches of the renal artery into the kidney; some filaments on the right side being distributed to the inferior vena cava, and others to the spermatic plexus, on both sides.

The **spermatic plexus** is derived from the renal plexus, receiving branches from the aortic plexus. It accompanies the spermatic vessels to the testes.

In the female, the **ovarian plexus** is distributed to the ovaries and fundus of the uterus.

The **cœliac plexus**, of large size, is a direct continuation from the solar plexus: it surrounds the cœliac axis, and subdivides into the gastric, hepatic, and splenic plexuses. It receives branches from the lesser splanchnic nerves, and, on the left side, a filament from the right pneumogastric.

The *gastric* or *coronary plexus* accompanies the gastric artery along the lesser curvature of the stomach, and joins with branches from the left pneumogastric nerve. It is distributed to the stomach.

The *hepatic plexus*, the largest offset from the cœliac plexus, receives filaments from the left pneumogastric and right phrenic nerves. It accompanies the hepatic artery, ramifying in the substance of the liver upon its branches, and upon those of the vena portæ.

Branches from this plexus accompany all the divisions of the hepatic artery. Thus there is a *pyloric plexus* accompanying the pyloric branch of the hepatic, which joins with the gastric plexus and pneumogastric nerves. There is also a *gastro-duodenal plexus*, which subdivides into the *pancreatico-duodenal plexus*, which accompanies the pancreatico-duodenal artery, to supply the pancreas and duodenum, joining with branches from the mesenteric plexus; and a *gastro-epiploic plexus*, which accompanies the right gastro-epiploic artery along the greater curvature of the stomach, and anastomoses with branches from the splenic plexus. A *cystic plexus*, which supplies the gall-bladder, also arises from the hepatic plexus, near the liver.

The *splenic plexus* is formed by branches from the cœliac plexus, the left semilunar ganglia, and from the right pneumogastric nerve. It accompanies the splenic artery and its branches to the substance of the spleen, giving off, in its course, filaments to the pancreas (*pancreatic plexus*), and the *left gastro-epiploic plexus*, which accompanies the gastro-epiploica sinistra artery along the convex border of the stomach.

The **superior mesenteric plexus** is a continuation of the lower part of the great solar plexus, receiving a branch from the junction of the right pneumogastric nerve with the cœliac plexus. It surrounds the superior mesenteric artery, which it accompanies into the mesentery, and divides into a number of secondary plexuses, which are distributed to all the parts supplied by the artery, viz. pancreatic branches to the pancreas; intestinal branches, which supply the whole of the small intestine; and ileo-colic, right colic, and middle colic branches, which supply the corresponding parts of the great intestine. The nerves com-

posing this plexus are white in colour and firm in texture, and have numerous ganglia developed upon them near their origin.

The **aortic plexus** is formed by branches derived, on each side, from the solar plexus and the semilunar ganglia, receiving filaments from some of the lumbar ganglia. It is situated upon the sides and front of the aorta, between the origins of the superior and inferior mesenteric arteries. From this plexus arise part of the spermatic, the inferior mesenteric, and the hypogastric plexuses; and it distributes filaments to the inferior vena cava.

The *inferior mesenteric plexus* is derived chiefly from the left side of the aortic plexus. It surrounds the inferior mesenteric artery, and divides into a number of secondary plexuses, which are distributed to all the parts supplied by the artery, viz. the left colic and sigmoid plexuses, which supply the descending and sigmoid flexure of the colon: and the superior hæmorrhoidal plexus, which supplies the upper part of the rectum, and joins in the pelvis with branches from the pelvic plexus.

Hypogastric Plexus

The **Hypogastric Plexus** supplies the viscera of the pelvic cavity. It is situated in front of the promontory of the sacrum, between the two common iliac arteries, and is formed by the union of numerous filaments, which descend on each side from the aortic plexus, and from the lumbar ganglia. This plexus contains no ganglia; and bifurcates, below, into two lateral portions, which form the *pelvic plexus*.

Pelvic Plexus

The **Pelvic Plexus** (sometimes called *inferior hypogastric*) supplies the viscera of the pelvic cavity, is situated at the sides of the rectum in the male, and at the sides of the rectum and vagina in the female. It is formed by a continuation of the hypogastric plexus, by branches from the second, third, and fourth sacral nerves, and by a few filaments from the first two sacral ganglia. At the point of junction of these nerves, small ganglia are found. From this plexus numerous branches are distributed to all the viscera of the pelvis. They accompany the branches of the internal iliac artery.

The **inferior hæmorrhoidal plexus** arises from the back part of the pelvic plexus. It supplies the rectum, joining with branches of the superior hæmorrhoidal plexus.

The **vesical plexus** arises from the fore part of the pelvic plexus. The nerves composing it are numerous, and contain a large proportion of spinal nerve-fibres. They accompany the vesical arteries, and are distributed to the side and base of the bladder. Numerous filaments also pass to the vesiculæ seminales and vas deferens; those accompanying the vas deferens join, on the spermatic cord, with branches from the spermatic plexus.

The **prostatic plexus** is continued from the lower part of the pelvic plexus. The nerves composing it are of large size. They are distributed to the prostate gland, vesiculæ seminales, and erectile structure of the penis. The nerves supplying the erectile structure of the penis consist of two sets, the small and large cavernous nerves. They are slender filaments, which arise from the fore part of the prostatic plexus, and, after joining with branches from the internal pudic nerve, pass forwards beneath the pubic arch.

The *small cavernous nerves* perforate the fibrous covering of the penis, near its root.

The *large cavernous nerve* passes forwards along the dorsum of the penis, joins with the dorsal branch of the pudic nerve, and is distributed to the corpus cavernosum and spongiosum.

The **vaginal plexus** arises from the lower part of the pelvic plexus. It is lost

on the walls of the vagina, being distributed to the erectile tissue at its anterior part and to the mucous membrane. The nerves composing this plexus contain, like the vesical, a large proportion of spinal nerve-fibres.

The **uterine plexus** arises from the upper part of the pelvic plexus, above the point where the branches from the sacral nerves join the plexus. Its branches accompany the uterine arteries to the side of the organ between the layers of the broad ligament, and are distributed to the cervix and lower part of the body of the uterus, penetrating its substance.

Other filaments pass separately to the body of the uterus and Fallopian tube.

Branches from the plexus accompany the uterine arteries into the substance of the uterus. Upon these filaments ganglionic enlargements are found.

ORGANS OF SENSE

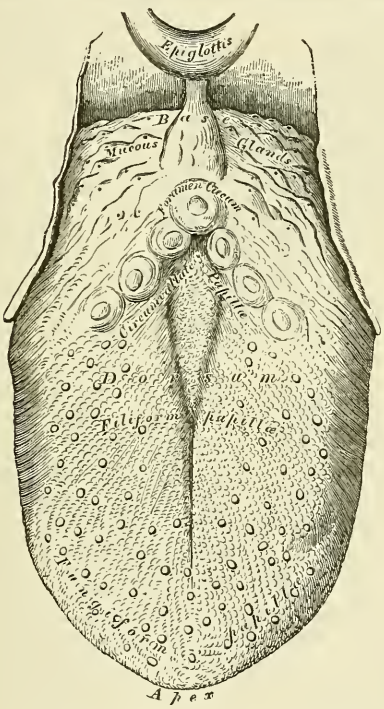
THE Organs of the Senses are five in number: viz. those of Touch, of Taste, of Smell, of Hearing, and of Sight. The skin, which is the principal seat of the sense of touch, has been described in the chapter on General Anatomy.

THE TONGUE

The tongue is the organ of the special sense of taste. It is situated in the floor of the mouth, in the interval between the two lateral portions of the body of the lower jaw.

Its base, or root, is directed backwards, and connected with the os hyoides by the Hyo-glossi and Genio-hyo-glossi muscles and the hyo-glossal membrane;

Fig. 520.—Upper surface of the tongue.



with the epiglottis by three folds of mucous membrane, which form the *glosso-epiglottic ligaments*; with the soft palate by means of the anterior pillars of the fauces; and with the pharynx by the Superior constrictors and the mucous membrane. Its apex, or tip, thin and narrow, is directed forwards against the inner surface of the lower incisor teeth. The under surface of the tongue is connected with the lower jaw by the Genio-hyo-glossi muscles; from its sides, the mucous membrane is reflected to the inner surface of the gums; and, in front, a distinct fold of that membrane, the *frænum linguæ*, is formed beneath its under surface.

The tip of the tongue, part of the under surface, its sides, and dorsum are free.

The dorsum of the tongue is convex, marked along the middle line by a raphé, which divides it into symmetrical halves; this raphé terminates behind, about an inch from the base of the organ, in a depression, the *foramen cæcum*. The anterior two-thirds of this surface are rough and covered with papillæ; the posterior third is smoother, and covered by the projecting orifices of numerous muciparous glands.

Structure of the tongue.—The tongue is partly invested by mucous membrane and a submucous fibrous layer. It consists of symmetrical halves, separated from each other, in the middle line, by a fibrous septum. Each half is composed of muscular fibres arranged in various directions (page 415), containing much interposed fat, and supplied by vessels and nerves.

The **mucous membrane** invests the entire extent of the free surface of the tongue. On the dorsum it is thicker behind than in front, and is continuous with the sheaths of the muscles attached to it, through the submucous fibrous layer. On the under surface of the organ, where it is thin and smooth, it can be traced on each side of the frænum, through the ducts of the submaxillary and the sublingual glands. As it passes over the borders of the organ, it gradually assumes its papillary character.

The **structure of the mucous membrane of the tongue** differs in different parts. That covering the under surface of the organ is thin, smooth, and identical in

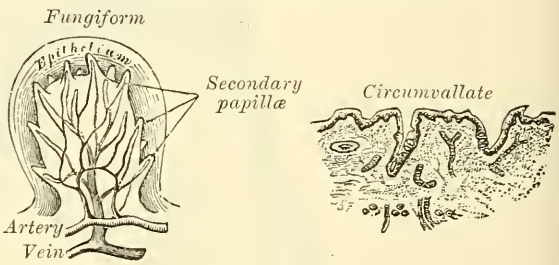


FIG. 521.—The three kinds of papillæ, magnified.

structure with that lining the rest of the oral cavity. The mucous membrane on the anterior part of the dorsum of the tongue is thin and intimately adherent to the muscular tissue, whilst that at the root is much thicker and looser. It consists of a layer of connective tissue, the *corium* or *mucosa*, supporting numerous *papillæ*, and covered, as well as the papillæ, with *epithelium*.

The epithelium is of the scaly variety, like that of the epidermis. It covers the free surface of the tongue, as may be easily demonstrated by maceration or boiling, when it can be easily detached entire: it is much thinner than on the skin: the intervals between the large papillæ are not filled up by it, but each papilla has a separate investment from root to summit. The deepest cells may sometimes be detached as a separate layer, corresponding to the rete mucosum, but they never contain colouring matter.

The *corium* consists of a dense felt-work of fibrous connective tissue, with numerous elastic fibres, firmly connected with the fibrous tissue forming the septa between the muscular bundles of the tongue. It contains the ramifications of the numerous vessels and nerves from which the papillæ are supplied, large plexuses of lymphatic vessels, and the glands of the tongue.

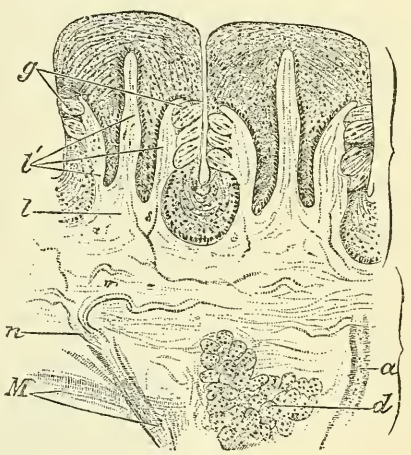
The papillæ of the tongue.—These are papillary projections of the corium. They are thickly distributed over the anterior two-thirds of its upper surface, giving to it its characteristic roughness. The varieties of papillæ met with are the

papillæ maximæ (*circumvallatæ*), papillæ mediæ (*fungiformes*), papillæ minimæ (*conicæ* or *filiformes*), and papillæ simplices.

The *papillæ maximæ* (circumvallatæ) are of large size, and vary from eight to twelve in number. They are situated at the back part of the dorsum of the tongue, near its base, forming a row on each side, which, running backwards and inwards, meet in the middle line, like the two lines of the letter V inverted. Each papilla consists of a projection of mucous membrane from $\frac{1}{20}$ to $\frac{1}{12}$ of an inch wide, attached to the bottom of a cup-shaped depression of the mucous membrane; the papilla is in shape like a truncated cone; the smaller end being directed downwards and attached to the tongue, the broader part or base projecting on the surface and being studded with numerous small secondary papillæ, which, however, are covered by a smooth layer of the epithelium. The cup-shaped depression forms a kind of fossa round the papilla, having a circular margin of about the same elevation, covered with smaller papillæ. At the point of junction of the two rows of papillæ is the deep depression, the *foramen cæcum*, mentioned above.

The *papillæ mediæ* (fungiformes), more numerous than the preceding, are scattered irregularly and sparingly over the dorsum of the tongue; but are found chiefly at its sides and apex. They are easily recognised, among the other papillæ, by their large size, rounded eminences, and deep red colour. They are narrow at their attachment to the tongue, but broad and rounded at their free extremities, and covered with secondary papillæ. Their epithelial investment is very thin.

FIG. 522.—Circumvallate papillæ of tongue of rabbit, showing position of taste-goblets. (Stöhr.)



a. Duct of gland. *d*. Serous gland. *g*. Taste-goblets. *l*. Primary septa, and *l'*, secondary septa, of papillæ. *n*. Medullated nerve. *M*. Muscular fibres.

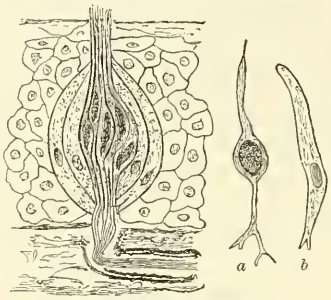
The *papillæ minimæ* (conicæ or filiformes) cover the anterior two-thirds of the dorsum of the tongue. They are very minute, more or less conical or filiform in shape, and arranged in lines corresponding in direction with the two rows of the papillæ circumvallatæ; excepting at the apex of the organ, where their direction is transverse. They have projecting from their apices numerous filiform processes, or secondary papillæ, which are of a whitish tint, owing to the thickness and density of the epithelium of which they are composed, and which has here undergone a peculiar modification, the cells having become cornified and elongated into dense, imbricated, brush-like processes. They contain also a number of elastic fibres, which render them firmer and more elastic than the papillæ of mucous membrane generally.

Simple papillæ, similar to those of the skin, cover the whole of the mucous membrane of the tongue, as well as the larger papillæ. They consist of closely set, microscopic elevations of the corium, containing a capillary loop, covered by a layer of epithelium.

Structure of the papillæ.—The papillæ apparently resemble in structure those of the cutis, consisting of a cone-shaped projection of connective tissue, covered with a thick layer of squamous epithelium, and contain one or more capillary loops, amongst which nerves are distributed in great abundance. If the epithelium is removed, it will be found that they are not simple elevations like the papillæ of the skin, for the surface of each is studded with minute conical processes of the mucous membrane, which form secondary papillæ (Todd and Bowman). In the papillæ circumvallatæ, the nerves are numerous and of large size; in the papillæ fungiformes, they are also numerous, and terminate in a plexiform network, from

which brush-like branches proceed; in the papillæ filiformes, their mode of termination is uncertain. Buried in the epidermis of the papillæ circumvallatæ, and in some of the fungiformes, certain peculiar bodies called *taste-goblets* have been described.* They are flask-like in shape, their broad base resting on the corium, and their neck opening by an orifice between the cells of the epithelium. They are formed by two kinds of cells: the external (cortical) are arranged in several layers; they are long and flattened, with tapering ends, and in contact by their edges; the tapering extremities extending from the base to the apex of the organ. They thus enclose the central cells (gustatory cells), which are spindle-shaped, and have a large spherical nucleus about the middle of the cell. Both extremities are filamentous, the outer or peripheral passes to the orifice of the taste-goblet, where it ends in an extremely fine projection, the *taste-hair*: the inner or central process is often branched, and was supposed by Engelmann to be continuous with the terminal fibril of a nerve; the investigations of Lenhossék and others would seem to prove, however, that this is not so, but that the nerve fibrils after losing their medullary sheaths enter the taste-goblet, and terminate in a fine extremity between the gustatory cells. Other nerve fibrils may be seen ramifying between the cortical cells and terminating in fine extremities; these, however, are believed to be nerves of ordinary sensation and not gustatory.

Fig. 523.—Taste-goblets.

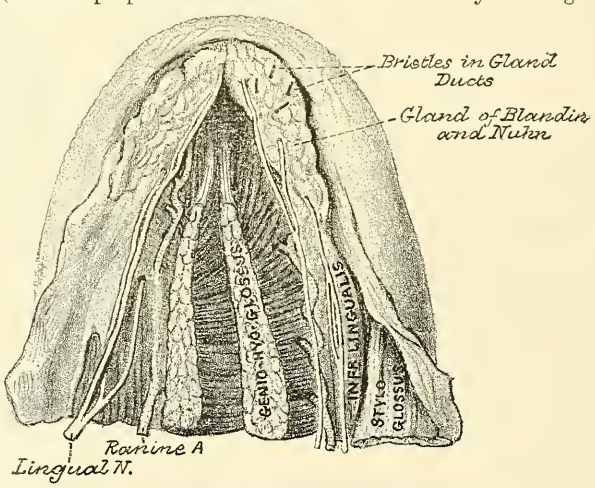


a. Central cell. *b*. Cortical cell.

Glands of the tongue.—The tongue is provided with mucous and serous glands and lymphoid follicles.

The *mucous glands* are similar in structure to the labial and buccal glands. They are found all over the surface of the mucous membrane of the tongue,

Fig. 524.—Under surface of tongue, showing position and relations of gland of Blandin and Nuhn. (From a preparation in the Museum of the Royal College of Surgeons.)



especially at the back part behind the circumvallate papillæ, but also at the apex and marginal parts. In connection with these glands, a special one has been described by Blandin and Nuhn. It is situated near the apex of the tongue on either side of the frænum, and is covered over by a fasciculus of muscular fibre derived from the Stylo-glossus and Inferior lingualis. It is from half an inch to

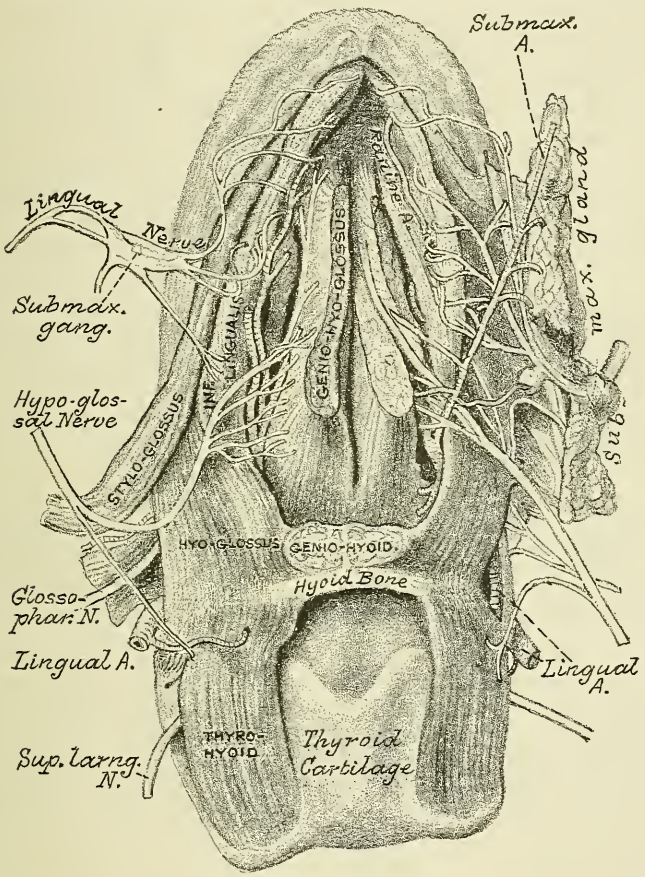
* These bodies are also found in considerable numbers at the side of the base of the tongue, just in front of the anterior pillars of the fauces, and on the posterior surface of the epiglottis and anterior surface of the soft palate.

nearly an inch long, and about the third of an inch broad. It has from four to six ducts, which open on the under surface of the apex.

The *serous glands* occur only at the back of the tongue in the neighbourhood of the taste-goblets, their ducts opening for the most part into the fossæ of the circumvallate papillæ. These glands are racemose, the duct branching into several minute ducts, which terminate in alveoli, lined by a single layer of more or less columnar epithelium. Their secretion is of a watery nature, and probably assists in the distribution of the substance to be tasted over the taste area. (Ebner.)

The lymphoid follicles.—The *lymphoid tissue* is situated, for the most part, at the back of the tongue, between the epiglottis and the circumvallate papillæ, and

Fig. 525.—Under surface of tongue, showing the distribution of nerves to this organ. (From a preparation in the Museum of the Royal College of Surgeons.)



is collected at numerous points into distinct masses known as *lymphoid follicles*. Here and there in this situation are depressions in the mucous membrane surrounded by nodules of lymphoid tissue, similar to the structure found in the tonsil: into them open some of the ducts of the mucous glands.

The *fibrous septum* consists of a vertical layer of fibrous tissue, extending throughout the entire length of the middle line of the tongue, from the base to the apex, though not quite reaching the dorsum. It is thicker behind than in front, and occasionally contains a small fibro-cartilage, about a quarter of an inch in length. It is well displayed by making a vertical section across the organ.

The **Hyo-glossal membrane** is a strong fibrous lamina, which connects the

under surface of the base of the tongue to the body of the hyoid bone. This membrane receives, in front, some of the fibres of the Genio-hyo-glossi.

Vessels of the tongue.—The *arteries of the tongue* are derived from the lingual, the facial, and ascending pharyngeal. The *veins of the tongue* accompany the arteries.

Muscles of the Tongue.—The muscular fibres of the tongue run in various directions. These fibres are divided into two sets, Extrinsic and Intrinsic.

The *Extrinsic muscles of the tongue* are those which have their origin external to it, and only their terminal fibres contained in the substance of the organ. They are the Stylo-glossus, the Hyo-glossus, the Palato-glossus, the Genio-hyo-glossus, and part of the Superior constrictor of the pharynx (Pharyngo-glossus).

The *Intrinsic muscles* are those which are contained entirely within the tongue, and form the greater part of its substance. Both sets have been already described (page 413 *et seq.*).

The *lymphatic vessels from the tongue* pass to one or two small glands situated on the Hyo-glossus muscle in the submaxillary region, and from thence to the deep glands of the neck.

The *nerves of the tongue* are five in number in each half: the lingual branch of the fifth, which is distributed to the papillæ at the fore part and sides of the tongue; the lingual branch of the glosso-pharyngeal, which is distributed to the mucous membrane at the base and side of the tongue, and to the papillæ circumvallatæ; the hypoglossal nerve, which is distributed to the muscular substance of the tongue; the chorda tympani from the facial which joins the lingual and accompanies it to the fore part and sides of the tongue, to which parts it probably serves as a nerve of taste; and the superior laryngeal, which sends some fine branches to the root near to the epiglottis. Sympathetic filaments also pass to the tongue from the nervi molles on the lingual and other arteries supplying it. The glosso-pharyngeal branch is the special nerve of the sense of taste; the lingual (gustatory) is the nerve of common sensation; and the hypoglossal is the motor nerve of the tongue.

Surgical Anatomy.—The diseases to which the tongue is liable are numerous, and its surgical anatomy of importance, since any or all the structures of which it is composed—muscles, connective tissue, mucous membrane, glands, vessels, nerves, and lymphatics—may be the seat of morbid changes. It is not often the seat of congenital defects, though a few cases of vertical cleft have been recorded, and it is occasionally, though much more rarely than is commonly supposed, the seat of 'tongue tie,' from shortness of the frænum (see page 562).

There is, however, one condition, which must be regarded as congenital, though it does not sometimes evidence itself until a year or two after birth, which is not uncommon. This is an enlargement of the tongue which is due primarily to a dilatation of the lymph-channels and a greatly increased development of the lymphatic tissue throughout the organ. This is often aggravated by inflammatory changes induced by injury or exposure, and the tongue may assume enormous dimensions and hang out of the mouth, giving the child an imbecile expression. The treatment consists in excising a V-shaped portion and bringing the cut surfaces together with deeply placed silver sutures. Compression has been resorted to in some cases and with success, but it is difficult to apply. Acute inflammation of the tongue, which may be caused by injury and the introduction of some septic or irritating matter, is attended by great swelling from infiltration of its connective tissue, which is in considerable quantity. This renders the patient incapable of swallowing or speaking, and may seriously impede respiration. It may run on to suppuration, and the formation of an acute abscess. Chronic abscess, which has been mistaken for cancer, may also occur in the substance of the tongue.

The mucous membrane of the tongue may become chronically inflamed, and presents different appearances in different stages of the disease, to which the terms leucoplakia, psoriasis, and ichthyosis have been given.

The tongue, being very vascular, is often the seat of nævoid growths, and these have a tendency to grow rapidly.

The tongue is frequently the seat of ulceration, which may arise from many causes, as from the irritation of jagged teeth, dyspepsia, tubercle, syphilis, and cancer. Of these the cancerous ulcer is the most important and probably also the most common. The variety is the squamous epithelioma, which soon develops into an ulcer with an indurated base.

It produces great pain, which speedily extends to all parts supplied with sensation by the fifth nerve, especially to the region of the ear. The pain in these cases is conducted to the ear and temporal region by the lingual nerve, and from it to the other branches of the inferior maxillary nerve, especially the auriculo-temporal. Possibly pain in the ear itself may be due to implication of the fibres of the glosso-pharyngeal nerve, which by its tympanic branch is conducted to the tympanic plexus.

Cancer of the tongue may necessitate removal of a part or the whole of the organ, and many different methods have been adopted for its excision. It may be removed from the mouth by the écraseur or the scissors. Probably the better method is by the scissors, usually known as Whitehead's method. The mouth is widely opened with a gag; the tongue transfixed with a stout silk ligature, by which to hold and make traction on it, and the reflexion of mucous membrane from the tongue to the jaw, and the insertion of the Genio-hyo-glossus first divided with a pair of curved, blunt scissors. The Palato-glossus is also divided. The tongue can now be pulled well out of the mouth. The base of the tongue is cut through by a series of short snips, each bleeding vessel being dealt with as soon as divided, until the situation of the ranine artery is reached. The remaining undivided portion of tissue is to be seized with a pair of Wells' forceps; the tongue removed, and the vessel secured. In the event of the ranine artery being accidentally injured, hæmorrhage can be at once controlled, by passing two fingers over the dorsum of the tongue as far as the epiglottis, and dragging the root of the tongue forcibly forwards.

In cases where the disease is confined to one side of the tongue, this operation may be modified by splitting the tongue down the centre and removing only the affected half. In cases where the submaxillary glands are involved, Kocher's operation should be performed. He removes the tongue from the neck, having performed a preliminary tracheotomy, by an incision from near the lobule of the ear, down the anterior border of the Sterno-mastoid to the level of the great cornu of the hyoid bone, then forwards to the body of the hyoid bone, and upwards to near the symphysis of the jaw. The lingual artery is now secured, and by a careful dissection the submaxillary lymphatic glands and the tongue removed. Regnoli advocated the removal of the tongue by a semilunar incision in the submaxillary triangle, along the line of the lower jaw, and a vertical incision from the centre of the semilunar one backwards to the hyoid bone. Care must be taken not to carry the first incision too far backwards, so as to wound the facial arteries. The tongue is thus reached through the floor of the mouth, pulled out through the external incision, and removed with the écraseur or knife. The great objection to this operation is that all the muscles which raise the hyoid bone and larynx are divided, and that therefore the movements of deglutition and respiration are interfered with.

Finally, where both sides of the floor of the mouth are involved in the disease, or where very free access is required on account of the extension backwards of the disease to the pillars of the fauces and the tonsil, or where the lower jaw is involved, the operation recommended by Syme must be performed. This is done by an incision through the central line of the lip, across the chin, and down as far as the hyoid bone. The lower jaw is sawn through at the symphysis, and the two halves of the bone forcibly separated from each other. The mucous membrane is separated from the bone, and the Genio-hyo-glossi detached from the bone, and the Hyo-glossi divided. The tongue is then drawn forwards, and removed close to its attachment to the hyoid bone. Any glands which are enlarged can be removed, and if the bone is implicated in the disease, it can also be removed by freeing it from the soft parts externally and internally, and making a second section with the saw beyond the diseased part.

Formerly many surgeons before removing the tongue performed a preliminary tracheotomy: (1) to prevent blood entering the air passages; and (2) to allow the patient to breathe through the tube and not inspire air which had passed over a sloughy wound, and which was loaded with septic organisms and likely to induce septic pneumonia. By the judicious use of iodoform, this secondary evil may be obviated, and the preliminary tracheotomy is now usually dispensed with.

THE NOSE

The nose is the special organ of the sense of smell: by means of the peculiar properties of its nerves, it protects the lungs from the inhalation of deleterious gases, and assists the organ of taste in discriminating the properties of food.

The organ of smell consists of two parts; one external, the *nose*; the other internal, the *nasal fossæ*.

The *nose* is the more anterior and prominent part of the organ of smell. It is of a triangular form, directed vertically downwards, and projects from the centre of the face, immediately above the upper lip. Its summit, or root, is connected directly with the forehead. Its inferior part, the base of the nose, presents two elliptical orifices, the nostrils, separated from each other by an antero-posterior

septum, the *columna*. The margins of these orifices are provided with a number of stiff hairs, or *vibrissæ*, which arrest the passage of foreign substances carried with the current of air intended for respiration. The lateral surfaces of the nose form, by their union, the *dorsum*, the direction of which varies considerably in different individuals. The dorsum terminates below in a rounded eminence, the *lobe of the nose*.

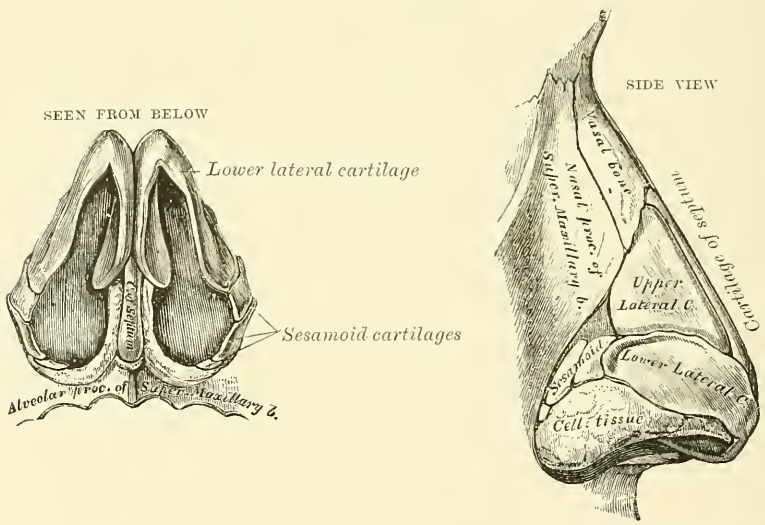
The nose is composed of a framework of bones and cartilages, the latter being slightly acted upon by certain muscles. It is covered externally by the integument, internally by mucous membrane, and supplied with vessels and nerves.

The *bony framework* occupies the upper part of the organ: it consists of the nasal bones, and the nasal processes of the superior maxillary.

The *cartilaginous framework* consists of five pieces, the two upper and the two lower lateral cartilages, and the cartilage of the septum.

The *upper lateral cartilages* are situated below the free margin of the nasal bones; each cartilage is flattened, and triangular in shape. Its anterior margin is thicker than the posterior, and connected with the cartilage of the septum. Its posterior margin is attached to the nasal process of the superior maxillary and

Figs. 526, 527.—Cartilages of the nose.

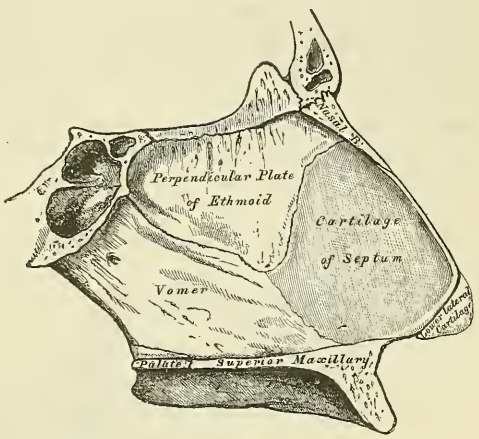


nasal bones. Its inferior margin is connected by fibrous tissue with the lower lateral cartilage: one surface is turned outwards, the other inwards towards the nasal cavity.

The *lower lateral cartilages* are two thin, flexible plates, situated immediately below the preceding, and bent upon themselves in such a manner as to form the inner and outer walls of each orifice of the nostril. The portion which forms the inner wall, thicker than the rest, is loosely connected with the same part of the opposite cartilage, and forms a small part of the columna. Its inferior border, free, rounded, and projecting, forms, with the thickened integument and subjacent tissue, and the corresponding parts of the opposite side, the tip of the nose. The part which forms the outer wall is curved to correspond with the ala of the nose; it is oval and flattened, narrow behind, where it is connected with the nasal process of the superior maxilla by a tough fibrous membrane, in which are found three or four small cartilaginous plates (sesamoid cartilages), *cartilagines minores*. Above, it is connected to the upper lateral cartilage and front part of the cartilage of the septum; below, it is separated from the margin of the nostril by dense cellular tissue; and in front, it forms, with its fellow, the lobe of the nose.

The *cartilage of the septum* is somewhat quadrilateral in form, thicker at its margins than at its centre, and completes the separation between the nasal fossæ in front. Its anterior margin, thickest above, is connected from above downwards with the nasal bones, the anterior margin of the two upper lateral cartilages, and the inner portion of the two lower lateral cartilages. Its posterior margin is connected with the perpendicular lamella of the ethmoid; its inferior margin with the vomer and the palate processes of the superior maxillary bones.

Fig. 528.—Bones and cartilages of septum of nose. Right side.



These various cartilages are connected to each other, and to the bones, by a tough fibrous membrane, which allows the utmost facility of movement between them.

The *muscles of the nose* are situated immediately beneath the integument: they are (on each side) the Pyramidalis nasi, the Levator labii superioris alæque nasi, the Dilatator naris, anterior and posterior, the Compressor nasi, the Compressor narium minor, and the Depressor alæ nasi. They have been described above (page 395).

The *integument* covering the dorsum and sides of the nose is thin, and loosely connected with the subjacent parts: but where it forms the tip, or lobe, and the alæ of the nose, it is thicker and more firmly adherent. It is furnished with a large number of sebaceous follicles, the orifices of which are usually very distinct.

The *mucous membrane*, lining the interior of the nose, is continuous with the skin externally, and with that which lines the nasal fossæ within.

The *arteries of the nose* are the lateralis nasi from the facial, and the inferior artery of the septum from the superior coronary, which supply the alæ and septum; the sides and dorsum being supplied from the nasal branch of the ophthalmic and the infra-orbital.

The *veins of the nose* terminate in the facial and ophthalmic.

The *nerves of the nose* are branches from the facial, infra-orbital, and infra-trochlear, and a filament from the nasal branch of the ophthalmic.

Nasal Fossæ

The nasal fossæ are two irregular cavities situated in the middle of the face, and extending from before backwards. They open in front by the two anterior nares, and terminate in the pharynx, behind, by the posterior nares. The *anterior nares* are somewhat pear-shaped apertures, each measuring about one inch vertically and half an inch transversely at their widest part. The *posterior nares* are two oval openings, situated at the upper part of the anterior wall of the pharynx. They are smaller in the body than in the skeleton, because narrowed by the mucous membrane. Each opening measures an inch in the vertical, and half an inch in the transverse direction in a well-developed adult skull.

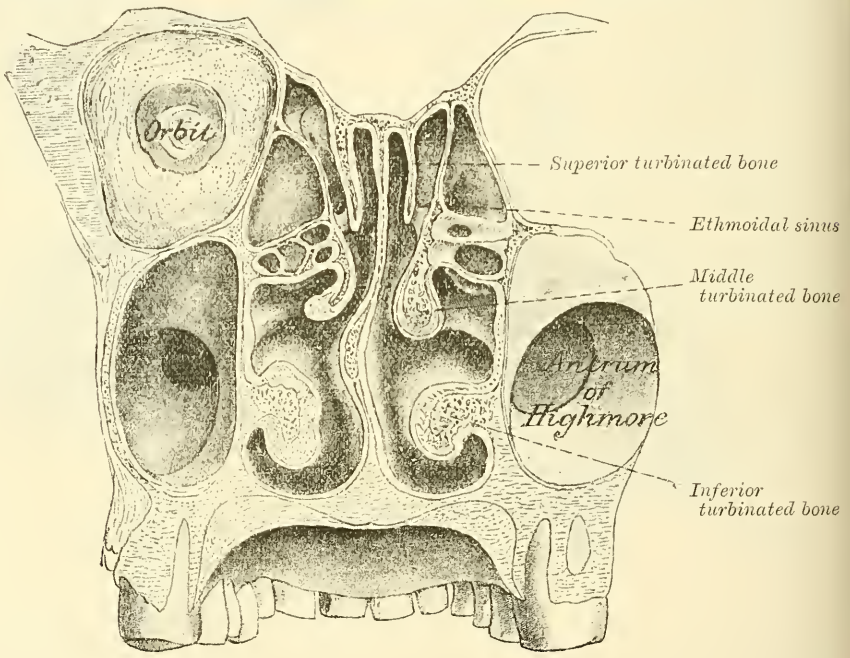
The *mucous membrane* lining the nasal fossæ is called the *pituitary* from the nature of its secretion; or *Schneiderian*, from Schneider, the first anatomist who showed that the secretion proceeded from the mucous membrane, and not, as was formerly imagined, from the brain. It is intimately adherent to the periosteum or perichondrium, over which it lies. It is continuous externally with the skin through the anterior nares, and with the mucous membrane of the pharynx through the posterior nares. From the nasal fossæ its continuity may be traced

with the conjunctiva, through the nasal duct and lachrymal canals; with the lining membrane of the tympanum and mastoid cells, through the Eustachian tube; and with the frontal, ethmoidal, and sphenoidal sinuses, and the antrum of Highmore, through the several openings in the meatuses. The mucous membrane is thickest, and most vascular, over the turbinated bones. It is also thick over the septum; but, in the intervals between the spongy bones, and on the floor of the nasal fossæ, it is very thin. Where it lines the various sinuses and the antrum of Highmore, it is thin and pale.

Owing to the great thickness of this membrane, the nasal fossæ are much narrower, and the turbinated bones, especially the lower ones, appear larger and more prominent than in the skeleton. From the same circumstance, also, the various apertures communicating with the meatuses are either narrowed or completely closed.

In the superior meatus, the aperture of communication with the posterior ethmoidal cells is considerably diminished in size, and the spheno-palatine foramen completely covered in.

Fig. 529.—Transverse vertical section of the nasal fossæ. (Henle.)



In the middle meatus, the opening of the infundibulum is partially hidden by a projecting fold of mucous membrane, and the orifice of the antrum is contracted to a small circular aperture, much narrower than in the skeleton.

In the inferior meatus, the orifice of the nasal duct is partially hidden by either a single or double valvular mucous fold, and the anterior palatine canal either completely closed in, or a tubular *cul-de-sac* of mucous membrane is continued a short distance into it. This *cul-de-sac* is termed the *organ of Jacobson*, and is present in all mammals as well as man. In the former it consists of a bilateral tube, situated in the nasal septum and supported by hyaline cartilage, the *cartilage of Jacobson*.

In the roof, the opening leading to the sphenoidal sinuses is narrowed, and the apertures in the cribriform plate of the ethmoid completely closed in.

Structure of the mucous membrane.—The epithelium covering the mucous membrane differs in its character according to the functions of the part of the

nose in which it is found. Near the orifice of the nostril, the *vestibule*, where common sensation is chiefly or alone required, the epithelium is of the ordinary pavement or scaly variety. In the rest of the cavity, below the distribution of the olfactory nerves, i.e. in the respiratory portion of the nasal cavity, the epithelium is columnar and ciliated. This is the case also in the meatuses of the nose. In this region, beneath the epithelium and its basement membrane, is a fibrous layer infiltrated with lymph-corpuscles, so as to form in many parts a diffuse adenoid tissue, and beneath this a nearly continuous layer of smaller and larger glands, some mucous and some serous, the ducts of which open upon the surface. In the olfactory region, i.e. the region in which the terminal filaments from the olfactory nerves are distributed (see page 777), the epithelial cells are columnar and non-ciliated, and contain an oval nucleus, situated in the deeper part of the cell: their free surface presents a sharp outline, and their deep extremity is prolonged into a process which runs inwards, branching to communicate with similar processes from neighbouring cells, so as to form a network in the deep part of the mucous membrane. Lying between these central processes of the columnar cells are a large number of spindle-shaped cells (termed by Max Schultze, *olfactory cells*), which consist of a large spherical nucleus surrounded by a small amount of granular protoplasm, and possessing two processes, of which one runs outwards between the columnar epithelial cells, and projects on the surface of the mucous membrane; the other (the deep) process runs inwards, is frequently beaded like a nerve-fibre, and is believed by most observers to be in connection with one of the terminal filaments of the olfactory nerve. Amongst the branched ends of the columnar cells there is a deep layer of epithelial cells, of a conical shape, their broad end resting on the basement membrane, and their tapering extremity projecting between the other cells. Beneath the epithelium, extending through the thickness of the mucous membrane, is a layer of glands, the *glands of Bowman*, identical in structure with serous glands.

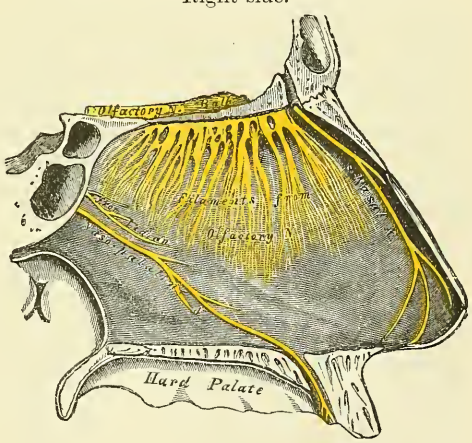


Fig. 530.—Nerves of septum of nose. Right side.

The mucous membrane is pigmented in the olfactory, but not in the other regions, being of a light yellow colour, at least in the white races.*

The *arteries of the nasal fossæ* are the anterior and posterior ethmoidal, from the ophthalmic, which supply the ethmoidal cells, frontal sinuses, and roof of the nose; a minute twig from the small meningeal; the spheno-palatine, from the internal maxillary, which supplies the mucous membrane covering the spongy bones, the meatuses and septum; the inferior artery of the septum from the superior coronary of the facial; and the alveolar branch of the internal maxillary, which supplies the lining membrane of the antrum. The ramifications of these vessels form a close, plexiform network, beneath and in the substance of the mucous membrane.

The *veins of the nasal fossæ* form a close network beneath the mucous membrane. They pass, some with the veins accompanying the spheno-palatine artery, through the spheno-palatine foramen; and others, through the alveolar branch, to join the facial vein; some accompany the ethmoidal arteries, and

* An interesting speculation has been suggested by Dr. W. Ogle (*Med.-Chir. Trans.* vol. liii. p. 277) as to the possible connection between the presence and abundance of this pigment and the perfection of the sense of smell.

terminate in the ophthalmic vein; and, lastly, a few communicate with the veins in the interior of the skull, through the foramina in the cribriform plate of the ethmoid bone, and the foramen cæcum.

The *nerves* are: the olfactory, the nasal branch of the ophthalmic, filaments from the anterior dental branch of the superior maxillary, the Vidian, the naso-palatine, descending anterior palatine, and nasal branches of Meckel's ganglion.

The *olfactory*, the special nerve of the sense of smell, is distributed over the upper third of the septum, and over the surface of the superior and middle spongy bones.

The *nasal branch of the ophthalmic* distributes filaments to the fore part of the septum, and outer wall of the nasal fossæ.

Filaments from the anterior dental branch of the superior maxillary supply the inferior meatus and inferior turbinated bone.

The *Vidian nerve* supplies the upper and back part of the septum, and superior spongy bone; and the *upper anterior nasal branches* from the spheno-palatine ganglion have a similar distribution.

The *naso-palatine nerve* supplies the middle of the septum.

The *larger*, or *anterior palatine nerve* supplies the middle and lower spongy bones.

Surgical Anatomy.—Instances of congenital deformity of the nose are occasionally met with, such as complete absence of the nose, an aperture only being present; or perfect development on one side, and suppression or malformation on the other; or there may be imperfect apposition of the nasal bones, so that the nose presents a median cleft or furrow. Deformities which have been acquired are much more common, such as flattening of the nose, the result of syphilitic necrosis; or imperfect development of the nasal bones in cases of congenital syphilis; or a lateral deviation of the nose may result from fracture.

The skin over the alæ and tip of the nose is thick and closely adherent to subjacent parts. Inflammation of this part is therefore very painful, on account of the tension. It is largely supplied with blood, and, the circulation here being terminal, vascular engorgement is liable to occur, especially in women at the menopause, and in both sexes from disorders of digestion, exposure to cold, etc. The skin of the nose also contains a large number of sebaceous follicles, and these, as the result of intemperance, are apt to become affected and the nose reddened, congested, and irregularly swollen. To this the term 'grog-blossom' is popularly applied. In some of these cases there is enormous hypertrophy of the skin and subcutaneous tissues, producing pendulous masses, termed lipomata nasi. Epithelioma and rodent ulcer may attack the nose, the latter being the more common of the two. Lupus and syphilitic ulceration frequently attack the nose, and may destroy the whole of the cartilaginous portion. In fact, lupus vulgaris begins more frequently on the ala of the nose than in any other situation.

Cases of congenital occlusion of one or both nostrils, or adhesion between the ala and septum, may occur and may require immediate operation, since the obstruction much interferes with sucking. Bony closure of the posterior nares may also occur.

To examine the nasal cavities, the head should be thrown back and the nose drawn upwards, the parts being dilated by some form of speculum. It can also be examined with the little finger or a probe, and in this way foreign bodies detected. A still more extensive examination can be made by Rouge's operation, which was introduced for the cure of ozæna, by the removal of any dead bone which may be present in this disease. The whole framework of the nose is lifted up by an incision made inside the mouth, through the junction of the upper lip with the bone; the septum nasi and the lateral cartilages are divided with strong scissors till the anterior nares are completely exposed. The posterior nares can be explored by reflected light from the mouth, by which the posterior nares can be illuminated. The examination is very difficult to carry out, and, as a rule, sufficient information regarding the presence of foreign bodies or tumours in the naso-pharynx can be obtained by the introduction of the finger behind the soft palate through the mouth. The septum of the nose may be displaced or deviate from the middle line: this may be the result of an injury or from some congenital defect in its development. Sometimes the deviation may be so great that the septum may come in contact with the outer wall of the nasal fossæ, and may even become adherent to it, thus producing complete obstruction. Perforation of the septum is not an uncommon affection, and may arise from several causes: syphilitic or tuberculous ulceration, blood tumour or abscess of the septum, and especially in workmen exposed to the vapour of bichromate of potash, from the irritating and corrosive action of the fumes. When small, the perforation may cause a peculiar whistling sound during respiration. When large, it may lead to the falling in of the bridge of the nose.

Epistaxis is a very common affection in children. It is rarely of much consequence, and will almost always subside, but in the more violent hæmorrhages of later life it may be necessary to plug the posterior nares. In performing this operation it is desirable to remember the size of the posterior nares. A ready method of regulating the size of the plug to fit the opening is to make it of the same size as the terminal phalanx of the thumb of the patient to be operated on.

Nasal polypus is a very common disease, and presents itself in three forms: the gelatinous, the fibrous, and the malignant. The first is by far the most common. It grows from the mucous membrane of the outer wall of the nasal fossa, where there is an abundant layer of highly vascular submucous tissue; rarely from the septum, where the mucous membrane is closely adherent to the cartilage and bone, without the intervention of much, if any, submucous tissue. Their most common seat is probably the middle turbinated bone. The fibrous polypus generally grows from the base of the skull behind the posterior nares, or from the roof of the nasal fossæ. The malignant polypi, both sarcomatous or carcinomatous, may arise in the nasal cavities and the naso-pharynx; or they may originate in the antrum, and protrude through its inner wall into the nasal fossa.

Rhinoliths, or nose-stones, may sometimes be found in the nasal cavities, from the formation of phosphate of lime, upon either a foreign body or a piece of inspissated secretion.

THE EYE

The eyeball is contained in the cavity of the orbit. In this situation it is securely protected from injury, whilst its position is such as to ensure the most extensive range of sight. It is acted upon by numerous muscles, by which it is capable of being directed to any part; it is supplied by vessels and nerves, and is additionally protected in front by several appendages, such as the eyebrow, eyelids, etc.

The eyeball is embedded in the fat of the orbit, but is surrounded by a thin membranous sac, the *capsule of Tenon*, which isolates it, so as to allow of free movement.

The capsule of Tenon (*tunica vaginalis oculi*) may be regarded as a distinct serous membrane, consisting of a parietal and visceral layer. The latter invests the posterior part of the globe from the ciliary margin of the cornea backwards to the entrance of the optic nerve, and is connected to it by very delicate connective tissue; the former (parietal) lines the hollow in the fat in which the eyeball is embedded, and is continued in front into the conjunctiva. It is strengthened in front at its lower part by a band of fibrous tissue, the *ligamentum suspensorium oculi*, which stretches across the orbit from its inner to its outer wall and forms a sort of sling for the eyeball. Both layers are lined on their free surfaces by endothelial cells. The cavity between them is continuous with the spaces between the different layers of the sheath of the optic nerve—that is to say, with the *subarachnoidean* between the pia-matral and the arachnoid sheath, and the *subdural* between the arachnoid and dural sheath—and into it empty the lymphatic vessels of the sclerotic. The capsule is pierced by the muscles of the eyeball near their insertion, and sends tubular prolongations on them, which become continuous with the sheath of the muscles. From the outer surface of these sheaths, expansions, consisting of elastic fibres and muscle cells, are given off to the margin of the orbit, which serve to limit the degree of contraction of the muscles.*

The eyeball is composed of segments of two spheres of different sizes. The anterior segment is one of a small sphere, and forms about one-sixth of the eyeball. It is more prominent than the posterior segment, which is one of a much larger sphere, and forms about five-sixths of the globe. The segment of the larger sphere is opaque, and formed by the sclerotic, the tunic of protection to the eyeball; the smaller sphere is transparent, and formed by the cornea. The axes of the eyeballs are nearly parallel, and do not correspond to the axes of the orbits which are directed outwards. The optic nerves follow the direction of the

* See a paper by Mr. C. B. Lockwood, *Journal of Anatomy and Physiology*, vol. xx. part i. p. 1.

axes of the orbits and are therefore not parallel; they enter the eyeball a little to their inner or nasal side. The eyeball measures rather more in its transverse than in its antero-posterior and vertical diameters, the former amounting to about an inch, the latter to about nine-tenths of an inch.

The eyeball is composed of several investing tunics, and of fluid and solid refracting media, called *humours*.

Tunics of the Eye

The tunics are three in number :

1. Sclerotic and Cornea.
2. Choroid, Iris, and Ciliary Processes.
3. Retina.

I. The Sclerotic and Cornea

The sclerotic and cornea (fig. 531) form the external tunic of the eyeball; they are essentially fibrous in structure, the sclerotic being opaque, and forming the posterior five-sixths of the globe ; the cornea, which forms the remaining sixth, being transparent.

The **Sclerotic** (σκληρός, *hard*) has received its name from its extreme density and hardness ; it is a firm, unyielding, fibrous membrane, serving to maintain the form of the globe. It is much thicker behind than in front. Its *external surface* is of a white colour, quite smooth, except at the points where the Recti and Obliqui muscles are inserted into it, and covered for part of its extent by the conjunctival membrane : hence the whiteness and brilliancy of the front of the eyeball. Its *inner surface* is stained of a brown colour, marked by grooves, in which are lodged the ciliary nerves, and connected by an exceedingly fine cellular tissue (*lamina fusca*) with the outer surface of the choroid. Behind, it is pierced by the optic nerve a little to its inner or nasal side, and is continuous with the fibrous sheath of the nerve, which is derived from the dura mater. At the point where the optic nerve passes through the sclerotic, this membrane forms a thin cribriform lamina (the *lamina cribrosa*) ; the minute orifices in this layer serve for the transmission of the nervous filaments, and the fibrous septa dividing them from one another are continuous with the membranous processes which separate the bundles of nerve-fibres. One of these openings, larger than the rest, occupies the centre of the lamella ; it is called the *porus opticus*, and transmits the arteria centralis retinæ to the interior of the eyeball. Around the cribriform lamella are numerous small apertures for the transmission of the ciliary vessels and nerves, and about midway between the margin of the cornea and the entrance of the optic nerve are four or five large apertures, for the transmission of veins (*venæ vorticosæ*). In front the sclerotic is continuous with the cornea by direct continuity of tissue, but the opaque sclerotic overlaps the cornea rather more on its outer than on its inner surface.

Structure.—The sclerotic is formed of white fibrous tissue intermixed with fine elastic fibres, and of flattened connective-tissue corpuscles, some of which are pigmented, contained in cell-spaces between the fibres. These fibres are aggregated into bundles, which are arranged chiefly in a longitudinal direction. It yields gelatin on boiling. Its vessels are not numerous, the capillaries being of small size, uniting at long and wide intervals. The existence of nerves in it is doubtful.

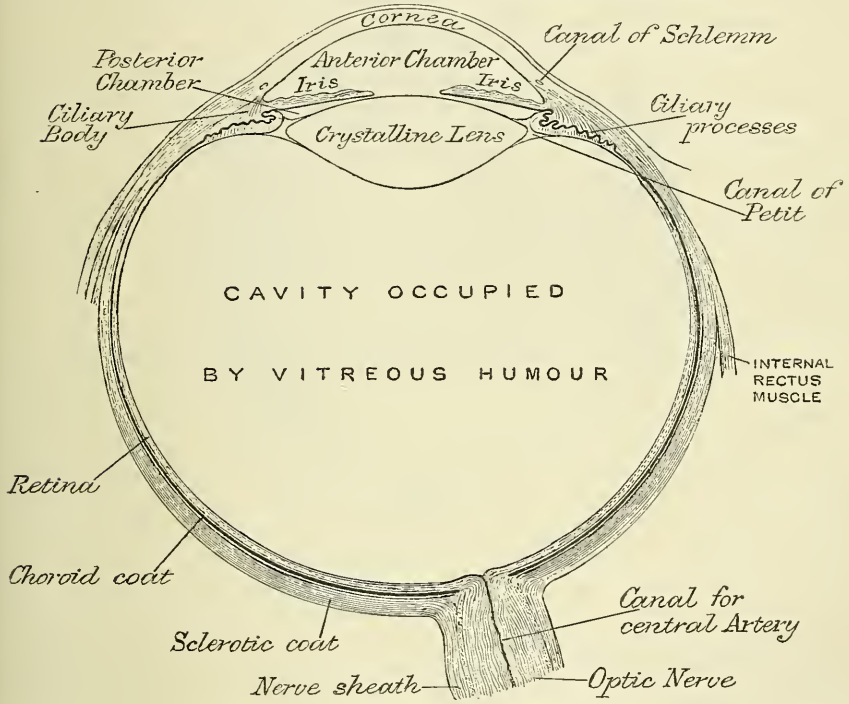
The **Cornea** is the projecting transparent part of the external tunic of the eyeball, and forms the anterior sixth of the globe. It is almost circular in shape, occasionally a little broader in the transverse than in the vertical direction. It is convex anteriorly, and projects forwards from the sclerotic in the same manner that a watch-glass does from its case. Its degree of curvature varies in different individuals, and in the same individual at different periods of life, it being more

prominent in youth than in advanced life, when it becomes flattened. The cornea is dense and of uniform thickness throughout; its posterior surface is perfectly circular in outline, and exceeds the anterior surface slightly in extent, from the latter being overlapped by the sclerotic.

Structure.—The cornea consists of four layers: namely (1) several strata of epithelial cells, continuous with those of the conjunctiva; (2) a thick central fibrous structure, the *cornea proper*; (3) a homogeneous elastic lamina; and (4) a single layer of epithelial cells, forming part of the lining membrane of the anterior chamber of the eyeball. The name of *membrane of Descemet* or *Demours* is given to this posterior elastic lamina and its endothelial coating.

The *conjunctival epithelium*, which covers the front of the cornea proper, consists of several strata of epithelial cells. The lowermost cells are columnar: then follow two or three layers of polyhedral cells, some of which present ridges and furrows, similar to those found in the cuticle. Lastly, there are three or four layers of scaly epithelium, with flattened nuclei.

FIG. 531.—A horizontal section of the eyeball. (Allen.)



The *proper substance of the cornea* is fibrous, tough, unyielding; perfectly transparent, and continuous with the sclerotic, with which it is identical in structure. It is composed of about sixty flattened lamellæ, superimposed one on another. These lamellæ are made up of bundles of fibrous connective tissue, the fibres of which are directly continuous with the fibres of the sclerotic. The fibres of each lamella are for the most part parallel with each other; those of alternating lamellæ at right angles to each other. Fibres, however, frequently pass from one lamella to the next.

The lamellæ are connected with each other by an interstitial cement-substance, in which are spaces, the *corneal spaces*. The spaces are stellate in shape and have numerous offsets, by which they communicate with other spaces. Each space contains a cell, the *corneal corpuscle*, which resembles in form the space in which it is contained, but does not entirely fill it.

Immediately beneath the conjunctival epithelium, the cornea proper presents

certain characteristic differences, which have led some anatomists to regard it as a distinct membrane, and it has been named by Bowman the *anterior elastic lamina*. It differs, however, from the true elastic lamina or membrane of Descemet in many essential particulars, presenting evidence of fibrillar structure, and not having the same tendency to curl inwards, or to undergo fracture, when detached from the other layers of the cornea. It consists of extremely closely interwoven fibrils, similar to those found in the rest of the cornea proper, but contains no corneal corpuscles. It seems therefore more proper to regard it as a part of the proper tissue of the cornea.*

The *posterior elastic lamina*, which covers the proper structure of the cornea behind, presents no structure recognisable under the microscope. It consists of a hard, elastic, and perfectly transparent homogeneous membrane, of extreme thinness, which is not rendered opaque by either water, alcohol, or acids. It is very brittle, but its most remarkable property is its extreme elasticity, and the tendency which it presents to curl up, or roll upon itself, with the attached surface innermost, when separate from the proper substance of the cornea. Its use appears to be (as suggested by Dr. Jacob) 'to preserve the requisite permanent correct curvature of the flaccid cornea proper.'

At the margin of the cornea this posterior elastic membrane breaks up into fibres to form a reticular structure at the outer angle of the anterior chamber, the intervals between the fibres forming small cavernous spaces, the *spaces of Fontana*. These little recesses communicate with a somewhat larger space in the substance of the sclerotic close to its junction with the cornea. This is the *canal of Schlemm*, or *sinus circularis iridis*, and, according to some authors, is a lymph canal, but according to others is a venous sinus. Some of the fibres of this reticulated structure are continued into the front of the iris, forming the *ligamentum pectinatum iridis*; while others are connected with the fore part of the sclerotic and choroid.

The *endothelial lining of the aqueous chamber* covers the posterior surface of the posterior elastic lamina. It consists of a single layer of polygonal flattened transparent nucleated cells, similar to those found lining other serous cavities.

Arteries and Nerves.—The cornea is a non-vascular structure, the capillary vessels terminating in loops at its circumference. Lymphatic vessels have not as yet been demonstrated in it, but are represented by the channels in which the bundles of nerves run; these are lined by an endothelium, and are continuous with the cell-spaces. The nerves are numerous, twenty-four to thirty-six in number (Kölliker); forty to forty-five (Waldeyer and Sümisch); they are derived from the ciliary nerves, and enter the laminated tissue of the cornea. They ramify throughout its substance in a delicate network, and their terminal filaments form a firm and closer plexus on the surface of the cornea proper beneath the epithelium. This is termed the *subepithelial plexus*, and from it fibrils are given off which ramify between the epithelial cells, forming a network which is termed the *intra-epithelial plexus*.

Dissection.—In order to separate the sclerotic and cornea, so as to expose the second tunic, the eyeball should be immersed in a small vessel of water, and held between the finger and thumb. The sclerotic is then carefully incised, in the equator of the globe, till the choroid is exposed. One blade of a pair of probe-pointed scissors is now introduced through the opening thus made, and the sclerotic divided around its entire circumference, and removed in separate portions. The front segment being then drawn forwards, the handle of the scalpel should be pressed gently against it at its connection with the iris, and these being separated, a quantity of perfectly transparent fluid will escape; this is the aqueous humour. In the course of the dissection, the ciliary nerves may be seen lying in the loose cellular tissue between the choroid and sclerotic, or contained in delicate grooves on the inner surface of the latter membrane.

* This layer has been called by Reichert the 'anterior limiting layer,' a name which appears more applicable to it than that of 'anterior elastic lamina.'

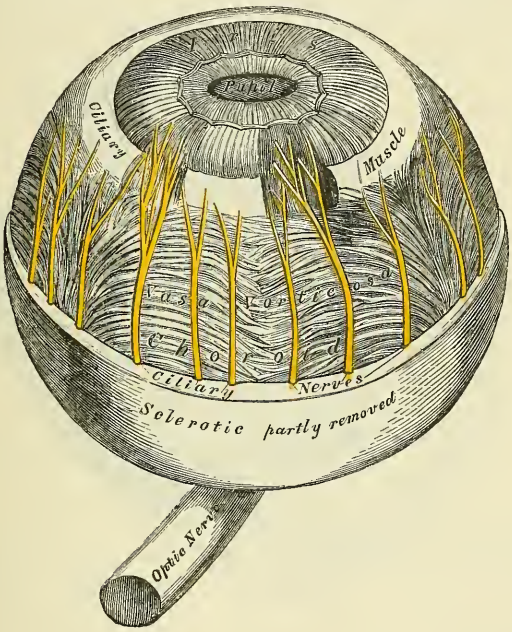
II. The Choroid, Iris, and Ciliary Processes

The Second Tunic of the Eye is formed by the choroid behind; the iris and ciliary processes in front; and by the ciliary muscle, opposite the junction of the sclerotic and cornea.

The choroid is the vascular and pigmentary tunic of the eyeball, investing the posterior five-sixths of the globe, and extending as far forwards as the cornea; the ciliary processes being appendages of the choroid developed from its inner surface in front. The iris is the circular muscular septum, which hangs vertically behind the cornea, presenting in its centre a large circular aperture, the *pupil*. The ciliary muscle forms the white ring observed at the point where the choroid and iris join with each other, and with the sclerotic and cornea.

The **Choroid** is a thin, highly vascular membrane, of a dark brown or chocolate colour, which invests the posterior five-sixths of the central part of the globe.

Fig. 532.—The choroid and iris. (Enlarged.)



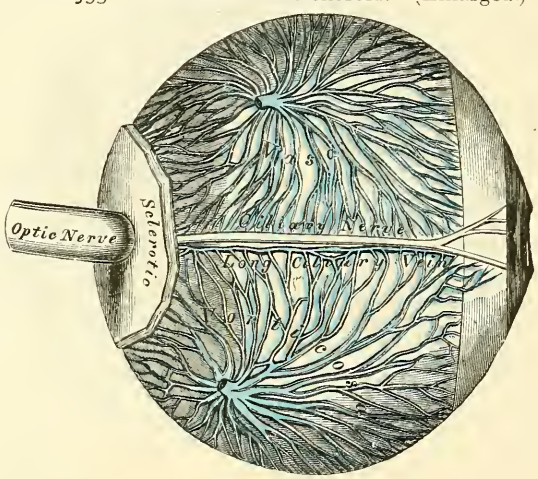
It is pierced behind by the optic nerve, and extends in front as far forwards as the ciliary ligament, where it is connected with the iris, and bends inwards, forming on its inner surface a series of folds or plaitings, the *ciliary processes*. It is thicker behind than in front. Externally, it is connected by a fine cellular web with the inner surface of the sclerotic. Its inner surface is attached to the retina.

Structure.—The choroid consists mainly of a dense capillary plexus and of small arteries and veins, carrying the blood to and returning it from this plexus. On its external surface, i.e. the surface next the sclerotic, is a thin membrane of fine elastic fibres, arranged in lamellæ, which are covered with endothelium, and form spaces, which communicate by perforations in the sclerotic, through which the vessels and nerves enter, with the capsule of Tenon. This layer is named the *lamina suprachoroidea*, and is loosely connected with the lamina fusca of the sclerotic.

Internal to this is the *choroid proper*, and in consequence of the small arteries and veins being arranged on the outer surface of the capillary network, it is customary to describe this as consisting of two layers: the outermost composed

of small arteries and veins, with pigment-cells interspersed between them, and the inner consisting of a capillary plexus. The *external layer* consists, in part, of the larger branches of the short ciliary arteries which run forwards between the veins, before they bend inwards to terminate in the capillaries; but is formed principally of veins, which are named, from their arrangement, *venæ vorticosæ*. They converge to four or five equidistant trunks, which pierce the sclerotic midway between the margin of the cornea and the entrance of the optic nerve. Interspersed between the vessels are lodged dark star-shaped pigment-cells, the fibrous offsets from which, communicating with similar branchings from neighbouring cells, form a delicate network or stroma, which towards the inner surface of the choroid loses its pigmentary character. The *internal layer* consists of an exceedingly fine capillary plexus, formed by the short ciliary vessels, and is known as the *tunica Ruyschiana*. The network is close, and finer at the hinder part of the choroid than in front. About half an inch behind the cornea its meshes become larger, and are continuous with those of the ciliary processes. On the inner surface of this tunic is a very thin, structureless, or, according to Kölliker,

Fig. 533.—The veins of the choroid. (Enlarged.)



faintly fibrous membrane, called the *lamina vitrea*; it is closely connected with the stroma of the choroid, and separates it from the pigmentary layer of the retina.

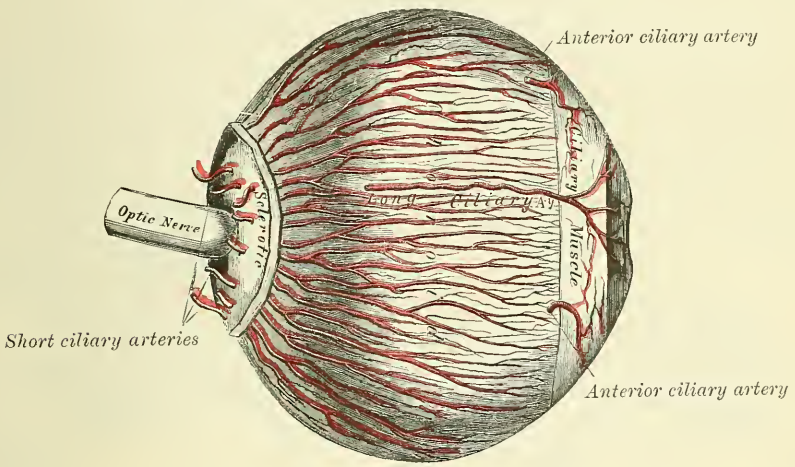
The ciliary processes should now be examined. They may be exposed, either by detaching the iris from its connection with the Ciliary muscle, or by making a transverse section of the globe, and examining them from behind.

The *ciliary processes* are formed by the plaiting and folding inwards of the various layers of the choroid (i.e. the choroid proper and the lamina vitrea) at its anterior margin, and are received between corresponding foldings of the suspensory ligament of the lens, thus establishing a connection between the choroid and inner tunic of the eye. They are arranged in a circle, and form a sort of plaited frill behind the iris, round the margin of the lens. They vary between sixty and eighty in number, lie side by side, and may be divided into large and small; the latter, consisting of about one-third of the entire number, are situated in the spaces between the former, but without regular alternation. The larger processes are each about one-tenth of an inch in length, and are attached by their periphery to the ciliary muscle, and are continuous with the layers of the choroid: the opposite margin is free, and rests upon the circumference of the lens. Their anterior surface is turned towards the back of the iris, with the circumference of which they are continuous. The posterior surface is closely connected with the suspensory ligament of the lens.

Structure.—The ciliary processes are similar in structure to the choroid, but the vessels are larger, and have chiefly a longitudinal direction. They are covered on their inner surface with a layer of black pigment-cells, continuous with the cells of the pigmentary layer of the retina, and in their stroma are also other, stellate, pigment-cells, which, however, are not so numerous as in the choroid itself, and towards the free extremities of the folds are devoid of pigment.

The **Iris** (*iris*, a rainbow) has received its name from its various colours in different individuals. It is a thin, circular-shaped, contractile curtain, suspended in the aqueous humour behind the cornea, and in front of the lens, being perforated a little to the nasal side of its centre by a circular aperture, the *pupil*, for the transmission of light. By its circumference it is intimately connected with the choroid; externally to this is the ciliary muscle, by which it is connected to the sclerotic and cornea; its inner edge forms the margin of the pupil; its surfaces are flattened, and look forwards and backwards, the anterior surface towards the cornea, the posterior towards the ciliary processes and lens. The circumference of the iris is connected to the cornea by a reticular structure denominated the *ligamentum pectinatum iridis*. The anterior surface of the iris is variously coloured in different individuals, and marked by lines which converge towards

Fig. 534.—The arteries of the choroid and iris.
The sclerotic has been mostly removed. (Enlarged.)



the pupil. The posterior surface is of a deep purple tint, from being covered by dark pigment; it is hence named *uvea*, from its resemblance in colour to a ripe grape.

Structure.—The iris is composed of the following structures:

1. In front is a layer of polyhedral cells on a delicate hyaline basement-membrane. This layer is continuous with the epithelial layer of the membrane of Descemet, and in men with dark coloured irides the cells contain pigment-granules.

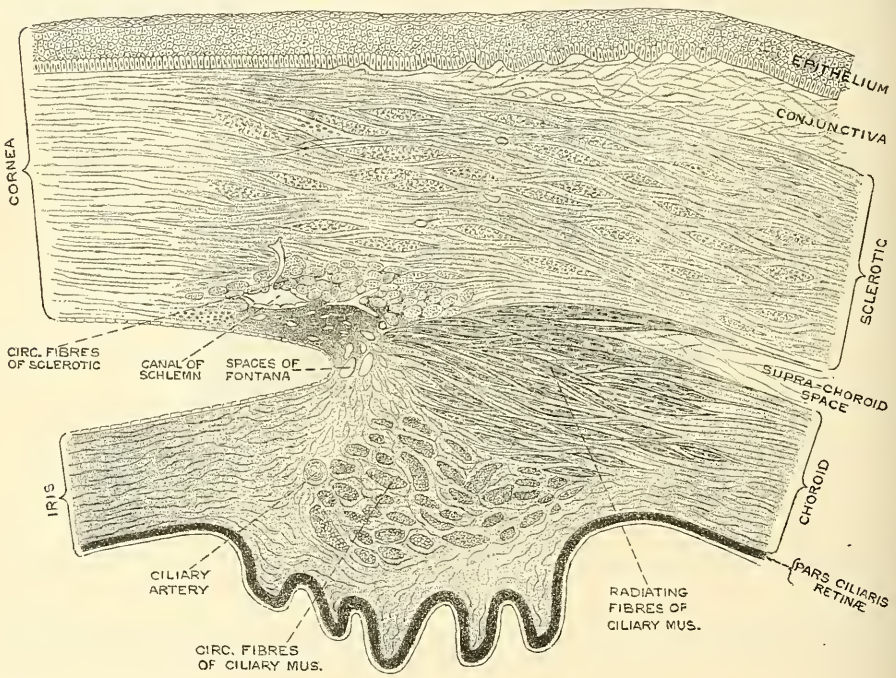
2. *Stroma.*—The stroma consists of fibres and cells. The former are made up of fine delicate bundles of fibrous tissue, of which some few fibres have a circular direction at the circumference of the iris; but the chief mass consists of fibres radiating towards the pupil. They form, by their interlacement, a delicate mesh, in which the vessels and nerves are contained. Interspersed between the bundles of connective tissue are numerous branched cells with fine processes. Many of them in dark eyes contain pigment-granules, but in blue eyes and the pink eyes of albinos they are unpigmented.

3. The *muscular fibre* is involuntary, and consists of circular and radiating fibres. The *circular fibres* (sphincter of the pupil) surround the margin of the

pupil on the posterior surface of the iris, like a sphincter, forming a narrow band about one-thirtieth of an inch in width ; those near the free margin being closely aggregated ; those more external somewhat separated, and forming less complete circles. The *radiating fibres* (dilator of the pupil) converge from the circumference towards the centre, and blend with the circular fibres near the margin of the pupil.

4. *Pigment.*—The situation of the pigment-cells differs in different irides. In the various shades of blue eyes, the only pigment-cells are several layers of small round or polyhedral cells, filled with dark pigment, situated on the posterior surface of the iris, and continuous with the pigmentary lining of the ciliary processes. The colour of the eye in these individuals is due to this colouring matter showing more or less through the texture of the iris. In the albino, even this pigment is absent. In the grey, brown, and black eye there are, as mentioned

Fig. 535.—Section of the eye, showing the relations of the cornea, sclerotic, and iris, together with the Ciliary muscle and the cavernous spaces near the angle of the anterior chamber. (Waldeyer.)



above, pigment-granules to be found in the cells of the stroma and in the epithelial layer on the front of the iris, to which the colour of the eye is due.

The *arteries of the iris* are derived from the long and anterior ciliary, and from the vessels of the ciliary processes (see page 580). The long ciliary arteries having reached the attached margin of the iris divide into an upper and lower branch, and encircling the iris anastomose with corresponding branches from the opposite side ; into this vascular zone (circulus major) the anterior ciliary pour their blood. From this zone vessels radiate to the free margin of the iris, and these communicate by branches from one to another and thus form a second zone (circulus minor) in this situation.

The *nerves of the iris* are derived from the ciliary branches of the lenticular ganglion, and the long ciliary from the nasal branch of the ophthalmic division of the fifth. After reaching the iris in the manner described above (page 786) they form a plexus around the attached margin of the iris ; from this are derived non-medullated fibres which terminate in the circular and radiating muscular

fibres. Their exact mode of termination has not been ascertained. Other fibres from the plexus terminate in a network on the anterior surface of the iris. The fibres derived from the motor root of the lenticular ganglion (third nerve) supply the circular fibres, while those derived from the sympathetic supply the radiating fibres.

Membrana pupillaris.—In the fœtus, the pupil is closed by a delicate transparent vascular membrane, the *membrana pupillaris*, which divides the space into which the iris is suspended into two distinct chambers. This membrane contains numerous minute vessels, continued from the margin of the iris to those on the front part of the capsule of the lens. These vessels have a looped arrangement, and converge towards each other without anastomosing. Between the seventh and eighth month the membrane begins to disappear by its gradual absorption, from the centre towards the circumference, and at birth only a few fragments remain. It is said sometimes to remain permanent and produce blindness.

The *Ciliary muscle* (Bowman) consists of unstriped fibres: it forms a greyish, semitransparent, circular band, about one-eighth of an inch broad, on the outer surface of the fore part of the choroid. It is thickest in front, and gradually becomes thinner behind. It consists of two sets of fibres, radiating and circular. The former, much the more numerous, arise at the point of junction of the cornea and sclerotic, and, passing backwards, are attached to the choroid opposite to the ciliary processes. One bundle, according to Waldeyer, is continued backwards to be inserted into the sclerotic. The circular fibres are internal to the radiating ones and to some extent unconnected with them, and have a circular course around the attachment of the iris. They are sometimes called the 'ring muscle' of Müller, and were formerly described as the ciliary ligament. The Ciliary muscle is admitted to be the chief agent in accommodation, i.e. in adjusting the eye to the vision of near objects. Mr. Bowman believed that this was effected by its compressing the vitreous body, and so causing the lens to advance; but the view which now prevails is that the contraction of the muscle, by drawing on the ciliary processes, relaxes the suspensory ligament of the lens, thus allowing the anterior surface of the lens to become more convex. The pupil is at the same time slightly contracted.*

III. The Retina

The **Retina** is a delicate nervous membrane, upon the surface of which the images of external objects are received. Its outer surface is in contact with the choroid; the inner surface with the vitreous body. Behind, it is continuous with the optic nerve; it gradually diminishes in thickness from behind forwards; and, in front, extends nearly as far forwards as the ciliary muscle, where it terminates by a jagged margin, the *ora serrata*. It is soft, semitransparent and of a pinkish tint in the fresh state; but soon becomes clouded, opaque, and bleached when exposed to sunlight. Exactly in the centre of the posterior part of the retina, and at a point, corresponding to the axis of the eye, in which the sense of vision is most perfect, is a round, elevated, yellowish spot, called, after its discoverer, the *yellow spot* or *limbus luteus* (macula lutea) of Sömmerring; having a central depression at its summit, the *fovea centralis*. The retina in the situation of the fovea centralis is exceedingly thin; so much so that the dark colour of the choroid is distinctly seen through it; so that it presents more the appearance of a foramen, and hence the name 'foramen of Sömmerring' at first given to it. It exists only in man, the quadrumana, and some saurian reptiles. About one-tenth of an inch to the inner side of the yellow spot is the point of entrance of the optic nerve (*porus opticus*); here the nervous substance is slightly raised so as to form an eminence (*colliculus nervi optici*); the arteria centralis retinæ pierces its centre. This is the only part of the surface of the retina from which the power of vision is absent.

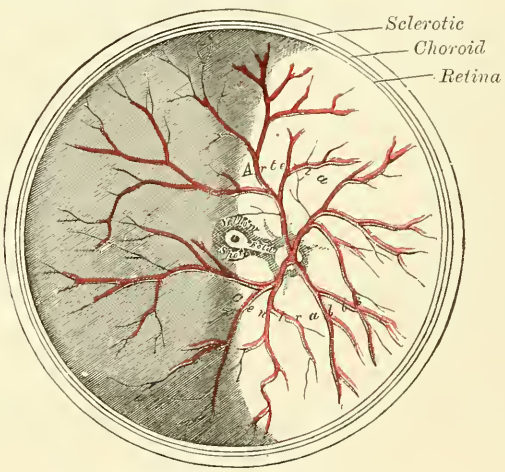
* See explanation and diagram in Power's *Illustrations of some of the Principal Diseases of the Eye*, p. 590.

Structure.—The retina is an exceedingly complex structure, and, when examined microscopically by means of sections made perpendicularly to its surface, is found to consist of ten layers, which are named from within outwards, as follows:

1. Membrana limitans interna.
2. Fibrous layer, consisting of nerve-fibres.
3. Vesicular layer, consisting of nerve-cells.
4. Inner molecular, or granular, layer.
5. Inner nuclear layer.
6. Outer molecular, or granular, layer.
7. Outer nuclear layer.
8. Membrana limitans externa.
9. Layer of rods and cones (Jacob's membrane).
10. Pigmentary layer.

1. The *membrana limitans interna* is the most internal layer of the retina, and is in contact with the hyaloid membrane of the vitreous humour. It is derived

Fig. 536.—The arteria centralis retinæ, yellow spot, etc., the anterior half of the eyeball being removed. (Enlarged.)



from the supporting framework of the retina, with which tissue it will be described.

2. The *fibrous layer* is made up of nerve-fibres, the direct continuation of the fibres of the optic nerve. This nerve therefore passes through all the other layers of the retina, except the one previously mentioned, to reach its destination in the fibrous layer. As the nerve passes through the lamina cribrosa of the sclerotic coat, the fibres of which it is composed lay aside their medullary sheaths and are continued onwards, through the choroid and retina, as simple axis-cylinders. When these non-medullated fibres reach the internal surface of the retina, they radiate from their point of entrance over the surface of the retina, grouped in bundles, and in many places, according to Michel, arranged in plexuses. The layer is thickest at the optic nerve entrance, and gradually diminishes in thickness towards the ora serrata.

3. The *vesicular layer* consists of a single layer of large ganglion-cells; except in the macula lutea, where there are several layers. The cells are somewhat flask-shaped; their rounded internal margin resting on the preceding layer and sending off a single process, which is prolonged into the fibrous layer, and is believed to be continuous with a nerve-fibre. From the opposite extremity of the cell one or more thicker processes extend into the inner molecular layer,

where they divide dichotomously and become lost in its reticulum, or, according to some, pass through this layer to reach the inner nuclear layer.

4. The *inner molecular layer* consists of a stratum of granular-looking substance, from which circumstance it is sometimes called the 'inner granular' layer. It is made up of a dense reticulum of minute fibrils, derived from the branched processes of the ganglion-cells and from processes derived from certain cells contained in the next layer, immediately to be described. Within the reticulum formed by these fibrils a few branched cells are embedded.

5. The *inner nuclear layer* is made up of a number of closely packed cells, of which there are three different kinds. (1) A large number of oval cells, which are commonly regarded as bipolar nerve-cells, and are much more numerous than either of the other kind. They consist of a large oval nuclear body placed vertically to the surface, containing a distinct nucleus: they are surrounded by a small amount of protoplasm, which is prolonged into two processes, one of these passes inwards into the inner molecular layer, is varicose in appearance,

Fig. 537.

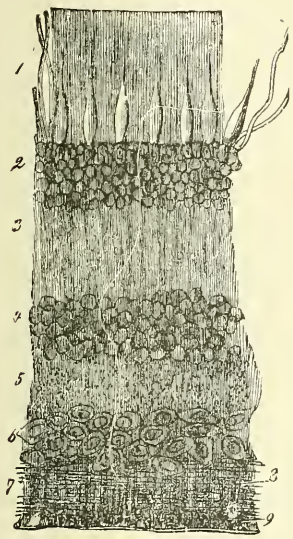


Fig. 538.

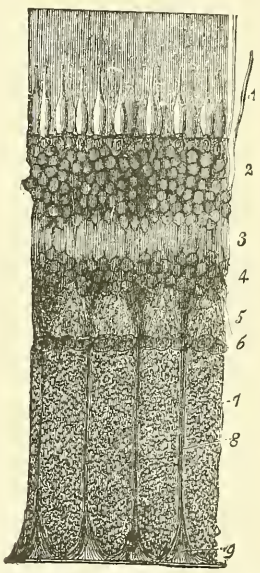


Vertical sections of the human retina. Fig. 537, half an inch from the entrance of the optic nerve. Fig. 538, close to the latter. 1. Layer of rods and cones (*columnar layer*), bounded underneath by the *membrana limitans externa*. 2. External nuclear layer. 3. Outer molecular layer. 4. Internal nuclear layer. 5. Inner molecular layer. 6. Layer of the ganglion-cells. 7. Expansion of optic fibres. 8. Sustentacular fibres of Müller. 9. Their attachment to the membrana limitans interna.

and, as stated above, is continuous with the processes of the ganglion-cells. The other process passes outwards, into the outer molecular layer, and there breaks up into a number of branches. According to some observers the divisions thus formed communicate with the rod and cone fibres (Merkel). (2) At the innermost part of this inner nuclear layer is a stratum of cells, which possess protoplasmic processes, which ramify in the inner molecular layer; while at the outermost part of the layer is a second stratum of cells, whose processes ramify in the outer molecular layer. (3) Some few cells are also found in this layer, connected with the fibres of Müller, and will be described with those structures.

6. The *outer molecular layer* is much thinner than the inner molecular layer; but, like it, consists of a dense network of minute fibrils, derived from the processes of the cells of the preceding layer, and presents the same granular appearance. It differs, however, from the inner molecular layer in containing branched stellate cells, the processes of which are extremely fine and exhibit varicosities, like nerve-fibrils. They are therefore considered by Schultze to be ganglion-cells.

7. *The outer nuclear layer.*—Like the inner nuclear layer, this layer contains several strata of clear oval nuclear bodies; they are of two kinds, and on account of their being respectively connected with the rods and cones of Jacob's membrane, are named rod-granules and cone-granules. The *rod-granules* are much the more numerous, and are placed at different levels throughout the layer. They present a peculiar cross-striped appearance, and have prolonged from either extremity a fine process: the outermost is continuous with a single rod of Jacob's membrane; the innermost passes inwards towards the outer molecular layer and terminates in an enlarged extremity, from which are given off a number of minute fibrils, which enter the outer molecular layer. In its course it presents numerous varicosities. The *cone-granules*, fewer in number than the rod-granules, are placed close to the membrana limitans externa, and are closely connected with the cones of Jacob's membrane. They do not present any cross-striping, but contain a pyriform nucleus, which almost completely fills the cell. From their inner extremity a thick process passes inwards to the outer molecular layer; where, like the processes of the rod-cells, it terminates in an enlargement, from which are given off numerous fine fibrils, which enter the outer molecular layer.

8. *The membrana limitans externa.*—This layer, like the membrana limitans interna, is derived from the fibres of Müller, with which structures it will be described.

9. *Jacob's membrane* (*bacillary layer*).—The elements which compose this layer are of two kinds, *rods* and *cones*, the former being much more numerous than the latter. The *rods* are solid, of nearly uniform size, and arranged perpendicularly to the surface. Each rod consists of two portions, an outer and inner, which are joined together by a cement-substance and are of about equal length. They differ from each other as regards refraction and in their behaviour with colouring reagents, the inner portion becoming stained by carmine, iodine, &c., the outer portion remaining unstained with these reagents, but staining yellowish-brown with osmic acid. The outer portion of each rod is marked by transverse striæ, and is made up of a number of thin discs superimposed on one another. It also exhibits faint longitudinal markings. The inner portion of each rod, at its inner extremity where it is joined to the processes of the rod-granules, is indistinctly granular; at its outer extremity it presents a fine longitudinal striation, being composed of fine, bright, highly refracting fibrils.

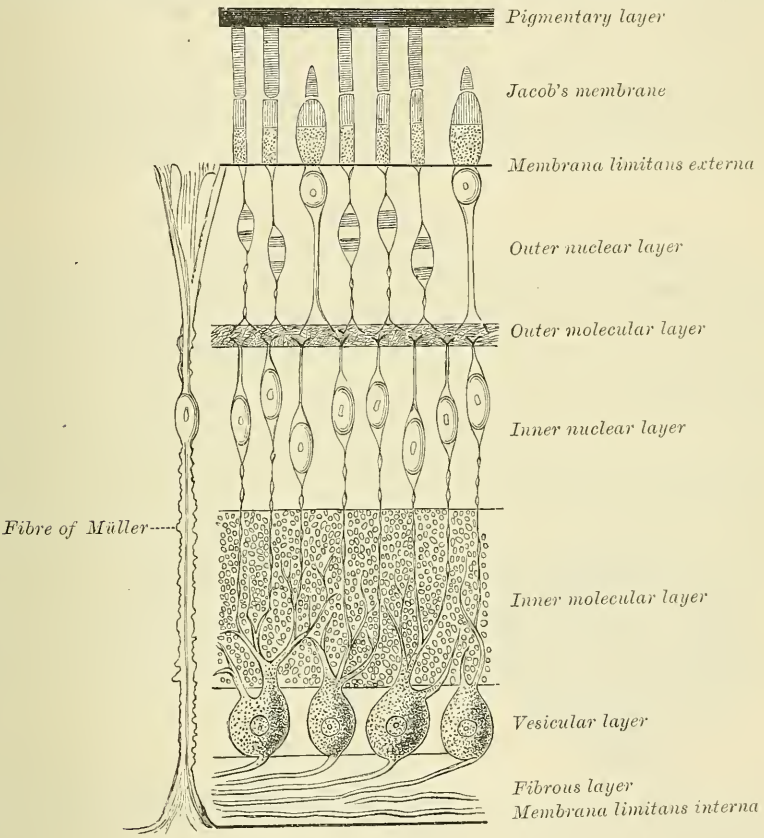
The *cones* are conical or flask-shaped, their broad ends resting upon the membrana limitans externa, the narrow pointed extremity being turned to the choroid. Like the rods, they are made up of two portions, outer and inner; the outer portion being a short conical process, which, like the outer segment of the rods, presents transverse striæ. The inner portion resembles the inner portion of the rods in structure, presenting an outer striated and an inner granular appearance; but differs from it in size, being bulged out laterally and presenting a flask shape. The chemical and optical character of the two portions is identical with that of the rods.

10. *The pigmentary layer, or tapetum nigrum.*—The most external layer of the retina, formerly regarded as a part of the choroid, consists of a single layer of hexagonal epithelium cells, loaded with pigment-granules (fig. 23). In the eyes of albinos, the cells of the pigmentary layer are present, but they contain no colouring matter. In many of the mammals also, as in the horse, and many of the carnivora, there is no pigment in the cells of this layer, and the choroid possesses a beautiful iridescent lustre, which is termed the *tapetum lucidum*.

Connective-tissue framework of the retina.—Almost all these layers of the retina are connected together by a sort of supporting connective tissue, which has been named the *fibres of Müller*, or *radiating fibres*, from which the membrana limitans interna et externa are derived. These fibres are found stretched between the two limiting layers, 'as columns between a floor and a ceiling,' and passing through all the nervous layers, except Jacob's membrane. They commence on the inner surface of the retina by a conical hollow base, which sometimes contains

a spheroidal body, which stains deeply with hæmatoxylin, the edges of the bases of adjoining fibres being united and thus forming a boundary line, which is the membrana limitans interna. As they pass through the various layers, they present a roughness on their surface, as if a number of membranous processes had been abruptly broken off. By these they are continuous with the reticulum of the inner and outer molecular layer and with a sponge-like stroma, in which the nuclei of the inner nuclear layer are embedded. In the inner nuclear layer each fibre of Müller presents a clear oval nucleus, referred to above, which is sometimes situated at the side of, sometimes altogether within the fibre. In the outer nuclear layer the fibre breaks up into fine lamellæ, which form a fenestrated or sponge-like tissue, in which the rod and cone granules are enclosed, and at

Fig. 539.—The layers of the retina (diagrammatic). (After Schultze.)



the outer border of this layer these lamellæ unite along a definite line, forming the membrana limitans externa.

Macula lutea and fovea centralis.—The structure of the retina at the yellow spot presents some modifications. In the macula lutea (1) the nerve-fibres are wanting as a continuous layer; (2) the vesicular layer consists of several strata of cells, instead of a single layer; (3) in Jacob's membrane there are no rods, but only cones, and these are longer and narrower than in other parts; and (4) in the outer nuclear layer there are only cone-fibres, which are very long and arranged in curved lines. At the fovea centralis the only parts which exist are the cones of Jacob's membrane; the outer nuclear layer, the cone-fibres of which are almost horizontal in direction; and an exceedingly thin inner granular layer. The colour of the spot seems to imbue all the layers except Jacob's membrane;

it is of a rich yellow, deepest towards the centre, and does not appear to consist of pigment-cells, but simply a staining of the constituent parts.

At the ora serrata the layers of the retina terminate abruptly, and the retina is continued onwards as a single layer of elongated columnar cells covered by the pigmentary layer. This prolongation is known as the *pars ciliaris retinæ*, and can be traced forwards to the tips of the ciliary processes, and there gives place to the uvea or layer of pigment on the posterior surface of the iris.

The *arteria centralis retinæ* and its accompanying vein pierce the optic nerve, and enter the globe of the eye through the porus opticus. It immediately divides into four or five branches, which at first run between the hyaloid membrane and the nervous layer; but they soon enter the latter membrane, and pass forwards, dividing dichotomously. From these branches a minute capillary plexus is given off, which does not extend beyond the inner nuclear layer. In the fœtus, a small vessel passes forwards, through the vitreous humour, to the posterior surface of the capsule of the lens.

Humours of the Eye

The Refracting media, or Humours of the Eye, are three in number:

Aqueous. Vitreous. Crystalline lens.

I. The Aqueous Humour

The **aqueous humour** completely fills the anterior and posterior chambers of the eyeball. It is small in quantity (scarcely exceeding, according to Petit, four or five grains in weight), has an alkaline reaction, in composition is little more than water, less than one-fiftieth of its weight being solid matter, chiefly chloride of sodium.

The *anterior chamber* is the space bounded in front by the cornea; behind, by the front of the iris. The *posterior chamber* was the name formerly given to a space which was believed to exist between the iris in front and the capsule of the lens, its suspensory ligament and the ciliary processes, behind. It is now known that the posterior surface of the iris is in immediate contact with the lens throughout the greater part of its extent. The only space which remains, to represent the posterior chamber, is a narrow chink between the peripheral part of the iris, the suspensory ligament and the ciliary processes.

In the adult, these two chambers communicate through the pupil; but in the fœtus in the seventh month, when the pupil is closed by the membrana pupillaris, the two chambers are quite separate.

II. Vitreous Body

The **vitreous body** forms about four-fifths of the entire globe. It fills the concavity of the retina, and is hollowed in front for the reception of the lens and its capsule. It is perfectly transparent, of the consistence of thin jelly, and is composed of an albuminous fluid enclosed in a delicate transparent membrane, the *hyaloid*. This membrane invests the outer surface of the vitreous body; it is intimately connected in front with the suspensory ligament of the lens; and is continued into the back part of the capsule of the lens. It has been supposed, by Hannover, that from its inner surface numerous thin lamellæ are prolonged inwards in a radiating manner, forming spaces in which the fluid is contained. In the adult, these lamellæ cannot be detected even after careful microscopic examination in the fresh state, but in preparations hardened in weak chromic acid, it is possible to make out a distinct lamellation at the periphery of the body; and in the fœtus a peculiar fibrous texture pervades the mass, the fibres joining at numerous points, and presenting minute nuclear granules at their point of junction. In the centre of the vitreous humour, running from the

position of the entrance of the optic nerve on the retina to the posterior surface of the lens, is a canal, filled with fluid and lined by a prolongation of the hyaloid membrane. This is the *canal of Stilling*, and is the canal which in the embryonic vitreous humour conveyed the minute artery from the central artery of the retina to the back of the lens. The fluid from the vitreous body resembles nearly pure water; it contains, however, some salts, and a little albumen.

The hyaloid membrane encloses the whole of the vitreous humour. At the situation of the ora serrata it splits into two layers, one of which passes over the anterior surface of the vitreous body, where it is hollowed out for the reception of the lens; the other passes over the ciliary body to be attached to the margin of the lens, forming the *suspensory ligament*. It is a delicate structureless membrane, except where it forms the suspensory ligament, where it contains longitudinal elastic fibres. Immediately beneath the hyaloid membrane are found small, granular, nucleated cells, which are said to be possessed of amœboid movements.

In the fœtus, the centre of the vitreous humour presents a tubular canal, through which a minute artery passes along the vitreous body to the capsule of the lens. *In the adult*, no vessels penetrate its substance; so that its nutrition must be carried on by the vessels of the retina and ciliary processes, situated upon its exterior.

III. Crystalline Lens

The crystalline lens, enclosed in its capsule, is situated immediately behind the pupil, in front of the vitreous body, and surrounded by the ciliary processes, which slightly overlap its margin.

The *capsule of the lens* is a transparent, highly elastic, and brittle membrane, which closely surrounds the lens. It rests, behind, in a depression in the fore part of the vitreous body; in front, it is in contact with the free border of the iris, this latter receding from it at the circumference, thus forming the posterior chamber of the eye; and it is retained in its position chiefly by the suspensory ligament of the lens. The capsule is much thicker in front than behind, structureless in texture; and when ruptured, the edges roll up with the outer surface innermost, like the elastic lamina of the cornea. The anterior surface of the lens is connected to the inner surface of the capsule by a single layer of transparent, polygonal, nucleated cells. At the circumference of the lens, these cells undergo a change in form: they become elongated, and Babucin states that he can trace the gradual transition of the cells into proper lens-fibres, with which they are directly continuous. There is no epithelium on the posterior surface.

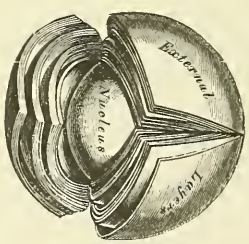


Fig. 540.—The crystalline lens, hardened and divided. (Enlarged.)

In the fœtus, a small branch from the arteria centralis retinæ runs forwards, as already mentioned, through the vitreous humour to the posterior part of the capsule of the lens, where its branches radiate and form a plexiform network, which covers its surface, and they are continuous round the margin of the capsule with the vessels of the pupillary membrane, and with those of the iris. In the adult no vessels enter its substance.

The *lens* is a transparent, double-convex body, the convexity being greater on the posterior than on the anterior surface. It measures about a third of an inch in the transverse diameter, and about one-fourth in the antero-posterior. It consists of concentric layers, of which the external in the fresh state are soft and

easily detached; those beneath are firmer, the central ones forming a hardened nucleus. These laminæ are best demonstrated by boiling, or immersion in alcohol. The same reagents demonstrate that the lens consists of three triangular segments, the sharp edges of which are directed towards the centre, the bases towards the circumference. The laminæ consist of minute parallel fibres, which are hexagonal prisms, the edges being dentated, and the dentations fitting accurately into each other; their breadth is about $\frac{1}{3000}$th of an inch. They run from the sutures or lines of junction of the triangular segments, on the one surface, to the periphery of the lens, and, curving round its margin, they terminate at the line of junction of the segments on the other. No fibres pass from pole to pole, but they are arranged in such a way that fibres which commence near the pole on the one aspect of the lens—that is to say, near the apex of the triangular segment—terminate near the peripheral extremity of the plane on the other, or near the base of the triangular segment, and *vice versâ*. The fibres of the outer layers of the lens each contain a nucleus, which together form a layer (nuclear layer) on the surface of the lens, most distinct towards its circumference. The meridians, or lines of junction of the three segments, are composed of an amorphous granular substance which sometimes becomes opaque, when the lines are seen forming a distinct star on the lens. The lines on one surface do not lie immediately opposite those on the other, but are intermediate.

The *changes produced in the lens by age* are the following:

In the fœtus, its form is nearly spherical, its colour of a slightly reddish tint, it is not perfectly transparent, and is so soft as to break down readily on the slightest pressure.

In the adult, the posterior surface is more convex than the anterior; it is colourless, transparent, and firm in texture.

In old age it becomes flattened on both surfaces, slightly opaque, of an amber tint, and increases in density.

The *suspensory ligament of the lens* is a thin, transparent, membranous structure, placed between the vitreous body and the ciliary processes of the choroid; it connects the anterior margin of the vitreous humour with the anterior surface of the lens near its circumference. It assists in retaining the lens in its position. Its outer surface presents a number of folds or plaitings in which the corresponding folds of the ciliary processes are received. These plaitings are arranged round the lens in a radiating form, and are stained by the pigment of the ciliary processes. The suspensory ligament is a part of the hyaloid membrane, which, as described above, is continued forwards to the anterior part of the margin of the lens. It is covered on its outer surface by the pars ciliaris, or connective-tissue framework of the retina, prolonged forwards from the ora serrata. That portion of this membrane which intervenes between the ciliary processes and the capsule of the lens forms part of the boundary of the posterior chamber of the eye. The posterior surface of this layer is turned towards the vitreous humour, being separated from it at the circumference of the lens by a space called the canal of Petit.

The *canal of Petit* is about one-tenth of an inch wide. It is bounded, in front, by the suspensory ligament; behind, by the vitreous humour, its base being formed by the capsule of the lens. When inflated with air, it is sacculated at intervals, owing to the foldings on its anterior surface.

The *arteries of the globe of the eye* are the short, long, and anterior ciliary arteries, and the arteria centralis retinæ. They have been already described (see page 580).

The *ciliary veins* are seen on the outer surface of the choroid, and are named, from their arrangement, the *venæ vorticosæ*. They converge to four or five equidistant trunks which pierce the sclerotic midway between the margin of the cornea and the entrance of the optic nerve. Another set of veins accompany the anterior ciliary arteries and open into the ophthalmic vein.

The *ciliary nerves* are derived from the nasal branch of the ophthalmic and from the ciliary or ophthalmic ganglion.

Surgical Anatomy.—From a surgical point of view the cornea may be regarded as consisting of three layers: (1) of an external epithelial layer, developed from the epiblast, and continuous with the external epithelial covering of the rest of the body, and therefore in its lesions resembling those of the epidermis and superficial layers of the derma; (2) of the cornea proper, derived from the mesoblast, and associated in its diseases with the fibro-vascular structures of the body; and (3) the posterior elastic layer with its endothelium, also derived from the mesoblast and having the characters of a serous membrane, so that inflammation of it resembles inflammation of the other serous and synovial membranes of the body.

The cornea contains no blood-vessels except at its periphery, where numerous delicate loops, derived from the anterior ciliary arteries, may be demonstrated on the anterior surface of the cornea. The rest of the cornea is nourished by lymph, which gains access to the proper substance of the cornea and the posterior layer through the spaces of Fontana. This lack of a direct blood-supply renders the cornea very apt to inflame in the cachectic and ill-nourished. In cases of granular lids, there is a peculiar affection of the cornea, called *pannus*, in which the anterior layers of the cornea becomes vascularised, and a rich network of blood-vessels may be seen upon it; and in interstitial keratitis new vessels extend into the cornea, giving it a pinkish hue, to which the term 'salmon patch' is applied. The cornea is richly supplied with nerves, derived from the ciliary, which enter the cornea through the fore part of the sclerotic and form plexuses in the stroma, terminating between the epithelial cells by free ends or in corpuscles. In cases of glaucoma the ciliary nerves may be pressed upon as they course between the choroid and sclerotic, and the cornea becomes anæsthetic. The sclerotic has very few blood-vessels and nerves. The blood-vessels are derived from the anterior ciliary, and form an open plexus in its substance. As they approach the corneal margin this arrangement is peculiar. Some branches pass through the sclerotic to the ciliary body; others become superficial and lie in the episcleral tissue, and form arches, by anastomosing with each other, some little distance behind the corneal margin. From these arches numerous straight vessels are given off, which run forwards to the cornea, forming its marginal plexus. In inflammation of the sclerotic and episcleral tissue these vessels become conspicuous, and form a pinkish zone of straight vessels radiating from the corneal margin, commonly known as the zone of ciliary injection. In inflammation of the iris and ciliary body this zone is present, since the sclerotic speedily becomes involved when these structures are inflamed. But in inflammation of the cornea the sclerotic is seldom much affected, though the cornea and sclerotic are structurally continuous. This would appear to be due to the fact, that the nutrition of the cornea is derived from a different source from that of the sclerotic. The sclerotic may be ruptured subcutaneously without any laceration of the conjunctiva, and the rupture usually occurs near the corneal margin, where the tunic is thinnest. It may be complicated with lesions of adjacent parts—laceration of the choroid, retina, iris, or suspensory ligament of the lens—and is then often attended with hæmorrhage into the anterior chamber, which masks the nature of the injury. In some cases the lens has escaped through the rent in the sclerotic and has been found under the conjunctiva. Wounds of the sclerotic are always dangerous, and are often followed by inflammation, suppuration, and by sympathetic ophthalmia.

One of the functions of the choroid is to provide nutrition for the retina, and to convey vessels and nerves to the ciliary body and iris. Inflammation of the choroid is therefore followed by grave disturbance in the nutrition of the retina, and is attended with early interference with vision. In its diseases it bears a considerable analogy to those which affect the skin, and, like it, is one of the places from which melanotic sarcomata may grow. These tumours contain a large amount of pigment in their cells, and grow only from those parts where pigment is naturally present. The choroid may be ruptured, without injury to the other tunics, as well as participating in general injuries of the eyeball. In cases of uncomplicated rupture, the injury is usually at its posterior part, and is the result of a blow on the front of the eye. It is attended by considerable hæmorrhage, which for a time may obscure vision, but, in most cases, this is restored, as soon as the blood is absorbed.

The iris is the seat of a malformation, termed *coloboma*, which consists in a deficiency or cleft, which in a great number of cases is clearly due to an arrest in development. In these cases it is found at the lower aspect, extending directly downwards from the pupil, and the gap frequently extends through the choroid to the entrance of the optic nerve. In some rarer cases the gap is found in other parts of the iris, and is then not associated with any deficiency of the choroid. The iris is abundantly supplied with blood-vessels and nerves, and is therefore very prone to become inflamed. And when inflamed, in consequence of the intimate relationship which exists between the vessels of the iris and choroid, this latter tunic is very apt to participate in the inflammation. And, in addition, inflammation of adjacent structures, the cornea and sclerotic, is apt to spread into the iris. The iris is covered with epithelium, and partakes of the character of a serous membrane, and, like these structures, is liable to pour out a plastic exudation, when inflamed, and contract adhesions, either to the cornea in front (*synechia anterior*), or to the capsule of the lens

behind (*synechia posterior*). In iritis the lens may become involved, and the condition known as secondary cataract may be set up. Tumours occasionally commence in the iris; of these, cysts, which are usually congenital, and sarcomatous tumours, are the most common and require removal. Gummata are not unfrequently found in this situation. In some forms of injury of the eyeball, as the impact of a spent shot, the rebound of a twig, or a blow with a whip, the iris may be detached from the Ciliary muscle, the amount of detachment varying from the slightest degree to separation of the whole iris from its ciliary connection.

The retina, with the exception of its pigment-layer and its vessels, is perfectly transparent, so as to be invisible when examined by the ophthalmoscope, so that its diseased conditions are recognised by its loss of transparency. In retinitis, for instance, there is more or less dense and extensive opacity of its structure, and not unfrequently extravasations of blood into its substance. Hæmorrhages may also take place into the retina, from rupture of a blood-vessel without inflammation.

The retina may become displaced from effusion of serum between it and the choroid, or by blows on the eyeball, or may occur without apparent cause in progressive myopia, and in this case the ophthalmoscope shows an opaque, tremulous cloud. Glioma, a form of sarcoma, and essentially a disease of early life, is occasionally met with in connection with the retina.

The lens has no blood-vessels, nerves, or connective tissue in its structure, and therefore is not subject to those morbid changes to which tissues containing these structures are liable. It does however present certain morbid or abnormal conditions of various kinds. Thus, variations in shape, absence of the whole or a part of the lens, and displacements are amongst its congenital defects. Opacities may occur from injury, senile changes, malnutrition, or errors in growth or development. Senile changes may take place in the lens, impairing its elasticity and rendering it harder than in youth, so that its curvature can only be altered to a limited extent by the Ciliary muscle. And, finally, the lens may be dislocated or displaced by blows upon the eyeball: and its relations to surrounding structures altered by adhesions or the pressure of new growths.

There are two particular regions of the eye which require special notice: one of these is known as the 'filtration area,' and the other as the 'dangerous area.' The *filtration area* is the circumcorneal zone immediately in front of the iris. Here are situated the cavernous spaces of Fontana, which communicate with the canal of Schlemm, through which the chief transudation of fluid from the eye is now believed to take place. The *dangerous area of the eye* is the region in the neighbourhood of the ciliary body, and wounds or injuries in this situation are peculiarly dangerous. For inflammation of the ciliary body is liable to spread to many of the other structures of the eye, especially to the iris and choroid, which are intimately connected by nervous and vascular supplies. Moreover, wounds which involve the ciliary region are especially liable to be followed by sympathetic ophthalmia, in which destructive inflammation of one eye is excited by some irritation in the other.

Appendages of the Eye

The appendages of the eye (*tutamina oculi*) include the eyebrows, the eyelids, the conjunctiva, and the lachrymal apparatus, viz. the lachrymal gland, the lachrymal sac, and the nasal duct.

The **eyebrows** (*supercilia*) are two arched eminences of integument, which surmount the upper circumference of the orbit on each side, and support numerous short, thick hairs, directed obliquely on the surface. In structure, the eyebrows consist of thickened integument, connected beneath with the Orbicularis palpebrarum, Corrugator supercilii, and Occipito-frontalis muscles. These muscles serve, by their action on this part, to control to a certain extent the amount of light admitted into the eye.

The **eyelids** (*palpebræ*) are two thin, movable folds, placed in front of the eye, protecting it from injury by their closure. The upper lid is the larger, and the more movable of the two, and is furnished with a separate elevator muscle, the *Levator palpebræ superioris*. When the eyelids are open, an elliptical space (*fissure palpebrarum*) is left between their margins, the angles of which correspond to the junction of the upper and lower lids, and are called *canthi*.

The *outer canthus* is more acute than the inner, and the lids here lie in close contact with the globe: but the *inner canthus* is prolonged for a short distance inwards towards the nose, and the two lids are separated by a triangular space, the *lacus lachrymalis*. At the commencement of the lacus lachrymalis, on the margin of each eyelid, is a small conical elevation, the *lachrymal papilla*, or tubercle, the apex of which is pierced by a small orifice, the *punctum lachrymale*, the commencement of the lachrymal canal.

The *eyelashes* (*cilia*) are attached to the free edges of the eyelids; they are short, thick, curved hairs, arranged in a double or triple row at the margin of the lids: those of the upper lid, more numerous and longer than the lower, curve upwards; those of the lower lid curve downwards, so that they do not interlace in closing the lids. Near the attachment of the eyelashes are the openings of a number of glands, *glands of Mohl*, arranged in several rows close to the free margin of the lid. They resemble in structure a portion of a sweat-gland, and are regarded as the modified sweat-glands of this region.

Structure of the eyelids.—The eyelids are composed of the following structures taken in their order from without inwards:

Integument, areolar tissue, fibres of the Orbicularis muscle, tarsal plate (cartilage), and its ligament, Meibomian glands and conjunctiva. The upper lid has, in addition, the aponeurosis of the Levator palpebræ.

The *integument* is extremely thin, and continuous at the margin of the lids with the conjunctiva.

The *subcutaneous areolar tissue* is very lax and delicate, seldom contains any fat, and is extremely liable to serous infiltration.

The *fibres of the Orbicularis muscle*, where they cover the palpebræ, are thin, pale in colour, and possess an involuntary action.

The *tarsal plates* (*cartilages*)* are two thin elongated plates of dense connective tissue, about an inch in length. They are placed one in each lid, contributing to their form and support.

The *superior*, the larger, is of a semilunar form, about one-third of an inch in breadth at the centre, and becoming gradually narrowed at each extremity. To the anterior surface of this plate the aponeurosis of the Levator palpebræ is attached.

The *inferior tarsal* plate, the smaller, is thinner, and of an elliptical form.

The *free* or *ciliary margin* of these plates is thick, and presents a perfectly straight edge. The *attached orbital margin* is connected to the circumference of the orbit by the fibrous membrane of the lids with which it is continuous. The outer angle of each plate is attached to the malar bone by the external palpebral or tarsal ligament. The inner angles of the two plates terminate at the commencement of the lacus lachrymalis, being fixed to the margins of the orbit by the tendo oculi.

The *tarsal ligament*, or *fibrous membrane of the lids*, is a layer of fibrous membrane, beneath the Orbicularis, attached marginally to the edge of the orbit, where it becomes continuous with the periosteum, and centrally to the tarsal plate, near its ciliary margin, with the tissue of which it is continuous. It is thickest and densest at the outer part of the orbit. Upon its under surface is a layer of unstriped muscle, which in the upper lid passes from the aponeurosis of the Levator palpebræ muscle to the tarsal plate. This ligament serves to support the eyelids, and retains the tarsal plates in their position.

The *Meibomian glands* (fig. 541) are situated upon the inner surface of the eyelids, between the tarsal plates and conjunctiva, and may be distinctly seen through the mucous membrane on everting the eyelids, presenting the appearance of parallel strings of pearls. They are about thirty in number in the upper eyelid, and somewhat fewer in the lower. They are embedded in grooves in the inner surface of the tarsal plates, and correspond in length with the breadth of each plate; they are, consequently, longer in the upper than in the lower eyelid. Their ducts open on the free margin of the lids by minute foramina, which correspond in number to the follicles. The peculiar parallel arrangement of these glands, side by side, forms a smooth layer adapted to the surface of the globe, over which they constantly glide. The use of their secretion is to prevent adhesions of the lids.

Structure of the Meibomian glands.—These glands are a variety of the

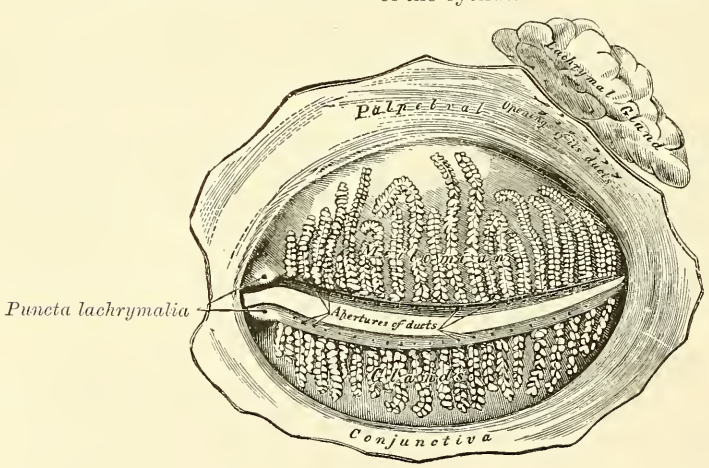
* Recent observations have proved that the so-called 'tarsal cartilages' do not contain any cartilage-cells, and that the name is a misnomer.

cutaneous sebaceous glands, each consisting of a single straight tube or follicle, having a cæcal termination, and with numerous small secondary follicles opening into it. The tubes consist of basement-membrane, covered by a layer of scaly epithelium; the secondary follicles are lined by a layer of polyhedral cells, continuous with the cells of the tube. The remainder of the follicle is filled with large polyhedral cells, charged with fat. They are thus identical in structure with the sebaceous glands.

The **conjunctiva** is the mucous membrane of the eye. It lines the inner surface of the eyelids, and is reflected over the fore part of the sclerotic and cornea. In each of these situations, its structure presents some peculiarities.

The *palpebral portion of the conjunctiva* is thick, opaque, highly vascular, and covered with numerous papillæ, its deeper parts presenting a considerable amount of lymphoid tissue. At the margin of the lids it becomes continuous with the lining membrane of the ducts of the Meibomian glands, and, through the lachrymal canals, with the lining membrane of the lachrymal sac and nasal duct. At the outer angle of the upper lid it may be traced along the lachrymal ducts into the lachrymal gland; and at the inner angle of the eye it forms a semilunar fold, the *plica semilunaris*. The folds formed by the reflection of the conjunctiva from the lids on to the eye are called the *superior* and *inferior palpebral folds*, the

Fig. 541.—The Meibomian glands, etc., seen from the inner surface of the eyelids.



former being the deeper of the two. Upon the *sclerotic*, the conjunctiva is loosely connected to the globe: it becomes thinner, loses its papillary structure, is transparent, and only slightly vascular in health. Upon the *cornea*, the conjunctiva consists only of epithelium, constituting the anterior layer of the cornea (conjunctival epithelium) already described (see page 881). *Lymphatics* arise in the conjunctiva in a delicate zone around the cornea, from which the vessels run to the ocular conjunctiva.

At the point of reflection of the conjunctiva from the lid on to the globe of the eye, termed the *fornix conjunctivæ*, are a number of mucous glands, which are much convoluted. They are chiefly found in the upper lid. Other glands, analogous to lymphoid follicles, and called by Henle *trachoma glands*, are found in the conjunctiva, and, according to Strohmeyer, are chiefly situated near the inner canthus of the eye. They were first described by Brush, in his description of Peyer's patches of the small intestines, as 'identical structures existing in the under eyelid of the ox.'

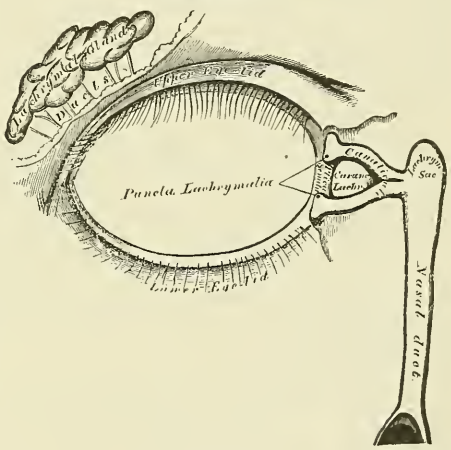
The nerves in the conjunctiva are numerous and form rich plexuses. According to Krause, they terminate in a peculiar form of tactile corpuscle, which he terms 'terminal bulb.'

The *caruncula lachrymalis* is a small, reddish, conical-shaped body, situated at the inner canthus of the eye, and filling up the small triangular space in this situation, the *lacus lachrymalis*. It consists of a cluster of follicles similar in structure to the Meibomian, covered with mucous membrane, and is the source of the whitish secretion which constantly collects at the inner angle of the eye. A few slender hairs are attached to its surface. On the outer side of the caruncula is a slight semilunar fold of mucous membrane, the concavity of which is directed towards the cornea; it is called the *plica semilunaris*. Müller found smooth muscular fibres in this fold, and in some of the domesticated animals a thin plate of cartilage has been discovered. This structure is considered to be the rudiment of the third eyelid in birds, the *membrana nictitans*.

Lachrymal Apparatus (fig. 542)

The lachrymal apparatus consists of the lachrymal gland, which secretes the tears, and its excretory ducts, which convey the fluid to the surface of the eye. This fluid is carried away by the lachrymal canals into the lachrymal sac, and along the nasal duct into the cavity of the nose.

Fig. 542.—The lachrymal apparatus. Right side.



The **lachrymal gland** is lodged in a depression at the outer angle of the orbit, on the inner side of the external angular process of the frontal bone. It is of an oval form, about the size and shape of an almond. Its upper convex surface is in contact with the periosteum of the orbit, to which it is connected by a few fibrous bands. Its under concave surface rests upon the convexity of the eyeball, and upon the Superior and External recti muscles. Its vessels and nerves enter its posterior border, whilst its anterior margin is closely adherent to the back part of the upper eyelid, where it is covered to a slight extent by the reflection of the conjunctiva. The fore part of the gland is separated from the rest by a fibrous septum; hence it is sometimes described as a separate lobe, called the *palpebral portion of the gland* (*accessory gland of Rosenmüller*). Its ducts, about seven in number, run obliquely beneath the mucous membrane for a short distance, and, separating from each other, open by a series of minute orifices on the upper and outer half of the conjunctiva, near its reflection on to the globe. These orifices are arranged in a row, so as to disperse the secretion over the surface of the membrane.

Structure of the lachrymal gland.—In structure and general appearance the lachrymal resembles the serous salivary glands (page 939). In the recent state the cells are so crowded with granules that their limits can hardly be defined. They contain an oval nucleus, and the cell protoplasm is finely fibrillated.

The **lachrymal canals** commence at the minute orifices, *puncta lachrymalia*, on the summit of a small conical elevation, the *lachrymal papilla*, seen on the margin of the lids, at the outer extremity of the lacus lachrymalis. The *superior canal*, the smaller and shorter of the two, at first ascends, and then bends at an acute angle, and passes inwards and downwards to the lachrymal sac. The *inferior canal* at first descends, and then, abruptly changing its course, passes almost horizontally inwards to the lachrymal sac. They are dense and elastic

in structure and somewhat dilated at their angle. The mucous membrane is covered with scaly epithelium.

The **lachrymal sac** is the upper dilated extremity of the nasal duct, and is lodged in a deep groove formed by the lachrymal bone and nasal process of the superior maxillary. It is oval in form, its upper extremity being closed in and rounded, whilst below it is continued into the nasal duct. It is covered by a fibrous expansion derived from the tendo oculi, and on the inner side it is crossed by the Tensor tarsi muscle (Horner's muscle, page 392) which is attached to the ridge on the lachrymal bone.

Structure.—It consists of a fibrous elastic coat, lined internally by mucous membrane: the latter being continuous, through the lachrymal canals, with the mucous lining of the conjunctiva, and through the nasal duct with the pituitary membrane of the nose.

The **nasal duct** is a membranous canal, about three-quarters of an inch in length, which extends from the lower part of the lachrymal sac to the inferior meatus of the nose, where it terminates by a somewhat expanded orifice, provided with an imperfect valve, the *valve of Hasner*, formed by the mucous membrane. It is contained in an osseous canal, formed by the superior maxillary, the lachrymal, and the inferior turbinated bones, is narrower in the middle than at each extremity, and takes a direction downwards, backwards, and a little outwards. It is lined by mucous membrane, which is continuous below with the pituitary lining of the nose. This membrane in the lachrymal sac and nasal duct is covered with columnar epithelium as in the nose. This epithelium is in places ciliated.

Surface Form.—The palpebral fissure, or opening between the eyelids, is elliptical in shape, and differs in size in different individuals and in different races of mankind. In the Mongolian races, for instance, the opening is very small, merely a narrow fissure, and this makes the eyeball appear small in these races, whereas the size of the eye is relatively very constant. The normal direction of the fissure is slightly oblique, in a direction upwards and outwards, so that the outer angle is on a slightly higher level than the inner. This is especially noticeable in the Mongolian races, in whom, owing to the upward projection of the malar bone and the shortness of the external angular process of the frontal bone, the tarsal plate of the upper lid is raised at its outer part, and gives an oblique direction to the palpebral fissure.

When the eyes are directed forwards, as in ordinary vision, the upper part of the cornea is covered by the upper lid, and the lower margin of the cornea corresponds to the level of the lower lid, so that about the lower three-fourths of the cornea is exposed under ordinary circumstances. On the margins of the lids, about a quarter of an inch from the inner canthus, are two small openings, the *puncta lachrymalia*, the commencement of the lachrymal canals. They are best seen by everting the eyelids. In the natural condition they are in contact with the conjunctiva of the eyeball, and are maintained in this position by the Tensor tarsi muscle, so that the tears running over the surface of the globe easily find their way into the lachrymal canals. The position of the lachrymal sac into which the canals open is indicated by a little tubercle (page 206), which is plainly to be felt on the lower margin of the orbit. The lachrymal sac lies immediately above and to the inner side of this tubercle, and a knife passed through the skin in this situation would open the cavity. The position of the lachrymal sac may also be indicated by the tendo oculi, or internal tarsal ligament. If both lids be drawn outwards so as to tense the skin at the inner angle, a prominent cord will be seen beneath the tightened skin. This is the *tendo oculi*, which lies immediately over the lachrymal sac, bisecting it, and thus forming a useful guide to its situation. A knife entered immediately beneath the tense cord would open the lower part of the sac. A probe introduced through this opening can be readily passed downwards through the duct into the inferior meatus of the nose. The direction of the duct is downwards, outwards, and backwards, and this course should be borne in mind in passing the probe, otherwise the point may be driven through the thin bony walls of the canal. A convenient plan is to direct the probe in such a manner, that if it were pushed onwards it would strike the first molar tooth of the lower jaw on the same side of the body. In other words, the surgeon standing in front of his patient should carry in his mind the position of the first molar tooth, and should push his probe onwards in such a way as if he desired to reach this structure.

Beneath the internal angular process of the frontal bone, the pulley of the Superior oblique muscle of the eye can be plainly felt by pushing the finger backwards between the upper and inner angle of the eye and the roof of the orbit; passing backwards and outwards from this pulley the tendon can be felt for a short distance.

Surgical Anatomy.—The eyelids are composed of various tissues, and consequently are liable to a variety of diseases. The skin which covers them is exceedingly thin and delicate, and is supported on a quantity of loose and lax subcutaneous tissue, which contains no fat. In consequence of this it is very freely movable, and is liable to be drawn down by the contraction of neighbouring cicatrices, and thus produce an eversion of the lid, known as *ectropion*. Inversion of the lids (*entropion*) from spasm of the Orbicularis palpebrarum or from chronic inflammation of the palpebral conjunctiva may also occur. The eyelids are richly supplied with blood, and are often the seat of vascular growths, such as nævi. Rodent ulcer also frequently commences in this situation. The loose cellular tissue beneath the skin is liable to become extensively infiltrated either with blood or inflammatory products, producing very great swelling. Even from very slight injuries to this tissue, the extravasation of blood may be so great as to produce considerable swelling of the lids and complete closure of the eye, and the same is the case when inflammatory products are poured out. The follicles of the eyelashes or the sebaceous glands associated with these follicles may be the seat of inflammation, constituting the ordinary 'sty.' The Meibomian glands are affected in the so-called 'tarsal tumour': the tumour, according to some, being caused by the retained secretion of these glands; by others it is believed to be a neoplasm connected with the gland. The ciliary follicles are liable to become inflamed, constituting the disease known as *blepharitis ciliaris* or 'blear eye.' Irregular or disorderly growth of the eyelashes not unfrequently occurs; some of them being turned towards the eyeball and producing inflammation and ulceration of the cornea, and possibly eventually complete destruction of the eye. The Orbicularis palpebrarum may be the seat of spasm, either in the form of slight quivering of the lids; or repeated twitchings, most commonly due to errors of refraction in children; or more continuous spasm, due to some irritation of the fifth or seventh cranial nerve. The Orbicularis may be paralysed, generally associated with paralysis of the other facial muscles. Under these circumstances, the patient is unable to close the lids, and, if he attempts to do so, rolls the eyeball upwards under the upper lid. The tears overflow from displacement of the lower lid, and the conjunctiva and cornea, being constantly exposed and the patient being unable to wink, become irritated from dust and foreign bodies. In paralysis of the Levator palpebræ superioris there is drooping of the upper eyelid and other symptoms of implication of the third nerve. The eyelids may be the seat of bruises, wounds, or burns. In these latter injuries, adhesions of the margins of the lids to each other, or adhesion of the lids to the globe may take place. The eyelids are sometimes the seat of emphysema, after fracture of some of the thin bones forming the inner wall of the orbit. If shortly after such an injury the patient blows his nose, air is forced from the nostril through the lacerated structures into the connective tissue of the eyelids, which suddenly swell up and present the peculiar crackling characteristic of this affection.

Foreign bodies frequently get into the conjunctival sac and cause great pain, especially if they come in contact with the corneal surface, during the movements of the lid and the eye on each other. The conjunctiva is frequently involved in severe injuries of the eyeball, but is seldom ruptured alone; the most common form of injury to the conjunctiva alone is from a burn, either from fire, strong acids, or lime. In these cases union is liable to take place between the eyelid and the eyeball. The conjunctiva is often the seat of inflammation arising from many different causes, and the arrangement of the conjunctival vessels should be remembered as affording a means of diagnosis between this condition and injection of the sclerotic, which is present in inflammation of the deeper structures of the globe. The inflamed conjunctiva is bright red; the vessels are large and tortuous, and greatest at the circumference, shading off towards the corneal margin; they anastomose freely and form a dense network, and they can be emptied or displaced by gentle pressure.

The lachrymal gland is occasionally, though rarely, the seat of inflammation, either acute or chronic; it is also sometimes the seat of tumours, benign or malignant, and for these may require removal. This may be done by an incision through the skin, just below the eyebrow; and the gland, being invested with a special capsule of its own, may be isolated and removed, without opening the general cavity of the orbit. The canaliculi may be obstructed, either as a congenital defect, or by some foreign body, as an eyelash or a dacryolith, causing the tears to run over the cheek. The canaliculi may also become occluded as a result of burns or injury; overflow of the tears may in addition result from deviation of the puncta, or from chronic inflammation of the lachrymal sac. This latter condition is set up by some obstruction to the nasal duct, frequently occurring in tuberculous subjects. In consequence of this the tears and mucus accumulate in the lachrymal sac, distending it. Suppuration in the lachrymal sac is sometimes met with; this may be the sequel of a chronic inflammation; or may occur after some of the eruptive fevers, in cases where the lachrymal passages were previously quite healthy. It may lead to lachrymal fistula.

THE EAR

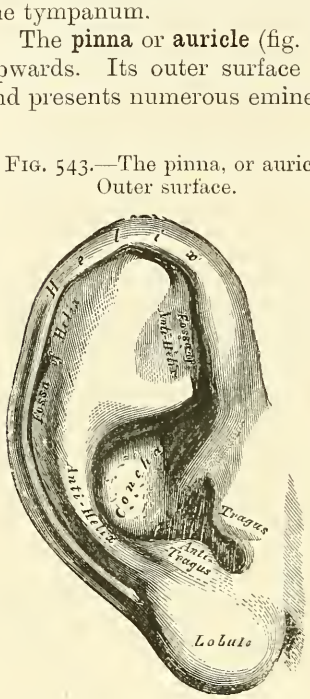
The organ of hearing is divisible into three parts: the external ear, the middle ear or tympanum, and the internal ear or labyrinth.

THE EXTERNAL EAR

The **external ear** consists of an expanded portion named *pinna* or *auricle*, and the auditory canal, or *meatus*. The former serves to collect the vibrations of the air by which sound is produced; the latter conducts those vibrations to the tympanum.

The **pinna** or **auricle** (fig. 543) is of an ovoid form, with its larger end directed upwards. Its outer surface is irregularly concave, directed slightly forwards, and presents numerous eminences and depressions which result from the foldings of its fibro-cartilaginous element. To each of these, names have been assigned. Thus the external prominent rim of the auricle is called the *helix*. Another curved prominence, parallel with and in front of the helix, is called the *antihelix*; this bifurcates above, so as to enclose a triangular depression, the *fossa of the antihelix* (*fossa triangularis*). The narrow curved depression between the helix and antihelix is called the *fossa of the helix* (*fossa innominata* or *scaphoidea*); the antihelix describes a curve round a deep, capacious cavity, the *concha*, which is partially divided into two parts by the commencement of the helix. In front of the concha, and projecting backwards over the meatus, is a small pointed eminence, the *tragus*: so called from its being generally covered on its under surface with a tuft of hair, resembling a goat's beard. Opposite the tragus, and separated from it by a deep notch (*incisura intertragica*), is a small tubercle, the *antitragus*. Below this is the *lobule*, composed of tough areolar and adipose tissue, wanting the firmness and elasticity of the rest of the pinna.

Fig. 543.—The pinna, or auricle. Outer surface.



Structure of the pinna.—The pinna is composed of a thin plate of yellow fibro-cartilage, covered with integument, and connected to the surrounding parts by the extrinsic ligaments and muscles; and to the commencement of the external auditory canal.

The *integument* is thin, closely adherent to the cartilage, and covered with hairs furnished with sebaceous glands, which are most numerous in the concha and scaphoid fossa. The hairs are most numerous and largest on the tragus and antitragus.

The *cartilage of the pinna* consists of one single piece: it gives form to this part of the ear, and upon its surface are found all the eminences and depressions above described. It does not enter into the construction of all parts of the auricle; thus it does not form a constituent part of the lobule; it is deficient, also, between the tragus and beginning of the helix, the notch between them being filled up by dense fibrous tissue. At the front part of the pinna, where the helix bends upwards, is a small projection of cartilage, called the *process of the helix*. The cartilage of the pinna presents several intervals or fissures in its substance, which partially separate the different parts. The fissure of the helix is a short vertical slit, situated at the fore part of the pinna, immediately behind a small conical projection of cartilage, opposite the first curve of the helix (process of the helix). Another fissure, the fissure of the tragus, is seen upon the anterior surface of the tragus. The antihelix is divided below, by a deep fissure, into two parts: one part terminates by a pointed, tail-like extremity (*processus caudatus*); the other is continuous with the antitragus. The carti-

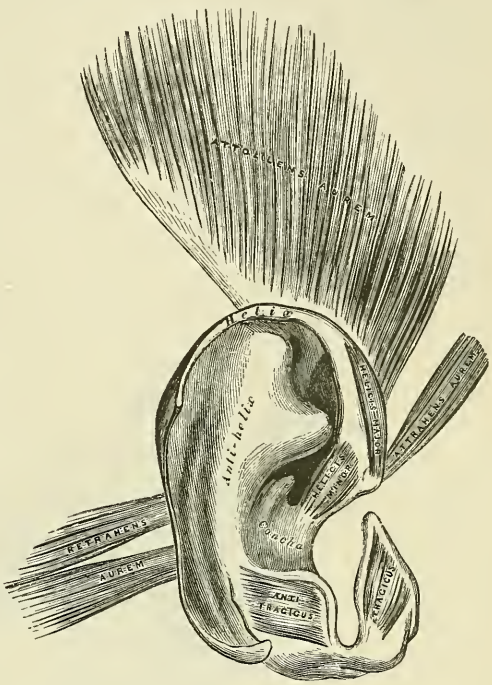
lage of the pinna is very pliable, elastic, of a yellowish colour, and belongs to that form of cartilage which is known under the name of yellow fibro-cartilage.

The *ligaments of the pinna* consist of two sets :—1. The extrinsic set, or those connecting it to the side of the head. 2. The intrinsic set, or those connecting various parts of its cartilage together.

The *extrinsic ligaments*, the most important, are two in number, anterior and posterior. The *anterior ligament* extends from the process of the helix to the root of the zygoma. A few fibres connect the tragus to the root of the zygoma. The *posterior ligament* passes from the posterior surface of the concha to the outer surface of the mastoid process of the temporal bone.

The *intrinsic ligaments* are also two in number. Of these, one is a strong fibrous band, stretching across from the tragus to the commencement of the helix, completing the meatus in front, and partly encircling the boundary of the concha; the other extends between the concha and the processus caudatus.

Fig. 544.—The muscles of the pinna.



The *muscles of the pinna* (fig. 544) consist of two sets :—1. The *extrinsic*, which connect it with the side of the head, moving the pinna as a whole, viz. the Attollens, Attrahens, and Retrahens aurem (page 390); and 2. the *intrinsic*, which extend from one part of the auricle to another, viz.:

Helicis major.	Antitragicus.
Helicis minor.	Transversus auriculæ.
Tragicus.	Obliquus auris.

The *Musculus helicis major* is a narrow vertical band of muscular fibres, situated upon the anterior margin of the helix. It arises, below, from the process of the helix, and is inserted into the anterior border of the helix, just where it is about to curve backwards. It is pretty constant in its existence.

The *Musculus helicis minor* is an oblique fasciculus, attached to that part of the helix which commences from the bottom of the concha.

The *Tragicus* is a short, flattened band of muscular fibres situated upon the outer surface of the tragus, the direction of its fibres being vertical.

The *Antitragicus* arises from the outer part of the antitragus: its fibres are inserted into the processus caudatus of the helix. This muscle is usually very distinct.

The *Transversus auriculæ* is placed on the cranial surface of the pinna. It consists of radiating fibres, partly tendinous and partly muscular, extending from the convexity of the concha to the prominence corresponding with the groove of the helix.

The *Obliquus auris* (Tod) consists of a few fibres extending from the upper and back part of the concha to the convexity immediately above it.

The *arteries of the pinna* are the posterior auricular from the external carotid,

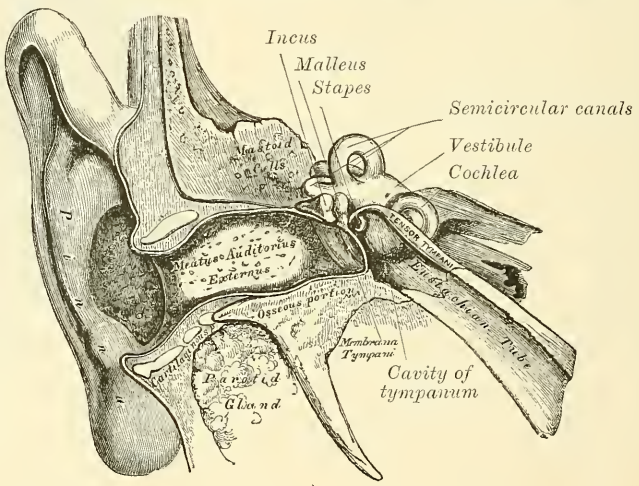
the anterior auricular from the temporal, and an auricular branch from the occipital artery.

The *veins* accompany the corresponding arteries.

The *nerves* are: the auricularis magnus, from the cervical plexus; the posterior auricular, from the facial to the muscles of the pinna; the auricular branch of the pneumogastric; the auriculo-temporal branch of the inferior maxillary nerve; the occipitalis minor from the cervical plexus, and the occipitalis major or internal branch of the posterior division of the second cervical nerve.

The **Auditory Canal** (*meatus auditorius externus*) extends from the bottom of the concha to the membrana tympani (fig. 545). It is about an inch and a quarter in length, its direction is obliquely forwards and inwards, and it is slightly curved upon itself, so as to be higher in the middle than at either extremity. It forms an oval cylindrical canal, the greatest diameter being in the vertical direction at the external orifice, but in the transverse direction at the tympanic end. The calibre of the canal is narrowest about the middle. The membrana tympani, which occupies the termination of the meatus, is

Fig. 545.—A front view of the organ of hearing. Right side.



obliquely directed, in consequence of which the floor of the canal is longer than the roof, and the anterior wall longer than the posterior. The auditory canal is formed partly by cartilage and membrane, and partly by bone, and is covered by skin.

The *cartilaginous portion* is about half an inch in length, being rather less than half the canal; it is formed by the cartilage of the concha and tragus, prolonged inwards, and firmly attached to the circumference of the auditory process of the temporal bone. The cartilage is deficient at its upper and back part, its place being supplied by fibrous membrane. This part of the canal is rendered extremely movable by two or three deep fissures (*incisuræ Santorini*), which extend through the cartilage in a vertical direction.

The *osseous portion* is about three-quarters of an inch in length, and narrower than the cartilaginous portion. It is directed inwards and a little forwards, forming a slight curve in its course, the convexity of which is upwards and backwards. Its inner end, which communicates, in the dry bone, with the cavity of the tympanum, is smaller than the outer and sloped, the anterior wall projecting beyond the posterior about two lines; it is marked, except at its upper part, by a narrow groove for the insertion of the membrana tympani. Its outer end is dilated and rough in the greater part of its circumference, for the attachment of

the cartilage of the pinna. Its vertical transverse section is oval, the greatest diameter being from above downwards. The front and lower parts of this canal are formed by a curved plate of bone, which, in the fœtus, exists as a separate ring (*tympanic plate*), incomplete at its upper part.

The *skin* lining the meatus is very thin, adheres closely to the cartilaginous and osseous portion of the tube, and covers the surface of the membrana tympani, forming its outer layer. After maceration, the thin pouch of epidermis, when withdrawn, preserves the form of the meatus. In the thick subcutaneous tissue of the cartilaginous part of the meatus are numerous ceruminous glands, which secrete the ear-wax. They resemble in structure sweat-glands, and their ducts open on the surface of the skin.

The *arteries* supplying the meatus are branches from the posterior auricular, internal maxillary, and temporal.

The *nerves* are chiefly derived from the auriculo-temporal branch of the inferior maxillary nerve and the auricular branch of the pneumogastric.

Surface Form.—At the point of junction of the osseous and cartilaginous portions, the tube forms an obtuse angle, which projects into the tube at its antero-inferior wall. This produces a sort of constriction in this situation, and renders it the narrowest portion of the canal—an important point to be borne in mind in connection with the presence of foreign bodies in the ears. The cartilaginous is connected to the bony part by fibrous tissue, which renders the outer part of the tube very movable, and therefore by drawing the pinna upwards and backwards the canal is rendered almost straight. At the external orifice are a few short, crisp hairs, which serve to prevent the entrance of small particles of dust, or flies or other insects. In the external auditory meatus the secretion of the ceruminous glands serves to catch any small particles which may find their way into the canal, and prevent their reaching the membrana tympani, where their presence might excite irritation. In young children the meatus is very short, the osseous part being very deficient, and consisting merely of a bony ring (the *tympanic plate*), which supports the membrana tympani. In the fœtus, the osseous part is entirely absent. The shortness of the canal in children should be borne in mind in introducing the aural speculum, so that it be not pushed in too far, at the risk of injuring the membrana tympani; indeed, even in the adult the speculum should never be introduced beyond the constriction which marks the junction of the osseous and cartilaginous portions. In using this instrument it is advisable that the pinna should be drawn upwards, backwards, and a little outwards, so as to render the canal as straight as possible, and thus assist the operator in obtaining, by the aid of reflected light, a good view of the membrana tympani. Just in front of the membrane is a well-marked depression, situated on the floor of the canal, and bounded by a somewhat prominent ridge; in this foreign bodies may become lodged. By aid of the speculum, combined with traction of the auricle upwards and backwards, the whole of the membrana tympani is rendered visible. It is a pearly-grey membrane, slightly glistening in the adult, placed obliquely, so as to form with the floor of the meatus a very acute angle, while with the roof it forms an obtuse angle. At birth it is more horizontal, situated in almost the same plane as the base of the skull. About midway between the anterior and posterior margins of the membrane, and extending from the centre obliquely upwards, is a reddish-yellow streak; this is the handle of the malleus, which is inserted into the membrane. At the upper part of this streak, close to the roof of the meatus, a little white, rounded prominence is plainly to be seen; this is the processus brevis of the malleus, projecting against the membrane. The membrana tympani does not present a plane surface; on the contrary, its centre is drawn inwards, on account of its connection with the handle of the malleus, and thus the external surface is rendered concave.

Middle Ear, or Tympanum

The **middle ear**, or **tympanum**, is an irregular cavity, compressed from without inwards, and situated within the petrous bone. It is placed above the jugular fossa; the carotid canal lying in front, the mastoid cells behind, the meatus auditorius externally, and the labyrinth internally. It is filled with air, and communicates with the pharynx by the Eustachian tube. The tympanum is traversed by a chain of movable bones, which connect the membrana tympani with the labyrinth, and serve to convey the vibrations communicated to the membrana tympani across the cavity of the tympanum to the internal ear.

The *cavity of the tympanum* measures about five lines from before backwards, three lines in the vertical direction, and between two and three in the transverse,

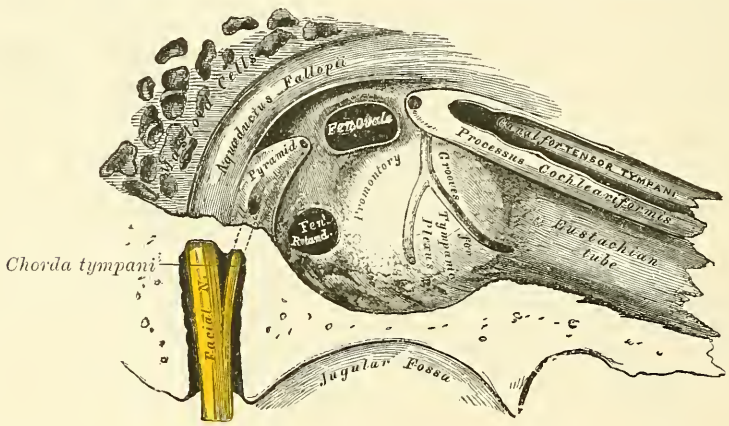
being a little broader behind and above than it is below and in front. It is bounded externally by the membrana tympani and meatus; internally, by the outer surface of the internal ear; and communicates, behind, with the mastoid cells; and in front with the Eustachian tube and canal for the Tensor tympani. Its roof and floor are formed by thin osseous laminæ, the one forming the roof being a thin plate situated on the anterior surface of the petrous portion of the temporal bone, close to its angle of junction with the squamous portion of the same bone.

The **roof** is broad, flattened, and formed of a thin plate of bone (*tegmen tympani*), which separates the cranial and tympanic cavities.

The **floor** is narrow, and corresponds to the jugular fossa, which lies beneath. It presents, near the inner wall, a small aperture for the passage of Jacobson's nerve.

The **outer wall** is formed mainly by the membrana tympani, partly by the ring of bone into which this membrane is inserted. This ring of bone is incomplete at its upper and front part, forming a notch (*incisura Rivini*), and here the

Fig. 546.—View of inner wall of tympanum. (Enlarged.)



membrane is extended outwards, and is united to the wall of the tympanum. Close to it are three small apertures: the iter chordæ posterius, the Glaserian fissure, and the iter chordæ anterius.

The *aperture of the iter chordæ posterius* is in the angle of junction between the posterior and external walls of the tympanum, immediately behind the membrana tympani and on a level with its centre; it leads into a minute canal, which descends in front of the aqueductus Fallopii, and terminates in that canal near the stylo-mastoid foramen. Through it the chorda tympani nerve enters the tympanum.

The *Glaserian fissure* opens just above and in front of the ring of bone into which the membrana tympani is inserted; in this situation it is a mere slit about a line in length. It lodges the long process of the malleus, and gives passage to some tympanic vessels.

The *aperture of the iter chordæ anterius* is seen just above the preceding fissure; it leads into a canal (*canal of Huguier*), which runs parallel with the Glaserian fissure. Through it the chorda tympani nerve leaves the tympanum.

The **internal wall of the tympanum** (fig. 546) is vertical in direction, and looks directly outwards. It presents for examination the following parts:

Fenestra ovalis.	Ridge of the aqueductus Fallopii.
Fenestra rotunda.	Pyramid.
Promontory.	Opening for the Stapedius.

The *fenestra ovalis* is a reniform opening, leading from the tympanum into the vestibule; its long diameter is directed horizontally, and its convex border is upwards. The opening in the recent state is occupied by the base of the stapes, which is connected to the margin of the foramen by an annular ligament.

The *fenestra rotunda* is an aperture placed at the bottom of a funnel-shaped depression leading into the cochlea. It is situated below and rather behind the fenestra ovalis, from which it is separated by a rounded elevation, the *promontory*; it is closed in the recent state by a membrane (*membrana tympani secundaria*, Scarpa). This membrane is concave towards the tympanum, convex towards the cochlea. It consists of three layers: the external, or mucous, derived from the mucous lining of the tympanum; the internal from the lining membrane of the cochlea; and an intermediate, or fibrous layer.

The *promontory* is a rounded hollow prominence, formed by the projection outwards of the first turn of the cochlea; it is placed between the fenestræ, and is furrowed on its surface by three small grooves, which lodge branches of the tympanic plexus.

The *rounded eminence of the aqueductus Fallopii*, the prominence of the bony canal in which the portio dura is contained, traverses the inner wall of the tympanum above the fenestra ovalis, and behind that opening curves nearly vertically downwards along the posterior wall.

The *pyramid* is a conical eminence, situated immediately behind the fenestra ovalis, and in front of the vertical portion of the eminence above described; it is hollow in the interior, and contains the Stapedius muscle; its summit projects forwards towards the fenestra ovalis, and presents a small aperture, which transmits the tendon of the muscle. The cavity in the pyramid is prolonged into a minute canal, which communicates with the aqueductus Fallopii, and transmits the nerve which supplies the Stapedius.

The **posterior wall of the tympanum** is wider above than below, and presents for examination the

Opening of the antrum.

This opening is a large irregular aperture, situated at the upper part of the posterior wall, leading into a considerable air space, the *antrum mastoideum* (see p. 154). The antrum communicates with large irregular cavities contained in the interior of the mastoid process. These cavities vary considerably in number, size, and form; they are lined by mucous membrane, continuous with that lining the cavity of the tympanum.

The **anterior wall of the tympanum** is wider above than below; it corresponds with the carotid canal, from which it is separated by a thin plate of bone, perforated by the tympanic branch of the internal carotid. It presents for examination the

Canal for the Tensor tympani. Orifice of the Eustachian tube.

The processus cochleariformis.

The orifice of the canal for the Tensor tympani and the orifice of the Eustachian tube are situated at the upper part of the anterior wall, being separated from each other by a thin, delicate, horizontal plate of bone, the *processus cochleariformis*. These canals run from the tympanum forwards, inwards, and a little downwards, to the retiring angle between the squamous and petrous portions of the temporal bone.

The *canal for the Tensor tympani* is the superior and the smaller of the two; it is rounded, and lies beneath the upper surface of the petrous bone, close to the hiatus Fallopii. The tympanic end of this canal forms a conical eminence, which is prolonged backwards into the cavity of the tympanum, and is perforated at its summit by an aperture, which transmits the tendon of the muscle contained in it. This eminence is sometimes called the *anterior pyramid*. The canal contains the Tensor tympani muscle.

The *Eustachian tube* is the channel through which the tympanum communicates with the pharynx. Its length is from an inch and a half to two inches, and its direction downwards, forwards, and inwards. It is formed partly of bone, partly of cartilage and fibrous tissue.

The *osseous portion* is about half an inch in length. It commences in the lower part of the anterior wall of the tympanum, below the processus cochleariformis, and, gradually narrowing, terminates in an oval dilated opening, at the angle of junction of the petrous and squamous portions, its extremity presenting a jagged margin which serves for the attachment of the cartilaginous portion.

The *cartilaginous portion*, about an inch in length, is formed of a triangular plate of elastic fibro-cartilage, curled upon itself, an interval being left below, between the margins of the cartilage, which is completed by fibrous and muscular tissue. Its canal is narrow behind, wide, expanded, and somewhat trumpet-shaped in front, terminating by an oval orifice, at the upper part and side of the pharynx, behind the back part of the inferior meatus. Through this canal the mucous membrane of the pharynx is continuous with that which lines the tympanum. The mucous membrane is covered with ciliated epithelium.

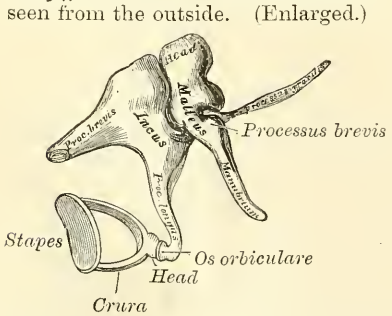
The **membrana tympani** separates the cavity of the tympanum from the bottom of the external meatus. It is a thin, semi-transparent membrane, nearly oval in form, somewhat broader above than below, and directed very obliquely downwards and inwards. Its circumference is contained in a groove at the inner end of the meatus, which skirts the circumference of this part, excepting above. The handle of the malleus descends vertically between the inner and middle layers of this membrane as far down as its centre, where it is firmly attached, drawing the membrane inwards, so that its outer surface is concave, its inner convex.

Structure.—This membrane is composed of three layers, an external (cuticular), a middle (fibrous), and an internal (mucous). The *cuticular lining* is derived from the integument lining the meatus. The *fibrous layer* consists of fibrous and elastic tissues ; some of the fibres radiate from near the centre to the circumference ; others are arranged, in the form of a dense circular ring, round the attached margin of the membrane. The *mucous lining* is derived from the mucous lining of the tympanum. The vessels pass to the membrana tympani along the handle of the malleus, and are distributed between its layers.

Ossicles of the Tympanum (fig. 547)

The tympanum is traversed by a chain of movable bones, three in number, the *malleus*, *incus*, and *stapes*. The former is attached to the membrana tympani, the latter to the fenestra ovalis, the incus being placed between the two, to both of which it is connected by delicate articulations.

Fig. 547.—The small bones of the ear seen from the outside. (Enlarged.)



The **Malleus**, so named from its fancied resemblance to a hammer, consists of a head, neck, and three processes : the handle or manubrium, the processus gracilis, and the processus brevis.

The head is the large upper extremity of the bone ; it is oval in shape, and articulates posteriorly with the incus, being free in the rest of its extent.

The *neck* is the narrow contracted part just beneath the head ; and below this is a prominence, to which the various processes are attached.

The *manubrium* is a vertical process of bone, which is connected by its outer margin with the membrana tympani. It decreases in size towards its extremity, where it is curved slightly forwards, and flattened from within outwards. On the

inner side, near its upper end, is a slight projection, into which the tendon of the Tensor tympani is inserted.

The *processus gracilis* is a long and very delicate process, which passes from the eminence below the neck forwards and outwards to the Glaserian fissure, to which it is connected by bone and ligamentous fibres.

The *processus brevis* is a slight conical projection, which springs from the root of the manubrium, and lies in contact with the membrana tympani.

The **Incus** has received its name from its supposed resemblance to an anvil, but it is more like a bicuspid tooth, with two roots, which differ in length, and are widely separated from each other. It consists of a body and two processes.

The *body* is somewhat quadrilateral but compressed laterally. On the anterior surface of its summit is a deeply concavo-convex facet, which articulates with the malleus; in the fresh state it is covered with cartilage and lined with synovial membrane.

The two processes diverge from one another nearly at right angles.

The *short process*, somewhat conical in shape, projects nearly horizontally backwards, and is attached to the margin of the opening leading into the mastoid cells, by ligamentous fibres.

The *long process*, longer and more slender than the preceding, descends nearly vertically behind and parallel to the handle of the malleus, and, bending inwards, terminates in a rounded globular projection, the *os orbiculare*, or *lenticular process* which is tipped with cartilage, and articulates with the head of the stapes. In the fœtus the os orbiculare exists as a separate bone.

The **Stapes**, so called from its close resemblance to a stirrup, consists of a head, neck, two branches, and a base.

The *head* presents a depression, tipped with cartilage, which articulates with the os orbiculare.

The *neck*, the constricted part of the bone below the head, receives the insertion of the Stapedius muscle.

The *two branches* (*crura*) diverge from the neck and are connected at their extremities by a flattened oval-shaped plate (the *base*), which forms the foot of the stirrup and is fixed to the margin of the fenestra ovalis by ligamentous fibres.

Ligaments of the Ossicula.—These small bones are connected with each other, and with the walls of the tympanum, by ligaments, and moved by small muscles. The articular surfaces of the malleus and incus, and the orbicular process of the incus and head of the stapes, are covered with cartilage, connected together by delicate capsular ligaments, and lined by synovial membrane. The ligaments connecting the ossicula with the walls of the tympanum are four in number: two for the malleus, one for the incus, and one for the stapes.

The *anterior ligament of the malleus* was formerly described by Sömmerring as a muscle (*Laxator tympani*). It is now, however, believed by most observers to consist of ligamentous fibres only. It is attached by one extremity to the neck of the malleus, just above the processus gracilis, and by the other to the anterior wall of the tympanum, close to the Glaserian fissure, some of its fibres being prolonged through the fissure.

The *suspensory ligament of the malleus* is a delicate, round bundle of fibres which descends perpendicularly from the roof of the tympanum to the head of the malleus.

The *external ligament of the malleus* is a triangular plane of fibres passing from the notch in the tympanic ring (*incisura Rivini*) to the short process of the malleus.

The *posterior ligament of the incus* is a short, thick, ligamentous band which connects the extremity of the short process of the incus to the posterior wall of the tympanum, near the margin of the opening of the mastoid cells.

The *annular ligament of the stapes* connects the circumference of the base of this bone to the margin of the fenestra ovalis.

A *suspensory ligament of the incus* has been described by Arnold, descending from the roof of the tympanum to the upper part of the incus, near its articulation with the malleus.

The **muscles of the tympanum** are two :

Tensor tympani. Stapedius.

The *Tensor tympani*, the larger, is contained in the bony canal, above the osseous portion of the Eustachian tube, from which it is separated by the processus cochleariformis. It arises from the under surface of the petrous bone, from the cartilaginous portion of the Eustachian tube, and from the osseous canal in which it is contained. Passing backwards through the canal, it terminates in a slender tendon which enters the tympanum and makes a sharp bend outward round the extremity of the processus cochleariformis, and is inserted into the handle of the malleus, near its root. It is supplied by a branch from the otic ganglion.

The *Stapedius* arises from the side of a conical cavity, hollowed out of the interior of the pyramid; its tendon emerges from the orifice at the apex of the pyramid, and, passing forwards, is inserted into the neck of the stapes. Its surface is aponeurotic, its interior fleshy; and its tendon occasionally contains a slender bony spine, which is constant in some mammalia. It is supplied by the tympanic branch of the facial nerve.

Actions.—The Tensor tympani draws the membrana tympani inwards, and thus heightens its tension. The Stapedius draws the head of the stapes backwards, and thus causes the base of the bone to rotate on a vertical axis drawn through its own centre : in doing this the back part of the base would be pressed inwards towards the vestibule, while the fore part would be drawn from it. It probably compresses the contents of the vestibule.

The **mucous membrane of the tympanum** is continuous with the mucous membrane of the pharynx, through the Eustachian tube. It invests the ossicula, and the muscles and nerves contained in the tympanic cavity; forms the internal layer of the membrana tympani; covers the foramen rotundum, and is reflected into the mastoid cells, which it lines throughout. It forms several vascular folds, which extend from the walls of the tympanum to the ossicles; of these one descends from the roof of the tympanum to the head of the malleus and upper margin of the body of the incus, a second passes backwards from the posterior crura of the stapes and invests the Stapedius muscle: other folds invest the cordi tympani nerve to the Tensor tympani muscle. These folds separate off pouch-like cavities, and give the interior of the tympanum a somewhat honeycomb appearance. In the tympanum this membrane is pale, thin, slightly vascular, and covered for the most part with columnar ciliated epithelium, but that covering the pyramid, ossicula, and membrana tympani possesses a flattened non-ciliated epithelium. In the antrum and mastoid cells its epithelium is also non-ciliated. In the osseous portion of the Eustachian tube the membrane is thin; but in the cartilaginous portion it is very thick, highly vascular, covered with laminated ciliated epithelium, and provided with numerous mucous glands.

The **arteries supplying the tympanum** are six in number. Three of them are larger than the rest, viz. the tympanic branch of the internal maxillary, which supplies the membrana tympani; the Vidian, and the stylo-mastoid branch of the posterior auricular, which supplies the back part of the tympanum and mastoid cells. The smaller branches are—the petrosal branch of the middle meningeal, which enters through the hiatus Fallopii; a branch from the ascending pharyngeal and another from the Vidian, which pass up the Eustachian tube; and the tympanic branch from the internal carotid, given off in the carotid canal and perforating the thin anterior wall of the tympanum.

The **veins of the tympanum** terminate in the temporo-maxillary vein and in the superior petrosal sinus.

The **nerves of the tympanum** constitute the tympanic plexus, which ramifies

upon the surface of the promontory. The plexus is formed by the (1) tympanic branch of the glosso-pharyngeal; (2) the small deep petrosal nerve; (3) the long petrosal nerve; and (4) the small superficial petrosal nerve.

The *tympanic branch of the glosso-pharyngeal* (Jacobson's nerve) enters the tympanum by an aperture in its floor close to the inner wall and divides into branches, which ramify on the promontory and enter into the formation of the plexus. The *small deep petrosal nerve* from the carotid plexus of the sympathetic, passes through the wall of the carotid canal and joins the branches of Jacobson's nerve. The *long petrosal nerve* from the great superficial petrosal is given off in the foramen lacerum medium and passes through an opening on the inner wall of the tympanum in front of the fenestra ovalis. It joins with the other branches of the plexus. The *small superficial petrosal nerve*, derived from the otic ganglion, passes through a foramen in the middle fossa of the base of the skull (sometimes the foramen ovale), passes backwards and enters the petrous bone through a small aperture, situated external to the hiatus Fallopii on the anterior surface of this bone; it then courses downwards through the bone, and, passing by the gangliform enlargement of the facial nerve, receives a connecting filament from it and enters the tympanic cavity, where it communicates with Jacobson's nerve, and assists in forming the tympanic plexus.

The *branches of distribution* of the tympanic plexus are distributed to the mucous membrane of the tympanum; one special branch passing to the fenestra ovalis, another to the fenestra rotunda, and a third to the Eustachian tube.

In addition to the tympanic plexus there are the nerves supplying the muscles. The Tensor tympani is supplied by a branch from the internal pterygoid of the third division of the fifth through the otic ganglion, and the Stapedius by the tympanic branch of the facial.

The *chorda tympani* nerve crosses the tympanic cavity. It is given off from the facial, as it passes vertically downwards at the back of the tympanum, about a quarter of an inch before its exit from the stylo-mastoid foramen. It passes from below upwards and forwards in a distinct canal, and enters the cavity of the tympanum through an aperture, *iter chordæ posterius*, on its posterior wall between the opening of the mastoid cells and the attachment of the membrana tympani, and becomes invested with mucous membrane. It passes forwards through the cavity of the tympanum, crossing behind the membrana tympani and over the handle of the malleus to the anterior inferior angle of the tympanum, and emerges from that cavity through a foramen at the inner end of the Glaserian fissure, which is called the *iter chordæ anterius*, or *canal of Huguier*. It is invested by the fold of mucous membrane already mentioned, and therefore lies between the mucous and fibrous layers of the membrana tympani.

Internal Ear, or Labyrinth

The **internal ear** is the essential part of the organ, receiving the ultimate distribution of the auditory nerve. It is called the **labyrinth**, from the complexity of its shape, and consists of two parts: the *osseous labyrinth*, a series of cavities channelled out of the substance of the petrous bone, and the *membranous labyrinth*, the latter being contained within the former.

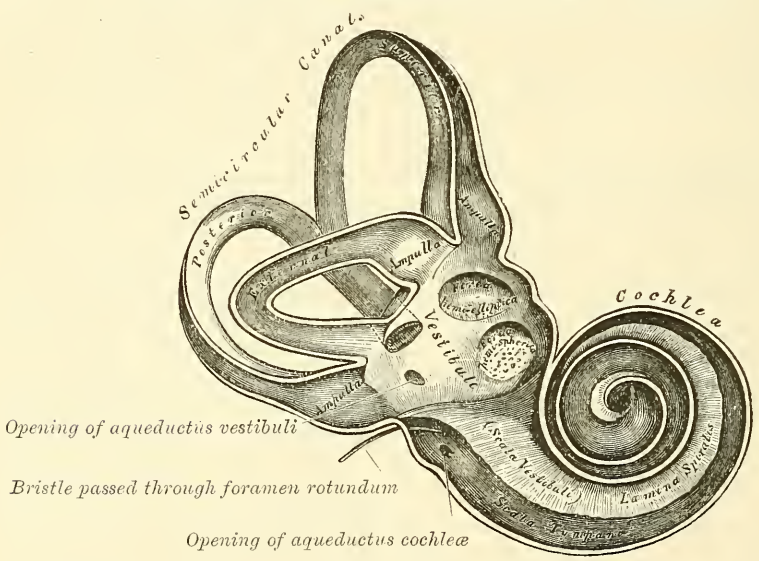
The Osseous Labyrinth

The **osseous labyrinth** consists of three parts: the *vestibule*, *semicircular canals*, and *cochlea*. These are cavities hollowed out of the substance of the bone, and lined by periosteum, and containing a clear fluid, perilymph, or liquor Cotunnii, in which the membranous labyrinth is contained.

The **Vestibule** (fig. 548) is the common central cavity of communication

between the parts of the internal ear. It is situated on the inner side of the tympanum, behind the cochlea, and in front of the semicircular canals. It is somewhat ovoidal in shape from before backwards, flattened from within outwards, and measures about one-fifth of an inch from before backwards, as well as from above downwards, being narrower from without inwards. On its *outer* or *tympanic wall* is the fenestra ovalis, closed, in the recent state, by the base of the stapes, and its annular ligament. On its *inner wall*, at the fore part, is a small circular depression, *fovea hemispherica*, which is perforated, at its anterior and inferior part, by several minute holes (*macula cribrosa*) for the passage of filaments of the auditory nerve; and behind this depression is a vertical ridge, the *pyramidal eminence* (*crista vestibuli*). This ridge bifurcates below to enclose a small depression, the *fossa cochlearis*, which is perforated by a number of holes for the passage of filaments of the auditory nerve. At the hinder part of the inner wall is the orifice of the *aqueductus vestibuli*, which extends to the posterior surface of the petrous portion of the temporal bone. It transmits a small vein, and, according to some, contains a tubular prolongation

Fig. 548.—The osseous labyrinth laid open. Enlarged.)



of the lining membrane of the vestibule, the *ductus endo-lymphaticus*, which ends in a *cul-de-sac* between the layers of the dura mater within the cranial cavity. On the *upper wall* or *roof* is a transversely oval depression, *fovea semi-elliptica*, separated from the fovea hemispherica by the pyramidal eminence already mentioned. *Behind*, the semicircular canals open into the vestibule by five orifices. In *front* is a large oval opening, which communicates with the scala vestibuli of the cochlea by a single orifice, *apertura scalæ vestibuli cochleæ*.

The **Semicircular canals** are three bony canals, situated above and behind the vestibule. They are of unequal length, compressed from side to side, and describe the greater part of a circle. They measure about one-twentieth of an inch in diameter, and each presents a dilatation at one end, called the *ampulla*, which measures more than twice the diameter of the tube. These canals open into the vestibule by five orifices, one of the apertures being common to two of the canals.

The *superior semicircular canal* is vertical in direction, and stretches across the petrous portion of the temporal bone, at right angles to its posterior surface; its arch forms a round projection on the anterior surface of the petrous bone. It

describes about two-thirds of a circle. Its outer extremity, which is ampullated, commences by a distinct orifice in the upper part of the vestibule; the opposite end of the canal, which is not dilated, joins with the corresponding part of the posterior canal, and opens by a common orifice with it in the back part of the vestibule.

The *posterior semicircular canal*, also vertical in direction, is directed backwards, nearly parallel to the posterior surface of the petrous bone; it is the longest of the three, its ampullated end commences at the lower and back part of the vestibule, its opposite end joining to form the common canal already mentioned.

The *external* or *horizontal canal* is the shortest of the three, its arch being directed outwards and backwards; thus each semicircular canal stands at right angles to the other two. Its ampullated end corresponds to the upper and outer angle of the vestibule, just above the fenestra ovalis; its opposite end opens by a distinct orifice at the upper and back part of the vestibule.

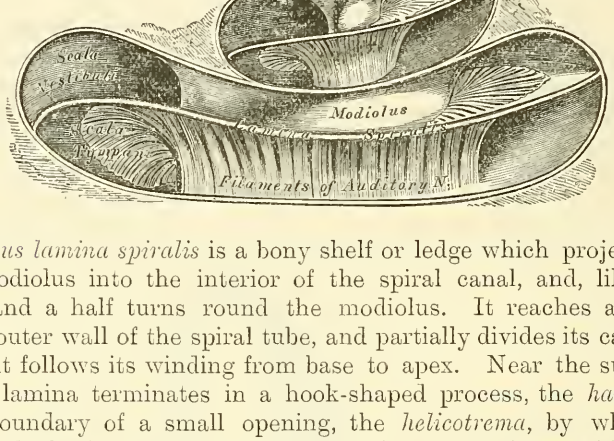
The **Cochlea** bears some resemblance to a common snail-shell: it forms the anterior part of the labyrinth, is conical in form, and placed almost horizontally in front of the vestibule; its apex is directed forwards and outwards, with a slight inclination downwards, towards the upper and front part of the inner wall of the tympanum; its base corresponds with the anterior depression at the bottom of the internal auditory meatus, and is perforated by numerous apertures, for the passage of the cochlear branch of the auditory nerve. It measures about a quarter of an inch in length, and its breadth towards the base is somewhat greater. It consists of a conical-shaped central axis, the *modiolus* or *columella*; of a canal, the inner wall of which is formed by the central axis, wound spirally around it for two turns and a half, from the base to the apex, and of a delicate lamina (the *lamina spiralis*) which projects from the modiolus, and, following the windings of the canal, partially subdivides into two. In the recent state certain membranous layers are attached to the free border of this lamina, which project into the canal and completely separate it into two passages, which, however, communicate with each other at the apex of the modiolus by a small opening, named the *helicotrema*.

The *modiolus* or *columella* is the central axis or pillar of the cochlea. It is conical in form, and extends from the base to the apex of the cochlea. Its base is broad, corresponds with the first turn of the cochlea, and appears at the bottom of the internal auditory meatus; it is perforated by numerous orifices, which transmit filaments of the cochlear branch of the auditory nerve; the axis diminishes rapidly in size in the second coil, and terminates within the last half-coil in an expanded, delicate, bony lamella, the *infundibulum*, which blends with the termination of the spiral canal. The outer surface of the modiolus is dense in structure, but its interior is spongy as far as the last half-coil, and is channelled by numerous branching canals, which transmit nervous filaments in regular succession into the canal of the cochlea, or on to the surface of the lamina spiralis. One of these, larger than the rest, occupies the centre of the modiolus, and is named the *canalis centralis modioli*; it extends from the base to the apex of the modiolus, and transmits a small nerve and artery (arteria centralis modioli).

The *spiral canal* (fig. 549) takes two turns and a half round the modiolus. It is about an inch and a half in length, measured along its outer wall, and diminishes gradually in size from the base to the summit, where it terminates in a *cul-de-sac*, the *cupola*, which forms the apex of the cochlea, and is continuous with the infundibulum of the modiolus. The commencement of this canal is about the tenth of an inch in diameter; it diverges from the modiolus towards the tympanum and vestibule, and presents three openings. One, the *fenestra rotunda*, communicates with the tympanum; in the recent state this aperture is closed by a membrane, the *membrana tympani secundaria*. Another aperture, of an oval form, enters the vestibule. The third is the aperture of the

aqueductus cochlea, leading to a minute funnel-shaped canal, which opens on the basilar surface of the petrous bone and transmits a small vein, and also forms a communication between the subarachnoidean space of the skull and the perilymph contained in the scala tympani.

Fig. 549.—The cochlea laid open. (Enlarged.)



The *osseous lamina spiralis* is a bony shelf or ledge which projects outwards from the modiolus into the interior of the spiral canal, and, like the canal, takes two and a half turns round the modiolus. It reaches about halfway towards the outer wall of the spiral tube, and partially divides its cavity into two portions, as it follows its winding from base to apex. Near the summit of the cochlea the lamina terminates in a hook-shaped process, the *hamulus*, which forms the boundary of a small opening, the *helicotrema*, by which the two scalæ, into which the spiral canal is divided, communicate with each other. These scalæ are named *scala vestibuli* and *scala tympani*.

The Membranous Labyrinth (fig. 550)

The **membranous labyrinth** is contained within the bony cavities just described. In the vestibule and semicircular canals it consists of a membranous sac, having the same general form as the cavities in which it is contained, though considerably smaller, being separated from the bony walls by a quantity of fluid, the *perilymph*. It does not, however, float loosely in this fluid, but in places is fixed to the walls of the cavity. The membranous sac contains fluid, the *endo-lymph*, and on it the ramifications of the auditory nerve are distributed. The membranous labyrinth of the cochlea consists of a tube containing endolymph, and partly surrounded by perilymph, which occupies the spiral canal of the osseous cochlea; but in addition to this it completes the septum between the scala vestibuli and the scala tympani, and also shuts off a small portion of the first-named scala, as a separate canal, the canalis cochleæ.

Within the osseous vestibule the membranous labyrinth does not quite preserve the form of the bony cavity, but presents two membranous sacs, the *utricle* and the *saccule*. The *utricle* is the larger of the two, of an oblong form, compressed laterally, and occupies the upper and back part of the vestibule, lying in contact with the fovea semi-elliptica and the part below it. That portion which is lodged in the fovea forms a sort of pouch or *cul-de-sac*, the wall of which is much thicker than elsewhere, and has attached to its internal surface a layer of calcareous particles (otoliths). Here numerous filaments of the auditory nerve are distributed to the wall of the sac. Its cavity communicates behind with the membranous semicircular canals by five orifices.

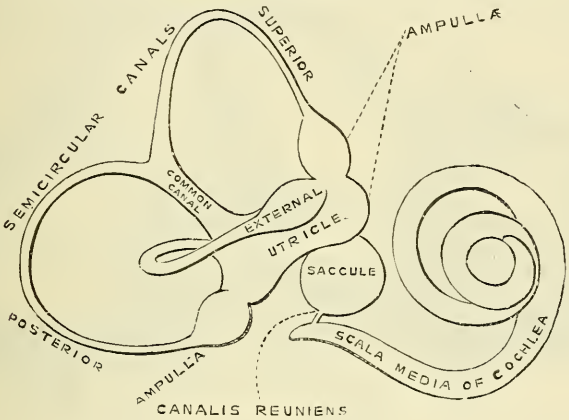
The *saccule* is the smaller of the two vestibular sacs; it is globular in form, lies in the fovea hemispherica near the opening of the scala vestibuli of the cochlea, and receives numerous nervous filaments, which enter from the bottom of the depression in which it is contained. Its cavity does not directly com-

municate with that of the utricle. From the lower part of the saccule a funnel-shaped tube passes downwards and outwards to open into the spiral canal of the cochlea. This is known by the name of the *canalis reuniens* (fig. 550). The *membranous semicircular canals* are about one-third the diameter of the osseous canals, but in number, shape, and general form they are precisely similar, and present at one end an ampullary enlargement. They are hollow and open by five orifices into the utricle, one opening being common to two canals. Their ampullæ are thicker than the rest of the tubes, and nearly fill the cavities in which they are contained.

The membranous labyrinth is held in its position by numerous fibrous bands which stretch across the space between the membranous and bony labyrinths. These fibrous bands convey the blood vessels and nervous filaments distributed to the utricle, to the saccule, and to the ampullæ of each canal.

Structure.—The wall of the membranous labyrinth is semi-transparent and consists of three layers. The *outer layer* is a loose and flocculent structure, apparently composed of ordinary fibrous tissue, containing blood vessels and pigment cells analogous to those in the pigment coat of the retina. The *middle layer*, thicker and more transparent, bears some resemblance to the hyaloid membrane, but it presents on its internal surface numerous papilliform projec-

Fig. 550.—The membranous labyrinth. (Enlarged.)



tions, and, on the addition of acetic acid, presents an appearance of longitudinal fibrillation and elongated nuclei. The *inner layer* is formed of polygonal nucleated epithelial cells. In the utricle, the saccule and the ampullæ of the canals at the part where they are connected to the bony walls, the middle coat is thickened and the epithelium is columnar, each epithelial cell being surmounted by a long, tapering filament (auditory hair) which projects into the cavity. The filaments of the auditory nerve enter this part, and having pierced the outer and thickened middle layer, they lose their medullary sheath, and their axis cylinders ramify between those columnar cells which bare the auditory hairs.

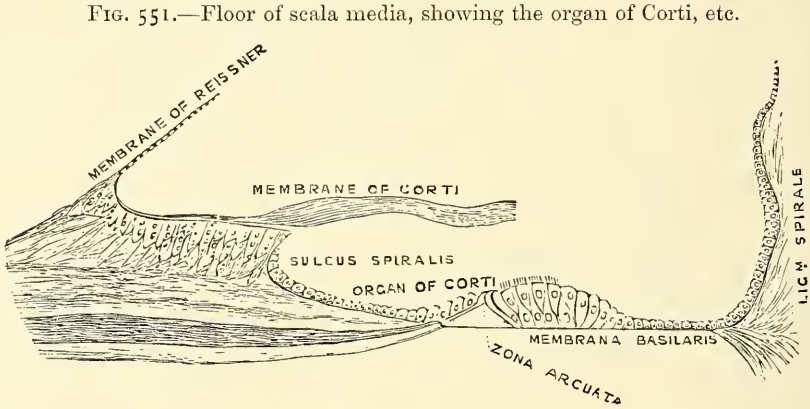
The *endo-lymph* (*liquor Scarpæ*) is a limpid serous fluid which fills the membranous labyrinth; in composition it closely resembles the perilymph.

The *otoliths* are two small rounded bodies, consisting of a mass of minute crystalline grains of carbonate of lime, held together in a mesh of delicate fibrous tissue, and contained in the walls of the utricle and saccule opposite the distribution of the nerves. A calcareous material is also, according to Bowman, sparingly scattered in the cells lining the ampullæ of the semicircular canals.

The **membranous labyrinth of the cochlea** consists of a tube enclosed in the spiral canal, which is divided into three compartments by certain other membranous structures, which will now be described.

The osseous lamina, as above stated, extends only part of the distance between the modiolus and the outer bony wall of the cochlea. Near its outer end it becomes somewhat thickened, and this thickened part is known as the *limbus laminæ spiralis*. It terminates abruptly in a grooved extremity, the *sulcus spiralis*, which presents the form of the letter C: the upper part of the letter, being formed by the overhanging extremity of the limbus, is named the *labium vestibulare*; the lower part, prolonged and tapering, is called the *labium tympanicum* (fig. 551). From the labium tympanicum a thin membrane extends over to the bony wall of the cochlea, completing the scala tympani. This membrane is called the *membrana basilaris*. At its outer attachment it swells out so as to form a thick, triangular structure, which was regarded as a muscle by Tod and Bowman (cochlearis), but is now recognised as ligamentous—the *ligamentum spirale*. Between the labium vestibulare and the attachment of the membrane of Reissner, presently to be described, a very delicate membrane extends over towards the outer wall of the cochlea, running nearly parallel to the membrana basilaris. It was described by Corti, and covers over the organ which is called after his name, and is therefore called the *membrane of Corti* or *membrana tectoria*. When this membrane passes over the specialised epithelium known as the rods of Corti, it swells out and forms a thick fibrillated membrane, which rests on the rods; beyond these structures it again thins out and forms a delicate membrane over

Fig. 551.—Floor of scala media, showing the organ of Corti, etc.



the outer hair-cells. Farther inwards, near the commencement of the limbus laminæ spiralis, another delicate membrane, the *membrane of Reissner*, is attached to the vestibular surface of the periosteum of the osseous lamina, and stretches across to the outer wall of the cochlea. The canal which lies below the osseous lamina and membrana basilaris is the *scala tympani*; that which is bounded by the osseous lamina and membrane of Reissner the *scala vestibuli*; while the space between the membrane of Reissner and membrana basilaris is generally described as the *Scala media, Canalis membranacea*, or *Canalis cochleæ*. The latter is the space in which the *organ of Corti** is contained. This organ (fig. 551) is situated upon the membrana basilaris, and appears at first sight as a papilla, winding spirally with the turns of this membrane throughout the whole length of the cochlea, from which circumstance it has been designated the *papilla spiralis*. More accurately viewed, it is seen to be composed of a remarkable arrangement of cells, which may be likened to the keyboard of a pianoforte. Of these cells, the two central ones are rodlike bodies, and are called the inner and outer *rods of Corti*. They are placed erect on the basilar membrane, at some little distance from each other, the space between them being denominated the *zona arcuata*; they are inclined towards each other, so as to meet at their opposite extremities, and form a series of arches roofing over the zona arcuata,

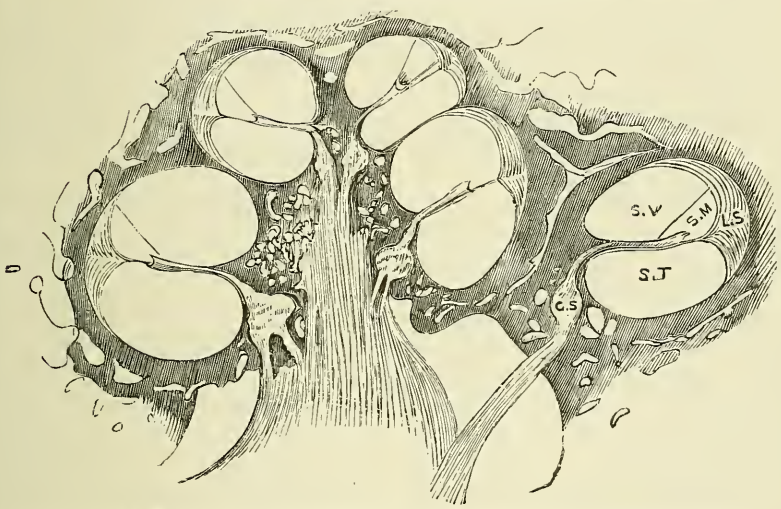
* Corti's original paper is in the *Zeitschrift f. Wissen. Zool.* iii. 109.

thus forming a minute tunnel between them and the basilar membrane, which ascends spirally through the whole length of the cochlea. They are estimated at over three thousand in number.

The inner rods, which are more numerous than the outer ones, rest on the basilar membrane, close to the labium tympanicum; they project obliquely forwards and outwards, and terminate above in expanded extremities, which resemble in shape the upper end of the ulna, with its sigmoid cavity, coronoid and olecranon processes. On the outer side of the rod, in the angle formed between it and the basilar membrane, is a protoplasmic cell; whilst on the inner side is a row of epithelial cells, surmounted by a brush of fine, stiff, hairlike processes, these cells being continuous with the cubical cells lining the sulcus spiralis.

The outer rods also rest by a broad foot on the basilar membrane; they incline forwards and inwards, and their upper extremity resembles the head and bill of a swan; the head fitting into the concavity—the analogue of the sigmoid cavity—of one or more of the internal rods, and the bill resting against the phalanges of the lamina reticularis, presently to be described.

Fig. 552.—Longitudinal section of the cochlea, showing the relations of the scalæ, the ganglion spirale, etc.



S. V. Scala vestibuli. S. T. Scala tympani. S. M. Scala media. L. S. Ligamentum spirale. G. S. Ganglion spirale.

In the head of these outer rods is an oval portion, where the fibres of which the rod appears to be composed are deficient, and which stains more deeply with carmine than the rest of the rod. This is supposed to represent the nucleus of the cell from which the rod was originally developed. At the base of the rod, on its internal side—that is to say, in the angle formed by the rod with the basilar membrane—is a similar protoplasmic cell to that found on the outer side of the base of the inner rod; whilst external to the outer rod are three or four successive rows of epithelial cells, more elongated than those found on the internal side of the inner rod, but, like them, furnished with minute hairs or cilia. These are termed the *outer hair-cells*, in contradistinction to the inner set, which are termed the *inner hair-cells*. They are attached by their bases to the basilar membrane, whilst from the opposite extremity a brush of hairs or cilia projects through the reticular membrane. They are continuous externally with the cubical cells on the lateral part of the basilar membrane.

The *reticular lamina* or *membrane of Kölliker* is a delicate framework perforated by rounded holes. It extends from the inner rods of Corti to the external row

of the outer hair-cells, and is formed by several rows of 'minute fiddle-shaped cuticular structures,' called *phalanges*, between which are holes for the projection of the ciliæ of the outer hair-cells.

Covering over these structures, but not touching them, is the membrana tectoria, or membrane of Corti, which is attached to the vestibular surface of the lamina spiralis close to the attachment of the membrane of Reissner; it courses over the denticulate lamina, and, passing outwards parallel to the basilar membrane, is blended with the ligamentum spirale on the outer wall of the spiral canal.*

The *inner surface of the osseous labyrinth* is lined by an exceedingly thin fibro-serous membrane, analogous to a periosteum, from its close adhesion to the inner surfaces of these cavities, and performing the office of a serous membrane by its free surface. It lines the vestibule, and from this cavity is continued into the semicircular canals and the scala vestibuli of the cochlea, and through the helicotrema into the scala tympani. A delicate tubular process is prolonged along the aqueduct of the vestibule to the inner surface of the dura mater. This membrane is continued across the fenestra ovalis and rotunda, and consequently has no communication with the lining membrane of the tympanum. Its attached surface is rough and fibrous, and closely adherent to the bone; its free surface is smooth and pale, covered with a layer of epithelium, and secretes a thin, limpid fluid, the *aqua labyrinthi, liquor Cotunnii,* or *perilymph* (Blainville).

The scala media is closed above and below. The upper blind extremity is attached to the cupola at the upper part of the helicotrema; the lower end fits into the angle at the commencement of the osseous lamina on the floor of the vestibule. Near this blind extremity, the scala media receives the *canalis reuniens* (fig. 550), a very delicate canal, by which the ductus cochlearis is brought into continuity with the saccule.

The **arteries of the labyrinth** are the internal auditory, from the basilar; the stylo-mastoid, from the posterior auricular; and, occasionally, branches from the occipital. The internal auditory divides at the bottom of the internal meatus into two branches: cochlear and vestibular.

The cochlear branch subdivides into from twelve to fourteen twigs, which traverse the canals in the modiolus, and are distributed, in the form of a capillary network, in the substance of the lamina spiralis.

The vestibular branches accompany the nerves, and are distributed, in the form of a minute capillary network, in the substance of the membranous labyrinth.

The **veins** (auditory) of the vestibule and semicircular canals accompany the arteries, and, receiving those of the cochlea at the base of the modiolus, terminate in the superior petrosal sinus.

The **auditory nerve**, the special nerve of the sense of hearing, divides, at the bottom of the internal auditory meatus, into two branches, the cochlear and vestibular. The trunk of the nerve, as well as the branches, contains numerous ganglion-cells with caudate prolongations.

The *vestibular nerve*, the posterior of the two, divides into three branches: superior, middle, and inferior.

The superior vestibular branch, the largest, divides into numerous filaments, which pass through minute openings at the upper and back part of the *cul-de-sac* at the bottom of the meatus, and, entering the vestibule, are distributed to the utricle and to the ampulla of the external and superior semicircular canals.

The middle vestibular branch consists of numerous filaments, which enter the vestibule by a smaller cluster of foramina, placed below those above-mentioned, and which correspond to the bottom of the fovea hemispherica; they are distributed to the saccule.

The inferior and smallest branch passes backwards in a canal behind the foramina for the nerves of the saccule, and is distributed to the ampulla of the posterior semicircular canal.

* In fig. 551 only the inner half of the membrane is represented.

The nervous filaments enter the ampullary enlargements at a deep depression seen on their external surface, with a corresponding elevation when seen from within; the nerve-fibres ending in loops and in free extremities. In the utricle and saccule the nerve-fibres spread out, some blending with the calcareous matter; others, radiating on the inner surface of the wall of each cavity, become blended with a layer of nucleated cells, and terminate in a thin fibrous film.

The *cochlear nerve* divides into numerous filaments at the base of the modiolus, which ascend along its canals, and then, bending outwards at right angles, pass through the substance of the bony lamina spiralis, close to its tympanic surface. During their passage through the spiral lamina the nerves form a plexus, which contains ganglion cells forming the ganglion spirale. From this ganglion delicate filaments pass through the osseous lamina to the sulcus spiralis and pass outwards to the organ of Corti. Their exact termination is uncertain. Waldeyer describes them as collected into two groups, one group ending in the outer and the other in the inner hair-cells.

Surgical Anatomy.—Malformations, such as imperfect development of the external parts, absence of the meatus, or supernumerary auricles, are occasionally met with. Or the pinna may present a congenital fistula, which is due to defective closure of the first visceral cleft, or rather of that portion of it which is not concerned in the formation of the Eustachian tube, tympanum, and meatus. The skin of the auricle is thin and richly supplied with blood, but in spite of this it is frequently the seat of frost-bite, due to the fact that it is much exposed to cold, and lacks the usual covering of subcutaneous fat found in most other parts of the body. A collection of blood is sometimes found between the cartilage and perichondrium (*hæmatoma auris*), usually the result of traumatism, but not necessarily due to this cause. It is said to occur most frequently in the ears of the insane. Keloid sometimes grows in the auricle around the puncture made for earrings, and epithelioma occasionally affects this part. Deposits of urate of soda are often met with in the pinna in gouty subjects.

The external auditory meatus can be most satisfactorily examined by light reflected down a funnel-shaped speculum; by gently moving the latter in different directions the whole of the canal and membrana tympani can be brought into view. The points to be noted are, the presence of wax or foreign bodies; the size of the canal; and the condition of the membrana tympani. Accumulation of wax is often the cause of deafness, and may give rise to very serious consequences, causing ulceration of the membrane and even absorption of the bony wall of the canal. Foreign bodies are not infrequently introduced into the ear by children, and, when situated in the first portion of the canal, may be removed with tolerable facility by means of a minute hook or loop of fine wire, aided by reflected light; but when they have slipped beyond the narrow middle part of the meatus, their removal is in no wise easy, and attempts to effect it, in inexperienced hands, may be followed by destruction of the membrana tympani and possibly the contents of the tympanum. The calibre of the external auditory canal may be narrowed by inflammation of its lining membrane, running on to suppuration; by periostitis; by polypi, sebaceous tumours, and exostoses. The membrana tympani, when seen in a healthy ear, 'reflects light strongly, and, owing to its peculiar curvature, presents a bright spot of triangular shape at its lower and anterior portion.' From the apex of this, proceeding upwards and slightly forwards, is a white streak formed by the handle of the malleus, while at the upper and middle part of the membrane may be seen a slight projection, caused by the short process of the malleus. In disease, alterations in colour, lustre, curvature or inclination, and perforation must be noted. Such perforations may be caused by a blow, a loud report, or a wound.

The upper wall of the meatus is separated from the cranial cavity by a thin plate of bone; the anterior wall is separated from the temporo-maxillary joint and parotid gland by the bone forming the glenoid fossa; and the posterior wall is in relation with the mastoid cells, hence inflammation of the external auditory meatus may readily extend to the membranes of the brain, to the temporo-maxillary joint, or to the mastoid cells; and, in addition to this, blows on the chin may cause fracture of the wall of the meatus.

The nerves supplying the meatus are, the auricular branch of the pneumogastric, the auriculo-temporal, and the auricularis magnus. The connections of these nerves explain the fact of the occurrence, in cases of any irritation of the meatus, of constant coughing and sneezing, from implication of the pneumogastric, or of yawning from implication of the auriculo-temporal. No doubt also the association of earache, with toothache, in cancer of the tongue is due to implication of the same nerve, a branch of the fifth, which supplies also the teeth and the tongue. The vessels of the meatus and membrana tympani are derived from the posterior auricular, temporal, and internal maxillary arteries. The upper half of the membrana tympani is much more richly supplied with blood than the lower half. For this reason, and also to avoid the chorda tympani nerve and ossicles, incisions through the membrane should be made at the lower and posterior part.

The principal point in connection with the surgical anatomy of the tympanum is its relations to other parts. Its roof is formed by a thin plate of bone, which, with the dura mater, is all that separates it from the temporo-sphenoidal lobe of the brain. Its floor is immediately above the jugular fossa behind and the carotid canal in front. Its posterior wall presents the openings of the mastoid cells. On its anterior wall is the opening of the Eustachian tube. Thus it follows that in disease of the middle ear we may get subdural abscess, septic meningitis, or abscess of the cerebrum or cerebellum, from extension of the inflammation through the bony roof; thrombosis of the lateral sinus, with or without pyæmia, by extension through the floor; or mastoid abscess, by extension backwards. In addition to this we may get fatal hæmorrhage from the internal carotid in destructive changes of the middle ear. And in throat disease we may get the inflammation extending up the Eustachian tube to the middle ear. The Eustachian tube is accessible from the nose. If the nose and mouth be closed, and an attempt made to expire air, a sense of pressure with dulness of hearing is produced in both ears, from the air finding its way up the Eustachian tube and bulging out the membrana tympani. During the act of swallowing, the pharyngeal orifice of the tube, which is normally closed, is opened, probably by the action of the Tensor tympani. This fact was employed by Politzer in devising an easy method of inflating the tube. The nozzle of an indiarubber syringe is inserted into the nostril; the patient takes a mouthful of water and holds it in his mouth; both nostrils are closed with the finger and thumb to prevent the escape of air, and the patient is then requested to swallow; as he does so, the air is forced out of the syringe into his nose, and is driven into the Eustachian tube, which is now open. The impact of the air against the membrana tympani can be heard, if the membrane is sound, by means of a piece of indiarubber tubing, one end of which is inserted into the meatus of the patient's ear, the other into that of the surgeon. The direct examination of the Eustachian tube is made by the Eustachian catheter. This is passed along the floor of the nostril, with the curve downwards, to the posterior wall of the pharynx. When this is felt, the catheter is to be withdrawn about half an inch, and the point rotated outwards through a quarter of a circle and pushed again slightly backwards, when it will enter the orifice of the tube, and will be found to be caught, and air forced into the catheter will be heard impinging on the tympanic membrane, if the ear of the patient and surgeon are connected by an indiarubber tube.

ORGANS OF DIGESTION

THE Apparatus for the Digestion of the Food consists of the alimentary canal and of certain accessory organs.

The **alimentary canal** is a musculo-membranous tube, about thirty feet in length, extending from the mouth to the anus, and lined throughout its entire extent by mucous membrane. It has received different names in the various parts of its course: at its commencement, the mouth, we find provision made for the mechanical division of the food (*mastication*), and for its admixture with a fluid secreted by the salivary glands (*insalivation*); beyond this are the organs of deglutition, the pharynx and the œsophagus, which convey the food into that part of the alimentary canal (the stomach) in which the principal chemical changes occur, and in which the reduction and solution of the food take place; in the small intestines, the nutritive principles of the food (the *chyle*) are separated, by its admixture with the bile and pancreatic fluid, from that portion which passes into the large intestine, most of which is expelled from the system.

Alimentary Canal

Mouth.	Small intestine	Duodenum.
Pharynx.		Jejunum.
Œsophagus.		Ileum.
Stomach.	Large intestine	Cæcum.
		Colon.
		Rectum.

Accessory Organs

Teeth.		
Salivary glands	Parotid.	Liver.
	Submaxillary.	Pancreas.
	Sublingual.	Spleen.

The **mouth** (*oral* or *buccal cavity*) is placed at the commencement of the alimentary canal; it is a nearly oval-shaped cavity, in which the mastication of the food takes place (fig. 553). It is bounded, in front, by the lips; laterally, by the cheeks and the alveolar processes of the upper and lower jaws; above, by the hard palate and teeth of the upper jaw; below, by the tongue and by the mucous membrane stretched between the under surface of that organ and the inner surface of the jaws, and by the teeth of the lower jaw; behind, by the soft palate and fauces.

The *mucous membrane* lining the mouth is continuous with the integument at the free margin of the lips, and with the mucous lining of the fauces behind; it is of a rose-pink tinge during life, and very thick where it covers the hard parts bounding the cavity. It is covered by stratified epithelium.

The **lips** are two fleshy folds which surround the orifice of the mouth, formed externally of integument and internally of mucous membrane, between which are found the Orbicularis oris muscle, the coronary vessels, some nerves, areolar tissue, and fat, and numerous small labial glands. The inner surface of each lip is connected in the middle line to the gum of the corresponding jaw by a fold of

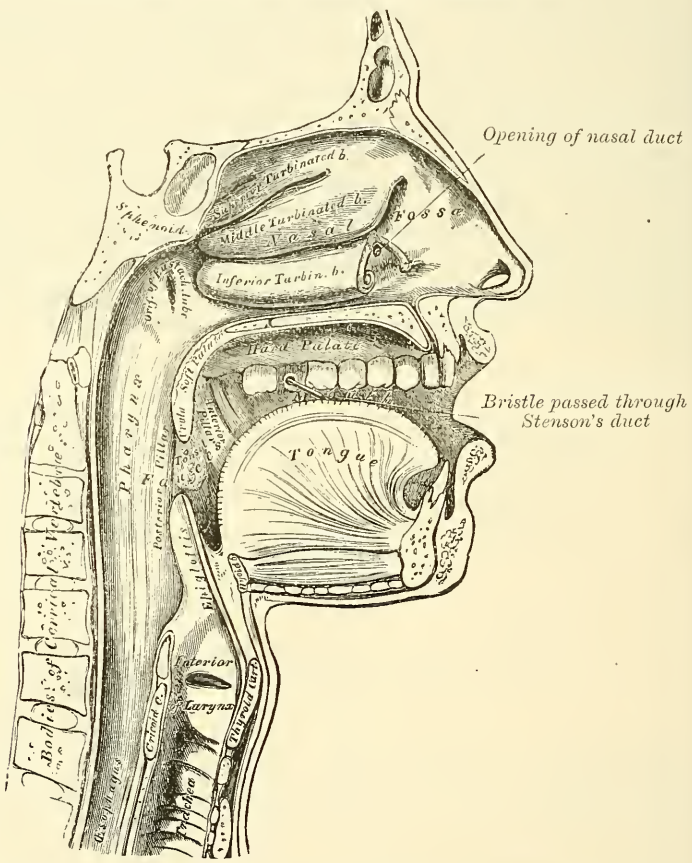
mucous membrane, the *frænum labii superioris* and *inferioris*—the former being the larger of the two.

The *labial glands* are situated between the mucous membrane and the Orbicularis oris, round the orifice of the mouth. They are rounded in form, about the size of small peas, their ducts opening by small orifices upon the mucous membrane. In structure they resemble the salivary glands.

The **cheeks** form the sides of the face, and are continuous in front with the lips. They are composed externally of integument; internally of mucous membrane; and between the two of a muscular stratum, besides a large quantity of fat, areolar tissue, vessels, nerves, and buccal glands.

The *mucous membrane* lining the cheek is reflected above and below upon the gums, and is continuous behind with the lining membrane of the soft palate.

Fig. 553.—Sectional view of the nose, mouth, pharynx, etc.



Opposite the second molar tooth of the upper jaw is a papilla, the summit of which presents the aperture of the duct of the parotid gland. The principal muscle of the cheek is the Buccinator; but numerous other muscles enter into its formation: viz. the Zygomatici, Risorius Santorini, and Platysma myoides.

The *buccal glands* are placed between the mucous membrane and Buccinator muscle: they are similar in structure to the labial glands, but smaller. Two or three of larger size than the rest are placed between the Masseter and Buccinator muscles; their ducts open in the mouth opposite the last molar tooth. They are called *molar glands*.

The **gums** are composed of a dense fibrous tissue, closely connected to the periosteum of the alveolar processes, and surrounding the necks of the teeth. They are covered by smooth and vascular mucous membrane, which is remark-

able for its limited sensibility. Around the necks of the teeth this membrane presents numerous fine papillæ; and from this point it is reflected into the alveolus, where it is continuous with the periosteal membrane lining that cavity.

The Teeth

The human subject is provided with two sets of teeth, which make their appearance at different periods of life. The first set appear in childhood, and are called the *temporary, deciduous,* or *milk teeth.* The second set, which also appear at an early period, continue until old age, and are named *permanent.*

The *temporary teeth* are twenty in number: four incisors, two canine, and four molars, in each jaw.

The *permanent teeth* are thirty-two in number: four incisors (two central and two lateral), two canines, four bicuspids, and six molars, in each jaw.

General Characters.—Each tooth consists of three portions: the *crown,* or *body,* projecting above the gum; the *root,* or *fang,* entirely concealed within the alveolus; and the *neck,* the constricted portion, between the other two.

The *roots of the teeth* are firmly implanted within the alveoli; these depressions are lined with periosteum, which is reflected on to the tooth at the point of the fang, and covers it as far as the neck. At the margin of the alveolus, the periosteum becomes continuous with the fibrous structure of the gums.

In consequence of the curve of the dental arch, such terms as anterior, posterior, internal and external, as applied to the teeth, are misleading and confusing. Special terms are therefore applied to the different surfaces of a tooth: that surface which is directed towards the lips or cheek is known as the *labial* surface; that which is directed towards the tongue is described as the *lingual* surface; that surface which is directed towards the mesial line, supposing the teeth were arranged in a straight line outwards from the central incisor, is known as the *proximal* surface; whilst that which is directed away from the mesial line is called the *distal* surface.

The teeth in the upper jaw form a larger arch than those in the lower jaw, so that they slightly overlap those of the inferior maxilla both in front and at the sides in the normal condition. In consequence of the greater width of the upper central incisors over those of the lower, the other teeth in the upper jaw are thrown somewhat distally and the two sets do not quite correspond to each other when the mouth is closed: thus the canine tooth of the upper jaw rests partly on the canine of the lower jaw and partly on the first premolar, and in the molar teeth the cusps of the teeth of the upper jaw lie behind the corresponding teeth of the lower jaw. The two series, however, terminate pretty nearly at the same point behind; this is mainly due to the smaller size of the molars in the upper jaw.

Permanent Teeth

The **incisors**, or cutting teeth, are so named from their presenting a sharp cutting edge, adapted for biting the food. They are eight in number, and form the four front teeth in each jaw.

The *crown* is directed vertically, and is chisel-shaped, presenting a sharp horizontal cutting edge, which, before being subject to attrition, presents three small prominent points separated by two slight notches. It is convex, smooth, and highly polished on its labial surface; concave on its lingual surface, where it is frequently marked by slight longitudinal furrows. The one in the centre, being the most prominent, is known as the *basal ridge* or *cingulum.*

The *neck* is constricted.

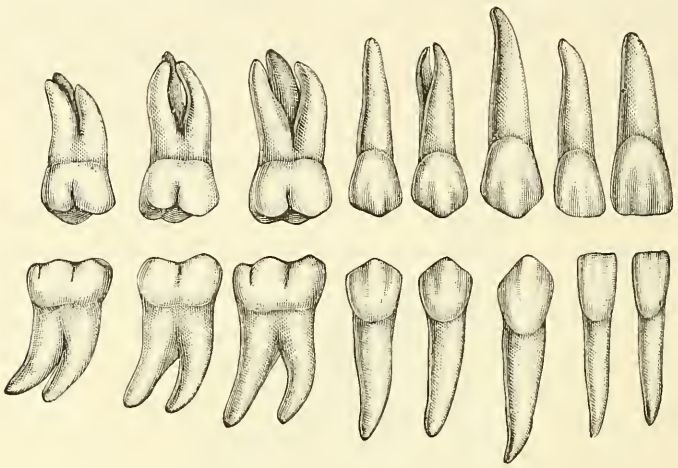
The *fang* is long, single, conical, transversely flattened, thicker before than behind, and slightly grooved on each side in the longitudinal direction.

The *incisors of the upper jaw* are altogether larger and stronger than those of the lower jaw. They are directed obliquely downwards and forwards. The

two central ones are larger than the two lateral, and their free edges are sharp and chisel-like, being bevelled at the expense of their posterior edge : the root is more rounded.

The *incisors of the lower jaw* are smaller than the upper : the two central ones are smaller than the two lateral, and are the smallest of all the incisor

Fig. 554.—Permanent teeth. Right side. (Burchard.)

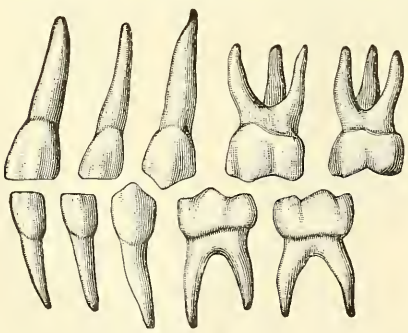


teeth. They are placed vertically in the jaw. These are somewhat bevelled in front, where they have been worn down by contact with the overlapping edge of the upper teeth. The lingulum is absent.

The **canine teeth** (*cuspidati*) are four in number : two in the upper, and two in the lower jaw ; one being placed distally to each lateral incisor. They are larger and stronger than the incisors, especially the root, which sinks deeply into the jaw, and causes a well-marked prominence upon its surface.

The crown is large and conical, very convex on its labial surface, a little hollowed and uneven on its lingual surface, and tapering to a blunted point or cusp, which rises beyond the level of the other teeth.

Fig. 555.—Deciduous teeth. Left side.



The *root* is single, but longer and thicker than that of the incisors, conical in form, compressed laterally, and marked by a slight groove on each side.

The *upper canine teeth* (vulgarly called *eye-teeth*) are larger and longer than the two lower, and situated a little distally to them.

The *lower canine teeth* are placed mesially to the upper, so that their summits correspond to the interval between the upper canine tooth and the neighbouring incisors on each side.

The **bicuspid teeth** (premolars, small, or false molars) are eight in number : four in each jaw, two being placed distally to each of the canine teeth. They are smaller and shorter than the canine.

The *crown* is compressed proximo-distally, and surmounted by two pyramidal eminences, or cusps, separated by a groove ; hence their name, *bicuspidate*. The labial of these cusps is larger and more prominent than the lingual.

The *neck* is oval.

The *root* is generally single, compressed, and presents a deep groove on each

side, which indicates a tendency in the root to become double. The apex is generally bifid.

The *upper bicuspids* are larger, and present a greater tendency to the division of their roots than the lower; this is especially marked in the second upper bicuspid.

The **molar teeth** (*multicuspidati*, true or large molars) are the largest of the permanent set and are adapted from the great breadth of their crowns for grinding and pounding the food. They are twelve in number: six in each jaw, three being placed distally to the second bicuspids.

The *crown* is nearly cubical in form, convex on its labial and lingual surfaces, flattened on its proximal and distal surfaces; the upper surface being surmounted by four or five tubercles, or cusps (four in the upper, five in the lower molars), separated from each other by a crucial depression; hence their name, *multicuspidati*.

The *neck* is distinct, large, and rounded.

The *root* is subdivided into from two to five fangs, each of which presents an aperture at its summit.

FIG. 556.—Front and side views of the teeth and jaws. (Cryer.)

The crown of the *first molar tooth* in the upper jaw has usually four, but occasionally five cusps; the root consists of three fangs, widely separated from one another, two being labial, the other lingual.

The crown of the first molar tooth in the lower jaw is larger than that of the upper; it has five cusps, and its root consists of two fangs, one being placed proximally, the other distally: they are both compressed from before backwards, and grooved on their contiguous faces, indicating a tendency to division.

The *second molar* is a little smaller than the first.

The crown has four cusps in the upper, and five in the lower jaw.

The root has three fangs in the upper jaw, and two in the lower, the characters of which are similar to the preceding tooth.

The *third molar tooth* is called the *wisdom-tooth* (*dens sapientiæ*), from its late appearance through the gum.

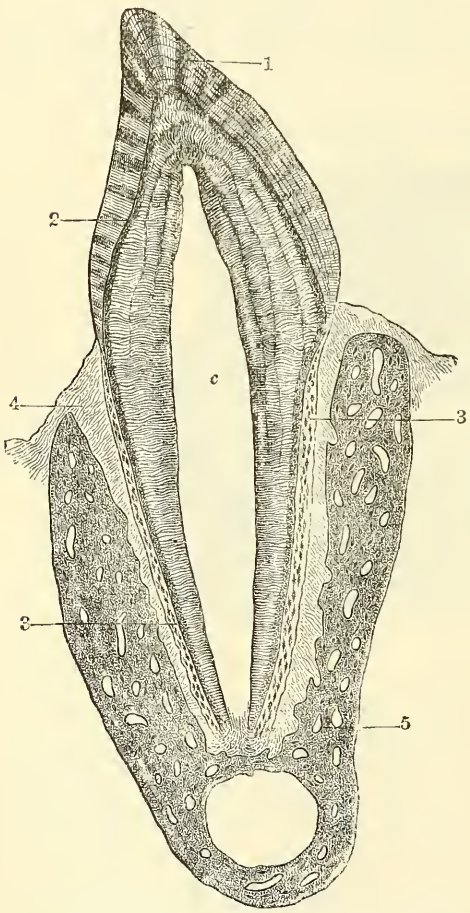
Its crown is usually as large and sometimes larger than the second molar, but smaller than the first. In the upper jaw it is usually furnished with three cusps, the two lingual ones being blended; in the lower jaw there are five cusps as in the other molars.

The root is generally single, short, conical, slightly curved, and grooved so as to present traces of a subdivision into three fangs in the upper, and two in the lower jaw.

Temporary Teeth

The **temporary** or **milk teeth** are smaller, but resemble in form those of the permanent set. The hinder of the two temporary molars is the largest of all the milk teeth, and is succeeded by the second permanent bicuspid. The first upper molar has only three cusps—two labial, one lingual; the second upper molar has four cusps. The first lower molar has four cusps; the second lower molar has five. The fangs of the temporary molar teeth are smaller and more diverging than those of the permanent set, but in other respects bear a strong resemblance to them.

Fig. 557.—Vertical section of a tooth *in situ* (15 diameters).

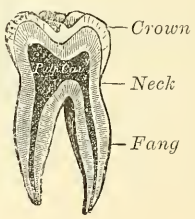


c. is placed in the pulp cavity, opposite the cervix or neck of the tooth; the part above it is the crown, that below is the root (fang). 1. Enamel with radial and concentric markings. 2. Dentine with tubules and incremental lines. 3. Cement or crusta petrosa, with bone corpuscles. 4. Dental periosteum. 5. Bone of lower jaw.

Structure of the Teeth

On making a vertical section of a tooth (fig. 557), a cavity will be found in the interior. This cavity is situated in the interior of the crown and the centre of each fang, and opens by a minute orifice at the extremity of the latter. The shape of the cavity corresponds somewhat with that of the tooth; it forms what is called the *pulp cavity*, and contains a soft, highly vascular, and sensitive substance,

Fig. 558.—Vertical section of a molar tooth.



the *dental pulp*. The pulp consists of a loose connective tissue and cells; it is richly supplied with vessels and nerves, which enter the cavity through the small aperture at the point of each fang. The cells of the pulp are partly found permeating the pulp matrix, and partly arranged as a layer on the wall of the pulp cavity. These latter cells are named the *odontoblasts of Waldeyer*. These cells, during the development of the tooth, are columnar in shape, but later on, after the dentine is fully formed, they become flattened and resemble the osteoblasts found in the osteo-genetic layer of the periosteum of bone. They have two fine processes, the outer or distal one passing into a dental tubule, the inner being continuous with the processes of the connective-tissue cells of the pulp matrix.

The solid portion of the tooth consists of three distinct structures, viz. the proper dental substance, which forms the larger portion of the tooth, the *ivory*

or *dentine*; a layer which covers the exposed part of the crown, the *enamel*; and a thin layer, which is disposed on the surface of the fang, the *cement* or *crusta petrosa*.

The **ivory**, or **dentine** (fig. 559), forms the principal mass of a tooth; in its central part is the cavity enclosing the pulp. It is a modification of osseous tissue, from which it differs, however, in structure. On microscopic examination it is seen to consist of a number of minute wavy and branching tubes, having distinct parietes. They are called the *dentinal tubuli*, and are embedded in a dense homogeneous substance, the *intertubular tissue*.

The *dentinal tubuli* (fig. 560) are placed parallel with one another, and open at their inner ends into the pulp cavity. In their course to the periphery they present two or three curves, and are twisted on themselves in a spiral direction. The direction of these tubes varies: they are vertical in the upper portion of the crown, oblique in the neck and upper part of the root, and towards the lower part of the root they are inclined downwards. The tubuli, at their commencement, are about $\frac{1}{4500}$ of an inch in diameter; in their course they divide and subdivide dichotomously, so as to give to the cut surface of the dentine a striated appearance. From the sides of the tubes, especially in the fang, ramifications of extreme minuteness are given off, which join together in loops in the intertubular substance, or terminate in small dilatations, from which branches are given off. Near the periphery of the dentine, the finer ramifications of the tubuli terminate imperceptibly by free ends. The dental tubuli have comparatively thick walls, consisting of an elastic homogeneous membrane, the dentinal sheath of Neumann, which resists the action of acids; they contain slender cylindrical prolongations, first described by Mr. Tomes, and named Tomes's fibres or dentinal fibres. These dentinal fibres are analogous to the soft contents of the canaliculi of bone.

Fig. 559.—Vertical section of a bicuspid tooth. (Magnified.)

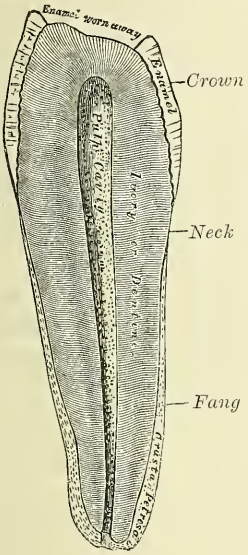


Fig. 560.—Canine tooth of man, presenting a transverse section of a portion of the root. (Magnified 300 diameters.)

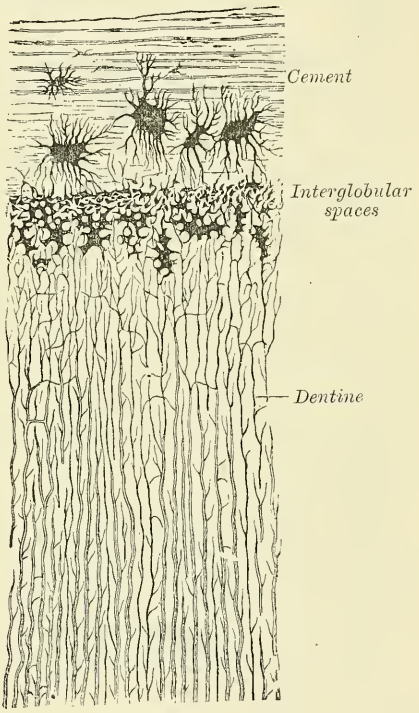


The *intertubular substance* is translucent, and contains the chief part of the earthy matter of the dentine. In it are a number of fine fibrils, which are

continuous with the fibrils of the dental pulp (Mummery). After the earthy matter has been removed by steeping a tooth in weak acid, the animal basis remaining may be torn into laminæ which run parallel with the pulp cavity, across the direction of the tubes. A section of dry-dentine often displays a series of somewhat parallel lines—the *incremental lines of Salter*. These lines are composed of imperfectly calcified dentine arranged in layers. In consequence of the imperfection in the calcifying process, little irregular cavities are left, termed *interglobular spaces*. These spaces are found especially towards the outer surface of the dentine, where they form a layer, which is sometimes known as the *granular layer* (fig. 560). They have received their name from the fact that they are surrounded by minute nodules or globules of dentine. Other curved lines may be seen parallel to the surface. These are the *lines of Schreger*, and are due to the optical effect of simultaneous curvature of the dentinal fibres.

Chemical Composition.—According to Berzelius and Bibra, dentine consists of 28 parts of animal and 72 of earthy matter. The animal matter is resolvable by boiling into gelatin. The earthy matter consists of phosphate of lime, carbonate of lime, a trace of fluoride of calcium, phosphate of magnesia, and other salts.

The **enamel** is the hardest and most compact part of a tooth, and forms a thin crust over the exposed part of the crown, as far as the commencement of the fang. It is thickest on the grinding surface of the crown, until worn away by attrition, and becomes thinner towards the neck. It consists of a congeries of minute hexagonal rods or columns. They lie parallel with one another, resting by one extremity upon the dentine, which presents a number of minute depressions for their reception; and forming the free surface of the crown by the other extremity. The columns are directed vertically on the summit of the crown, horizontally at the sides; they are about the $\frac{1}{3500}$ of an inch in diameter, and pursue a more or less wavy course. Each column is a six-sided prism and presents numerous dark transverse shadings; these shadings are probably due to the manner in which the columns are developed in successive stages, producing shallow constrictions, as will be explained in the sequel. Another series of lines, having a brown appearance, and denominated the *parallel striæ of Retzius*, are seen on a section of the enamel. According to Ebner, they are produced by air in the interprismatic spaces.

Numerous minute interstices intervene between the enamel fibres near their dentinal surface, a provision calculated to allow of the permeation of fluids from the dentinal tubule into the substance of the enamel. It is a disputed point whether the dentinal fibres penetrate a certain distance between the rods of the enamel or not. No nutritive canals exist in the enamel.

Chemical Composition.—According to Bibra, enamel consists of 96·5 per cent. of earthy matter, and 3·5 per cent. of animal matter. The earthy matter consists of phosphate of lime, with traces of fluoride of calcium, carbonate of lime, phosphate of magnesia, and other salts.

The **cortical substance**, or **cement** (*crusta petrosa*), is disposed as a thin layer on the roots of the teeth, from the termination of the enamel, as far as the apex of the fang, where it is usually very thick. In structure and chemical composition it resembles bone. It contains, sparingly, the lacunæ and canaliculi which characterise true bone; the lacunæ placed near the surface have the canaliculi radiating from the side of the lacunæ towards the periodontal membrane; and those more deeply placed join with the adjacent dental tubuli. In the thicker portions of the crusta petrosa, the lamellæ and Haversian canals peculiar to bone are also found.

As age advances, the cement increases in thickness, and gives rise to those bony growths, or exostoses, so common in the teeth of the aged; the pulp cavity becomes also partially filled up by a hard substance, intermediate in structure between dentine and bone (*osteo-dentine*, Owen; *secondary dentine*, Tomes). It appears to be formed by a slow conversion of the dental pulp, which shrinks, or even disappears.

Development of the Teeth

In describing the development of the teeth, we have first to consider the mode of formation of the temporary or milk teeth, and then that of the permanent series.

Development of the temporary teeth.—The development of these teeth begins at a very early period of fœtal life—about the sixth week. It commences as a thickening of the epithelium along the line of the future jaw; the thickening being due to a rapid multiplication of the more deeply situated epithelial cells. As these cells multiply they extend into the subjacent mesoblast, and thus form a semicircular ridge or strand of cells, enclosed by mesoblast. About the seventh week a longitudinal splitting or cleavage of this strand of cells takes place, and it becomes divided into two strands; the separation beginning in front and extending laterally: the process occupying four or five weeks. Of the two strands thus formed, the *outer* or *labial* forms the future labio-dental furrow, and is therefore termed the *labio-dental strand*: whilst the other, the *inner* or *lingual*, is the ridge of cells in connection with which the teeth, both temporary and permanent, are developed. Hence it is known as the *dental lamina* or *common dental germ*. It forms a flat band of cells, which grow into the substance of the embryonic jaw, at first horizontally inwards, and then, as the teeth develop, vertically, i.e. upwards in the upper jaw, and downwards in the lower jaw. Whilst still maintaining a horizontal direction, it has two edges: the one, the *attached edge*, which is continuous with the epithelium lining the mouth; the other, the *free edge*, projecting inwards, and embedded in the mesoblastic tissue of the embryonic jaw. Along its line of attachment to the buccal epithelium is a shallow groove, the *dental furrow*.

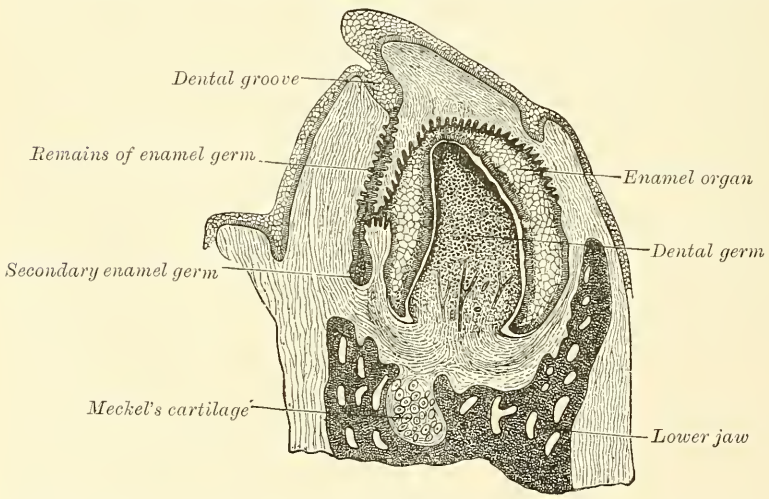
About the ninth week this dental lamina begins to develop enlargements along its free border. These are ten in number in each jaw, and each one corresponds to a future milk tooth. They consist of masses of epithelial cells; and the cells of the lower part—that is, the part farthest from the margin of the jaw—increase rapidly and spread out in all directions. Each mass thus comes to assume a flask shape, connected by a narrow neck, embraced by mesoblast, with the general epithelial lining of the mouth. They are now known as *special dental germs*. After a time the lower expanded portion, the body of the flask, inclines outwards, so as to form an angle with the superficial constricted portion, which is sometimes known as the *neck* of the special dental germ. About the tenth week the mesoblastic tissue beneath these special dental germs becomes differentiated into papillæ; these grow upwards, and come in contact with the epithelial cells of the special dental germs, which become folded over them like a hood or cap. We have, then, at this stage a papilla or papillæ, which have already begun to assume somewhat the shape of the crown of the future tooth, and from which the dentine and pulp of the milk teeth are formed, surmounted by a dome or cap of epithelial cells, from which the enamel is derived.

In the meantime, while these changes have been going on, the dental lamina has been extending backwards behind the special dental germ corresponding to the second molar tooth of the temporary set, and at about the seventeenth week it presents an enlargement, the special dental germ for the first permanent molar, soon followed by the formation of a papilla in the mesoblastic tissue for the same tooth. This is followed by a further extension backwards of the dental lamina; the formation of another enlargement and its corresponding papilla about the sixth month after birth for the second molar. And finally the process is repeated for the third molar, its papilla appearing about the fifth year of life.

After the formation of the special dental germs, the dental lamina undergoes atrophic changes and becomes cribriform, except behind and lateral to each of the special germs of the temporary teeth, where it undergoes a local thickening, forming the special dental germ of each of the successional permanent teeth—i.e. the ten anterior ones in each jaw. Here the same process goes on as was

described in connection with those of the milk teeth; that is, they recede into the substance of the gum behind the germs of the temporary teeth. As they recede they become flask-shaped, form an expansion at their distal extremity, and finally meet a papilla, which has been formed in the mesoblast, just in the same manner as was the case in the temporary teeth. The apex of the papilla indentates the dental germ, which encloses it, and forming a cap for it, becomes converted into the enamel, whilst the papilla forms the dentine and pulp of the permanent tooth. The special dental germs consist at first of rounded or polyhedral epithelial cells; after the formation of the papillæ, these cells undergo a differentiation into three classes. Those which are in immediate contact with the papilla become elongated, and form a layer of well-marked and regular columnar epithelium coating the papilla. They are the cells which form the enamel fibres, and are therefore termed *enamel-cells* or *adamantoblasts*. The outer layer of cells of the special dental germ, which are in contact with the inner surface of the dentinal sac, presently to be described, are much shorter, cubical in form, and are named the *external enamel epithelium*. All the intermediate round cells of the dental germ between these two layers undergo a peculiar change. They become stellate in shape and develop processes, which

Fig. 561.—Vertical section of the inferior maxilla of an early human fœtus. (Magnified 25 diameters.)



unite to form a network into which fluid is secreted, which has the appearance of a jelly, and to which the name of enamel pulp is given. This transformed special dental germ is now known under the name of *enamel organ*.

While these changes have been going on, a sac is formed around each enamel organ from the mesoblastic tissue around. This is known as the *dentinal sac*, and is a vascular membrane of connective tissue. It grows up from below, and thus encloses the whole tooth germ; as it grows it causes the neck of the enamel organ to atrophy and disappear; so that all communication between the enamel organ and the superficial epithelium is cut off. We have now vascular papillæ surmounted by inverted caps or capsules of epithelial cells, the whole being surrounded by membranous sacs. The cap or capsule consists of an internal layer of cells—the enamel cells or adamantoblasts—in contact with the papilla; of an external layer of cells—the external enamel epithelium—lining the interior of the dentinal sac; and of an intermediate mass of stellate cells, with anastomosing process—the enamel pulp (fig. 562).

Formation of the enamel.—The enamel is formed exclusively from the enamel cells or adamantoblasts of the original special dental germ, either by direct calcification of the columnar cell, which becomes elongated into the hexagonal

rods of the enamel; or, as is believed by some, as a secretion from the adamantoblasts, within which calcareous matter is subsequently deposited.

The process begins at the apex of each cusp, at the end of the enamel cells, in contact with the dental papilla. Here a fine globular deposit takes place, being apparently shed from the end of the adamantoblasts. It is known by the name of *enamel droplet*, and resembles keratin in its resistance to the action of mineral acids. This droplet then calcifies and forms the first layer of the enamel; a second droplet now appears and calcifies, and so on, successive droplets of keratin-like material are shed from the adamantoblasts and form successive layers of enamel, the adamantoblast gradually receding as each layer is produced, until they have almost disappeared at the termination of the process. The intermediate cells of the enamel pulp atrophy and disappear, so that the newly formed calcified material and the external enamel epithelium come into apposition. This latter layer, however, soon disappears on the emergence of the tooth beyond the gum. After its disappearance the crown of the tooth is still covered by a distinct membrane, which remains persistent for some time. This is known as the *cuticular dentis*, or *Nasmyth's membrane*, and is believed to be the last formed layer of enamel derived from the *adamantoblast*, which has not become calcified. It forms a horny layer, which may be separated from the calcified mass below by the action of strong acids. It is marked by the hexagonal impressions of the enamel prisms, and when stained by nitrate of silver, shows the characteristic appearance of epithelium.

Formation of the dentine.—While these changes are taking place in the epithelium to form the enamel, contemporaneous changes are occurring in the differentiated mesoblast of the dental papillæ which result in the formation of the dentine. As before stated, the first germ of the dentine consists in the formation of papillæ, corresponding in number to the teeth, from the soft mesoblastic tissue which bounds the depressions containing the special enamel germ. The papillæ grow upwards into the enamel germ and become covered by it, both being enclosed in a vascular connective tissue, the dentinal sac, in the manner above described. Each papilla then constitutes the formative pulp from which the dentine and permanent pulp are developed; it consists of rounded cells, and is very vascular, and soon begins to assume the shape of the tooth which is to be developed from it. The next step is the development of the odontoblasts, which have a relation to the development of the teeth similar to that of the osteoblasts in the formation of bone. They are formed first from the cells of the periphery of the papilla—that is to say, from the cells in immediate contact with the adamantoblasts of the special dental germ. These cells become elongated; one end of the elongated cell resting against the epithelium of the special dental germs, the other being tapering and often branched. By the direct transformation of the peripheral end of these cells, or by a secretion from it, a layer of uncalcified matrix is formed which caps the cusp or cusps, if there are more than one, of the papillæ. In this matrix islets of calcification make their appearance, and coalescing form a continuous layer of calcified material, which, capping each cusp, forms the first layer of dentine. The odontoblasts having thus formed the

first layer, retire towards the centre of the papilla, and as they do so form successive layers of dentine from their peripheral extremities—that is to say, they form the dentinal matrix in which calcification subsequently takes place. As they thus retire from the periphery of the papilla, they leave behind them filamentous processes of cell protoplasm, provided with finer side processes; these are surrounded on all sides by calcified material, and thus form the dentinal tubules, and, by their side branches, the anastomosing tubules, whereby the dentinal tubules communicate: the processes of protoplasm contained within them, forming the dentinal fibres (Tomes' fibres) which, as mentioned above, are found within the tubules. In this way the entire thickness of the dentine is formed, each tubule being completed throughout its whole length by a single odontoblast. The central part of the papilla does not undergo calcification; its cells proliferate, nerve fibres are developed in it, and it remains persistent as the pulp of the tooth. In this process of formation of dentine it has been shown that an uncalcified matrix is first formed, and that in this islets of calcification appear, which subsequently blend together to form a cap to each cusp: in like manner a succession of layers become formed, which become ultimately blended with each other. In certain places this blending is not complete, portions of the matrix remaining uncalcified between the successive layers; this gives rise, in the macerated tooth, to little spaces, which are the interglobular spaces alluded to above.

Formation of the cement.—The root of the tooth begins to be formed shortly before the crown emerges through the gum, but is not completed until some time afterwards. It is formed by a downward growth of the epithelium of the dental germ, which extends almost as far as the situation of the apex of the future fang, and determines the form of this portion of the tooth. This fold of epithelium is known as the *epithelial sheath*, and on its papillary surface odontoblasts are formed, which in turn form dentine, so that the dentine formation is identical in the crown and root of the tooth. After the dentine of the root has been formed, the vascular tissues of the dental sac begin to break through the epithelial sheath, and spread over the surface of the fang as a layer of bone-forming material. In this osteoblasts form, and the process of ossification goes on identically in the same manner as in the ordinary intra-membranous ossification of bone. In this way the cement is formed, and is simply ordinary bone, containing canaliculi and lacunæ.

Formation of the alveoli.—About the fourteenth week of embryonic life the dental lamina becomes enclosed in a trough or groove of mesoblastic tissue, which at first is common to all the dental germs, but subsequently becomes divided, by bony septa, into loculi, each loculus containing the special dental germ of a temporary tooth and its corresponding permanent tooth. After birth each cavity becomes subdivided, so as to form separate loculi (the future alveoli) for the milk tooth and its corresponding permanent tooth. Although at one time the whole of the growing tooth is contained in the cavity of the alveolus, which closely invests it, it never completely encloses it, but there is always an aperture over the top of the crown filled by soft tissue, by which the dental sac is connected with the surface of the gum, and which in the permanent teeth is called the *gubernaculum dentis*.

Development of the permanent teeth.—The permanent teeth as regards their development may be divided into two sets: (1) those which replace the temporary teeth, and which, like them, are ten in number; these are the *successional permanent teeth*; and (2) those which have no temporary predecessors, but are superadded at the back of the dental series. These are three in number on either side in each jaw, and are termed *superadded permanent teeth.* They are the three molars of the permanent set, the molars of the temporary set being replaced by the premolars or bicuspids of the permanent set. The development of the successional permanent teeth—the ten anterior ones in either jaw—will first be considered. As already stated, the original dental lamina, after the

formation of the special dental germs of the temporary teeth, undergoes atrophic changes, except at one spot behind and lateral to each of the special germs of the milk teeth; here a local thickening takes place, and forms the special dental germ of each successional permanent tooth. In this, identically the same changes go on as took place in the special germs of the temporary teeth: they elongate and recede into the gum behind the germs of the milk tooth; a papilla springs up from the mesoblastic tissue to meet them, and the two become enclosed in a dental sac; the formation of the dentine and enamel goes on in the same way as in the temporary teeth. During their development the permanent teeth, enclosed in their sacs, come to be placed behind and at a lower level than the temporary teeth, that is to say, at a further distance from the margin of the future gum, and, as already stated, are separated from it by a bony partition. As the crown of the permanent tooth grows, absorption of this bony partition and of the fang of the temporary tooth takes place, through the agency of osteoblasts; which appear at this time, and finally nothing but the crown of the temporary tooth remains. This is shed or removed, and the permanent tooth takes its place.

The superadded permanent teeth are developed in the manner already described, by extensions backward of the back part of the dental lamina of the immediately preceding tooth. About the seventeenth week, that portion of the common dental germ of the last temporary tooth which lies behind the tooth, and which has remained unaltered, is prolonged backwards, and forms the special dental germ of the first permanent molar, and into this a papilla projects. In a similar manner about the fourth month after birth, a further extension backwards having taken place, a second enlargement occurs, into which a papilla projects about the sixth month, and thus the rudiment of the second molar is formed. Finally a third enlargement takes place, posterior to the other two, for the third molar, and its papilla becomes visible about the fifth year.

Eruption.—When the calcification of the different tissues of the tooth is sufficiently advanced to enable it to bear the pressure to which it will be afterwards subjected, its eruption takes place; the tooth making its way through the gum. The gum is absorbed by the pressure of the crown of the tooth against it, which is itself pressed up by the increasing size of the fang. At the same time the septa between the dental sacs, at first fibrous in structure, ossify, and constitute the alveoli; these firmly embrace the necks of the teeth, and afford them a solid basis of support.

The eruption of the temporary teeth commences at the seventh month, and is complete about the end of the second year, those of the lower jaw preceding the upper.

The following, according to C. S. Tomes, is the most usual time of eruption:

Lower central incisors	6 to 9 months.
Upper incisors	8 to 10 months.
Lower lateral incisors and first molars	15 to 21 months.
Canines	16 to 20 months.
Second molars	20 to 24 months.

Calcification of the permanent teeth proceeds in the following order in the lower jaw; in the upper jaw it takes place a little later:—First molar, soon after birth; the central incisor, lateral incisor, and canine, about six months after birth; the bicuspids, at the second year, or a little later; second molar, end of second year; third molar, about the twelfth year.

The eruption of the permanent teeth takes place at the following periods, the teeth of the lower jaw preceding those of the upper by a short interval:

6 years, first molars.
7th year, two middle incisors.
8th year, two lateral incisors.
9th year, first bicuspid.
10th year, second bicuspid.
11th to 12th year, canine.
12th to 13th year, second molars.
17th to 25th year, wisdom-teeth.

The Palate

The **palate** forms the roof of the mouth: it consists of two portions, the hard palate in front, the soft palate behind.

The **hard palate** is bounded in front and at the sides by the alveolar arches and gums; behind, it is continuous with the soft palate. It is covered by a dense structure formed by the periosteum and mucous membrane of the mouth, which are intimately adherent together. Along the middle line is a linear ridge or raphé, which terminates anteriorly in a small papilla, corresponding with the inferior opening of the anterior palatine fossa. This papilla receives filaments from the naso-palatine and anterior palatine nerves. On either side and in front of the raphé the mucous membrane is thick, pale in colour, and corrugated; behind, it is thin, smooth, and of a deeper colour: it is covered with squamous epithelium, and furnished with numerous glands (palatal glands), which lie between the mucous membrane and the surface of the bone.

The **soft palate** (*velum pendulum palati*) is a movable fold, suspended from the posterior border of the hard palate, and forming an incomplete septum between the mouth and pharynx. It consists of a fold of mucous membrane, enclosing muscular fibres, an aponeurosis, vessels, nerves, adenoid tissue, and mucous glands. When occupying its usual position (i.e. relaxed and pendent), its anterior surface is concave, continuous with the roof of the mouth, and marked by a medium ridge or raphé, which indicates its original separation into two lateral halves. Its posterior surface is convex, and continuous with the mucous membrane covering the floor of the posterior nares. Its upper border is attached to the posterior margin of the hard palate, and its sides are blended with the pharynx. Its lower border is free.

Hanging from the middle of its lower border is a small, conical-shaped, pendulous process, the *uvula*; and arching outwards and downwards from the base of the uvula on each side are two curved folds of mucous membrane, containing muscular fibres, called the *arches* or *pillars of the soft palate*.

The *anterior pillars* run downwards, outwards, and forwards to the sides of the base of the tongue, and are formed by the projection of the Palato-glossi muscles, covered by mucous membrane.

The *posterior pillars* are nearer to each other, and larger than the anterior; they run downwards, outwards, and backwards to the sides of the pharynx, and are formed by the projection of the Palato-pharyngei muscles, covered by mucous membrane. The anterior and posterior pillars are separated below by a triangular interval, in which the tonsil is lodged.

The space left between the arches of the palate on the two sides is called the *isthmus of the fauces*. It is bounded, above, by the free margin of the soft palate; below, by the back of the tongue; and on each side, by the pillars of the soft palate and the tonsil.

The *mucous membrane of the soft palate* is thin, and covered with squamous epithelium on both surfaces, excepting near the orifice of the Eustachian tube, where it is columnar and ciliated.* Beneath the mucous membrane on the oral surface of the soft palate is a considerable amount of adenoid tissue. The palatine glands form a continuous layer on its posterior surface and round the uvula.

The *aponeurosis of the soft palate* is a thin but firm fibrous layer attached above to the posterior border of the hard palate, and becoming thinner towards the free margin of the velum. Laterally, it is continuous with the pharyngeal aponeurosis. It forms the framework of the soft palate, and is joined by the tendon of the Tensor palati muscle.

* According to Klein, the mucous membrane on the nasal surface of the soft palate is in the fœtus covered throughout by columnar ciliated epithelium, and some anatomists state that it is covered with columnar ciliated epithelium, except at its free margin, throughout life.

The *muscles of the soft palate* are five on each side: the Levator palati, Tensor palati, Azygos uvulæ, Palato-glossus, and Palato-pharyngeus (see page 420). The following is the relative position of these structures in a dissection of the soft palate from the posterior or nasal to the anterior or oral surface. Immediately beneath the nasal mucous membrane is a thin stratum of muscular fibres, the posterior fasciculus of the Palato-pharyngeus muscle, joining with its fellow of the opposite side in the middle line. Beneath this is the Azygos uvulæ, consisting of two rounded fleshy fasciculi, placed side by side in the median line of the soft palate. Next comes the aponeurosis of the Levator palati joining with the muscle of the opposite side in the middle line. Fourthly, the anterior fasciculus of the Palato-pharyngeus, thicker than the posterior, and separating the Levator palati from the next muscle, the Tensor palati. This muscle terminates in a tendon which, after winding round the hamular process, expands into a broad aponeurosis in the soft palate, anterior to the other muscles which have been enumerated. Finally we have a thin muscular stratum, the Palato-glossus muscle, placed in front of the aponeurosis of the Tensor palati, and separated from the oral mucous membrane by adenoid tissue.

The **tonsils** (*amygdalæ*) are two prominent bodies situated one on each side of the fauces, between the anterior and posterior pillars of the soft palate. They are of a rounded form, and vary considerably in size in different individuals. Externally the tonsil is in relation with the inner surface of the Superior constrictor, which separates it from the internal carotid and ascending pharyngeal arteries. It corresponds to the angle of the lower jaw. Its *inner surface* presents from twelve to fifteen orifices, leading into small recesses, from which numerous follicles branch out into the substance of the gland. These follicles are lined by a continuation of the mucous membrane of the pharynx, covered with epithelium; around each follicle is a layer of closed capsules embedded in the submucous tissue. These capsules are analogous to those of Peyer's glands, consisting of adenoid tissue. No openings from the capsules into the follicles can be recognised. They contain a thick greyish secretion. Surrounding each follicle is a close plexus of lymphatic vessels. From these plexuses the lymphatic vessels pass to the deep cervical glands in the upper part of the neck, which frequently become enlarged in affections of these organs.

The *arteries* supplying the tonsil are the dorsalis linguæ from the lingual, the ascending palatine and tonsillar from the facial, the ascending pharyngeal from the external carotid, the descending palatine branch of the internal maxillary, and a twig from the small meningeal.

The *veins* terminate in the tonsillar plexus, on the outer side of the tonsil.

The *nerves* are derived from Meckel's ganglion, and from the glosso-pharyngeal.

The Salivary Glands (fig. 563)

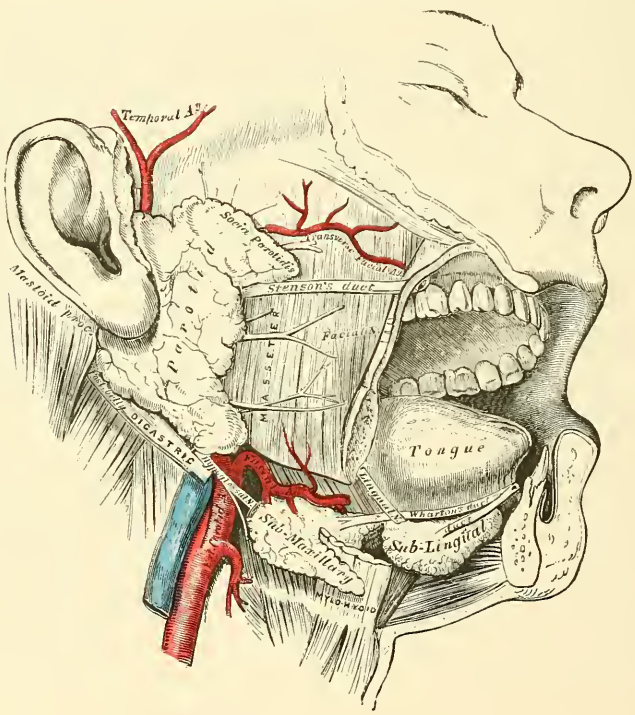
The principal salivary glands communicating with the mouth, and pouring their secretion into its cavity, are the parotid, submaxillary, and sublingual.

The **parotid gland**, so called from being placed near the ear (*παρά*, near; *οὖς*, *ὠτός*, the ear), is the largest of the three salivary glands, varying in weight from half an ounce to an ounce. It lies upon the side of the face, immediately below and in front of the external ear. It is limited above by the zygoma; below, by the angle of the jaw, and by a line drawn between it and the mastoid process; anteriorly, it extends to a variable extent over the Masseter muscle; posteriorly, it is bounded by the external meatus, the mastoid process, and the Sterno-mastoid and Digastric muscles, slightly overlapping the latter.

Its *anterior surface* is grooved to embrace the posterior margin of the ramus of the lower jaw, and advances forwards beneath the ramus, between the two Pterygoid muscles and in front of the ramus over the Masseter muscle. Its *outer surface*, slightly lobulated, is covered by the integument and parotid fascia,

and has one or two lymphatic glands resting on it. Its *inner surface* extends deeply into the neck, by means of two large processes, one of which dips behind the styloid process, and projects beneath the mastoid process and the Sterno-mastoid muscle; the other is situated in front of the styloid process, and passes into the back part of the glenoid fossa, behind the articulation of the lower jaw. The structures passing through the parotid gland are, the external carotid artery, giving off its three terminal branches: the posterior auricular artery emerges from the gland behind; the temporal artery above; the transverse facial, a branch of the temporal, in front; and the internal maxillary winds through it as it passes inwards, behind the neck of the jaw. Superficial to the external carotid is the trunk formed by the union of the temporal and internal maxillary veins: a branch, connecting this trunk with the internal jugular, also passes through the gland. It is also traversed by the facial nerve and its branches, which emerge at its anterior border; branches of the great auricular nerve pierce the gland to join

Fig. 563.--The salivary glands.



the facial, and the auriculo-temporal branch of the inferior maxillary nerve emerges from the upper part of the gland. The internal carotid artery and internal jugular vein lie close to its deep surface.

The **duct of the parotid gland** (*Stenson's*) is about two inches and a half in length. It commences by numerous branches from the anterior part of the gland, crosses the Masseter muscle, and at its anterior border dips down into the substance of the Buccinator muscle, which it pierces; it then runs for a short distance obliquely forwards between the Buccinator and mucous membrane of the mouth, and opens upon the inner surface of the cheek by a small orifice, opposite the second molar tooth of the upper jaw. While crossing the Masseter, it receives the duct of a small detached portion of the gland, *socia parotidis*, which occasionally exists as a separate lobe, just beneath the zygomatic arch. In this position it has the transverse facial artery above it and some branches of the facial nerve below it.

Structure.—The parotid duct is dense, of considerable thickness, and its canal about the size of a crow-quill ; it consists of an external or fibrous coat, of considerable density, containing contractile fibres, and of an internal or mucous coat lined with short columnar epithelium.

Surface Form.—The direction of the duct corresponds to a line drawn across the face about a finger's breadth below the zygoma, that is, from the lower margin of the concha to midway between the free margin of the upper lip and the ala of the nose.

Vessels and Nerves.—The *arteries* supplying the parotid gland are derived from the external carotid, and from the branches given off by that vessel in or near its substance. The *veins* empty themselves into the external jugular, through some of its tributaries. The *lymphatics* terminate in the superficial and deep cervical glands, passing in their course through two or three lymphatic glands, placed on the surface and in the substance of the parotid. The *nerves* are derived from the plexus of the sympathetic on the external carotid artery, the facial, the auriculo-temporal, and great auricular nerves.

It is probable that the branch from the auriculo-temporal nerve is derived from the glosso-pharyngeal through the otic ganglion (see page 794). At all events in some of the lower animals this has been proved experimentally to be the case.

The **submaxillary gland** is situated below the jaw, in the anterior part of the submaxillary triangle of the neck. It is irregular in form, and weighs about two drachms. It is covered by the integument, Platysma, deep cervical fascia, and the body of the lower jaw, corresponding to a depression on the inner surface of that bone ; and lies upon the Mylo-hyoid, Hyo-glossus, and Stylo-glossus muscles, a portion of the gland passing beneath the posterior border of the Mylo-hyoid. In front of it is the anterior belly of the Digastric ; behind it is separated from the parotid gland by the stylo-maxillary ligament, and from the sublingual gland in front by the Mylo-hyoid muscle. The facial artery lies embedded in a groove in its posterior and upper border.

The **duct of the submaxillary gland** (*Wharton's*) is about two inches in length, and its walls are much thinner than those of the parotid duct. It commences by numerous branches from the deep portion of the gland which lies on the upper surface of the Mylo-hyoid muscle, and passes forwards and inwards between the Mylo-hyoid and the Hyo-glossus and Genio-hyo-glossus muscles, then between the sublingual gland and the Genio-hyo-glossus, and opens by a narrow orifice on the summit of a small papilla, at the side of the frænum linguæ. On the Hyo-glossus muscle it lies between the lingual and hypoglossal nerves, but at the anterior border of the muscle it crosses under the lingual nerve, and is then placed above it.

Vessels and Nerves.—The *arteries* supplying the submaxillary gland are branches of the facial and lingual. Its *veins* follow the course of the arteries. The *nerves* are derived from the submaxillary ganglion, through which it receives filaments from the chorda tympani of the facial and lingual branch of the inferior maxillary, sometimes from the mylo-hyoid branch of the inferior dental, and from the sympathetic.

The **sublingual gland** is the smallest of the salivary glands. It is situated beneath the mucous membrane of the floor of the mouth, at the side of the frænum linguæ, in contact with the inner surface of the lower jaw, close to the symphysis. It is narrow, flattened, in shape somewhat like an almond, and weighs about a drachm. It is in relation, *above*, with the mucous membrane ; *below*, with the Mylo-hyoid muscle ; *in front*, with the depression on the side of the symphysis of the lower jaw, and with its fellow of the opposite side ; *behind*, with the deep part of the submaxillary gland ; and *internally*, with the Genio-hyo-glossus, from which it is separated by the lingual nerve and Wharton's duct. Its excretory ducts (*ducts of Rivini*), from eight to twenty in number, open separately into the mouth, on the elevated crest of mucous membrane, caused by the projection of the gland, on either side of the frænum linguæ. One or more join to

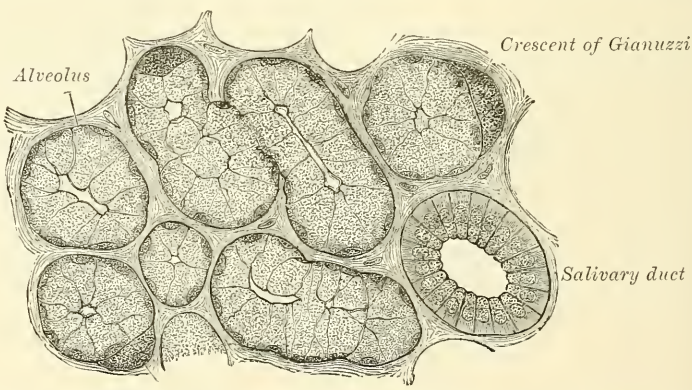
form a tube, which opens into the Whartonian duct; this is called the *duct of Bartholin*.

Vessels and Nerves.—The sublingual gland is supplied with blood from the sublingual and submental arteries. Its nerves are derived from the lingual.

Structure of Salivary Glands.—The salivary are compound racemose glands, consisting of numerous lobes, which are made up of smaller lobules, connected together by dense areolar tissue, vessels, and ducts. Each lobule consists of the ramifications of a single duct, 'branching frequently in a tree-like manner,' the branches terminating in dilated ends or alveoli on which the capillaries are distributed. These alveoli, however, as Pflüger points out, are not necessarily spherical, though sometimes they assume that form; sometimes they are perfectly cylindrical, and very often they are mutually compressed. The alveoli are enclosed by a basement membrane, which is continuous with the membrana propria of the duct. It presents a peculiar reticulated structure, having the appearance of a basket with open meshes, and consisting of a network of branched and flattened nucleated cells.

The alveoli of the salivary glands are of two kinds, which differ both in the appearance of their secreting cells, in their size, and in the nature of their secretion. The one variety secretes a ropy fluid, which contains mucin, and has therefore been named the *mucous*; whilst the other secretes a thinner and

Fig. 564.—A highly magnified section of the submaxillary gland of the dog, stained with carmine. (Kölliker.)



more watery fluid, which contains serum-albumin, and has been named *serous* or *albuminous*. The sublingual gland may be regarded as an example of the former variety: the parotid of the latter. The submaxillary is of the mixed variety, containing both mucous and serous alveoli, the latter, however, preponderating.

Both alveoli are lined by cells, and it is by the character of these cells that the nature of the gland is chiefly to be determined. In addition, however, the alveoli of the serous glands are smaller than those of the mucous ones.

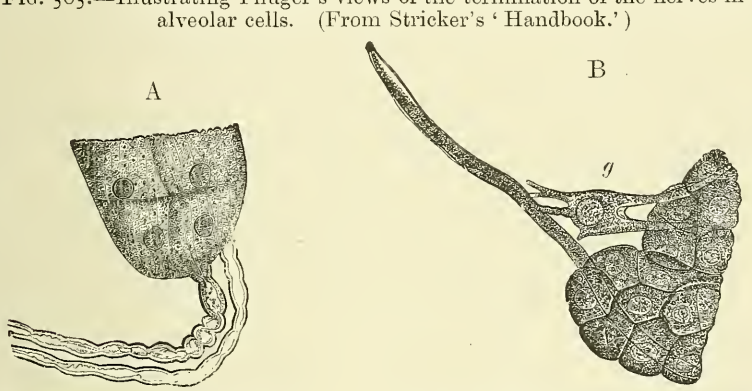
The **cells in the mucous alveoli** are spheroidal in shape, glassy, transparent, and dimly striated in appearance. The nucleus is usually situated in the part of the cell which is next the basement membrane, against which it is sometimes flattened. The most remarkable peculiarity presented by these cells is, that they give off an extremely fine process, which is curved in a direction parallel to the surface of the alveolus, lies in contact with the membrana propria, and overlaps the processes of neighbouring cells. The cells contain a quantity of mucin, to which their clear, transparent appearance is due.

Here and there in the alveoli are seen peculiar half-moon-shaped bodies, lying between the cells and the membrana propria of the alveolus. They are termed the *crescents of Gianuzzi*, or the *demilunes of Heidenhain* (fig. 564), and are regarded by Pflüger as due to post-mortem change, but by most other later observers

they are believed to be composed of polyhedral granular cells, which Heidenhain regards as young epithelial cells destined to supply the place of those salivary cells which have undergone disintegration. This view, however, is not accepted by Klein.

Serous alveoli.—In the serous alveoli the cells almost completely fill the cavity, so that there is hardly any lumen perceptible. Instead of presenting the clear transparent appearance of the cells of the mucous alveoli, they present a granular appearance, due to distinct granules, of an albuminous nature, embedded in a closely reticulated protoplasm. The ducts which originate out of the alveoli are lined at their commencement by epithelium which differs little from the pavement type. As the ducts enlarge, the epithelial cells change to the columnar type, and they are described by Pflüger as attached to the basement membrane by a brush of fine hair-like processes, which he believes to be continuous with the nerve-fibres. Other anatomists regard these cells as merely striated on their deep surface. The lobules of the salivary glands are richly supplied with blood-vessels which form a dense network in the interalveolar spaces. Fine plexuses of nerves are also found in the interlobular tissue. Pflüger describes the nerves as being directly continuous with the salivary cells of the alveolus, the nerve sometimes passing through a ganglion-cell just before joining the alveolus (fig. 565 A and B). This fact has not, however, been corroborated by other observers.

Fig. 565.—Illustrating Pflüger's views of the termination of the nerves in the alveolar cells. (From Stricker's 'Handbook.')



A. Direct passage of nerve into a salivary cell. B. By the medium of a multipolar ganglion-cell, *g*.

There is no doubt that ganglia are to be found in some salivary glands in connection with the nerve-plexuses in the interlobular tissue; thus they are to be found in the submaxillary, but not in the parotid; but whether the ultimate fibrils are connected with the salivary cells, as asserted by Pflüger, remains to be proved.

In the submaxillary and sublingual glands the lobes are larger and more loosely united than in the parotid.

Mucous Glands.—Besides the salivary glands proper, numerous other glands are found in the mouth. They appear to secrete mucus only, which serves to keep the mouth moist during the intervals of the salivary secretion, and which is mixed with that secretion in swallowing. Many of these glands are found at the posterior part of the dorsum of the tongue, behind the circumvallate papillæ, and also along its margins as far forward as the apex.* Others lie around and in the tonsil between its crypts, and a large number in the soft palate. These glands are of the ordinary compound racemose type.

* It has recently been shown by Ebner that many of these glands open into the trenches around the circumvallate papillæ, and that their secretion is more watery than that of ordinary mucous glands. He supposes that they assist in the more rapid distribution of the substance to be tasted over the region where the special apparatus of the sense of taste is situated.

Surface Form.—The orifice of the mouth is bounded by the lips: two thick, fleshy folds covered externally by integument and internally by mucous membrane, and consisting of muscles, vessels, nerves, areolar tissue, and numerous small glands. The size of the orifice of the mouth varies considerably in different individuals, but seems to bear a close relation to the size and prominence of the teeth. Its corners correspond pretty accurately to the outer border of the canine teeth. In the Mongolian tribes, where the front teeth are large and inclined forward, the mouth is large; and this, combined with the thick and everted lips, which appear to be associated with prominent teeth, gives to the Negro's face much of the peculiarity by which it is characterised. The smaller teeth, and the slighter prominence of the alveolar arch of the more highly civilised races, render the orifice of the mouth much smaller, and thus a small mouth is an indication of intelligence, and is regarded as an evidence of the higher civilisation of the individual.

Upon looking into the mouth, the first thing we may note is the tongue, the upper surface of which will be seen occupying the floor of the cavity. This surface is convex, and is marked along the middle line by a raphé, which divides it into two symmetrical portions. The anterior two-thirds is rough and studded with papillæ; the posterior third smooth and tuberculated, covered by numerous glands which project from the surface. Upon raising the tongue, the mucous membrane which invests the upper surface may be traced covering the sides of the under surface and then reflected over the floor of the mouth on to the inner surface of the lower jaw, a part of which it covers. As it passes over the borders of the tongue it changes its character, becoming thin and smooth, and losing the papillæ which are to be seen on the upper surface. In the middle line the mucous membrane on the under surface of the tip of the tongue forms a distinct fold, the *frænum linguæ*, by which this organ is connected to the symphysis of the jaw. Occasionally it is found that this frænum is rather shorter than natural, and, acting as a bridle, prevents the complete protrusion of the tongue. When this condition exists and an attempt is made to protrude the organ, the tip will be seen to remain buried in the floor of the mouth, and the dorsum of the tongue is rendered very convex, and more or less extruded from the mouth: at the same time a deep furrow will be noticed to appear in the middle line of the anterior part of the dorsum. Sometimes, a little external to the frænum, the ranine vein may be seen immediately beneath the mucous membrane. The corresponding artery, being more deeply placed, does not come into view, nor can its pulsation be felt with the finger. On either side of the frænum, in the floor of the mouth, is a longitudinal elevation or ridge, produced by the projection of the sublingual gland, which lies immediately beneath the mucous membrane. And close to the attachment of the frænum to the tip of the tongue may be seen on either side the slit-like orifices of Wharton's ducts, into which a fine probe may be passed without much difficulty. By everting the lips the smooth mucous membrane lining them may be examined, and may be traced from them on to the outer surface of the alveolar arch. In the middle line, both of the upper and lower lip, a small fold of mucous membrane passes from the lip to the bone, constituting the *fræna*; these are not so large as the frænum linguæ. By pulling outwards the angle of the mouth the mucous membrane lining the cheeks can be seen, and on it may be perceived a little papilla which marks the position of the orifice of Stenson's duct—the duct of the parotid gland. The exact position of the orifice of the duct will be found to be opposite the second molar tooth of the upper jaw. The introduction of a probe into this duct is attended with considerable difficulty. The teeth are the next objects which claim our attention upon looking into the mouth. There are, as stated above, ten in either jaw in the temporary set, and sixteen in the permanent set. The gums, in which they are implanted, are dense, firm, and vascular.

At the back of the mouth is seen the *isthmus of the fauces*, or, as it is popularly called, 'the throat': this is the space between the pillars of the fauces on either side, and is the means by which the mouth communicates with the pharynx. Above, it is bounded by the soft palate, the anterior surface of which is concave and covered with mucous membrane, which is continuous with that lining the roof of the mouth. Projecting from the middle of its lower border is a conical-shaped projection, the *uvula*. On either side of the isthmus of the fauces are the anterior and posterior pillars, formed by the Palato-glossus and Palato-pharyngeus muscles respectively, covered over by mucous membrane. Between the two pillars on either side is situated the tonsil. The extirpation of this body is not unattended with danger of hæmorrhage. Dr. Weir has stated that he believes that when hæmorrhage occurs after their removal, it arises from one of the palatine arteries having been wounded. These vessels are large: they lie in the muscular tissue of the palate, and when wounded are constantly exposed to disturbance from the contraction of the palatine muscles. The vessels of the tonsil, Dr. Weir states, are small, and lie in the soft tissue, and readily contract when wounded.

When the mouth is wide open a prominent tense fold of mucous membrane may be seen and felt extending upwards and backwards from the position of the fang of the last molar tooth to the posterior part of the hard palate. This is caused by the Pterygo-maxillary ligament which is attached by one extremity to the apex of the internal pterygoid plate, and by the other to the posterior extremity of the mylo-hyoid ridge of the lower jaw. It connects the Buccinator with the Superior constrictor of the pharynx. The fang of the last molar tooth indicates the position of the lingual (gustatory) nerve, where it is easily

accessible, and can with readiness be divided in cases of cancer of the tongue (see page 795). On the inner side of the last molar tooth we can feel the hamular process of the internal pterygoid plate of the sphenoid bone, around which the tendon of the Tensor palati plays. The exact position of this process is of importance in performing the operation of staphyloraphy. About one-third of an inch in front of the hamular process and the same distance directly inwards from the last molar tooth is the situation of the opening of the posterior palatine canal, through which emerges the posterior or descending palatine branch of the internal maxillary artery, and one of the descending palatine nerves from Meckel's ganglion. The exact position of the opening on the subject may be ascertained by driving a needle through the tissues of the palate in this situation, when it will be at once felt to enter the canal. The artery emerging from the opening runs forwards in a groove in the bone, just internal to the alveolar border of the hard palate, and may be wounded in the operation for the cure of cleft palate. Under these circumstances the palatine canal may require plugging. By introducing the finger into the mouth the anterior border of the coronoid process of the jaw can be felt, and is especially prominent when the jaw is dislocated. By throwing the head well back a considerable portion of the posterior wall of the pharynx may be seen through the isthmus faucium, and on introducing the finger the anterior surfaces of the bodies of the upper cervical vertebræ may be felt immediately beneath the thin muscular stratum forming the wall of the pharynx. The finger can be hooked round the posterior border of the soft palate, and by turning it forwards, the posterior nares, separated by the septum, can be felt, or the presence of any adenoid or other growths in the naso-pharynx ascertained.

The Pharynx

The **pharynx** is that part of the alimentary canal which is placed behind the nose, mouth, and larynx. It is a musculo-membranous sac, somewhat conical in form, with the base upwards, and the apex downwards, extending from the under surface of the skull to the cricoid cartilage in front, and the intervertebral disc between the fifth and sixth cervical vertebræ behind.

The pharynx is about four inches and a half in length, and broader in the transverse than in the antero-posterior diameter. Its greatest breadth is opposite the cornua of the hyoid bone; its narrowest point at its termination in the œsophagus. It is limited, *above*, by the body of the sphenoid and basilar process of the occipital bone; *below*, it is continuous with the œsophagus; *posteriorly*, it is connected by loose areolar tissue with the cervical portion of the vertebral column, and the Longi colli and Recti capitis antici muscles; *anteriorly*, it is incomplete, and is attached in succession to the internal pterygoid plate, the pterygo-maxillary ligament, the lower jaw, the tongue, hyoid bone, and thyroid and cricoid cartilages; *laterally*, it is connected to the styloid processes and their muscles, and is in contact with the common and internal carotid arteries, the internal jugular veins, and the glosso-pharyngeal, pneumogastric, hypoglossal, and sympathetic nerves, and above with a small part of the Internal pterygoid muscles.

It has seven openings communicating with it: the two posterior nares, the two Eustachian tubes, the mouth, larynx, and œsophagus.

The *posterior nares* are the two oval openings (see page 204) situated at the upper part of the anterior wall of the pharynx.

The *two Eustachian tubes* open one at each side of the upper part of the pharynx, at the back part of the inferior meatus. Below the posterior nares are the posterior surface of the soft palate and uvula, the large aperture of the mouth, the base of the tongue, the epiglottis, and the cordiform opening of the larynx.

The *œsophageal opening* is the lower contracted portion of the pharynx.

Structure.—The pharynx is composed of three coats: mucous, fibrous, and muscular.

The *pharyngeal aponeurosis*, or *fibrous coat*, is situated between the mucous and muscular layers. It is thick above where the muscular fibres are wanting, and is firmly connected to the basilar process of the occipital and petrous portion of the temporal bones. As it descends it diminishes in thickness, and is gradually lost. It is strengthened posteriorly by a strong fibrous band, which is attached above to the pharyngeal spine on the under surface of the basilar portion of the

occipital bone, and passes downwards, forming a median raphé, which gives attachment to the Constrictor muscles of the pharynx.

The *mucous coat* is continuous with that lining the Eustachian tubes, the nares, the mouth, and the larynx. It is covered by columnar ciliated epithelium, as low down as on a level with the floor of the nares: below that point the epithelium is of the squamous variety. Beneath the mucous membrane are found racemose mucous glands; they are especially numerous at the upper part of the pharynx around the orifices of the Eustachian tubes. Throughout the pharynx are also numerous crypts or recesses, the walls of which are surrounded by lymphoid tissue, similar to what is found in the tonsils. Across the back part of the pharyngeal cavity, between the two Eustachian tubes, a considerable mass of this tissue exists, and has been named the *pharyngeal tonsil*. Above this in the middle line is an irregular, flask-shaped depression of the mucous membrane, extending up as far as the basilar process of the occipital bone. It is known as the *bursa pharyngea*, and was regarded by Luschka as the remains of the diverticulum of the alimentary canal, which is concerned in the development of the pituitary body (see page 94). Other anatomists believe that it is connected with the formation of the pharyngeal tonsils. In addition to this recess of the mucous membrane there are to be seen two others in the pharynx: one between the Eustachian tube and the posterior wall of the pharynx, the other above the tonsil. These are regarded as the remains of the upper and lower part of the second visceral cleft respectively, the Eustachian tube being formed from the first cleft.

The *muscular coat* has been already described (page 418).

Surgical Anatomy.—The internal carotid artery is in close relation with the pharynx, so that its pulsations can be felt through the mouth. It has been occasionally wounded by sharp-pointed instruments, introduced into the mouth and thrust through the wall of the pharynx. In aneurism of this vessel in the neck; the tumour necessarily bulges into the pharynx, as this is the direction in which it meets with the least resistance, nothing lying between the vessel and the mucous membrane except the thin Constrictor muscle, whereas on the outer side there is the dense cervical fascia, the muscles descending from the styloid process and the margin of the Sterno-mastoid.

The mucous membrane of the pharynx is very vascular, and is often the seat of inflammation, frequently of a septic character, and dangerous on account of its tendency to spread to the larynx. On account of the tissue which surrounds the pharyngeal wall being loose and lax, the inflammation is liable to spread through it far and wide, extending downwards into the posterior mediastinum along the œsophagus. Abscess may form in the connective tissue behind the pharynx, between it and the vertebral column, constituting what is known as post-pharyngeal abscess. This is most commonly due to caries of the cervical vertebræ; but may also be caused by suppuration of a lymphatic gland, which is situated in this position opposite the axis, and which receives lymphatics from the nares; by a gumma; or by acute pharyngitis. The abscess may be most easily evacuated by an incision, with a guarded bistoury, through the mouth. It has recently been proposed to open the abscess aseptically by an incision in the neck behind the Sterno-mastoid. The operation, however, is a difficult one, unless the abscess is pointing laterally and does not give such free access to the seat of disease for the removal of necrosed bone, if any exists, and does not appear to present sufficient advantages to warrant its performance.

Foreign bodies not unfrequently become lodged in the pharynx, and most usually at its termination at about the level of the cricoid cartilage, just beyond the reach of the finger, as the distance from the arch of the teeth to the commencement of the œsophagus is about six inches.

The position of the opening of the Eustachian tubes should be carefully studied with a view to catheterism of these tubes, and the student should practise passing a catheter into them. This is to be done by introducing the instrument through the anterior nares, so that its point rests on the floor of the nasal cavity close to the septum; it is then pushed gradually and slowly backwards until the posterior wall of the pharynx is reached. Then, having been slightly withdrawn so as to free the point from the wall of the pharynx, it is rotated outwards and upwards, so that the ring of the instrument is turned towards the external ear, and it can then be made to glide into the Eustachian tube.

The Œsophagus

The **œsophagus**, or **gullet**, is a muscular canal, about nine inches in length, extending from the pharynx to the stomach. It commences at the upper border

of the cricoid cartilage, opposite the intervertebral disc between the fifth and sixth cervical vertebræ, descends along the front of the spine, through the posterior mediastinum, passes through the Diaphragm, and, entering the abdomen, terminates at the cardiac orifice of the stomach, opposite the tenth dorsal vertebra or the intervertebral disc between the tenth and eleventh dorsal vertebræ. The general direction of the œsophagus is vertical; but it presents two or three slight curves in its course. At its commencement it is placed in the median line; but it inclines to the left side as far as the root of the neck, gradually passes to the middle line again, and finally again deviates to the left as it passes forwards to the œsophageal opening of the Diaphragm. The œsophagus also presents an antero-posterior flexure, corresponding to the curvature of the cervical and thoracic portions of the spine. It is the narrowest part of the alimentary canal. being most contracted at its commencement, and at the point where it passes through the Diaphragm.

Relations.—*In the neck*, the œsophagus is in relation, *in front*, with the trachea; and, at the lower part of the neck, where it projects to the left side, with the thyroid gland and thoracic duct; *behind*, it rests upon the vertebral column and Longi colli muscles; *on each side*, it is in relation with the common carotid artery (especially the left, as it inclines to that side), and part of the lateral lobes of the thyroid gland; the recurrent laryngeal nerves ascend between it and the trachea.

In the thorax, it is at first situated a little to the left of the median line; it then passes behind the left side of the aortic arch, and descends in the posterior mediastinum, along the right side of the aorta, nearly to the Diaphragm, where it passes in front and a little to the left of the artery, previous to entering the abdomen. It is in relation, *in front*, with the trachea, the arch of the aorta, left carotid, and left subclavian arteries, the left bronchus, and the posterior surface of the pericardium; *behind*, it rests upon the vertebral column, the Longi colli muscles, and the intercostal vessels; and below, near the Diaphragm, upon the front of the aorta; *laterally*, it comes in contact with both pleuræ, especially with the left pleura above and the right pleura below: the vena azygos major lies on the right, and the descending aorta on the left side. The pneumogastric nerves descend in close contact with it, the right nerve passing down behind, and the left nerve in front of it.

Structure.—The œsophagus has three coats: an external or muscular; a middle or areolar; and an internal or mucous coat.

The *muscular coat* is composed of two planes of fibres of considerable thickness: an external longitudinal, and an internal circular.

The *longitudinal fibres* are arranged, at the commencement of the tube, in three fasciculi: one in front, which is attached to the vertical ridge on the posterior surface of the cricoid cartilage; and one at each side, which is continuous with the fibres of the inferior constrictor: as they descend they blend together, and form a uniform layer, which covers the outer surface of the tube.

Accessory slips of muscular fibres are described by Dr. Cunningham as passing between the œsophagus and the pleura, where it covers the thoracic aorta (almost always), or the root of the left bronchus (usually), or the back of the pericardium, or corner of the mediastinum (more rarely), as well as other still more rare accessory fibres. In fig. 566, taken from a dissection in the Museum of the Royal College of Surgeons, several of these accessory slips may be seen passing from the œsophagus to the pleura, and two slips to the back of the trachea just above its bifurcation.

The *circular fibres* are continuous above with the Inferior constrictor; their direction is transverse at the upper and lower parts of the tube, but oblique in the central part.

The muscular fibres in the upper part of the œsophagus are of a red colour, and consist chiefly of the striped variety; but below, they consist for the most part of involuntary muscular fibre.

The *areolar coat* connects loosely the mucous and muscular coats.

The *mucous coat* is thick, of a reddish colour above, and pale below. It is disposed in longitudinal folds, which disappear on distension of the tube. Its surface is studded with minute papillæ, and it is covered throughout with a thick layer of stratified pavement epithelium. Beneath the mucous membrane, between it and the areolar coat, is a layer of longitudinally arranged non-striped muscular fibres. This is the *muscularis mucosæ*. At the commencement it is absent, or only represented by a few scattered bundles; lower down it forms a considerable stratum.

The *œsophageal glands* are numerous small compound racemose glands scattered throughout the tube: they are lodged in the submucous tissue, and open upon the surface by a long excretory duct. They are most numerous at the lower part of the tube, where they form a ring round the cardiac orifice.

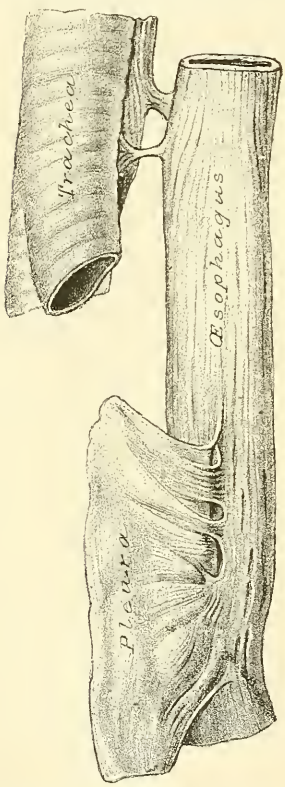


Fig. 566.—Accessory muscular fibres between the œsophagus and pleura, and œsophagus and trachea. (From a preparation in the Museum of the Royal College of Surgeons.)

Vessels of the œsophagus.—The arteries supplying the œsophagus are derived from the inferior thyroid branch of the thyroid axis of the subclavian; from the descending thoracic aorta, and from the gastric branch of the cœliac axis from the abdominal aorta. They have for the most part a longitudinal direction.

Nerves of the œsophagus.—The nerves are derived from the pneumogastric and from the sympathetic; they form a plexus, in which are groups of ganglion-cells, between the two layers of the muscular coats, and also a second plexus in the submucous tissue.

Surgical Anatomy.—The relations of the œsophagus are of considerable practical interest to the surgeon, as he is frequently required, in cases of stricture of this tube, to dilate the canal by a bougie, when it is of importance that the direction of the œsophagus, and its relations to surrounding parts, should be remembered. In cases of malignant disease of the œsophagus, where its tissues have become softened from infiltration of the morbid deposit, the greatest care is requisite in directing the bougie through the strictured part, as a false passage may easily be made, and the instrument may pass into the mediastinum, or into one or the other pleural cavity, or even into the pericardium.

The student should also remember that contraction of the œsophagus, and consequent symptoms of stricture, are occasionally produced by an aneurism of some part of the aorta pressing upon this tube. In such a case, the passage of a bougie could only hasten the fatal issue.

In passing a bougie the left forefinger should be introduced into the mouth, and the epiglottis felt for, care being taken not to throw the head too far backwards. The bougie is then to be passed beyond the finger until it touches the posterior wall of the pharynx. The patient is now asked to swallow, and at the moment of swallowing the bougie is passed gently onwards, all violence being carefully avoided.

It occasionally happens that a foreign body becomes impacted in the œsophagus, which can neither be brought upwards nor moved downwards. When all ordinary means for its removal have failed, excision is the only resource. This, of course, can only be performed when it is not very low down. If the foreign body is allowed to remain, extensive inflammation and ulceration of the œsophagus may ensue. In one case the foreign body ultimately penetrated the intervertebral substance, and destroyed life by inflammation of the membranes and substance of the cord.

The operation of œsophagotomy is thus performed. The patient being placed upon his back, with the head and shoulders slightly elevated, an incision, about four inches in length, should be made on the left side of the trachea, from the thyroid cartilage downwards, dividing the skin and Platysma. The edges of the wound being separated, the Omo-hyoid

muscle should. if necessary, be divided, and the fibres of the Sterno-hyoid and Sterno-thyroid muscles drawn inwards; the sheath of the carotid vessels, being exposed, must be drawn outwards, and retained in that position by retractors: the œsophagus will now be exposed, and should be divided over the foreign body, which can then be removed. Great care is necessary to avoid wounding the thyroid vessels, the thyroid gland, and the laryngeal nerves.

The œsophagus may be obstructed not only by foreign bodies, but also by changes in its coats, producing stricture, or by pressure on it from without of new growths or aneurism, etc.

The different forms of stricture are: (1) the spasmodic, usually occurring in nervous women, and intermittent in character, so that the dysphagia is not constant; (2) fibrous, due to cicatrisation after injuries, such as swallowing corrosive fluids or boiling water; and (3) malignant, usually epitheliomatous in its nature. This is situated generally either at the upper end of the tube, opposite the cricoid cartilage, or at its lower end at the cardiac orifice, but is also occasionally found at that part of the tube where it is crossed by the left bronchus.

The operation of œsophagostomy has occasionally been performed in cases where the stricture in the œsophagus is at the upper part, with a view to making a permanent opening below the stricture through which to feed the patient, but the operation has been far from a successful one, and the risk of setting up diffuse inflammation in the loose planes of connective tissue deep in the neck is so great that it would appear to be better, if any operative interference is undertaken, to perform gastrostomy. The operation is performed in the same manner as œsophagotomy, but the edges of the opening in the œsophagus are stitched to the skin incision.

THE ABDOMEN

The **Abdomen** is the largest cavity in the body. It is of an oval form, the extremities of the oval being directed upwards and downwards: the upper one being formed by the under surface of the Diaphragm, the lower by the upper concave surface of the Levator ani. In order to facilitate description, it is artificially divided into two parts: an upper and larger part, the *abdomen proper*; and a lower and smaller part, the *pelvis*. These two cavities are not separated from each other, but the limit between them is marked by the brim of the true pelvis. The space is wider above than below, and measures more in the vertical than in the transverse diameter.

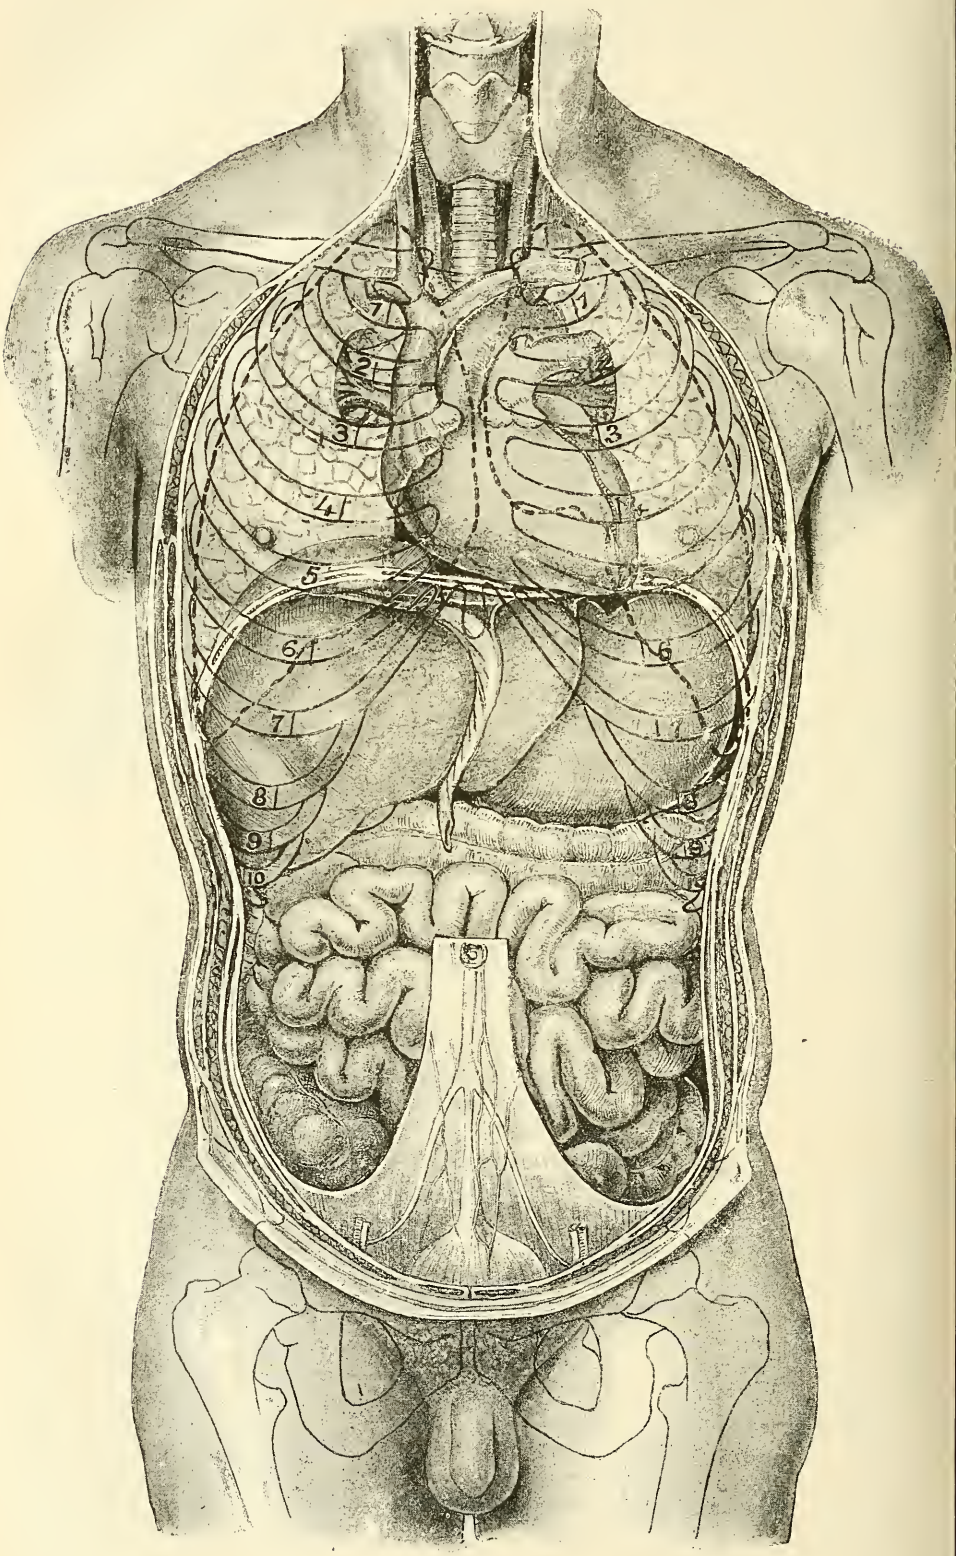
Boundaries.—The **abdomen proper** is bounded *in front*, and *at the sides*, by the lower ribs, the abdominal muscles, and the venter ilii; *behind*, by the vertebral column and the Psoas and Quadratus lumborum muscles; *above*, by the Diaphragm; *below*, by the brim of the pelvis. The muscles forming the boundaries of the cavity are lined upon their inner surface by a layer of fascia, differently named according to the part which it covers.

The abdomen contains the greater part of the alimentary canal; some of the accessory organs to digestion, viz. the liver, pancreas, and spleen; and the kidneys and suprarenal capsules. Most of these structures, as well as the wall of the cavity in which they are contained, are covered by an extensive and complicated serous membrane, the *peritoneum*.

The *apertures* found in the walls of the abdomen, for the transmission of structures to or from it, are, the *umbilicus*, for the transmission (in the fœtus) of the umbilical vessels; the *caval opening* in the Diaphragm, for the transmission of the inferior vena cava; the *aortic opening*, for the passage of the aorta, vena azygos, and thoracic duct; and the *œsophageal opening*, for the œsophagus and pneumogastric nerves. *Below*, there are two apertures on each side: one for the passage of the femoral vessels, and the other for the transmission of the spermatic cord in the male, and the round ligament in the female.

Regions.—For convenience of description of the viscera, as well as of reference to the morbid condition of the contained parts, the abdomen is artificially divided into nine regions. Thus, if two circular lines are drawn round the body, the one through the extremities of the ninth ribs, where they join their costal cartilages, and the other through the highest point of the crests of the ilia, the abdominal cavity is divided into three zones—an upper, a middle,

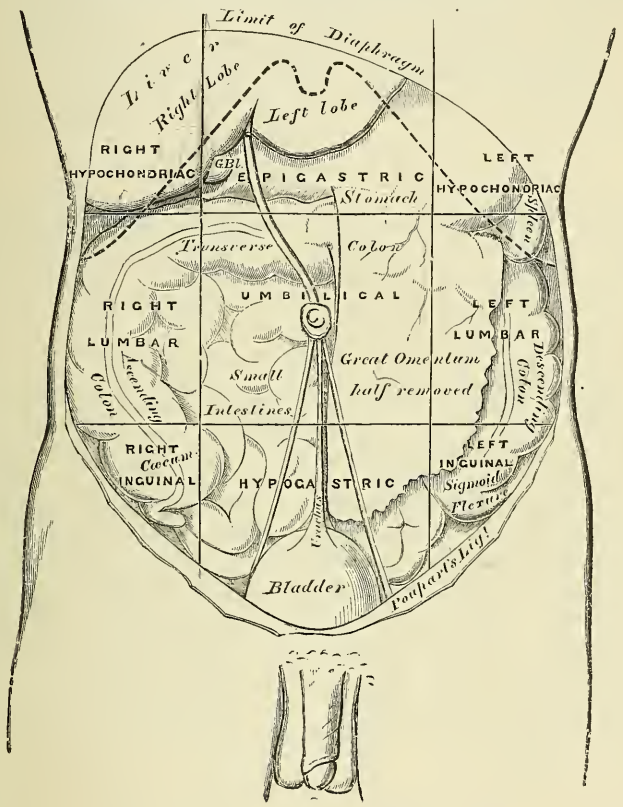
Fig. 567.—Topography of thoracic and abdominal viscera.



and a lower. If two parallel lines are drawn perpendicularly upwards from the centre of Poupart's ligament, each of these zones is subdivided into three parts—a middle and two lateral.

The middle region of the upper zone is called the *epigastric* (ἐπί, *over*; γαστήρ, *the stomach*); and the two lateral regions, the *right* and *left hypochondriac* (ὑπό, *under*; χόνδροι, *the cartilages*). The central region of the middle zone is the *umbilical*; and the two lateral regions, the *right* and *left lumbar*. The middle region of the lower zone is the *hypogastric* or *pubic region*; and the lateral regions

FIG. 568.—The regions of the abdomen and their contents.
(Edge of costal cartilages in dotted outline.)



are the *right* and *left inguinal* or *iliac*. The viscera contained in these different regions are the following (fig. 566):

Right Hypochondriac

The greater part of right lobe of the liver, the hepatic flexure of the colon, and part of the right kidney.

Epigastric Region

The greater part of the stomach, including both cardiac and pyloric orifices, the left lobe and part of the right lobe of the liver and the gall-bladder, the pancreas, the duodenum, parts of the kidneys and the suprarenal capsules.

Left Hypochondriac

The splenic end of the stomach, the spleen and extremity of the pancreas, the splenic flexure of the colon, and part of the left kidney.

Right Lumbar	*Umbilical Region*	*Left Lumbar*
Ascending colon, part of the right kidney, and some convolutions of the small intestines.	The transverse colon, part of the great omentum and mesentery, transverse part of the duodenum, and some convolutions of the jejunum and ileum, and part of both kidneys.	Descending colon, part of the omentum, part of the left kidney, and some convolutions of the small intestines.
Right Inguinal (Iliac)	*Hypogastric Region*	*Left Inguinal (Iliac)*
The cæcum, appendix cæci.	Convolutions of the small intestines, the bladder in children, and in adults if distended, and the uterus during pregnancy.	Sigmoid flexure of the colon.

The Peritoneum

The **peritoneum** (*περιτείνειν*, to extend around) is a serous membrane, and partially invests all the viscera contained in the abdominal and pelvic cavities. In consequence of the number and different shapes of these viscera, the reflections of the peritoneum, as it invests them, are exceedingly complex and difficult to understand.

The peritoneum partially invests all the viscera contained in the abdominal and pelvic cavities, forming the visceral layer of the membrane; it is then reflected upon the internal surface of the parietes of those cavities, forming the parietal layer. The *free surface of the peritoneum* is smooth, moist, and covered by a layer of flattened endothelial cells; its *attached surface* is rough, being connected to the viscera and inner surface of the parietes by means of areolar tissue called the *subserous areolar tissue*. The parietal portion is loosely connected with the fascia lining the abdomen and pelvis; but more closely to the under surface of the Diaphragm, and in the middle line of the abdomen.

The description of the peritoneum is difficult, and cannot be made very clear without referring to its more primitive and simpler type in the embryo. The following essential facts in the Development of the Peritoneum, from the pen of Mr. Fred T. Brockway, are here given with a view to rendering the description of this complex structure more intelligible to the student.

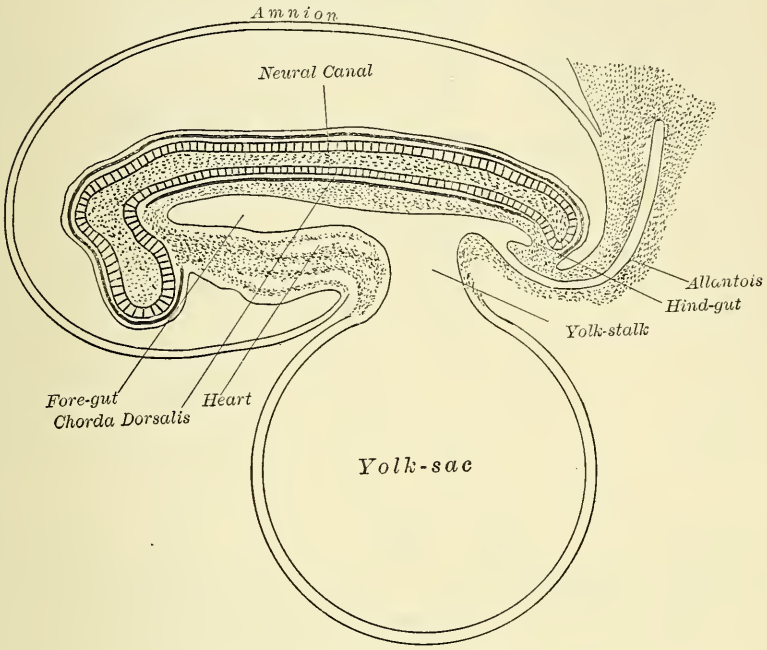
Development of the Peritoneum

In the early development of the alimentary canal, before the twelfth day in the human embryo, all three germ-layers push forward, are folded over, and produce the head and the anterior part of the *fore-gut*. This is blind at the front end, and the *mouth* is developed later by an invagination from the exterior. The middle part of the future alimentary tract, *mid-gut*, is in free communication for some time with the blastodermic vesicle which is later called the *yolk-sac*. The approximation of the body-walls at the umbilicus gradually pinches the *yolk-stalk* off into the *vitelline duct*, so the sac finally lies wholly outside the body of the embryo, and that part of it enclosed within is the *pleuro-peritoneal cavity* (fig. 569). Finally, at the caudal end a *hind-gut* is formed and an *anus* added by a process of invagination.

Thus the whole alimentary canal was originally a straight tube placed in front of the aorta, or the original two primary aortæ, and that in front of the future vertebral column, the *chorda dorsalis* (fig. 570). Along its middle region, the anterior wall is lacking as it opens here into the yolk-sac.

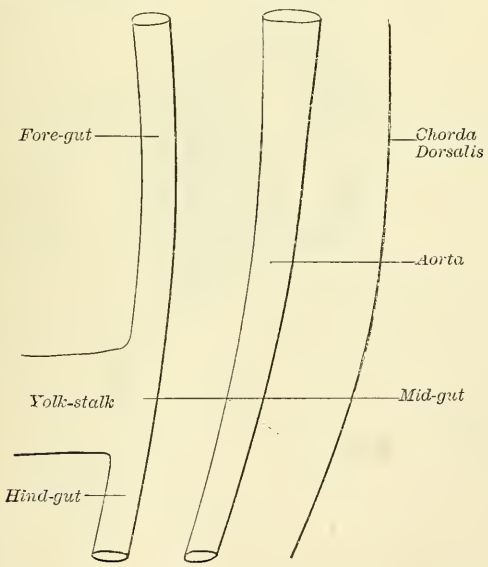
The fore-gut contracts to form the *œsophagus*, which is very short (fig. 571). This gradually widens into a spindle-like dilatation indicating the *stomach*. The

Fig. 569.—Diagram of a longitudinal section of a mammalian embryo. Very early. (After Quain.)



small intestine is short and straight with a wide opening into the yolk-sac. Just below the stomach, the liver is budding out from the duodenum. This

Fig. 570.—Schematic median section of a human embryo. (After Dexter.)



stage is attained in the fourth week in the human embryo. There are now five successive districts in the whole canal, *mouth*, *throat*, and *visceral clefts*,

œsophagus, spindle-shaped *stomach*, and the remaining *tube* connected with the yolk-sac.

By the fifth or sixth week, the *stomach*, at first straight and parallel with the

Fig. 571.—Schematic median section of a human embryo of fourth week. (After Dexter.)

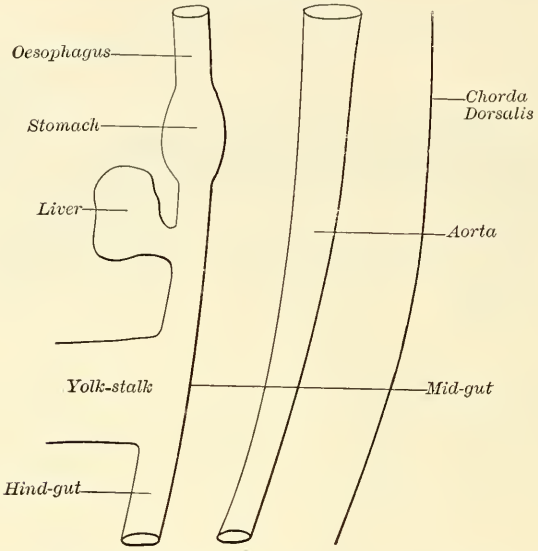


Fig. 572.—Schematic median section of a human embryo of fifth or sixth week. (After Dexter.)

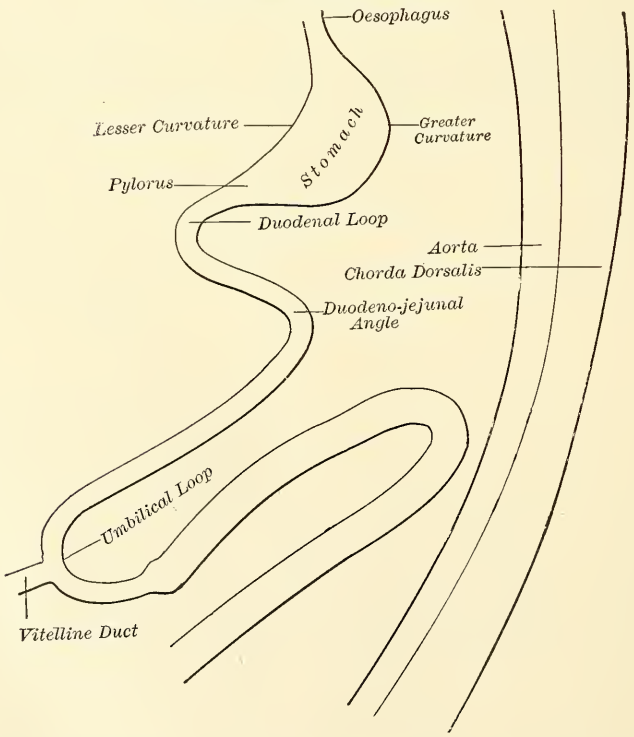
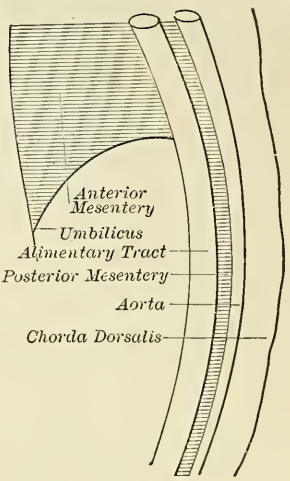


axis of the body, begins to show a convex *greater curvature* toward the vertebral column and a concave *lesser curvature* on the opposite side. This is covered by the voluminous liver. The *pyloric end* is tilted away from the column,

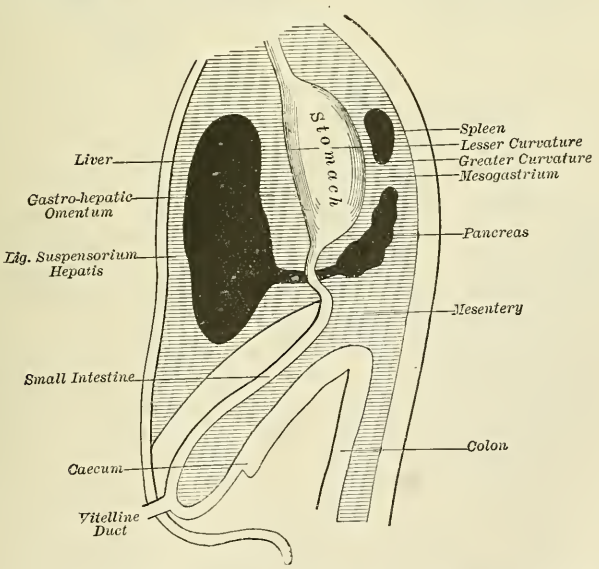
and this forms the *duodenal loop* (fig. 572). As the communication with the yolk-sac becomes constricted and absorbed there is developed a long *umbilical loop* of intestine opposite the *vitelline duct*. The end of this loop passes for a time into the umbilical cord surrounded by a protrusion of the peritoneum. This loop passes downward and forward, and consists of nearly two parallel arms between which is stretched the mesentery. At a little distance from the vitelline duct on the lower arm of the loop is seen a small enlargement; this marks the future *cæcum* and beginning of the *colon* and end of small intestine. Five portions of intestine are now to be distinguished: the short part passing back from the stomach toward the spinal column becomes *duodenum*; at the turning point into the umbilical loop is the *duodeno-jejunal junction*; the anterior descending arm and bend of the loop become *small intestine*; most of the ascending posterior arm becomes *colon*, and the terminal part, *sigmoid flexure* and *rectum*.

Fig. 573.—Fig. 570 with mesenteries added. (Dexter.)



At first the alimentary tract is mostly in contact with the chorda dorsalis held by a broad mass of embryonal connective tissue. This tissue contains two primitive aortæ. The right and left portions of the body-cavity approach each other and compress this tissue into a *mesentery*, which is attached to the whole length of the tube beginning with the stomach, connecting it with the chorda. The special part of this membrane attached to the stomach posteriorly is called *mesogastrium*; that to the small intestine is called *mesentery* (*medium intestinum* or μέσον ἔντερον, middle intestine); that to the colon, the *mesocolon*; that to the sigmoid

Fig. 574.—Diagram to show the original positions of the liver, stomach, duodenum, pancreas and spleen, and the mesenteries connected. A longitudinal section. (Hertwig.)



flexure, the *mesosigmoidea* or *sigmoid mesocolon*; and that to the rectum the *mesorectum*. This has not been represented in the above figures for the sake of simplicity. There is also a *ventral mesentery*, but not of such extent as the

dorsal. It extends along the front of the alimentary canal from the throat to the lower end of the duodenum and in front as far down as the umbilicus (fig. 573). It almost makes the body-cavity a paired structure. In the upper part of this mesentery is developed the heart, the part enclosing it being called *mesocardium anterius* and *posterius*. The lower part extends from the stomach and duodenum to the anterior wall and has many names—*ventral gastric and duodenal mesentery, liver-ridge* and *prohepaticus*; it is never called anterior mesogastrium.

The *liver* is here developed anterior to the stomach, budding from the anterior part of the beginning of the duodenum (fig. 574).

The *pancreas* buds from the posterior part of the duodenum, vertical at first and covered on both sides by the mesentery of the small intestine; it passes into the mesogastrium later and becomes transverse.

The *spleen* is developed in the second month in the mesogastrium and is not connected directly with the alimentary canal.

At this stage, passing from before backward, we find the structures arranged: anteriorly, liver; in the centre, stomach; posteriorly, spleen and pancreas. The anterior mesentery in front of the liver becomes the suspensory or *falciform ligament* of the liver, extending to the umbilicus below and embracing the intra-

Fig. 575.—Cross section in duodenal region to show same structures as in fig. 574. (Hertwig.)

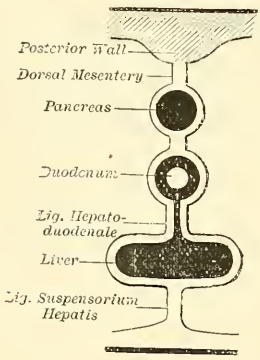


Fig. 576.—Schematic representation of the mesentery in a six weeks' human embryo. (Toldt.)

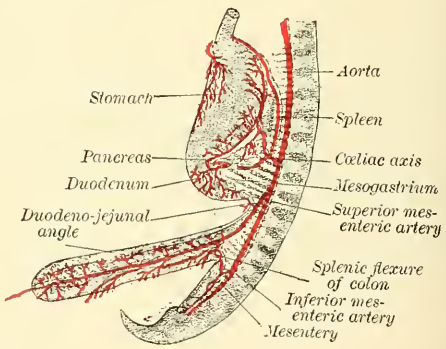

abdominal part of the umbilical vein. The anterior mesentery between the liver and stomach becomes the *lesser omentum* or *lig. hepato-gastro duodenale*. The mesogastrium between stomach and spleen becomes *gastro-splenic omentum*, and that part between the spleen and vertebral column forms the *great omentum*.

Fig. 575 is a cross-section of the same embryo. Anteriorly are the two sacs of the liver projecting one into each side of the body-cavity. The right sac grows to a larger size than the left; they form respectively the right and left lobes. Behind these is the duodenum and behind that the pancreas. The intervening parts of the mesentery are called ligaments, viz. first, *suspensory ligament* of liver, next *hepato-duodenal ligament*, next *duodeno-pancreatic ligament*, and lastly, the dorsal mesentery. Note that pancreas and duodenum are wholly enclosed.

The *vascular arrangement* of this stage is shown in fig. 576. The *cœliac axis*, the *superior mesenteric* and *inferior mesenteric arteries* have their points of supply definitely marked out even in the sixth week. They pass from the aorta between the two layers of the mesogastrium and mesentery to their destinations, which never change. The cœliac axis goes to the stomach, spleen, pancreas, liver and part of duodenum; the superior mesenteric, to part of duodenum, the small intestines, and part of colon; the inferior mesenteric, to the remainder of the tube.

The length of the intestine continually increases, and it becomes more bent

and tortuous, till from the third month on there occur two important changes : one in regard to a twist of the intestinal loop, and one in regard to a change in position of the stomach. The ascending and descending arms of the umbilical loop have been lying side by side one above the other ; now the lower arm, which

Fig. 577.—Torsion of the umbilical loop. Initial position. (Jonnesco.)

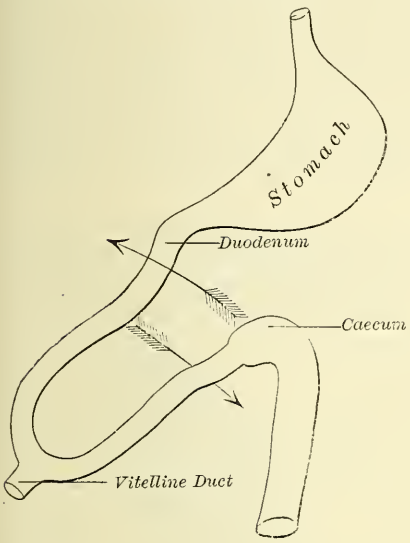

Fig. 578.—Torsion of the umbilical loop. Acquired position. (Jonnesco.)

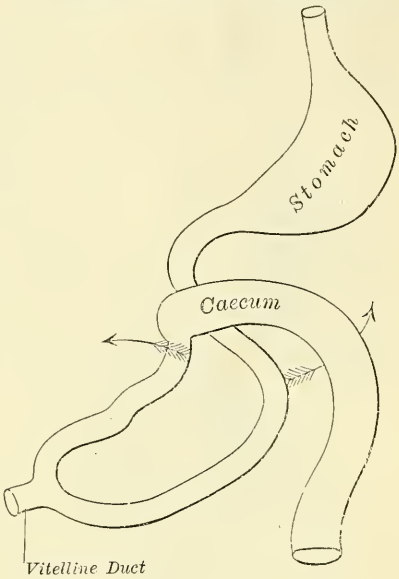

becomes cæcum and colon, begins to pass over the upper arm and crosses the small intestine transversely (fig. 577). The upper arm moves but little or none, as it is already fixed to the vertebral column at its upper duodeno-jejunal end, perhaps by the muscle of Treitz.

The cæcum, which has already developed an appendix, is thus landed wholly on the right side of the body up under the liver (figs. 578 and 580). At first

Fig. 579.—Development of human alimentary canal and mesentery. Earlier stage. (Hertwig.)

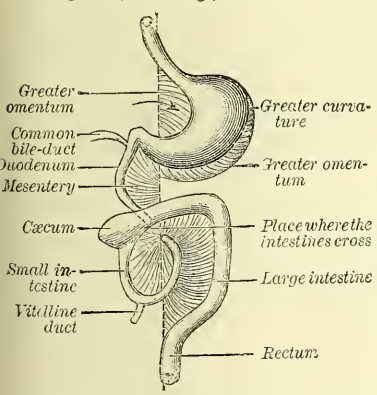

Fig. 580.—Development of human alimentary canal and mesentery. Later stage. (Hertwig.)

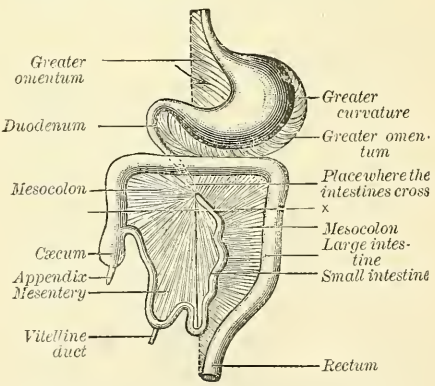
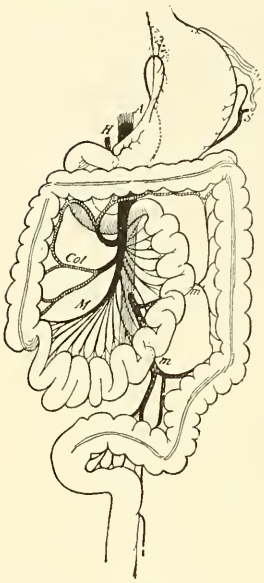


there is no ascending colon, the transverse colon running across the duodenum, inferior to the stomach and up to the spleen, making a splenic flexure ; it passes through the left lumbar region and is continued into the sigmoid flexure and rectum. The cæcum increases in length, and finding least resistance below, finally settles into the right iliac fossa, dragging down a short ascending colon.

The mesentery, seen in the loop of fig. 576, makes a half rotation, as does the loop, and its anterior surface becomes posterior, as may be inferred from figs. 579 and 580.

Fig. 581.—Final disposition of the intestines and their vascular relations. (Jonnesco.)



A. Aorta. *H.* Hepatic artery. *S.* Splenic artery. *M, Col.* Branches of superior mesenteric artery. *m, m'.* Branches of inferior mesenteric artery.

Fig. 581 shows the arterial supply after the twist of the umbilical loop, with the cœliac axis behind the stomach, the superior mesenteric artery fastening the duodenum between itself and the aorta, and the inferior mesenteric coming off below.

During this period of intestinal torsion, the stomach has suffered a double change. First the stomach twists around an antero-posterior axis, so its cardiac or œsophageal end moves to the left and downward, while its pyloric end moves a little to the right and upward; and its vertical position becomes more transverse.

Secondly, its long axis having been parallel to the vertebral column, it originally presented a right and left surface, supplied respectively by the right and left vagus nerves. It now falls over so that its right side becomes posterior and its left side anterior, and the greater curvature becomes more inferior and the lesser curvature more superior. The vagus nerves still supply the same surfaces, which have changed their positions: the right nerve now goes to the posterior surface and the left one to the anterior surface.

The lower end of the œsophagus also experiences the same torsion.

The *mesogastrium* is modified by this rotation to the right. In the anterior mesentery is the liver (fig. 574), but in the adult we find it shifted to the right side of the body. The spleen was posterior to the stomach; in the adult it is to its left. So these three antero-posterior organs have become laterally placed, and from right to left are hereafter found: liver, stomach, spleen.

Fig. 582.—Wood and cloth to illustrate stomach and mesogastrium of two layers viewed from the side. (G. S. H.)

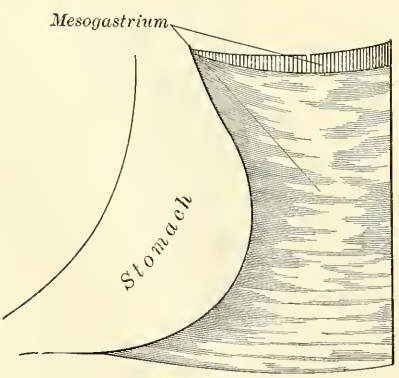


Fig. 583.—Stomach turned to right enclosing a space behind it, representing the great omentum and its cavity view from the front. (G. S. H.)

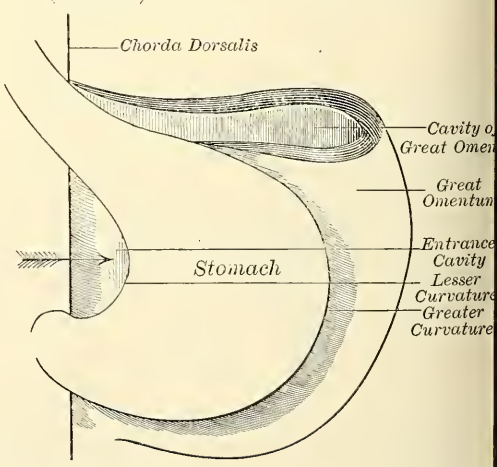

Again connected with this torsion of the stomach is associated the formation of the *great omentum*. To illustrate this, carve a piece of wood to represent the

stomach; let two layers of cloth attached to the posterior border represent the mesogastrium attached to the vertebral column (fig. 582). This was the original condition (fig. 576). Now turn the stomach to the right, allowing the cloth to fall loosely to the left, and immediately a cavity is formed included between two layers of cloth anteriorly and two layers posteriorly (fig. 583). In the embryo a similar cavity is formed called the *cavity of the great omentum*, the *lesser sac of peritoneum*, *bursa omentalis*; and a similar fold of four layers is formed called the *great omentum*, which in the embryo and infant contains this cavity.

The entrance to this cavity is indicated by the arrow in figs. 579, 580, and 583, and the bulging of the great omentum is seen to the left of and below the greater curvature of the stomach. Compare the above with fig. 584, and the position of the sac will be better understood.

The front wall of the bursa omentalis is formed by the stomach; the posterior wall by the mesogastrium, which at first completely invests the

Fig. 584.—Schematic and enlarged cross section through the body of a human embryo in the region of the mesogastrium. Beginning of third month. (Toldt.)

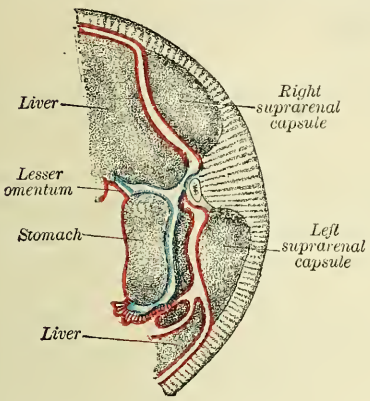

Fig. 585.—Same section as in fig. 584, at end of third month. (Toldt.)

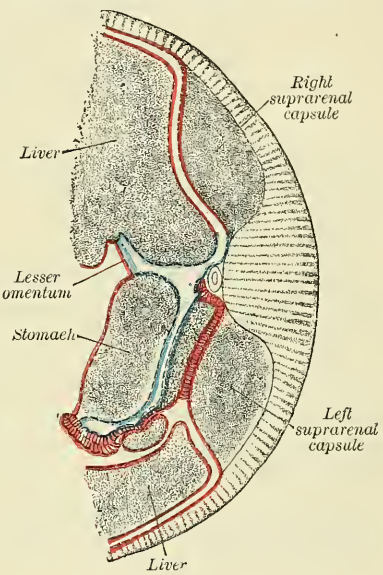


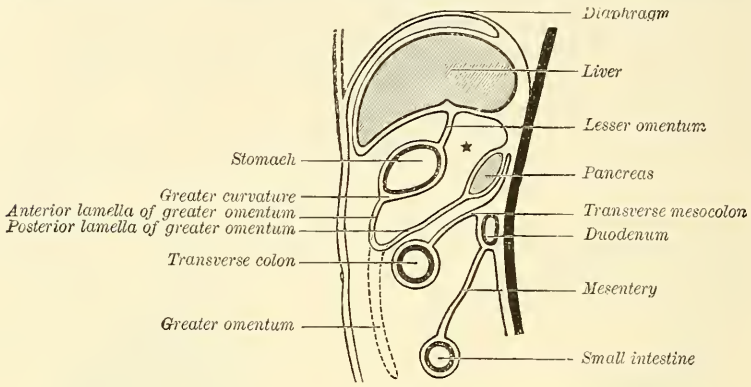
pancreas, touches the spleen, and covers part of the left suprarenal capsule. The opening is turned to the right and covered anteriorly by the lesser omentum. The space between the lesser omentum and right end of pancreas is the *atrium bursæ omentalis* or the *antechamber* or *lesser omental pocket*. It lies below and behind the Spigelian lobe of the liver. The bursa proper, or lesser sac, is that part behind the stomach.

By the end of the third month the pancreas touches the left suprarenal capsule (fig. 585), the layer of mesogastrium separating the two becomes later absorbed, and the pancreas is then an extraperitoneal organ separated from the kidney or capsule by connective tissue. By further development this lesser sac continues to push between the layers of the great omentum downward and to the left, and fuses with neighbouring viscera. The great omentum, formerly a part of the mesogastrium, comes to hang freely down over the transverse colon and then in front of the small intestines, as about to do in figs. 580 and 586.

The lamellæ composing the bursa omentalis or lesser sac are each composed of two layers; they are placed close together and are continuous below (figs. 586 and 587). The more anterior one is attached to the greater curvature of the stomach, and the posterior one lying on the intestines was originally attached to the vertebral column and enclosed most of the pancreas (figs. 584 and 586). In many mammals no further change occurs. In man fusions follow: the posterior lamella covers a large part of the posterior abdominal wall, and its original

line of vertebral attachment gets displaced to the left; it joins the Diaphragm and forms the *lig. phreno-lienale*, suspensory ligament of the spleen. Below it becomes fused to the upper layer of the transverse mesocolon and to the transverse colon (fig. 587). These two contiguous layers, i.e. the posterior layer of the mesogastrium and the upper layer of the transverse mesocolon, may present

Fig. 586.—Diagram to illustrate the development of the bursa omentalis, cavity of the great omentum or lesser sac. Fœtal stage. *. Lesser sac. (Hertwig.)

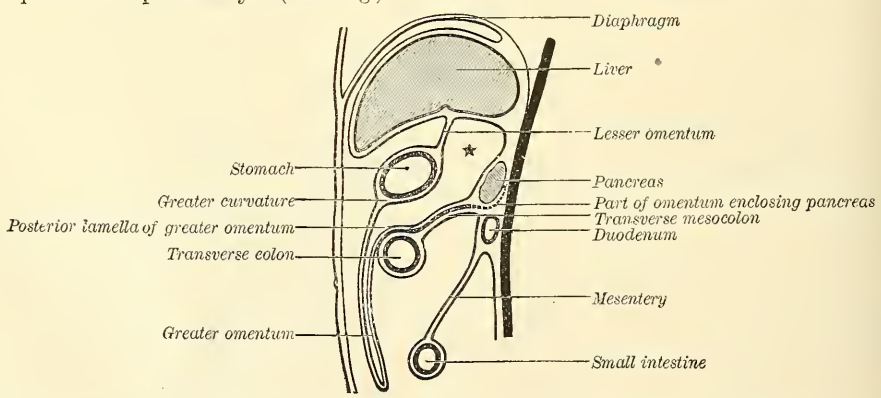


a fissure at birth in many mammals. During early infancy in the human species they form a single lamella with a deposit of fat (fig. 587). In adult life no trace of the extra layer is seen.

There are then three types of relation of the posterior layer of the great omentum to the transverse mesocolon: *fœtal*, where they are separate (fig. 586); *infantile*, where they are fused into one layer (fig. 587); and *adult*, where all trace of this layer has disappeared and the posterior lamella of the great omentum seems to enclose the transverse colon.

The lesser sac of peritoneum (bursa omentalis) is still continuous with the greater sac or general peritoneal cavity, something like the two cavities of an hour-glass, only the upper cavity (lesser sac) is comparatively small and bent down behind the other. In fig. 587 the cavity behind the stomach is connected

Fig. 587.—Development of bursa omentalis. Infantile stage. Great omentum covers the intestines and has fused with the transverse mesocolon. Pancreas is free of peritoneum posteriorly. (Hertwig.)



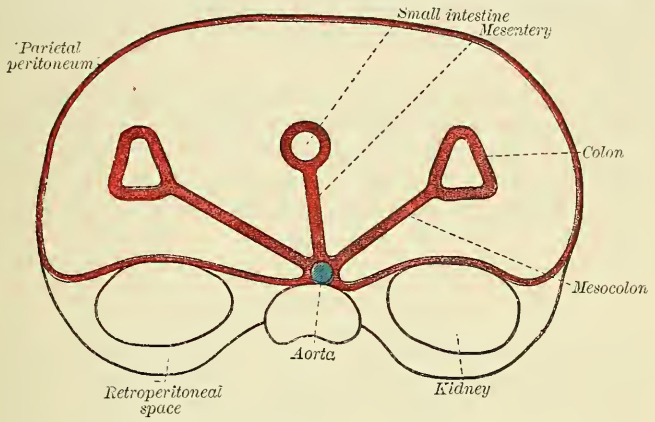
with the larger cavity in front of it by means of a foramen to the right of the lesser omentum. It is the *foramen of Winslow*, and is to be found just under the hilus (the black spot on a bean) of the liver to the right side of the neck of the gall-bladder.

After childhood the cavity of the lesser sac descending into the great omentum is obliterated and the four layers are fused into an *omental plate*.

Mesentery of the Small Intestine and Colon

The mesentery is influenced by the increase in length of the small intestine. It becomes fan-shaped, and its length at its insertion into the intestine is many times that of its origin from the lumbar vertebræ; so it lies in folds and is called a *frill*. In man, after the fourth month, this becomes more complicated by fusions with the posterior body-wall or neighbouring viscera. It affects especially the mesentery of the duodenum and colon.

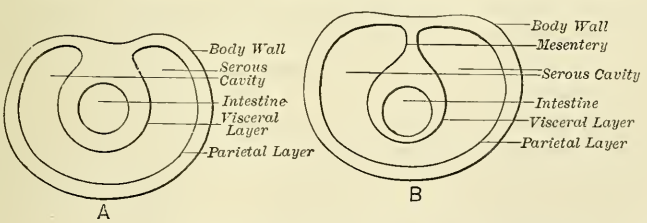
Fig. 588.—Cross section of alimentary canal of fig. 580 to show mesenteries. (Dexter



The duodenum at first is completely invested with peritoneum (fig. 579); later other viscera growing faster are thought to pull it away and appropriate it, and so posteriorly it comes to lie on the posterior wall of the body and becomes an immovable organ (fig. 587).

The large intestine possesses a suspensorium attached to the vertebral column and designated the *mesocolon*. When the twist of the umbilical loop occurred, the transverse colon and its mesocolon were drawn transversely across the duodenum, and a new secondary line of attachment was thus formed. This explains why in the adult we find the body-cavity divided by the transverse colon and transverse mesocolon into chambers, an upper and a lower. In the upper are the stomach, liver, pancreas, spleen and part of duodenum; in the lower, part of duodenum and the small intestines. The duodenum, in order to get from the

Fig. 589.—Schematic drawing of a cross section of a serous cavity. (Gegenbaur.)



upper to the lower space, passes underneath the transverse colon or apparently through the mesocolon (fig. 580).

The cæcum, ascending and descending colon also lie with their posterior walls more or less in contact with the body-wall, but sometimes they have a more or less distinct mesentery, as they did originally. The original disposition can be seen by taking a cross section of the alimentary canal in fig. 580 along the line X. Each colon and the small intestine is fixed to the aorta and vertebral column by its special mesentery, which allows freedom of motion (fig. 588).

The *mesentery* is seen to be formed of two layers of peritoneum which surround an intestine completely, except at a posterior line where there is opportunity for vessels, nerves, and lymphatics to enter or return. Two layers of peritoneal connective tissue, which lodge vessels, nerves, and lymphatics, constitute a mesentery. The intestine looks as though it had pushed its way into the sac of peritoneum as a finger enters a glove. That comparison is incorrect, for intestine and peritoneum are developed simultaneously. The intestine is not first made and then pushed, as would appear (fig. 589).

The intestine and the two layers of peritoneum are formed together. As the intestine recedes, the serous membrane comes from the wall to it in a duplicature. The layer covering the intestine is called *visceral*; that reflected upon the parietes or wall is the *parietal layer*, and the passage from one to the other is the *mesentery*.

In the *adult* the small intestine is unchanged, but the mesentery of the right and left colon has been widely separated posteriorly, and it and some of the parietal peritoneum have been changed to connective tissue, so each colon becomes fixed and partly extraperitoneal, like the duodenum and pancreas (fig. 587). The kidneys were always outside, being developed in the retroperitoneal space.

Adult Peritoneum

In order to get a first general idea of the peritoneum and its reflections, the student should bear in mind that all the abdominal and pelvic viscera are placed external to it, and that it is a shut sac superimposed upon the viscera.*

Let the student imagine that all the viscera are in their proper positions in the abdominal cavity, but uninvested by peritoneum. Upon the top of them is placed a large closed sac, the walls of which are of extreme thinness, and wherever there is a cleft between two viscera a process of peritoneum derived from the part of the sac in contact with the viscera is tucked in between them, so as to cover the adjacent surfaces of the two viscera and separate them from each other, and at the same time, by becoming adherent to the viscera, form an investment for them. Thus in fig. 590 such a diverticulum or process may be seen tucked in between the under surface of the liver and the upper surface of the stomach, and extending between the two as far backwards as the portal vein, hepatic artery, and hepatic duct, which it covers on their anterior surfaces, forming the anterior layer of what is termed the lesser omentum.

Another diverticulum or process is tucked in round the hepatic artery, as it passes forwards and upwards to the liver, and afterwards expands into a large sac or bag, which covers the posterior surface of the liver and stomach, and the upper part of the posterior wall of the abdomen, separating these structures from each other. This large *cul-de-sac* of peritoneum is called the *lesser cavity of the peritoneum*, but is only a part of the general cavity differentiated from it by the constriction produced at the situation of the hepatic artery. In this respect the peritoneum may be compared to an hour-glass with two unequal globes: the smaller one constituting the lesser cavity of the peritoneum; the larger one the greater cavity; and the constriction where the two globes communicate corresponding to the constriction in the peritoneum where it hooks round the hepatic artery. This constriction is called the foramen of Winslow.

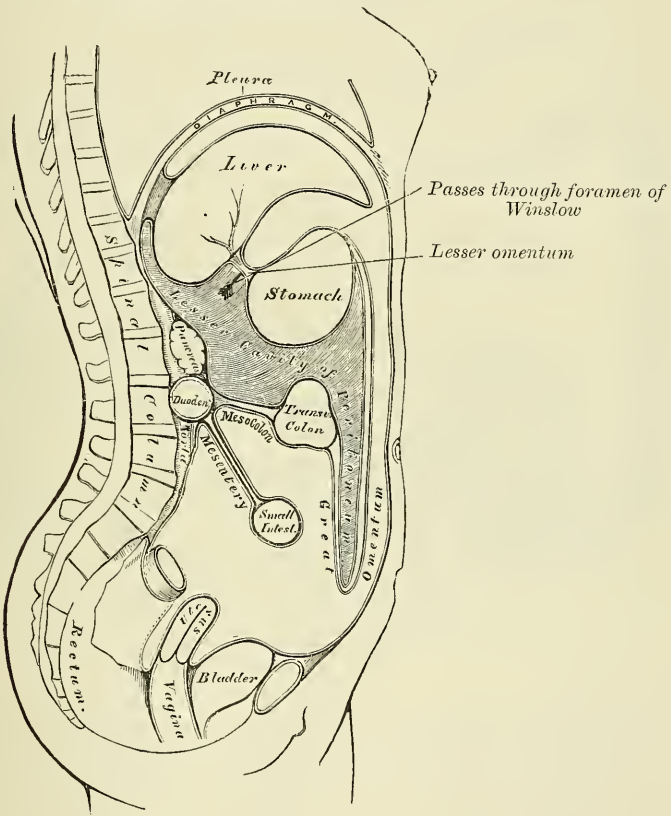
Between the transverse fissure of the liver and the lesser curvature of the stomach there is thus a double layer of peritoneum: the anterior layer being part of the greater bag of the peritoneum, where it is tucked in between the liver and the stomach from the front; while the posterior layer is part of the lesser bag of the peritoneum where it is tucked in round the hepatic artery. These two layers

* We may disregard, for the present, the fact that the peritoneum in the female is not an absolutely closed sac, since the Fallopian tubes open into it at their free extremities.

constitute the lesser omentum. Between the two layers are situated the hepatic artery, the portal vein, and the hepatic duct.

A process of this lesser bag of the peritoneum is pushed backwards and upwards behind the liver, extending as far as the under surface of the Diaphragm, the posterior part of which it covers. At its extremity this process approaches a diverticulum of the greater bag of the peritoneum, which is pushed in from the front, in the cleft between the upper surface of the liver and the under surface of the Diaphragm. Another process of this lesser bag is pushed downwards between the stomach and the transverse colon and forms the two inner of the four layers of the great omentum. Thus the lesser cavity of the peritoneum is seen to be a complete sac or bag, separating the back and part of the under surface of the liver, the posterior wall of the stomach, and the upper surface of

FIG. 590.—The reflections of the peritoneum, as seen in a vertical section of the abdomen.



the transverse colon from the back part of the under surface of the Diaphragm and the upper part of the posterior wall of the abdomen.

The *greater cavity of the peritoneum* separates the anterior surfaces of the viscera from the front wall of the abdomen; so that in our comparison of the two cavities to an hour-glass it must be borne in mind that they are not in the same straight line as the two globes of the hour-glass, but that, at the point of constriction, the smaller cavity is bent round the hepatic artery, so as to lie behind the greater cavity.

The greater sac of the peritoneum is placed in front of the viscera, one layer being in contact with them, the other lining the inner surface of the anterior wall of the abdomen. The layer which is in relation with the viscera sends backwards diverticula which pass between the various organs, and in certain

places comes in contact with the peritoneum forming the lesser bag, in the manner described above. Thus we have one of these diverticula sent backwards between the liver and Diaphragm, covering the anterior part of the under surface of the Diaphragm and the upper surface of the liver as far backwards as the ligaments. The extremity of this diverticulum approaches a similar diverticulum of the lesser bag, already described, and the two layers form the anterior and posterior layers of the coronary ligament of the liver. Another process, which has already been mentioned, is sent backwards between the under surface of the liver and the stomach, to meet a similar process of the lesser cavity prolonged from behind forwards. Where the two are in apposition the lesser or gastro-hepatic omentum is formed. A third diverticulum is carried backwards to the posterior wall of the abdomen between the transverse colon and the small intestine. This prolongation covers the under surface of the transverse colon and forms the under layer of the transverse mesocolon, and the upper layer of the mesentery; by its extremity it is in contact with the posterior wall of the abdomen, and covers a part of the abdominal aorta. Between the greater curvature of the stomach and the transverse colon there is a fold or reduplication of the peritoneum, which contains between its layers a similar fold from the lesser cavity, and forms the apron or great omentum. Another fold of the greater bag of the peritoneum is pushed backwards to the spine between the small intestines and the pelvic viscera. This fold forms the lower layer of the mesentery, covers a considerable portion of the lower part of the abdominal wall, and passes over the sacro-vertebral angle into the pelvis. Below, where it covers the upper part of the pelvic viscera, it sends diverticula *downwards* between them, separating them from one another; thus one is sent downwards between the back of the rectum and the sacrum, another between the rectum and the bladder. In the female, one is sent down between the rectum and uterus, another between the uterus and bladder. These, then, are the various diverticula sent off from the posterior layer of the greater bag of the peritoneum; the anterior layer simply lines the anterior wall of the abdomen, and is continuous at its extremities with the posterior layer.

The student will perhaps be better able to follow these various folds or reflections of the peritoneum by a reference to the accompanying plan (fig. 591), which should be studied in conjunction with fig. 590. He must not forget, however, that though the lesser and greater cavities of the peritoneum are here represented, for the sake of clearness, as quite distinct from each other, they are not really so, but that they both form part of one great cavity.

The reflections of the peritoneum may be traced in two different ways, either by considering the folds which form each cavity separately, or by describing them together.

According to the first plan (fig. 590), the liver should be raised and supported in that position, and the stomach should be depressed, when a thin membranous layer is seen passing from the transverse fissure of the liver to the upper border of the stomach: this is the *lesser* or *gastro-hepatic omentum*. It consists of two delicate layers of peritoneum, an anterior and a posterior, between which are contained the hepatic vessels and nerves. Of these two layers, the anterior should first be traced, and then the posterior.

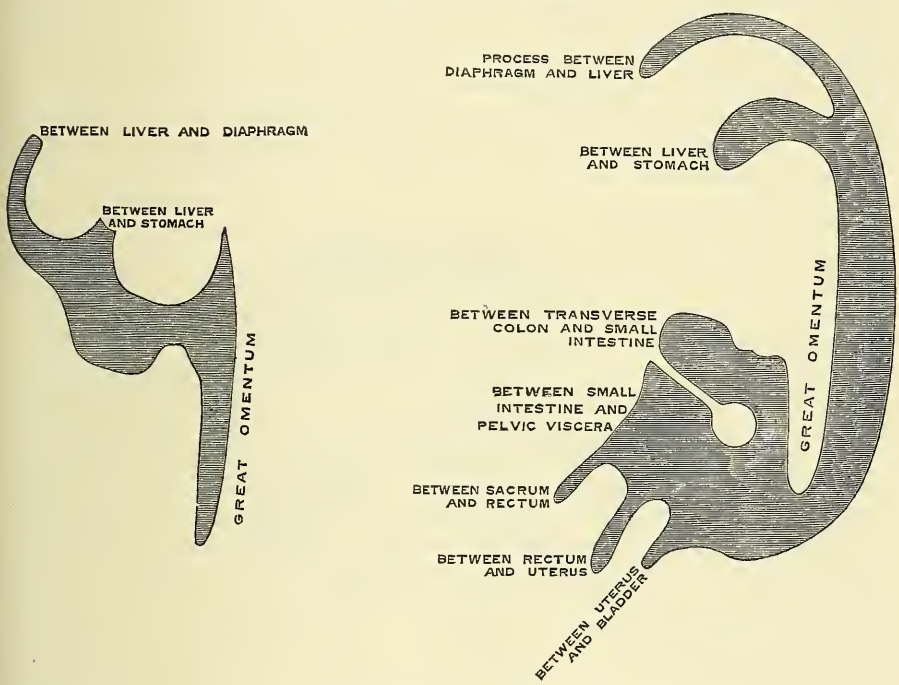
The *anterior layer* descends to the lesser curvature of the stomach, and covers its anterior surface as far as the great curvature: it descends for some distance in front of the small intestines, and, returning upon itself to the transverse colon, forms the *external layer of the great omentum*; it then covers the under surface of the transverse colon, and, passing to the back part of the abdominal cavity, forms the *inferior layer of the transverse mesocolon*. It then descends in front of the duodenum, over the superior mesenteric artery, along which it passes to invest the small intestines, and, returning to the vertebral column, forms the *mesentery*; whilst, on either side, it covers the ascending and descending colon, and is thus continuous with the peritoneum lining the walls of the abdomen.

From the root of the mesentery it descends along the front of the spine into the pelvis, and surrounds the upper part of the rectum, which it holds in its position by means of a distinct fold, the *meso-rectum*. Its course in the male and female now differs.

In the male it forms a fold between the rectum and bladder, the *recto-vesical fold*, and ascends over the posterior surface of the latter organ as far as its summit.

In the female it descends into the pelvis surrounding the rectum, forms a fold between the rectum and vagina, the *recto-vaginal fold* (pouch of Douglas), covers a small part of the posterior wall of the vagina, and passes on to the uterus, the fundus and body of which it covers. From the sides of the uterus it is reflected to the wall of the pelvis, forming the broad ligaments; and from the anterior surface of the uterus it ascends upon the posterior wall of the bladder as far as its summit.

FIG. 591.—Plan of the peritoneum.



From this point it may be traced, as in the male, ascending upon the anterior parietes of the abdomen, to the under surface of the Diaphragm; from which it is reflected upon the liver, forming the anterior layer of the coronary, and the lateral and longitudinal ligaments. It then covers the upper and under surfaces of the liver, and at the transverse fissure becomes continuous with the anterior layer of the lesser omentum, the point whence its reflection was originally traced.

The *posterior layer of the lesser omentum* descends to the lesser curvature of the stomach, and covers its posterior surface as far as the great curvature; it then descends for some distance in front of the small intestines, between the two layers of the great omentum formed by the anterior layer, and, returning upon itself to the transverse colon, forms the internal layer of the great omentum; it covers the upper surface of the transverse colon, and, passing backwards to the spine, forms the upper layer of the transverse meso-colon. Ascending in front of the pancreas and crura of the Diaphragm, it lines the back part of the under surface of that muscle, from which it is reflected on to the posterior border of the liver, forming the posterior layer of the coronary ligament. It then passes to the under surface of the liver, as far as the transverse fissure, where it is

continuous with the posterior layer of the lesser omentum, the point whence its reflection was originally traced.

The space included in the reflections of this layer of the peritoneum is called the *lesser cavity of the peritoneum*, or *cavity of the great omentum*. It is bounded, *in front*, by the lesser omentum, the stomach, and the descending part of the great omentum; *behind*, by the ascending part of the great omentum, the transverse colon, transverse meso-colon, and its ascending layer; *above*, by the liver; and *below*, by the folding of the great omentum. This space communicates with the general peritoneal cavity through the foramen of Winslow, which is situated behind the right, or free border of the lesser omentum.

In order to trace the two layers together, we commence at the top of the abdominal cavity; that is to say, the under surface of the Diaphragm. This muscle is covered throughout the greater part of its extent by peritoneum; one layer extending from its anterior border, backwards; the other from its posterior border, forwards. Where the two layers approach each other they are reflected downwards to the liver, forming the coronary and lateral ligaments of this organ. When these two layers reach the liver, they again separate to enclose the greater part of this viscus, the one passing in front and the other behind, and they meet again on its under surface at the transverse fissure. From this fissure they turn downwards to the lesser curvature of the stomach, forming the gastro-hepatic or lesser omentum, and enclosing the hepatic artery, the portal vein, and the hepatic duct, which are contained between the two folds in this situation. From the lesser curvature of the stomach, the two layers pass over the anterior and posterior surfaces of the viscus, enclosing it and meeting again at the greater curvature. From this point they pass down in front of the small intestines, between this tube and the abdominal wall, and are reflected on themselves, passing upwards to the transverse colon, and forming the apron or great omentum. This reflection, therefore, consists of *four* layers of peritoneum. When the two posterior layers of the great omentum, in their reflection upwards, reach the transverse colon, they separate to enclose this portion of the intestinal tube, the one layer passing above it and the other below. They meet on its posterior surface, and pass backwards to the vertebral column, forming what is called the *transverse meso-colon*. At this point the two layers separate. The one which formed the upper surface of the transverse meso-colon, and which belongs to the lesser cavity, passes upwards in front of the pancreas and crura of the Diaphragm to the back part of the under surface of the Diaphragm, the point from which the description of this layer was commenced. The other, which formed the inferior layer of the transverse meso-colon, turns downwards in front of the duodenum, aorta, and inferior vena cava, and can be traced, as a single layer, in the manner above described, investing the small intestines and forming the mesentery; then passing over the sacro-vertebral angle into the pelvis, the viscera of which it partially invests, and finally over the posterior surface of the front wall of the abdomen to the under surface of the Diaphragm, the point from which the description of this layer was commenced.

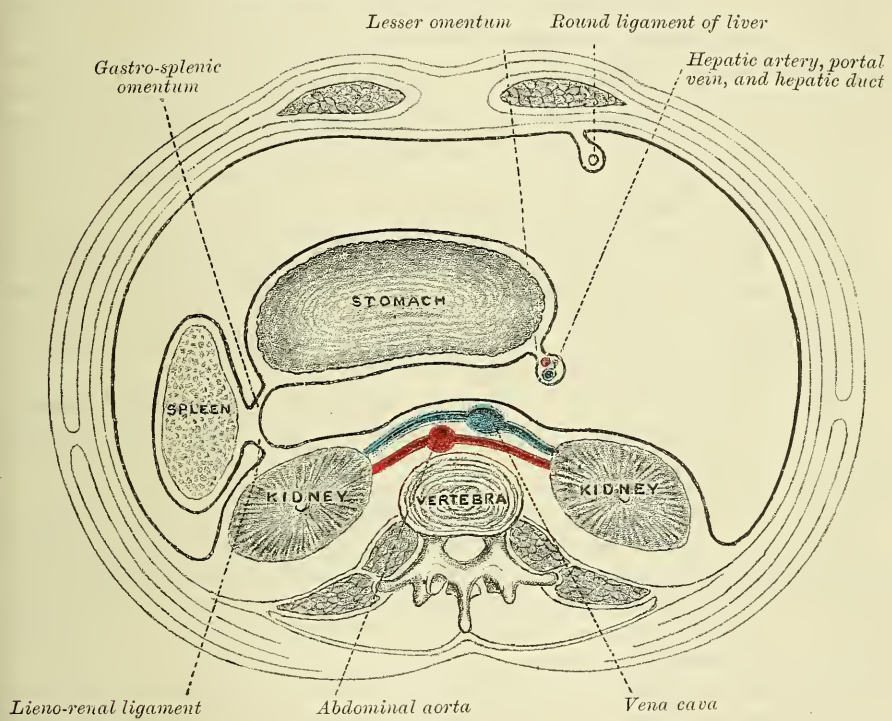
In addition to tracing the peritoneum vertically, as has now been done, it is necessary to trace it horizontally. If this is done below the transverse colon, the circle is extremely simple, as it includes only the greater bag of the peritoneum (fig. 590). Above the level of the transverse colon the arrangement is more complicated, on account of the existence of two sacs.

Starting from the linea alba, below the level of the transverse colon, and tracing the continuity in a horizontal direction to the right, we find the peritoneum covering the internal surface of the abdominal wall almost as far as the anterior border of the Quadratus lumborum muscle; it encloses the cæcum, forming the meso-cæcum, and is reflected over the sides and anterior surface of the ascending colon, fixing it to the abdominal wall, thus forming the ascending meso-colon, from which it can be traced over the kidney to the front of the bodies of the vertebræ. It then passes along the mesenteric vessels to invest the small

intestines, and back again to the spine, forming the mesentery, between the layers of which are contained the blood-vessels, nerves, lacteals, and glands. Lastly, it passes over the left kidney to the sides and anterior surface of the descending colon, and, reaching the abdominal wall, it passes along it to the middle line of the abdomen.

Above the transverse colon (fig. 592) the peritoneum can be traced, forming the greater and lesser cavities, and their communication through the foramen of Winslow can be demonstrated. Commencing in the middle line of the abdomen, the membrane may be traced lining its anterior wall, and on the right side sending a process backwards to encircle the obliterated umbilical vein (the round ligament of the liver), forming the falciform or longitudinal ligament of the liver. Continuing its course to the right, it is reflected over the front of the upper part of the right kidney, across the vena cava inferior and aorta, and over the left kidney

Fig. 592.—Transverse section of peritoneum.



to the hilum of the spleen, forming the anterior layer of the *lieno-renal ligament*: the posterior layer being formed by the termination of the *cul-de-sac* of the greater cavity between the kidney and spleen (fig. 592). From the hilum of the spleen it is reflected on to the posterior surface of the stomach; at the point where it is reflected it comes in contact with the *cul-de-sac* of the greater cavity between the spleen and stomach, and forms the *gastro-splenic omentum*. It covers the posterior surface of the stomach, and from its right extremity it passes around the vessels to the transverse fissure of the liver, and back again to the stomach, as the lesser omentum, and thus it forms the anterior boundary of the foramen of Winslow. It now covers the front of the stomach, and upon reaching the cardiac extremity it passes to the spleen, which it encloses, forming the gastro-splenic omentum. From the hilum of the spleen it turns backwards to reach the abdominal wall, along which it courses to reach the median line of the abdomen.

The *foramen of Winslow* is bounded, *in front*, by the lesser omentum, enclosing

the vena portæ and the hepatic artery and duct; *behind*, by the inferior vena cava; *above*, by the lobulus Spigelii and lobulus caudatus; *below*, by the hepatic artery curving forwards from the cœliac axis.

The reflections of the peritoneum over the transverse colon are somewhat differently described by some authors (Luschka, Holden), and there is no doubt, as was long ago pointed out by Haller, that the arrangement in the fœtus is different from that which has been described above. In the fœtus, and even in the young child, the two ascending layers of the great omentum can be traced passing together *over* the transverse colon, instead of embracing it, as described above, and passing back to the spine as a double fold, which can be separated from the transverse colon and transverse meso-colon. Upon reaching the spine the two layers separate: the upper one (the inner of the two ascending layers of the great omentum) passes upwards in front of the pancreas and crura of the Diaphragm, forming the posterior boundary of the lesser bag of the peritoneum, in a similar manner to the upper layer of the transverse meso-colon in the former description. The other fold (the outer of the ascending layer of the great omentum), after reaching the spine, is turned forwards again on itself as far as the transverse colon, which it covers, and is again reflected back to the spine, to pass down in front of the aorta to form the mesentery, in a similar manner to the lower layer of the transverse meso-colon in the former description. Thus the transverse colon is invested by a distinct fold of peritoneum, prolonged forwards from the spine to surround it, in a very similar manner to the way in which the small intestines are surrounded.

In the adult, however, as a rule, this arrangement disappears. Probably adhesion of the layers of which the fœtal duplication is composed takes place, and then absorption, and thus the arrangement is brought about which has been described above as most frequently seen in the adult subject. It may be that the fœtal duplicature is 'drawn or pushed forwards from its place in the progress of visceral development, and thus effaced.' *

Viscera covered by peritoneum.—The viscera thus shown to be almost entirely invested by peritoneum are, the liver, stomach, spleen, first portion of the duodenum, the jejunum and ileum, the transverse colon, the cæcum, sigmoid flexure, upper half of the rectum, the uterus, and ovaries.

Viscera partially covered by peritoneum.—The viscera only partially invested by peritoneum are, the descending and transverse portions of the duodenum, the ascending and descending colon, the middle portion of the rectum, and the upper part of the vagina and posterior wall of the bladder. The kidneys, suprarenal capsules, and pancreas are covered by the membrane without receiving any special investment from it.

Viscera uncovered by peritoneum.—The lower end of the rectum, the neck base, and anterior surface of the bladder, the whole of the front, and the lower part of the posterior wall of the vagina, have no peritoneal covering.

Numerous folds are formed by the peritoneum, extending between the various organs. These serve to hold them in position, and, at the same time, enclose the vessels and nerves proceeding to each part. Some of these folds are called *ligaments*, from their serving to support the organs in position. Others, which connect certain parts of the intestine with the abdominal wall, constitute the *mesenteries*; and lastly, those which proceed from the stomach to certain viscera in its neighbourhood are called *omenta*.

The **Ligaments**, formed by folds of the peritoneum, include those of the liver, spleen, bladder, and uterus. They will be found described with their respective organs.

The **Omenta** are, the lesser omentum, the great omentum, and the gastro-splenic omentum.

The *lesser omentum* (*gastro-hepatic*) is the duplicature which extends between

* Quain's *Anatomy*, vol. ii. p. 485, 8th ed.

the transverse fissure of the liver and the lesser curvature of the stomach. It is extremely thin, and consists of two layers of peritoneum; that is, the two layers covering the anterior and posterior surfaces of the stomach. When these two layers reach the lesser curvature of the stomach, they join together and ascend as the double fold to the transverse fissure of the liver; to the left of this fissure the double fold is attached to the fissure of the ductus venosus as far as the Diaphragm, on which it extends to the œsophagus. The two layers here separate to embrace the end of the œsophagus. At the right border the lesser omentum is free, and the two layers of which it is composed are continuous. The anterior layer, which belongs to the greater sac, turns round the hepatic vessels to become continuous with the posterior layer belonging to the lesser one. They here form a free, rounded margin, which contains between its layers the hepatic artery, the common bile-duct, the portal vein, lymphatics, and the hepatic plexus of nerves—all these structures being enclosed in loose areolar tissue, called *Glisson's capsule*. Between the layers where they are attached to the stomach lie the gastric artery and the pyloric branch of the hepatic, anastomosing with it.

The *great omentum* (*gastro-colic*) is the largest peritoneal fold. It consists of four layers of peritoneum, two of which descend from the stomach, one from its anterior, the other from its posterior surface, and, uniting at its lower border, descend in front of the small intestines, as low down as the pelvis; they then turn upon themselves, and ascend again as far as the transverse colon, where they separate and enclose that part of the intestine. These separate layers may be easily demonstrated in the young subject, but in the adult they are more or less inseparably blended. The left border of the great omentum is continuous with the gastro-splenic omentum; its right border extends as far only as the duodenum. The great omentum is usually thin, presents a cribriform appearance, and always contains some adipose tissue, which in fat subjects accumulates in considerable quantity. Its use appears to be to protect the intestines from the cold, and to facilitate their movement upon each other during their vermicular action. Between its two anterior layers is the anastomosis between the right and left gastro-epiploica arteries.

The *gastro-splenic omentum* is the fold which connects the concave surface of the spleen to the *cul-de-sac* of the stomach, being continuous by its lower border with the great omentum. It contains vasa brevia vessels.

The **Mesenteries** are, the mesentery proper, the meso-cæcum, the ascending, transverse, and descending meso-colon, the sigmoid meso-colon, and the meso-rectum.

The *mesentery* (μέσον, ἔντερον), so called from being connected to the middle of the cylinder of the small intestine, is the broad fold of peritoneum which connects the convolutions of the jejunum and ileum with the posterior wall of the abdomen. Its *root*, the part connected with the vertebral column, is narrow, about six inches in length, and directed obliquely from the left side of the second lumbar vertebra to the right sacro-iliac symphysis (fig. 593). Its intestinal border is much longer; and here its two layers separate, so as to enclose the intestine, and form its peritoneal coat. Its breadth, between its vertebral and intestinal border, is about four inches. Its *upper border* is continuous with the under surface of the transverse meso-colon: its *lower border*, with the peritoneum covering the cæcum and ascending colon. It serves to retain the small intestines in their position, and contains between its layers the mesenteric vessels and nerves, the lacteal vessels, and mesenteric glands.

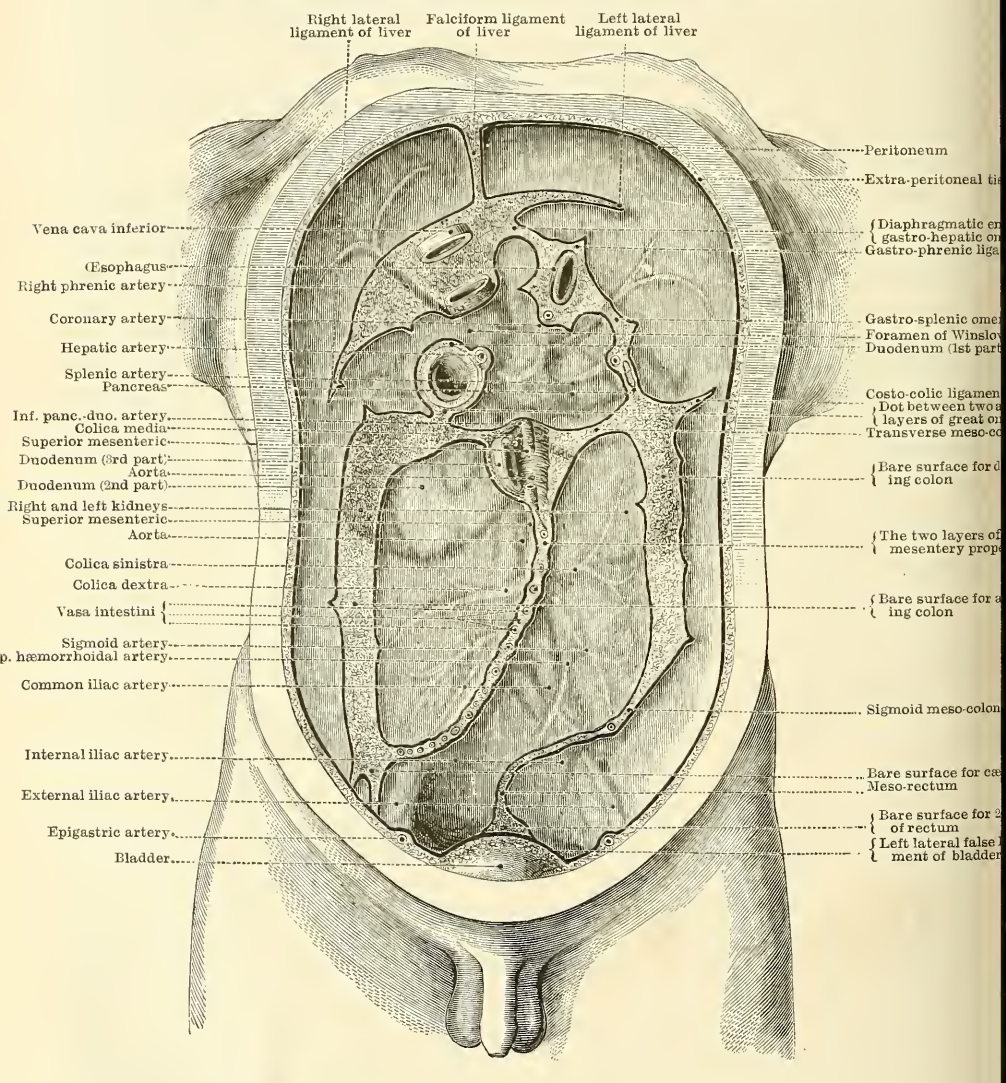
The *meso-cæcum* serves to connect the back part of the cæcum with the posterior wall of the abdomen, being continuous with the ascending meso-colon.

The *ascending meso-colon* is the fold which connects the back part of the ascending colon with the posterior wall of the abdomen; and the *descending meso-colon* retains the descending colon in connection with the posterior abdominal wall; more frequently the peritoneum merely covers the anterior surface and

sides of these two portions of the intestine. At the place where the transverse colon turns downwards to form the descending colon, a fold of peritoneum is continued upwards to the under surface of the Diaphragm opposite the tenth and eleventh ribs. This is the *phreno-colic ligament*; it passes below the spleen, and serves to support this organ and prevent it moving.

The *transverse meso-colon* is a broad fold, which connects the transverse colon to the posterior wall of the abdomen. It is formed by the two ascending layers of the great omentum, which, after separating to surround the transverse colon,

FIG. 593.—Diagram devised by Dr. Delépine to show the lines along which the peritoneum leaves the wall of the abdomen to invest the viscera.



join behind it, and are continued backwards to the spine, where they diverge in front of the duodenum. This fold contains between its layers the vessels which supply the transverse colon.

The *sigmoid meso-colon* is the fold of peritoneum which retains the sigmoid flexure in connection with the left iliac fossa.

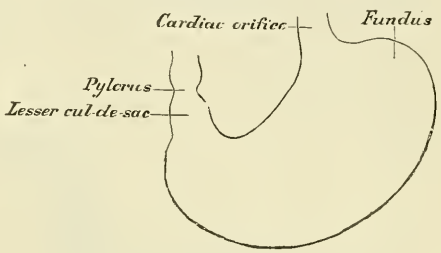
The *meso-rectum* is the narrow fold which connects the upper part of the rectum with the front of the sacrum. It contains the superior hæmorrhoidal vessels.

The *appendices epiploicæ* are small pouches of the peritoneum filled with fat, and situated along the colon and upper part of the rectum. They are chiefly appended to the transverse colon.

The Stomach

The **Stomach** is the principal organ of digestion. It is the most dilated part of the alimentary canal. Its form is somewhat pyriform, curved upon itself, and presenting a rounded base, turned to the left side. It is placed, in part, immediately behind the anterior wall of the abdomen, and, in part, beneath the liver and Diaphragm and above the transverse colon. It is placed almost vertically in the abdomen, with a slight obliquity from left to right, so that the fundus which projects upwards and to the left of the œsophageal opening touches the Diaphragm, while the pyloric or lesser extremity is directed downwards and to the right, so that the opening by which the stomach communicates with the small intestine is situated slightly to the right of the median line of the body (fig. 594): the stomach is situated, therefore, for the most part, in the left hypochondriac region; the pyloric extremity occupying, however, the epigastric region. Its size varies considerably in different subjects, and also according to its state of distension. When moderately full its vertical diameter is about twelve inches, its transverse diameter about four. Its weight, according to Clendenning, is about four ounces and a half. It presents for examination two extremities, two orifices, two borders, and two surfaces.

Fig. 594.—Diagrammatic outline of the stomach.



Its *upper extremity* is called the *greater* or *splenic end*. This is the largest part of the stomach, and extends two or three inches to the left of the point of entrance of the œsophagus. This expanded part is called the great *cul-de-sac* or *fundus*. It lies behind the lower ribs, in contact with the Diaphragm, and is connected posteriorly to the spleen by the gastro-splenic omentum.

The *lesser* or *pyloric end* is much smaller than the fundus, and situated on a plane anterior and inferior to it. It lies in contact with the wall of the abdomen, and the under surface of the liver. Its position on the surface of the body varies with the degree of distension of the organ. Near the pyloric end there is a double bend in the stomach, attended by an appearance of constriction. The distal bend corresponds to the situation of the pyloric valve, and between the two there is a bulging which is named the *lesser cul-de-sac* or *antrum pylori*.

The *œsophageal* or *cardiac orifice* communicates with the œsophagus, and is the most fixed part of the stomach. It is situated on a level with the spine of the ninth dorsal vertebra; in front and to the left of the aorta.

The *pyloric orifice* communicates with the duodenum, the aperture being guarded by a valve, the pylorus. This valve is formed by a thickening of the circular muscular fibres of the stomach in this situation; they form a thick ring, which can be felt from the outside. The mucous membrane is also thickened where it is pushed in by the ring of muscular tissue. The position of the pylorus varies with the movements of the stomach.

The *lesser curvature* extends between the œsophageal and pyloric orifices, along the right border of the organ, and is connected to the under surface of the liver by the lesser omentum.

The *greater curvature* extends between the same two points, along the left border, and gives attachment to the great omentum. The surfaces of the organ are limited by these two curvatures.

The *anterior surface* is directed upwards and forwards, and is in relation

with the Diaphragm, the under surface of the left lobe of the liver, and with the abdominal parietes when distended.

The *posterior surface* is directed downwards and backwards, and is in relation with the Diaphragm, the spleen, the pancreas, the left kidney and suprarenal capsule, and the transverse meso-colon, which separates it from the termination of the duodenum and commencement of the rest of the small intestine.

The stomach is held in position by the lesser omentum, which extends from the transverse fissure of the liver to its lesser curvature, and by a fold of peritoneum, which passes from the Diaphragm on to the œsophageal end of the stomach, the *gastro-phrenic ligament*: this constitutes the most fixed point of the stomach, whilst the pyloric end and greater curvature are the most movable parts. To its greater curvature is attached the great omentum, by which it is connected to the transverse colon.

Alterations in Position.—There is no organ in the body the position and connections of which present such frequent alterations as the stomach. *When empty*, it lies at the back part of the abdomen, some distance from the surface. Its pyloric end is situated close to or very slightly to the right of the middle line, covered in front by the left lobe of the liver, and being on a level with the first lumbar vertebra. The direction of the long axis of the stomach, whilst in this condition, is a disputed point, some anatomists asserting that it is vertical, but the majority of authorities are agreed in maintaining that there is always a certain, though varying, obliquity from left to right. When empty, the stomach assumes a more or less cylindrical form, especially noticeable at its pyloric end. *When the stomach is distended*, its surfaces, which are flattened when the organ is empty, become convex. The greater curvature is elevated and carried forwards, so that the anterior surface is turned more or less upwards and the posterior surface downwards, and the stomach brought well against the anterior wall of the abdomen. Its fundus expands and rises considerably above the level of the cardiac orifice, in doing this the Diaphragm is forced upwards, contracting the cavity of the chest; hence the dyspnœa complained of, from inspiration being impeded. The apex of the heart is also tilted upwards; hence the oppression in this region and the palpitation experienced in extreme distension of the stomach. The left lobe of the liver is pushed to the right side. When the stomach becomes distended the change in the position of the pylorus is very considerable; it is shifted to the right, some two or three inches from the median line, and lies under cover of the liver, near the neck of the gall-bladder. In consequence of the distension of the stomach the lesser *cul-de-sac* bulges over the pylorus, concealing it from view, and causing it to undergo a rotation, so that its orifice is directed backwards. *During inspiration* the stomach is displaced downwards by the descent of the Diaphragm, and elevated by the pressure of the abdominal muscles during expiration. *Pressure from without*, as from tight lacing, pushes the stomach down towards the pelvis. In disease, also, the position and connection of the organ may be greatly changed, from the accumulation of fluid in the chest or abdomen, or from alteration in size of any of the surrounding viscera. *Variations according to age.*—In an early period of development the stomach is vertical, and in the new-born child it is more vertical than later on in life, as owing to the large size of the liver it is more pushed over to the left side of the abdomen, and the whole of the anterior surface is covered by the left lobe of this organ.

On looking into the pyloric end of the stomach, the mucous membrane is found projecting inwards in the form of a circular fold, the *pylorus*, leaving a narrow circular aperture, about half an inch in diameter, by which the stomach communicates with the duodenum.

The *pylorus* is formed by a reduplication of the mucous membrane of the stomach, containing numerous muscular fibres, which are aggregated into a thick circular ring; the longitudinal fibres and serous membrane being continued over the fold without assisting in its formation. The aperture is occasionally oval. Sometimes the circular fold is replaced by two crescentic folds, placed one above and the other below the pyloric orifice: and more rarely there is only one crescentic fold.

Structure.—The stomach consists of four coats: serous, muscular, areolar, and mucous, together with vessels and nerves.

The *serous coat* is derived from the peritoneum, and covers the entire surface of the organ, excepting along the greater and lesser curvatures, at the points of attachment of the greater and lesser omenta; here the two layers of peritoneum leave a small triangular space, along which the nutrient vessels and nerves

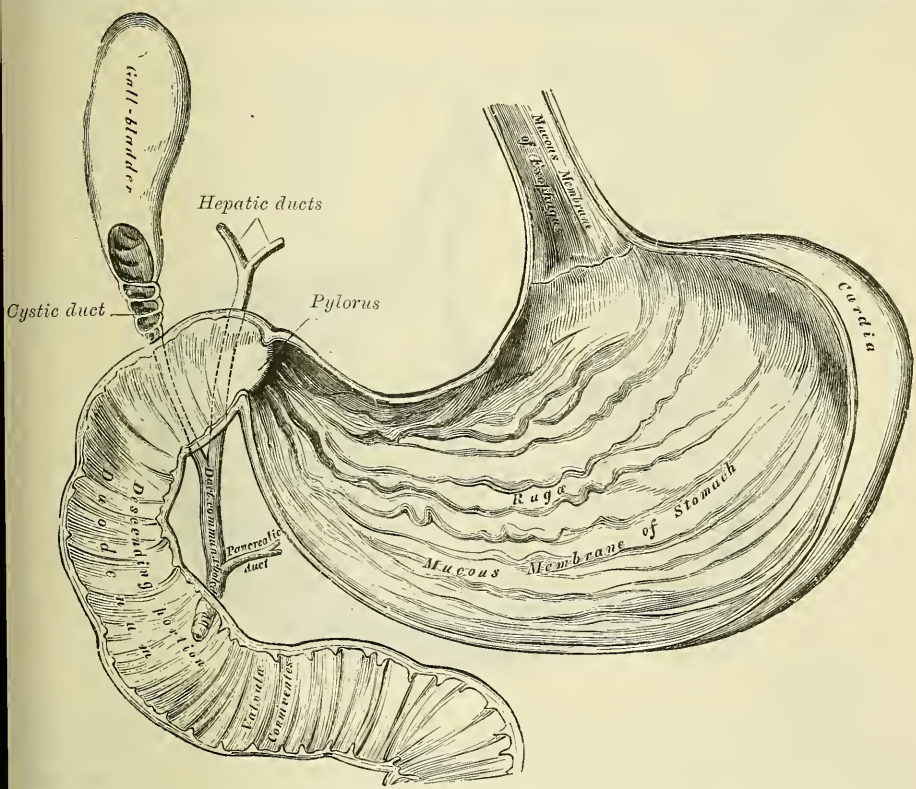
pass. On the posterior surface of the stomach, close to the cardiac orifice there is also a small area uncovered by peritoneum, where the organ is in contact with the under surfaces of the Diaphragm.

The *muscular coat* (fig. 596) is situated immediately beneath the serous covering. It consists of three sets of fibres—longitudinal, circular, and oblique.

The *longitudinal fibres* are most superficial; they are continuous with the longitudinal fibres of the œsophagus, radiating in a stellate manner from the cardiac orifice. They are most distinct along the curvatures, especially the lesser, but are very thinly distributed over the surfaces. At the pyloric end they are more thickly distributed, and continuous with the longitudinal fibres of the small intestine.

The *circular fibres* form a uniform layer over the whole extent of the stomach beneath the longitudinal fibres. At the pylorus they are most

Fig. 595.—The mucous membrane of the stomach and duodenum with the bile ducts.



abundant, and are aggregated into a circular ring, which projects into the cavity, and forms, with the fold of mucous membrane covering its surface, the *pyloric valve*.

The *oblique fibres* are limited chiefly to the cardiac end of the stomach, where they are disposed as a thick uniform layer, covering both surfaces, some passing obliquely from left to right, others from right to left, round the cardiac end. They are continuous with the circular fibres of the œsophagus.

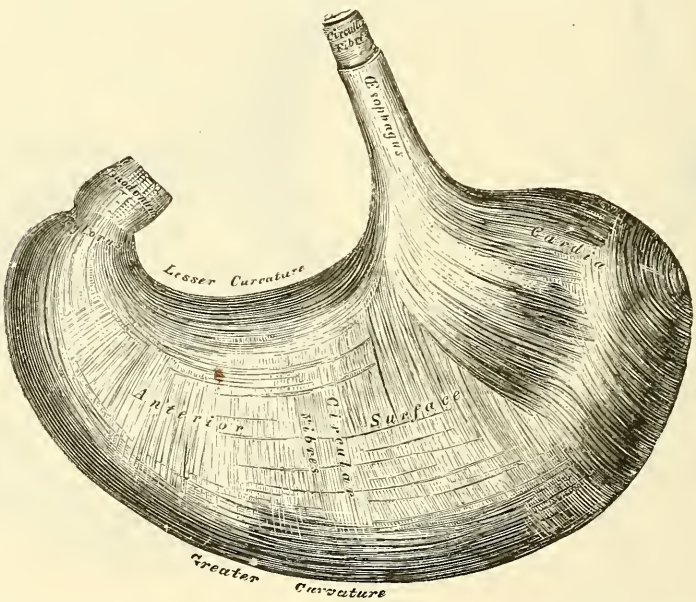
The *areolar* or *submucous coat* consists of a loose, filamentous, areolar tissue, connecting the mucous and muscular layers. It supports the blood-vessels previous to their distribution to the mucous membrane: hence it is sometimes called the *vascular coat*.

The *mucous membrane* is thick; its surface smooth, soft, and velvety. In the fresh state it is of a pinkish tinge at the pyloric end, and of a red or reddish-

brown colour over the rest of its surface. In infancy it is of a brighter hue, the vascular redness being more marked. It is thin at the cardiac extremity, but thicker towards the pylorus. During the contracted state of the organ it is thrown into numerous plaits or rugæ, which, for the most part, have a longitudinal direction, and are most marked towards the lesser end of the stomach, and along the greater curvature (fig. 595). These folds are entirely obliterated when the organ becomes distended.

Structure of the Mucous Membrane.—When examined with a lens, the inner surface of the mucous membrane presents a peculiar honeycomb appearance from being covered with small shallow depressions or alveoli, of a polygonal or hexagonal form, which vary from $\frac{1}{100}$ to $\frac{1}{200}$ of an inch in diameter, and are separated by slightly elevated ridges. In the bottom of the alveoli are seen the orifices of minute tubes, the *gastric follicles*, which are situated perpendicularly side by side throughout the entire substance of the mucous membrane. The epithelium which covers the surface of the mucous membrane of the stomach is a single layer of columnar epithelium, it lines the alveoli and also for

Fig. 596.—The muscular coat of the stomach.



a certain distance the mouths of the gastric follicles. This epithelium commences very abruptly at the cardiac orifice, where the cells suddenly change in character from the stratified epithelium of the œsophagus. The cells are elongated and consist of two parts, the inner or attached portions being granular, and the outer or free parts being clear and occupied by a muco-albuminous substance.

The gastric follicles are of two kinds, which differ from each other in structure, and it is believed also in the nature of their secretion. They are named respectively *pyloric* and *cardiac oxyntic glands*. They are both tubular in character, and are formed of a delicate basement membrane, supporting epithelium. The basement membrane consists of flattened transparent endothelial cells, with processes which extend and support the epithelium. The *pyloric glands* (fig. 597) are most numerous at the pyloric end of the stomach, and from this fact have received their name. They were formerly termed mucous glands, and were supposed to secrete mucus; but, as Klein points out, 'the cells are serous, not mucous, and the secretion of the glands cannot therefore be mucus.' They consist of two or three short, closed tubes opening into a common duct, the external orifice of which is situated at the bottom of an alveolus. The cæcal

tubes are wavy, and are of about equal length with the duct. The tubes and duct are lined throughout with epithelium, the duct being lined by columnar cells, continuous with the epithelium lining the surface of the mucous membrane of the stomach, the tubes with shorter and more cubical cells which are finely granular. The *cardiac glands* (fig. 598) are found all over the surface of the stomach, but occur most numerously at the cardiac end. Like the pyloric glands they consist of a duct, into which open two or more cæcal tubes. The duct, however, in these glands is shorter than in the other variety, sometimes not amounting to more than one-sixth of the whole length of the gland; it is lined throughout by columnar epithelium. At the point where the terminal tubes open into the duct, and which is termed the neck, the epithelium alters, the cells becoming much shorter, polyhedral and granular, and almost fill the tubercle, so that the lumen becomes suddenly constricted, and is continued down as a very fine channel. They are known as the *chief* cells or *central* cells of the glands.

Fig. 597.—Pyloric gland.

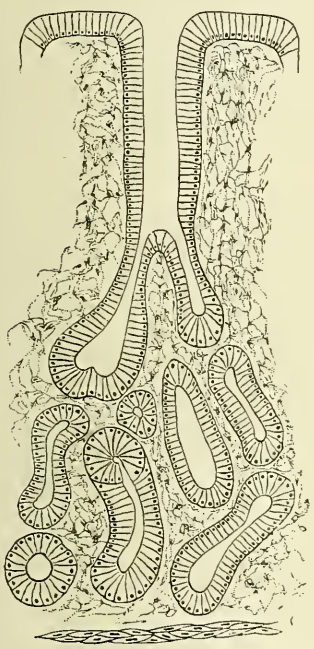


Fig. 598.—Cardiac gland.

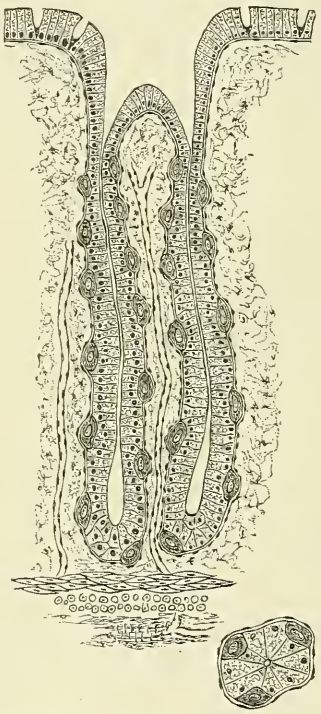

Between these cells and the basement membrane are found other darker granular-looking cells, studded throughout the tube at intervals, and giving it a beaded or varicose appearance. These are known as the *parietal* or *oxyntic* cells. Between the glands the mucous membrane consists of a connective-tissue framework, with lymphoid tissue. In places, this latter tissue, especially in early life, is collected into little masses, which to a certain extent resemble the solitary glands of the intestine, and are by some termed the *lenticular* glands of the stomach. They are not, however, so distinctly circumscribed as the solitary glands. Beneath the mucous membrane, and between it and the submucous coat, is a thin stratum of involuntary muscular fibre (*muscularis mucosæ*), which in some parts consists only of a single longitudinal layer; in others of two layers, an inner, circular, and an outer, longitudinal.

Vessels and Nerves.—The arteries supplying the stomach are: the gastric, the pyloric and right gastro-epiploic branches of the hepatic, the left gastro-epiploic and vasa brevia from the splenic. They supply the muscular coat, ramify in the

submucous coat, and are finally distributed to the mucous membrane. The arrangement of the vessels in the mucous membrane is somewhat peculiar. The arteries break up at the base of the gastric tubules into a plexus of fine capillaries which run upwards between the tubules, anastomosing with each other, and ending in a plexus of larger capillaries, which surround the mouths of the tubes, and also form hexagonal meshes around the alveoli. From these latter the *veins* arise, and pursue a straight course backwards, between the tubules, to the submucous tissue, and terminate either in the splenic and superior mesenteric veins, or directly in the portal vein. The *lymphatics* are numerous; they consist of a superficial and deep set, which pass through the lymphatic glands found along the two curvatures of the organ. The *nerves* are the terminal branches of the right and left pneumogastric, the former being distributed upon the back, and the latter upon the front part of the organ. A great number of branches from the sympathetic also supply the organ.

Surface Form.—The stomach lies for the most part in the left hypochondriac region, but also slightly in the epigastric region, and is partly in contact with the abdominal wall, partly under cover of the lower ribs on the left side, and partly under the left lobe of the liver. Its cardiac orifice is behind the seventh costal cartilage of the left side, about one inch from its junction with the sternum, on a level with the tenth dorsal vertebra. The pyloric orifice is in a vertical line drawn from the right border of the sternum, two and a half or three inches below the level of the sterno-xiphoid articulation. According to Braune, when the stomach is distended, the pylorus moves considerably to the right, as much sometimes as three inches. The lesser curvature of the stomach is represented by a curved line with its convexity downwards from the cardiac to the pyloric extremities; the greater curvature by a similarly curved line between the same points, but with a curve of much greater extent, so that its lowest point reaches a horizontal line drawn between the tips of the tenth costal cartilages. The fundus of the stomach reaches, on the left side, as high as the level of the sixth chondro-sternal articulation, being a little below and behind the apex of the heart. The portion of the stomach which is in contact with the abdominal walls, and is therefore accessible for opening in the operations of gastrotomy and gastrostomy, is represented by a triangular space, the base of which is formed by a line drawn from the tip of the tenth costal cartilage on the left side to the tip of the ninth costal cartilage on the right, and the sides by two lines drawn from the extremity of the eighth costal cartilage on the left side to the ends of the base line.

Surgical Anatomy.—Operations on the stomach are frequently performed. By 'gastrotomy' is meant an incision into the stomach for the removal of a foreign body, the opening being immediately afterwards closed—in contradistinction to 'gastrostomy,' the making of a more or less permanent fistulous opening. *Gastrotomy* is probably best performed by an incision in the linea alba, especially if the foreign body is large, by a cut from the ensiform cartilage to the umbilicus; but may be performed by an incision over the body itself, where this can be felt, or by one of the incisions for gastrostomy, to be mentioned immediately. The peritoneal cavity is opened, and the point at which the stomach is to be incised decided upon. This portion is then brought out of the abdominal wound and sponges carefully packed around. The stomach is now opened by a transverse incision and the foreign body extracted. The wound in the stomach is then closed by Lembert's sutures, i.e. by sutures passed through the peritoneal and muscular coats in such a way that the peritoneal surfaces on each side of the wound are brought into apposition, and in this way the wound is closed. *Gastrostomy* is performed in two stages. The first stage consists in opening the peritoneal cavity and stitching the stomach to the abdominal wall. The second stage consists in opening the stomach, after a few days have elapsed, and adhesions formed between the peritoneal surfaces of the stomach and abdominal wall. The operation is usually performed by an oblique incision, about one finger's breadth below and parallel with the margin of the left costal cartilages, commencing an inch and a half from the median line and being about three inches in length. Some surgeons prefer a straight incision, beginning opposite to the end of the eighth intercostal space, and passing down for three inches over the Rectus abdominis muscle. The skin, fasciæ, and muscles are to be severally divided down to the peritoneum. Howse recommends that the sheath of the Rectus should be opened longitudinally and the fibres of this muscle separated, and not cut, in the same direction, so as to secure a sphincter-like action around the opening. After the peritoneum has been opened, the stomach is recognised by its pink red colour and smooth surface. It is to be pulled up into the wound and sutured to the opening. This may be done in several ways, but in whatever way it is done the following points should be carefully attended to. (1) In taking up the stomach, only to pass the needle through the serous and muscular coats, and avoid puncturing the mucous membrane. (2) To take up plenty of the muscular coat. (3) In passing the needle through the parietes of the abdomen, to be careful to include the parietal peritoneum. (4) To enclose a circle of the stomach at least an inch in

diameter. If the symptoms admit of it, the parts are now to be left quiet for four or five days, and a small puncture is then to be made through the exposed portion of the stomach, and a gum elastic catheter passed through it into the viscus, through which fluid can be injected, in small quantities at first. In more urgent cases it may be necessary to make the opening much earlier.

In cases of perforation of gastric ulcer an attempt has been made, in many cases, to close the perforation, and when this has been done before acute peritonitis has actually been established, a very large measure of success has during the last two or three years been obtained. The operation consists in opening the abdomen, and having found the perforation, which is usually on the anterior surface of the stomach, closing it by Lembert's sutures, so that a considerable portion of the peritoneum around the perforation is brought together.

Excision of the pylorus has occasionally been performed, but the results of this operation are by no means favourable, and, in cases of cancer of the pylorus, gastro-enterostomy is generally preferred. The object of this operation is to make a fistulous communication between the stomach, on the cardiac side of the disease, and the small intestine, as high up as is possible.

Digital dilatation of the pylorus for simple stricture was first performed by Loreta. He exposed the stomach and opened it by a transverse incision near the pylorus. He then inserted the forefingers of both hands and passed these through the pylorus and stretched it with some degree of force. The operation has now, however, dropped out of use and been replaced by pyloro-plasty. This operation consists in making a longitudinal incision from the stomach through the pylorus into the duodenum, and converting this longitudinal incision into a transverse one by traction at the centre of the incision, and retaining it permanently in this position by sutures. W. H. Bennett has recently treated dilatation of the stomach by exposing it and making a fold by turning in a portion of the anterior wall and sewing the edges of the fold together.

The Small Intestine

The small intestine is a convoluted tube, about twenty feet in length,* which gradually diminishes in size from its commencement to its termination. It is contained in the central and lower parts of the abdominal and pelvic cavities, surrounded above and at the sides by the large intestine; it is in relation, in front, with the great omentum and abdominal parietes; and connected to the spine by a fold of peritoneum, the mesentery. The small intestine is divisible into three portions—the duodenum, the jejunum, and ileum.

The **duodenum** has received its name from being about equal in length to the breadth of twelve fingers (ten inches). It is the shortest, the widest, and the most fixed part of the small intestine; it has no mesentery, and is only partially covered by the peritoneum. Its course presents a remarkable curve, somewhat like a horseshoe in form, when the stomach is distended, but almost a complete circle when the stomach is empty. The convexity of the curve is directed towards the right and the concavity to the left, embracing the head of the pancreas. Commencing at the pylorus, it passes obliquely upwards and backwards to the right, to the under surface of the liver; it then descends in front of the right kidney to the level of the third lumbar vertebra; it now takes a bend to the left, and passes across the front of the vertebral column from right to left, and finally ascends on the left side of the aorta to the level of the upper border of the second lumbar vertebra, and there terminates in the jejunum. Hence the duodenum may be divided for purposes of anatomical description into four portions—superior, descending, transverse, and ascending.

The first, or *superior portion* (fig. 577), about two inches in length, is free, movable, and completely covered by peritoneum near the pylorus, but only covered in front as it approaches the liver. It varies in direction according to the degree of distension of the stomach. When this organ is empty it commences

* Treves states that, in one hundred cases, the average length of the small intestine in the adult male was 22 feet 6 inches, and in the adult female 23 feet 4 inches: but that it varies very much, the extremes in the male being 31 feet 10 inches in one case, and 15 feet 6 inches in another, a difference of over 15 feet. He states that he has convinced himself that the length of the bowel is independent, in the adult, of age, height, and weight.

near the middle line of the body and passes obliquely upwards and backwards to the right to the neck of the gall-bladder, where it takes a sudden turn down-

wards to become the second portion. When the stomach is distended in consequence of the shifting of the position of the pylorus, the first portion of the

* In the subject from which the cast was taken the left kidney was lower than normal.

duodenum becomes shortened, and it is directed almost backwards to its termination in the second portion. It is in relation, above and in front, with the quadrate lobe of the liver and the gall-bladder; behind, with the vessels which run between the layers of the lesser omentum, viz. the hepatic artery and duct and vena porta. This portion of the intestine is usually found, after death, stained with bile, especially on its anterior surface.

The second, or *descending portion*, about three inches in length, is firmly fixed by the peritoneum and pancreas. It passes from the neck of the gall-bladder vertically downwards, in front of the right kidney, as far as the third lumbar vertebra. It is covered by peritoneum only on its anterior surface. It is in relation, in front, with the right arch of the colon and the meso-colon; behind, with the front of the right kidney, to which it is connected by loose areolar tissue, and the renal vessels and vena cava inferior; at its inner side is the head of the pancreas, and the ductus communis choledochus. The common bile-duct and the pancreatic duct perforate the inner side of this portion of the intestine obliquely, a little below its middle.

The third, or *transverse portion*, the longest and narrowest part of the duodenum, beginning on the right side of the third lumbar vertebra, passes across the front of the spine, with a slight inclination upward, to the left side, and ends in the fourth portion just to the left of the abdominal aorta. In front it is covered by peritoneum, which in the middle line is separated from the bowel by the superior mesenteric vessels which cross this portion of the duodenum; behind, it rests upon the aorta, the vena cava inferior, and the crura of the Diaphragm; above it is the lower border of the pancreas, the superior mesenteric vessels passing forwards between the two.

The fourth, or *ascending portion*, is from one to two inches long. It ascends on the left side of the vertebral column as far as the level of the upper border of the second lumbar vertebra, where it turns abruptly forwards to become the jejunum. It is covered entirely in front and partly at the sides by peritoneum; on the left side the peritoneum forms a triangular pouch with its base upwards, the *fossa duodeno-jejunalis*. This pouch is of importance in connection with retro-peritoneal hernia. The fourth portion of the duodenum rests on the left Psoas muscle. It is fixed in position by a band which extends upwards from it, obliquely across the aorta to the connective tissue around the cœliac axis and the left crus of the Diaphragm, and is termed the *musculus suspensorius duodeni*, from possessing, according to Treitz, plain muscular fibres, mixed with the fibrous tissue of which it is principally made up.

Vessels and Nerves.—The *arteries* supplying the duodenum are the pyloric and pancreatico-duodenal branches of the hepatic, and the inferior pancreatico-duodenal branch of the superior mesenteric. The *veins* terminate in the splenic and superior mesenteric. The *nerves* are derived from the solar plexus.

The **jejunum** (*jejunus*, empty), so called from its formerly having been supposed to be empty after death, includes the upper two-fifths of the small intestine below the duodenum. It commences at the duodenum on the left side of the upper border of the second lumbar vertebra, and terminates in the ileum; its convolutions being chiefly confined to the umbilical and left iliac regions. The jejunum is wider, its coats thicker, more vascular, and of a deeper colour than those of the ileum; but there is no characteristic mark to distinguish the termination of the one and the commencement of the other.

The **ileum** (εἱλεῖν, to twist), so called from its numerous coils or convolutions, includes the remaining three-fifths of the small intestine. It occupies chiefly the umbilical, hypogastric, right iliac, and occasionally the pelvic regions, and terminates in the right iliac fossa by opening into the inner side of the commencement of the large intestine. The ileum is narrower, its coats thinner and less vascular than those of the jejunum; a given length of it weighing less than the same length of the jejunum.

Meckel's diverticulum.—Occasionally there may be found connected with the

lower part of the ileum, from one to three feet from its termination, a blind diverticulum or tube, varying in length. It is attached to and communicates with the free margin of the bowel by one extremity, and by the other is unattached or may be connected with the abdominal wall or some other portion of the intestine by a fibrous band. This is Meckel's diverticulum, and represents the remains of the vitelline duct, or duct of communication between the umbilical vesicle and the alimentary canal (see page 82).

Structure.—The wall of the small intestine is composed of four coats—serous, muscular, areolar, and mucous.

The *serous coat* is derived from the peritoneum. The first or ascending portion of the duodenum is almost completely surrounded by that membrane near its pyloric end, but only in front at the other extremity; the second or descending portion is covered by it only in front; and the third or transverse portion lies behind the peritoneum, which passes over it, without being closely incorporated with the other coats of this part of the intestine, and separated from it in the middle line by the superior mesenteric artery. The remaining portion of the small intestine is surrounded by the peritoneum, excepting along its attached or mesenteric border; here a space is left for the vessels and nerves to pass to the gut.

The *muscular coat* consists of two layers of fibres, an external or longitudinal, and an internal or circular layer. The *longitudinal fibres* are thinly scattered over the surface of the intestine, and are more distinct along its free border. The *circular fibres* form a thick, uniform layer; they surround the cylinder of the intestine in the greater part of its circumference, and are composed of plain muscle cells of considerable length. The muscular coat is thicker at the upper than at the lower part of the small intestine.

The *areolar* or *submucous coat* connects together the mucous and muscular layers. It consists of loose, filamentous areolar tissue, which forms a nidus for the subdivision of the nutrient vessels, previous to their distribution to the mucous surface.

The *mucous membrane* is thick and highly vascular at the upper part of the small intestine, but somewhat paler and thinner below. It consists of the following structures: next the areolar or submucous coat is a layer of unstriped muscular fibres, the *muscularis mucosæ*; internal to this is a quantity of retiform tissue, enclosing in its meshes lymph-corpuscles, and in which the blood-vessels and nerves ramify. Lastly, a basement membrane, supporting a single layer of epithelial cells, which throughout the intestines are columnar in character. They are granular in appearance, and possess a clear oval nucleus. At their superficial or unattached end they present a distinct layer of highly refracting material, marked by vertical striæ, which were formerly believed to be minute channels, by which the chyle was taken up into the interior of the cell, and by them transferred to the lacteal vessels of the mucous membrane.

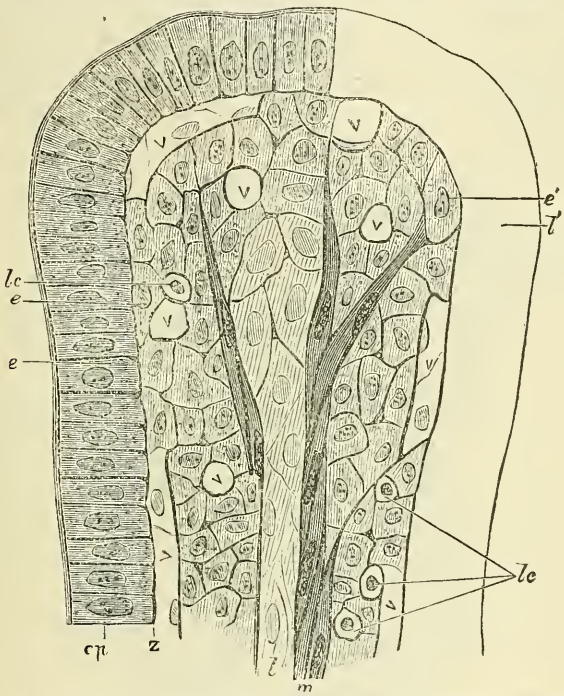
The mucous membrane presents for examination the following structures, contained within it or belonging to it:

Valvulæ conniventes.	Glands	Duodenal glands.
Villi.		Solitary glands.
Simple follicles.		Agminate or Peyer's glands.

The **valvulæ conniventes** (valves of Kerkring) are large folds or valvular flaps projecting into the lumen of the bowel. They are composed of reduplications or folds of the mucous membrane, the two layers of the fold being bound together by submucous tissue: they contain no muscular fibres, and therefore, unlike the folds in the stomach, they are permanent, and are not obliterated when the intestine is distended. They extend transversely across the cylinder of the intestine for about one-half or two-thirds of its circumference. The larger folds are about two inches in length, and one-third of an inch in depth at their broadest

part; but the greater number are of smaller size. The larger and smaller folds alternate with each other. They are not found at the commencement of the duodenum, but begin to appear about one or two inches beyond the pylorus. In the lower part of the descending portion, below the point where the common choledic and pancreatic ducts enter the intestine, they are very large and closely approximated. In the transverse portion of the duodenum and upper half of the jejunum they are large and numerous; and from this point, down to the middle of the ileum, they diminish considerably in size. In the lower part of the ileum they almost entirely disappear; hence the comparative thinness of this portion of the intestine, as compared with the duodenum and jejunum. The valvulæ

FIG. 600.—Diagrammatic section of a villus. (Watney.)



ep. Epithelium only partially shaded in. *l*. Central chyle-vessel; the cells forming the vessel have been less shaded to distinguish them from the cells of the parenchyma of the villus. *m*. Muscle-fibres running up by the side of the chyle-vessel. It will be noticed that each muscle-fibre is surrounded by the reticulum, and by this reticulum the muscles are attached to the cells forming the membrana propria, as at *e'*, or to the reticulum of the villus. *lc*. Lymph-corpuscles, marked by a spherical nucleus and a clear zone of protoplasm. *l'*. Upper limit of the chyle-vessel. *e*, *e*, *e'*. Cells forming the membrana propria. It will be seen that there is hardly any difference between the cells of the parenchyma, the endothelium of the *upper* part of the chyle-vessel, and the cells of the membrana propria. V. Blood-vessels. *z*. Dark line at the base of the epithelium formed by the reticulum. It will be seen that the reticulum penetrates between all the other elements of the villus. The reticulum contains thickenings or 'nodal points.' The diagram shows that the cells of the upper part of the villus are larger and contain a larger zone of protoplasm than those of the lower part. The cells of the upper part of the chyle-vessel differ somewhat from those of the lower part, in that they more nearly resemble the cells of the parenchyma.

conniventes retard the passage of the food along the intestines, and afford a more extensive surface for absorption.

The **villi** are minute, highly vascular processes, projecting from the mucous membrane of the small intestine throughout its whole extent, and giving to its surface a velvety appearance. In shape some are triangular and laminated, others conical or cylindrical, with clubbed or filiform extremities. They are largest and most numerous in the duodenum and jejunum, and become fewer and smaller in the ileum. Krause estimates their number in the upper part of the small intestine at from fifty to ninety in a square line; and in the lower part from forty to seventy; the total number for the whole length of the intestine being about four millions.

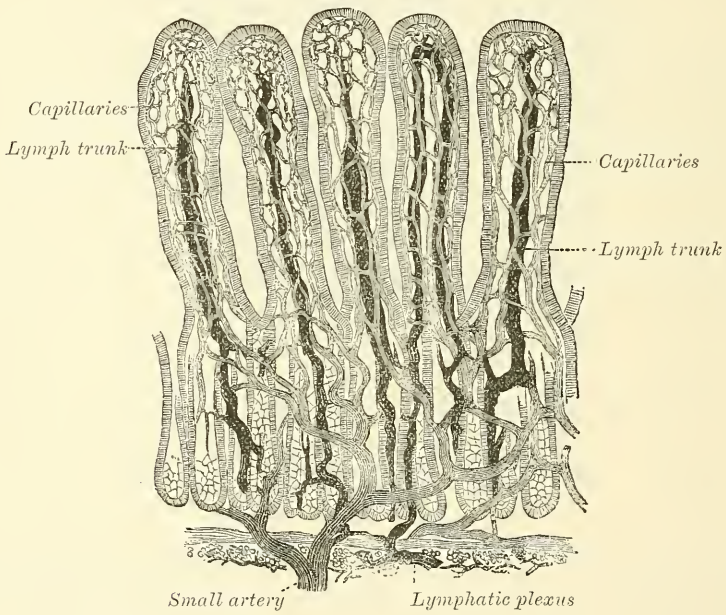
Structure of the villi (fig. 600).—The structure of the villi has been studied recently by many eminent anatomists. We shall here follow the description of

Dr. Watney,* whose researches have a most important bearing on the physiology of the absorption of fat, which is the peculiar function of this part of the intestine.

The essential parts of a villus are, the lacteal vessel, the blood-vessels, the epithelium, the basement membrane and muscular tissue of the mucosa, these structures being supported and held together by retiform lymphoid tissue.

These structures are arranged in the following manner. Situated in the centre of the villus is the lacteal, terminating near the summit in a blind extremity; running along this vessel are unstriped muscular fibres; surrounding it is a plexus of capillary vessels, the whole being enclosed by a basement membrane, supporting columnar epithelium. Those structures which are contained within the basement membrane—namely, the lacteal, the muscular tissue, and the blood-vessels—are surrounded and enclosed by a delicate reticulum which forms the matrix of the villus, and in the meshes of which are found large flattened cells, with an oval nucleus, and, in smaller numbers, lymph-corpuscles. These latter are to be distinguished from the larger cells of the villus by their behaviour

FIG. 601.—Villi of small intestine. (Cadiat.)



with reagents, by their size, and by the shape of their nucleus, which is spherical. Transitional forms, however, of all kinds are met with between the lymph-corpuscle and the proper cells of the villus. Nerve-fibres are contained within the villi: they form ramifications throughout the reticulum.

The *lacteals* are in some cases double, and in some animals multiple. Situated in the axis of the villi, they commence by dilated cæcal extremities near to, but not quite at, the summit of the villus. The walls are composed of a single layer of endothelial cells, the interstitial substance between the cells being continuous with the reticulum of the matrix.

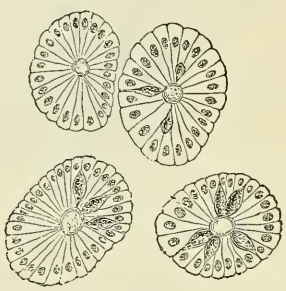
The *muscular fibres* are derived from the muscularis mucosæ, and are arranged in longitudinal bundles around the lacteal vessel, extending from the base to the summit of the villus, and giving off, laterally, individual muscle-cells, which are enclosed by the reticulum, and by it are attached to the basement membrane.

The *blood-vessels* form a plexus between the lacteal and the basement membrane, and are enclosed in the reticular tissue. In the interstices of the capillary plexus, which they form, are contained the cells of the villus.

* *Phil. Trans.* vol. clxvi. pt. ii.

These structures are surrounded by the basement membrane, which is made up of a stratum of endothelial cells, and upon which is placed a layer of columnar epithelium. The reticulum of the matrix is continuous through the basement membrane (that is, through the interstitial substance between the individual endothelial cells) with the interstitial cement-substance of the columnar cells on the surface of the villus. Thus we are enabled to trace a direct continuity between the interior of the lacteal and the surface of the villus by means of the reticular tissue, and it is along this path that, according to Dr. Watney, the chyle passes in the process of absorption by the villi. That is to say, it passes through the interstitial substance between the epithelium cells, through the interstitial substance of the basement membrane, the reticulum of the matrix, and the interstitial substance between the endothelial plates of the lacteal, all which structures have been shown to be continuous with one another, and being probably semi-fluid do not offer any obstacle to the passage of the molecular basis of the chyle.

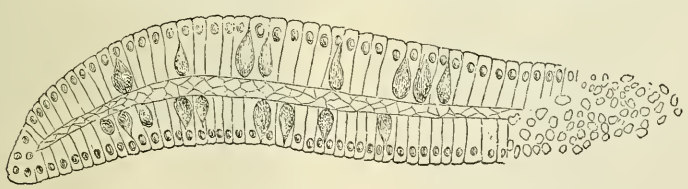
Fig. 602.—Transverse section of crypts of Lieberkühn. (Klein and Noble Smith.)



The **simple follicles**, or *crypts of Lieberkühn* (figs. 602, 603), are found in considerable numbers over every part of the mucous membrane of the small intestine. They consist of minute tubular depressions of the mucous membrane, arranged perpendicularly to the surface, upon which they open by small circular apertures. They may be seen with the aid of a lens, their orifices appearing as minute dots, scattered between the villi. Their walls are thin, consisting of a layer of basement membrane (which is, in fact, an endothelial membrane) lined by columnar epithelium, and covered on their exterior by capillary vessels.

The **duodenal** or **Brunner's glands** are limited to the duodenum and commencement of the jejunum. They are small, flattened, granular bodies, embedded in the submucous areolar tissue, and open upon the surface of the mucous membrane by minute excretory ducts. They are most numerous and largest near the pylorus. They may be compared to the elementary lobules of a salivary gland spread out over a broad surface, instead of being collected in a mass.

Fig. 603.—Longitudinal section of crypts of Lieberkühn. Goblet-cells seen among the columnar epithelial cells. (Klein and Noble Smith.)

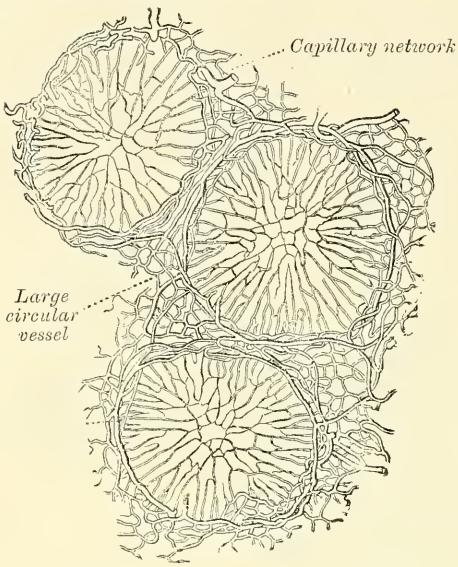


They consist of a number of tubular alveoli, lined by epithelium, and opening by a single duct on the inner surface of the intestine.

The **solitary glands** (*glandulæ solitariæ*) are found scattered throughout the mucous membrane of the small intestine, but are most numerous in the lower part of the ileum. They are small, round, whitish bodies, from half a line to a line in diameter. Their free surface is covered with villi, and each gland is surrounded by the openings of the follicles of Lieberkühn. They are now recognised as lymph-follicles, and consist of a dense interlacing retiform tissue, closely packed with lymph-corpuscles, and permeated with an abundant capillary network (fig. 604). The interspaces of the retiform tissue are continuous with larger lymph-spaces at the base of the gland through which they communicate

with the lacteal system. They are situated partly in the submucous tissue, partly in the mucous membrane, where they form slight projections of its epithelial layer, after having penetrated the muscularis mucosæ. The villi which are situated on them are generally absent from the very summit (or 'cupola,' as Frey calls it) of the gland.

Fig. 604.—Transverse section through the equatorial plane of three of Peyer's follicles from the rabbit.



Peyer's glands (figs. 604 to 607) may be regarded as aggregations of solitary glands, forming circular or oval patches from twenty to thirty in number, and varying in length from half an inch to four inches. They are largest and most numerous in the ileum. In the lower part of the jejunum they are small, of a circular form, and few in number. They are occasionally seen in the duodenum. They are placed lengthwise in the intestine, covering the portion of the tube most distant from the attachment of the mesentery. Each patch is formed of a group of the above-described solitary glands covered with mucous membrane, and in almost every respect are similar in structure to them. They do not, however, as a rule, possess villi on their free surface. Each patch is surrounded by a circle of the crypts of Lieberkühn. They are best marked in the young subject, becoming indistinct in middle age, and sometimes altogether disappearing in advanced life. They are largely supplied with blood-vessels, which form an abundant plexus around each follicle, from which fine branches are given off which permeate the lymphoid tissue in the interior of the follicle. The lacteal plexuses which are

Fig. 605.—Patch of Peyer's glands. From the lower part of the ileum.

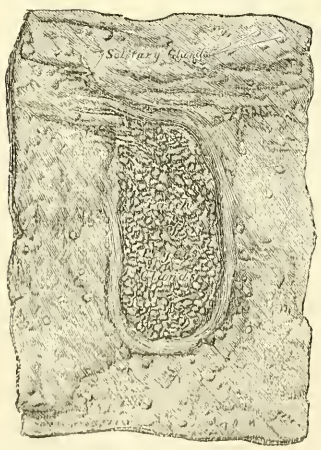


Fig. 606.—A portion of the above magnified.

found throughout the small intestine are especially abundant around these patches; here they form rich plexuses with sinuses around the glands (fig. 607).

Vessels and Nerves.—The jejunum and ileum are supplied by the superior mesenteric artery, the branches of which, having reached the attached border of the bowel, run between the serous and muscular coats, with frequent inoscula-

ions to the free border, where they also anastomose with other branches unning round the opposite surface of the gut. From these vessels numerous

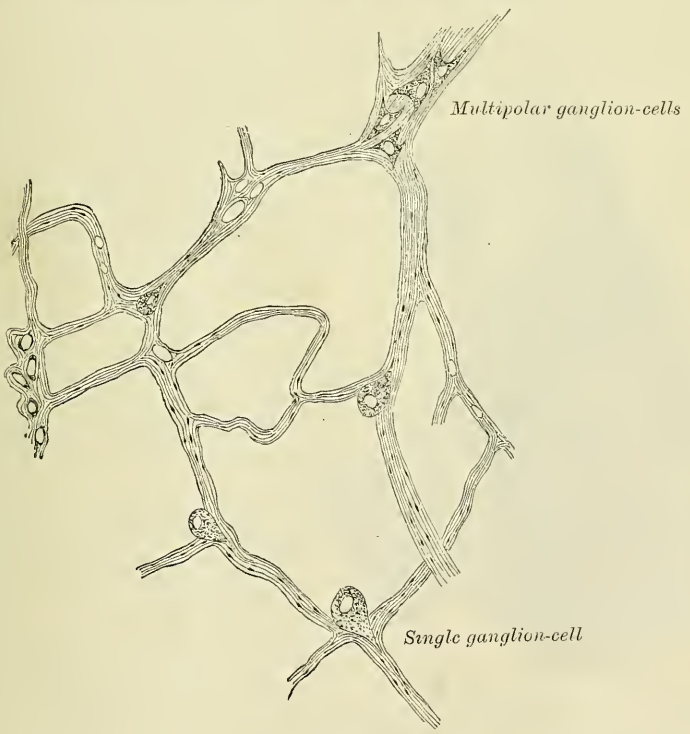
Fig. 608.—Meissner's plexus. (Klein and Noble Smith.)



nches are given off, which pierce the muscular coat, supplying it and forming intricate plexus in the submucous tissue. From this plexus minute vessels ss to the glands and villi of the mucous membrane. The veins have a similar

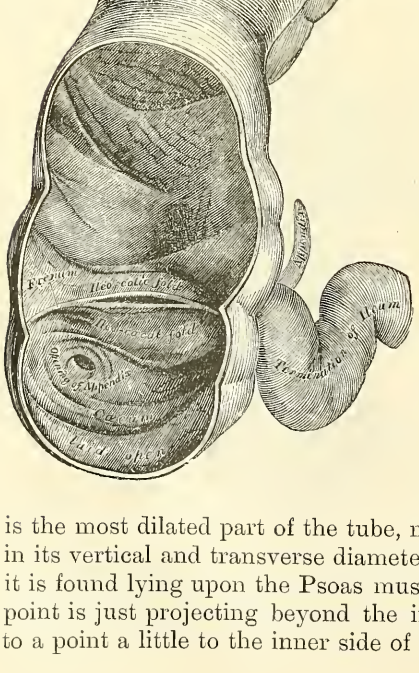
course and arrangement to the arteries. The *lymphatics of the small intestine* (lacteals) are arranged in two sets, those of the villi and those of the muscular coat. The lymphatics of the villi commence in these structures in the manner described above, and form an intricate plexus in the mucous and submucous tissue, being joined by the lymphatics from the lymph-spaces at the bases of the solitary glands, and from this pass to larger vessels at the mesenteric border of the gut. The lymphatics of the muscular coats are situated to a great extent between the two layers of muscular fibres, where they form a close plexus, and throughout their course communicate freely with the lymphatics from the mucous membrane, and empty themselves in the same manner into the commencement of the lacteal vessels at the attached border of the gut.

The *nerves of the small intestines* are derived from the plexuses of sympathetic nerves around the superior mesenteric artery. From this source they run to a plexus of nerves and ganglia situated between the circular and longitudinal muscular fibres (Auerbach's plexus), from which the nervous branches are distributed to the muscular coats of the intestine. From this plexus a secondary plexus is derived (Meissner's plexus), which is formed by branches which have perforated the circular muscular fibres (fig. 608). This plexus lies between the muscular and mucous coats of the intestine. It is also gangliated, and from it the ultimate fibres pass to the muscularis mucosæ and to the villi and mucous membrane.

The Large Intestine

The large intestine extends from the termination of the ileum to the anus. It is about five feet in length, being one-fifth of the whole extent of the intestinal canal. It is largest at its commencement at the cæcum, and gradually diminishes as far as the rectum, where there is a dilatation of considerable size just above the anus. It differs from the small intestine in its greater size, its more fixed position, and its sacculated form. The large intestine, in its course, describes an arch, which surrounds the convolutions of the small intestine. It commences in the right inguinal region, in a dilated part, the *cæcum*. It ascends through the right lumbar and hypochondriac regions to the under surface of the liver; passes transversely across the abdomen on the confines of the epigastric and umbilical regions, to the left hypochondriac region; descends through the left lumbar region to the left iliac fossa, where it becomes convoluted, and forms the sigmoid flexure; finally it enters the pelvis, and descends along its posterior wall to the anus. The large intestine is divided into the cæcum, colon, and rectum.

Fig. 609.—The cæcum and colon laid open to show the ileo-cæcal valve.



The **cæcum** (cæcus, *blind*) is the large blind pouch, or *cul-de-sac*, in which the large intestine commences (fig. 609). It is the most dilated part of the tube, measuring about two and a half inches, both in its vertical and transverse diameters. Its position varies somewhat; usually it is found lying upon the Psoas muscle, and so placed that its apex or lowest point is just projecting beyond the inner border of that muscle, corresponding to a point a little to the inner side of the middle of Poupart's ligament. Some-

times, however, it is situated external to this, in the right iliac fossa, in relation with the Iliacus muscle; and at other times it lies internal to both Psoas and Iliacus, either resting on the pelvic brim, or altogether contained within the pelvis. It is entirely enveloped on all sides by peritoneum, which, after enclosing it, is reflected on to the posterior wall of the abdomen, being continuous with the ascending meso-colon, when this fold exists. The cæcum, therefore, lies quite free in the abdominal cavity, and enjoys a considerable amount of movement. On its inner side it is joined by the ileum, while attached to its lower and back part is the appendix vermiformis.

The **appendix vermiformis** is a long, narrow, worm-shaped tube, the rudiment of the lengthened cæcum found in nearly all the mammalia. The appendix varies from three to six inches in length, its average diameter being about equal to that of a goose-quill. It is usually directed upwards and inwards behind the cæcum, coiled upon itself, and terminates in a blunt point; being retained in its position by a fold of peritoneum, which sometimes forms a mesentery for it. Its canal is small, and communicates with the cæcum by an orifice, which is placed below and behind that of the ileum. It is sometimes guarded with an incomplete valve formed of a fold of mucous membrane. Its coats are thick, and its mucous lining furnished with a large number of solitary glands.

In the neighbourhood of the cæcum, and especially in the vicinity of the ileo-cæcal valve, are certain pouches of peritoneum or fossæ, which are of surgical importance. Three of these fossæ may be mentioned. The *ileo-colic fossa* (superior ileo-cæcal) is situated at the junction of the ileum and colon, in the angle between the ascending colon which forms the outer boundary of the pouch, and the ileum which forms the lower boundary. Often a fold of peritoneum, arching over a branch of the ileo-colic artery, roofs in this angle and thus forms a pouch, the floor of which is formed by the mesentery. The *ileo-cæcal fossa* (inferior ileo-cæcal) is situated behind the angle of junction of the ileum and cæcum. It is formed by a fold of peritoneum (ileo-cæcal fold), which extends from the border of the ileum, and, passing over the ileo-cæcal junction, joins the mesentery of the appendix. Between this fold and the appendix is the fossa, which is bounded to the right by the ascending meso-colon, and to the left by the mesentery. It may extend a considerable distance upwards, behind and parallel with the colon. The *subcæcal fossa* (retro-cæcal) is situated immediately beneath the cæcum, which has to be raised to bring it into view. It lies close to the ileo-cæcal fossa, from which it is separated by the meso-cæcum and ascending meso-colon. It is not so constant as either the ileo-cæcal or ileo-colic fossæ.

Hernia of the vermiform appendix into one of these pouches frequently takes place, when it is often concealed and might escape the search of the surgeon were he not familiar with their existence. Moreover, a herniated appendix into one of these pouches is very liable to become strangulated. The presence of these pouches also explains the course which pus has been known to take in cases of perforation of the appendix, where it travels upwards behind the ascending colon as far as the Diaphragm.*

Ileo-cæcal valve.—The lower end of the ileum terminates at the inner and back part of the large intestine, opposite the junction of the cæcum with the colon. At this point the mucous membrane forms two valvular folds, which project into the large intestine, and are separated from each other by a narrow elongated aperture. These folds form the ileo-cæcal valve (*valvula Bauhini*). Each fold is semilunar in form. The upper one, nearly horizontal in direction, is attached by its convex border to the point of junction of the ileum with the colon; the lower segment, to the point of junction of the ileum with the cæcum. Their free concave margins project into the intestine, separated from one another by a narrow slit-like aperture, directed transversely. At each end of this

* On the anatomy of these fossæ, see a paper by Dr. Rolleston and Mr. Lockwood, *Journal of Anatomy and Physiology*, vol. xxvi. p. 130.

aperture the two segments of the valve coalesce, and are continued as a narrow membranous ridge around the canal of the intestine for a short distance, forming the *frœna*, or *retinacula*, of the valve. The left or anterior end of this aperture is rounded; the right or posterior end is narrow and pointed.

Each segment of the valve is formed by a reduplication of the mucous membrane and of the circular muscular fibres of the intestine, the longitudinal fibres and peritoneum being continued uninterruptedly across from one intestine to the other. When these are divided or removed, the ileum may be drawn outwards, and all traces of the valve will be lost, the ileum appearing to open into the large intestine by a funnel-shaped orifice of large size.

The surface of each segment of the valve directed towards the ileum is covered with villi, and presents the characteristic structure of the mucous membrane of the small intestine; whilst that turned towards the large intestine is destitute of villi, and marked with the orifices of the numerous tubular glands peculiar to the membrane in the large intestine. These differences in structure continue as far as the free margin of the valve.

When the cæcum is distended, the margins of the opening are approximated so as to prevent any reflux into the ileum.

The **colon** is divided into four parts—the ascending, transverse, descending, and the sigmoid flexure.

The **ascending colon** is smaller than the cæcum. It passes upwards, from its commencement at the cæcum, opposite the ileo-cæcal valve, to the under surface of the liver, on the right of the gall-bladder, where it bends abruptly inwards to the left, forming the *hepatic flexure*. It is retained in contact with the posterior wall of the abdomen by the peritoneum, which covers its anterior surface and sides, its posterior surface being connected by loose areolar tissue with the Quadratus lumborum, right kidney, and descending portion of the duodenum (figs. 610 and 611): sometimes the peritoneum almost completely invests it, and forms a distinct but narrow meso-colon.* It is in relation, in front, with the convolutions of the ileum and the abdominal parietes; behind it lies on the Quadratus lumborum muscle, right kidney and descending portion of the duodenum.

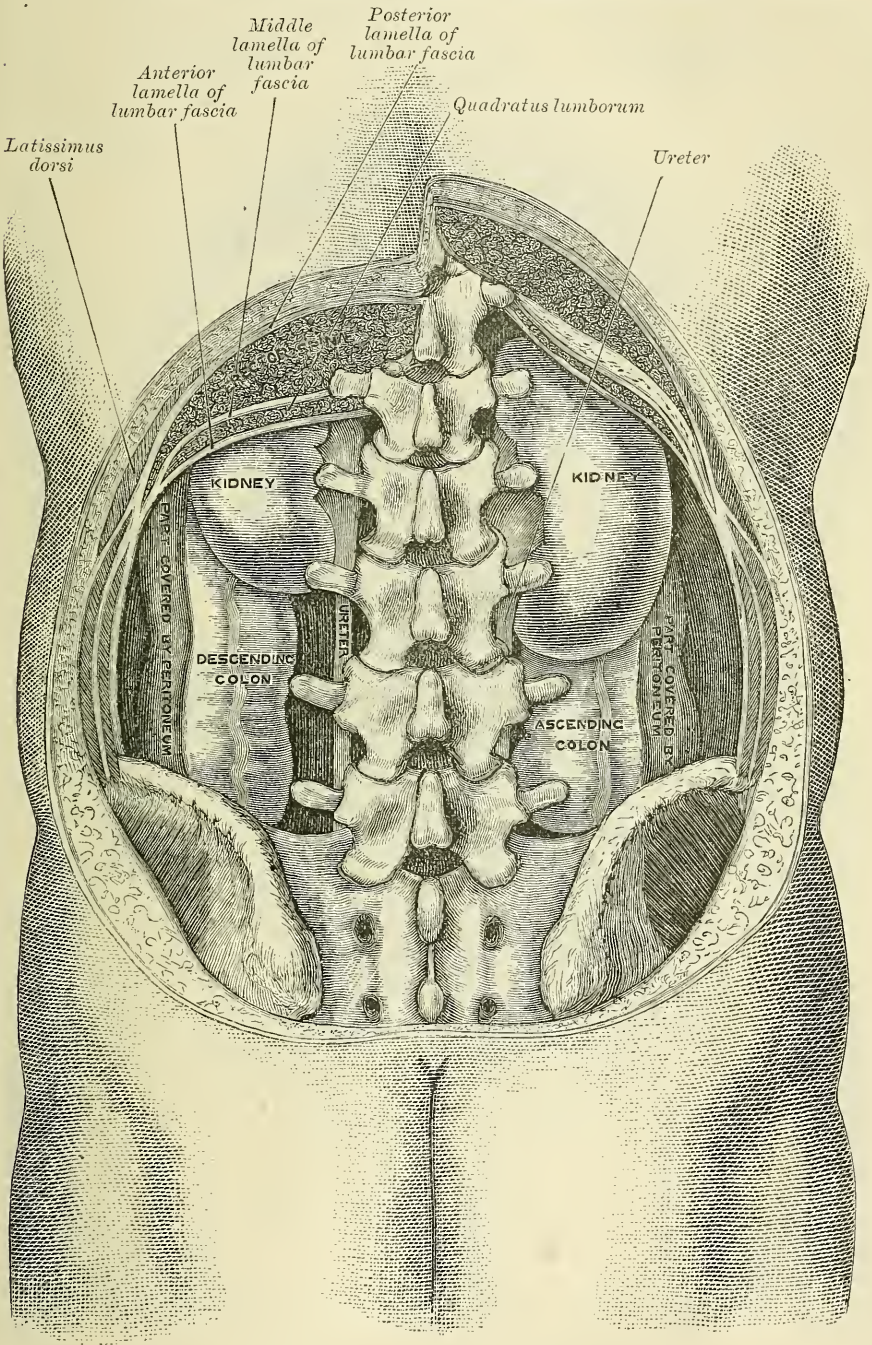
The **transverse colon**, the longest part of the large intestine, passes transversely from right to left across the abdomen, opposite the confines of the epigastric and umbilical zones, into the left hypochondriac region, where it curves downwards beneath the lower end of the spleen, forming the *splenic flexure*. In its course it describes an arch, the concavity of which is directed backwards towards the vertebral column and a little upwards; hence the name transverse *arch* of the colon. This is the most movable part of the colon, being almost completely invested by peritoneum, and connected to the spine behind by a large and wide duplicature of that membrane, the *transverse meso-colon*. It is in relation, by its upper surface, with the liver and gall-bladder, the great curvature of the stomach, and the lower end of the spleen; by its under surface, with the small intestines; by its anterior surface with the anterior layers of the great omentum and the abdominal parietes; by its posterior surface with the transverse meso-colon and third portion of the duodenum.

The **descending colon** passes almost vertically downwards through the left hypochondriac and lumbar regions to the upper part of the left iliac fossa, where it terminates in the sigmoid flexure. At its commencement it is connected with

* Mr. Treves states that, after a careful examination of one hundred subjects, he found that in fifty-two there was neither an ascending nor a descending meso-colon. In twenty-two there was a descending meso-colon, but no trace of a corresponding fold on the other side. In fourteen subjects there was a meso-colon to both the ascending and the descending segments of the bowel; while in the remaining twelve there was an ascending meso-colon, but no corresponding fold on the left side. It follows, therefore, that in performing lumbar colotomy a meso-colon may be expected upon the left side in 36 per cent. of all cases, and on the right 26 per cent.—*The Anatomy of the Intestinal Canal and Peritoneum in Man*, 1885, p. 55.

the Diaphragm by a fold of peritoneum, the *phreno-colic* ligament (see page 966). It is retained in position by the peritoneum, which covers its anterior surface and sides, its posterior surface being connected by areolar tissue with the outer

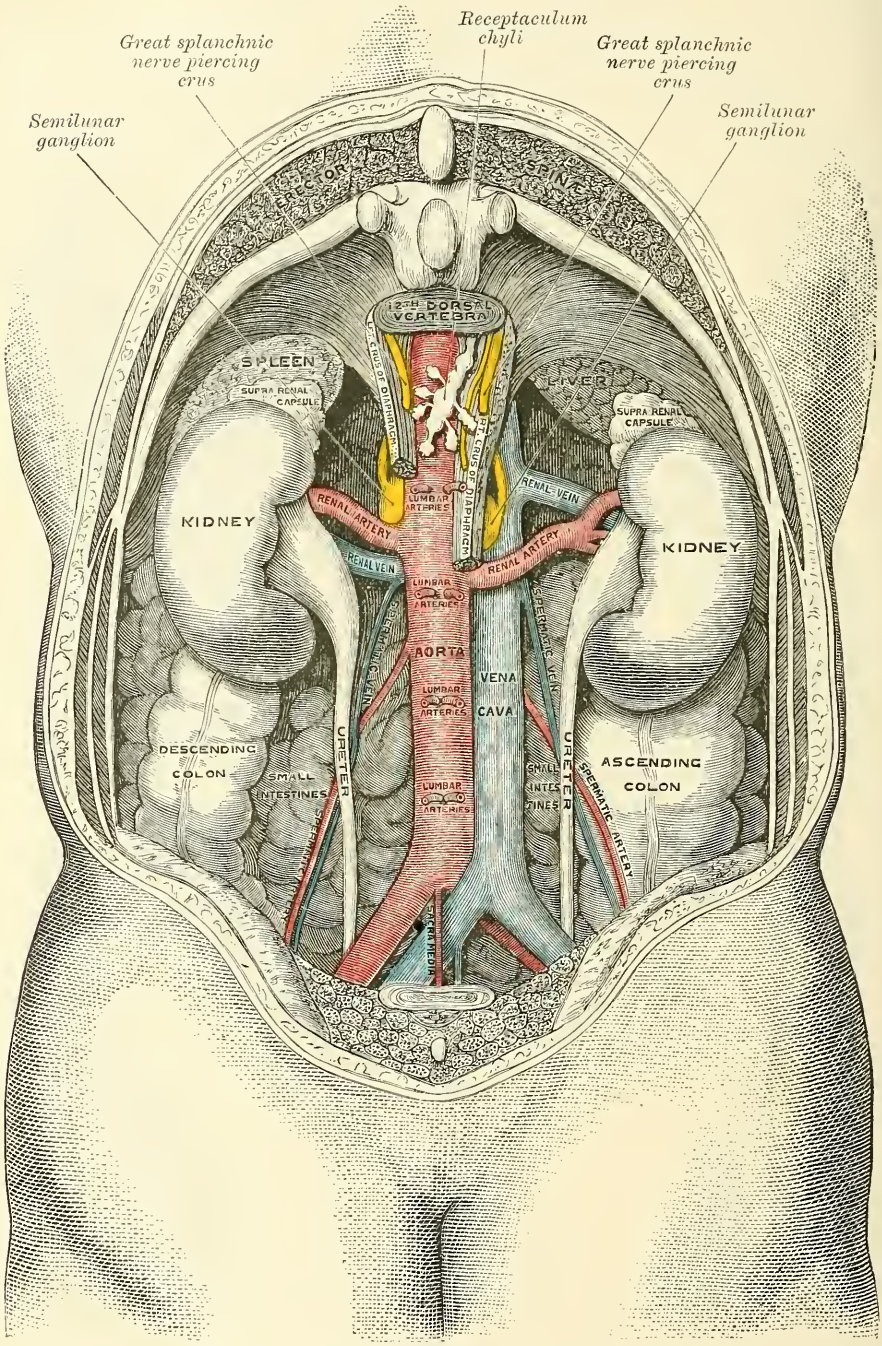
Fig. 610.—Diagram of the relations of the large intestine and kidney, from behind.



border of the left kidney, and the Quadratus lumborum (figs. 610, 611). It is smaller in calibre and more deeply placed than the ascending colon, and is more frequently covered with peritoneum on its posterior surface than the ascending colon (Treves).

The **sigmoid flexure** is the narrowest part of the colon; it is situated in the left iliac fossa, commencing from the termination of the descending colon, at the

Fig. 611.—The relations of the viscera and large vessels of the abdomen. (Seen from behind, the last dorsal vertebra being well raised.)



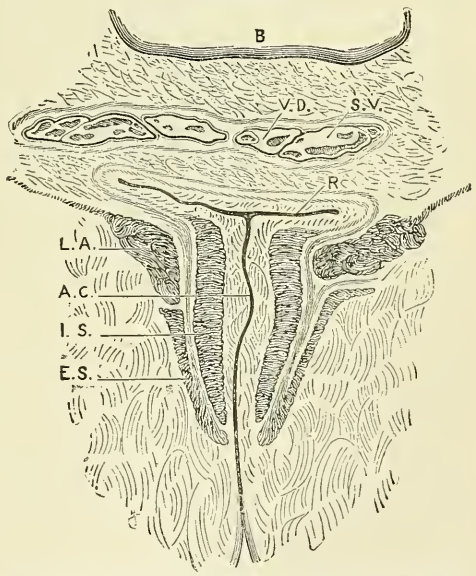
margin of the crest of the ilium, and ending in the rectum, opposite the left sacro-iliac symphysis. It curves in the first place forwards, downwards, and inwards for about two inches and then forms a loop, which varies in length and position

and which terminates in the rectum.* The first position is in close relation with the iliac fascia, and is covered by peritoneum on its sides and anterior surface only. The loop is entirely surrounded by peritoneum, and is retained in its place by a loose fold of peritoneum, the *sigmoid meso-colon*, which connects it to the Psoas muscle. This loop, which normally hangs downwards, sometimes into the true pelvis, is very movable, and may be displaced upwards in cases of distension of the pelvic viscera. Beneath the sigmoid flexure and its meso-colon is a peritoneal pouch, the *inter-sigmoïd* fossa, which extends upwards in the direction of the ureter. The sigmoid flexure is in relation in front with the small intestines and abdominal parietes.

The **rectum** is the terminal part of the large intestine, and extends from the sigmoid flexure to the anus ; it varies in length from six to eight inches, and has received its name from being less flexuous than any other part of the intestinal canal. It commences opposite the left sacro-iliac symphysis, passes obliquely downwards from left to right to the middle of the sacrum, forming a gentle curve to the right side ; it then descends in front of the lower part of the sacrum and coccyx, presenting a curve with its concavity forwards, and, near the extremity of the latter bone, inclines backwards to terminate at the anus. The rectum is, therefore, not straight, the upper part being directed obliquely from the left side to the median line, the middle portion being curved in the direction of the hollow of the sacrum and coccyx, and the lower portion presenting a short curve in the opposite direction. The rectum is cylindrical, not sacculated like the rest of the large intestine : it is narrower in its upper part than the sigmoid flexure, gradually increases in size as it descends, and immediately above the anus presents a considerable dilatation, capable of acquiring an enormous size. The rectum is divided into three portions—upper, middle, and lower.

The *upper portion*, which includes about half the length of the tube, extends obliquely from the left sacro-iliac symphysis to the middle of the third piece of the sacrum. It is almost completely surrounded by peritoneum, and connected to the sacrum behind by a duplicature of that membrane, the *meso-rectum*. It is in relation, behind, with the Pyriformis muscle, the sacral plexus of nerves and the branches of the internal iliac artery of the left side, which separate it from the sacrum and sacro-iliac symphysis ; in front, it is separated, in the male, from the posterior surface of the bladder ; in the female, from the posterior surface of the uterus and its appendages, by some convolutions of the small intestine.

FIG. 612.—Coronal section through the anal canal. (Symington.)



B. Cavity of bladder. VD. Vas deferens. SV. Seminal vesicle. R. Second part of rectum. AC. Anal canal. LA. Levator ani. IS. Internal sphincter. ES. External sphincter.

The *middle portion of the rectum* is about three inches in length, and extends as far as the tip of the coccyx. It is closely connected to the concavity of the sacrum, and covered by peritoneum only on the upper part of its anterior surface.

* Treves describes the sigmoid flexure somewhat differently. He includes in his description of this portion of the bowel the upper part of the rectum, and makes it terminate opposite the third portion of the sacrum. Instead of forming a sigmoid curve, he describes it as a large loop or bend, more like the Greek letter Ω (omega).

It is in relation, in front, in the male, with the triangular portion of the base of the bladder, the vesiculæ seminales, and vasa deferentia; more anteriorly, with the under surface of the prostate. In the female, with the posterior wall of the vagina, to which it is adherent.

The *lower portion* of the rectum is sometimes termed the *anal canal*. It differs from the second portion in the direction of its curve and in forming an antero-posterior slit, with its lateral walls in apposition, whereas the rest of the lower part of the rectum, when empty, is elongated laterally, so as to appear more like a transverse slit (fig. 612). It is about an inch or an inch and a half in length, and curves backwards at the fore part of the prostate gland to terminate at the anus. This portion of the intestine receives no peritoneal covering. It is invested by the Internal sphincter, supported by the Levatores ani muscles, and surrounded at its termination by the External sphincter. In the male, it is separated from the membranous portion and bulb of the urethra by a triangular space; and in the female a similar space intervenes between it and the vagina in which is contained the perineal body. The base of this space forms the perinæum. The rectum in the female is more capacious and less curved than in the male.

Structure.—The large intestine has four coats—serous, muscular, areolar and mucous.

The *serous coat* is derived from the peritoneum, and invests the different portions of the large intestine to a variable extent. The cæcum is completely covered by the serous membrane. The ascending and descending colon are usually covered only in front.* The transverse colon is almost completely invested, the parts corresponding to the attachment of the great omentum and transverse meso-colon being alone excepted. The first portion of the sigmoid flexure is covered in front and the sides by peritoneum, the remainder is almost completely surrounded, the point corresponding to the attachment of the sigmoid meso-colon being excepted. The upper part of the rectum is almost completely invested by the peritoneum; the middle portion is covered only on its anterior surface; and the lower portion is entirely devoid of any serous covering. In the course of the colon and upper part of the rectum, the peritoneal coat is thrown into a number of small pouches filled with fat, called *appendices epiploicæ*. They are chiefly appended to the transverse colon.

The *muscular coat* consists of an external longitudinal and an internal circular layer of muscular fibres.

The *longitudinal fibres*, although found to a certain extent all round the intestine, do not form a uniform layer over the whole surface of the large intestine. In the cæcum and colon they are especially collected into three flat longitudinal bands, each being about half an inch in width. These bands commence at the attachment of the appendix vermiformis, which is surrounded by a uniform layer of longitudinal muscular fibres, to the cæcum: one, the posterior, is placed along the attached border of the intestine; the anterior band, the largest, corresponds along the arch of the colon to the attachment of the great omentum, but is in front in the ascending and descending colon and sigmoid flexure; the third, or lateral band, is found on the inner side of the ascending and descending colon, and on the under border of the transverse colon. These bands are nearly one-half shorter than the other parts of the intestine, and serve to produce the sacculi which are characteristic of the cæcum and colon; accordingly, when they are dissected off, the tube can be lengthened, and its sacculated character becomes lost. In the sigmoid flexure the longitudinal fibres become more scattered; but upon its lower part, and round the rectum, they spread out and form a layer, which completely encircles this portion of the gut, but is thicker on the anterior and posterior surfaces, where it forms two bands, than on the lateral surfaces.

The *circular fibres* form a thin layer over the cæcum and colon, being especially

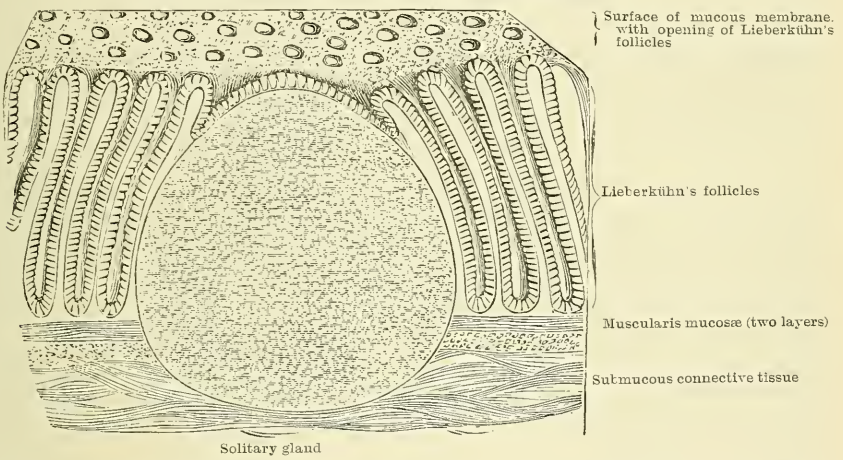
* See foot-note, p. 984.

accumulated in the intervals between the sacculi; in the rectum they form a thick layer, especially at its lower end, where they become numerous, and form the Internal sphincter.

The *areolar coat* connects the muscular and mucous layers closely together.

The *mucous membrane*, in the cæcum and colon, is pale, and of a greyish or pale yellow colour. It is quite smooth, destitute of villi, and raised into numerous crescentic folds which correspond to the intervals between the sacculi. In the rectum it is thicker, of a darker colour, more vascular, and connected loosely to the muscular coat, as in the œsophagus. When the lower part of the rectum is contracted, its mucous membrane is thrown into a number of folds, some of which, near the anus, are longitudinal in direction, and are effaced by the distension of the gut. Besides these there are certain permanent folds, of a semilunar shape, known as Houston's valves.* They are usually three in number; sometimes a fourth is found, and occasionally only two are present. One is situated near the commencement of the rectum, on the right side; another extends inwards from the left side of the tube, opposite the middle of the sacrum; the largest and most constant one projects backwards from the fore part of the rectum, opposite the base of the bladder. When a fourth is present, it is situated about an inch above the anus on the back of the rectum. These folds are about half an inch in width, and contain some of the circular fibres of the gut. In the

FIG. 613.—Minute structure of large intestine.



empty state of the intestine they overlap each other, as Mr. Houston remarks, so effectually as to require considerable manœuvring to conduct a bougie or the finger along the canal of the intestine. Their use seems to be, 'to support the weight of fæcal matter, and prevent its urging towards the anus, where its presence always excites a sensation demanding its discharge.'

As in the small intestine, the mucous membrane consists of a muscular layer, the muscularis mucosæ; of a quantity of retiform tissue in which the vessels ramify; of a basement membrane and epithelium, which is of the columnar variety, and exactly resembles the epithelium found in the small intestine. The mucous membrane of this portion of the bowel presents for examination simple follicles and solitary glands.

The *simple follicles* are minute tubular prolongations of the mucous membrane arranged perpendicularly, side by side, over its entire surface; they are longer, more numerous, and placed in much closer apposition than those of the small intestine; and they open by minute rounded orifices upon the surface, giving it a cribriform appearance.

The *solitary glands* (fig. 613) in the large intestine are most abundant in the

* *Dublin Hosp. Reports*, vol. v. p. 163

cæcum and *appendix vermiformis*, but are irregularly scattered also over the rest of the intestine. They are similar to those of the small intestine.

Vessels and Nerves.—The arteries supplying the large intestine give off large branches, which ramify between the muscular coats, supplying them, and, after dividing into small vessels in the submucous tissue, pass to the mucous membrane. The rectum is supplied mainly by the superior hæmorrhoidal branch of the inferior mesenteric, but also at its lower end by the middle hæmorrhoidal from the internal iliac, and the inferior hæmorrhoidal from the pudic artery. The superior hæmorrhoidal, the continuation of the superior mesenteric, divides into two branches, which run down either side of the rectum to within about five inches of the anus; they here split up into about six branches, which pierce the muscular coat and descend between it and the mucous membrane in a longitudinal direction, parallel with each other as far as the Internal sphincter, where they anastomose with the other hæmorrhoidal arteries and form a series of loops around the anus. The veins of the rectum commence in a plexus of vessels which surrounds the lower extremity of the intestinal canal. In the vessels forming this plexus are small saccular dilatations just within the margin of the anus; from it about six vessels of considerable size are given off. These ascend between the muscular and mucous coats for about five inches, running parallel to each other; they then pierce the muscular coat, and, by their union, form a single trunk, the superior hæmorrhoidal vein. This arrangement is termed the *hæmorrhoidal plexus*; it communicates with the tributaries of the middle and inferior hæmorrhoidal veins at its commencement, and thus a communication is established between the systemic and portal circulations. The nerves are derived from the plexuses of the sympathetic nerve around the branches of the superior and inferior mesenteric arteries that are distributed to the large intestine. They are distributed in a similar way as those in the small intestine.

Surface Form.—The coils of the small intestine occupy the front of the abdomen, below the transverse colon, and are covered more or less completely by the great omentum. For the most part the coils of the jejunum occupy the left side of the abdominal cavity, i.e. the left lumbar and inguinal regions and the left half of the umbilical region; whilst the coils of the ileum are situated to the right, in the right lumbar and inguinal regions, in the right half of the umbilical region, and also the hypogastric. The cæcum is situated in the right inguinal region. Its position varies slightly, but the mid-point of a line drawn from the anterior superior spinous process of the ilium to the symphysis pubis will about mark the middle of its lower border. It is comparatively superficial. From it the ascending colon passes upwards through the right lumbar and hypochondriac regions, and becomes more deeply situated as it ascends to the hepatic flexure, which is deeply placed, under cover of the liver. The transverse colon crosses the belly transversely on the confines of the umbilical and epigastric regions; its lower border being on a level slightly above the umbilicus, its upper border just below the greater curvature of the stomach. The splenic flexure of the colon is situated behind the stomach in the left hypochondrium, and is on a higher level than the hepatic flexure. The descending colon is deeply seated, passing down through the left hypochondriac and lumbar regions to the sigmoid flexure, which is situated in the left inguinal regions and which can be felt in thin persons, with relaxed abdominal walls, rolling under the fingers when empty, and when distended forming a distinct tumour. The position of the vermiform appendix is indicated by a point midway between the anterior superior spinous process of the right innominate bone and the umbilicus. This is known as McBurney's spot.

Surgical Anatomy.—The small intestines are much exposed to injury, but, in consequence of their elasticity and the ease with which one fold glides over another, they are not so frequently ruptured as would otherwise be the case. Any part of the small intestine may be ruptured, but probably the most common situation is the transverse duodenum, on account of its being more fixed than other portions of the bowel, and because it is situated in front of the bodies of the vertebræ, so that if this portion of the abdomen is struck by a sharp blow, as from the kick of a horse, it is unable to glide out of the way, but is compressed against the bone and so lacerated. Wounds of the intestine sometimes occur. If the wound is a small puncture, under, it is said, three lines in length, no extravasation of the contents of the bowel takes place. The mucous membrane becomes everted and plugs the little opening. The bowels, therefore, may be safely punctured with a fine capillary trocar, in cases of excessive distension of the intestine with gas, without fear of extravasation. A longitudinal wound gapes more than a transverse, owing to the greater amount of circular muscular fibres. The small intestine, and most frequently the ileum, may become

strangulated by internal bands, or through apertures, normal or abnormal. The bands may be formed in several different ways: they may be old peritoneal adhesions from previous attacks of peritonitis; or an adherent omentum from the same cause; or the band may be formed by Meckel's diverticulum, which has contracted adhesions at its distal extremity; or the band may be the result of the abnormal attachment of some normal structure, as the adhesion of two appendices epiploicæ, or an adherent vermiform appendix or Fallopian tube. Intussusception or invagination of the small intestine may take place in any part of the jejunum and ileum, but the most frequent situation is at the ileo-cæcal valve, the valve forming the apex of the entering tube. This form may attain great size, and it is not uncommon in these cases to find the valve projecting from the anus. Stricture, the impaction of foreign bodies, and twisting of the gut (*volvulus*) may lead to intestinal obstruction.

The vermiform appendix is very liable to become inflamed, leading to so-called perityphlitis, i.e. a localised inflammation of the peritoneum in the vicinity of the cæcum. This condition may be set up by the appendix becoming twisted, owing to the shortness of its mesentery, in consequence of distension of the cæcum. As the result of this its blood supply, which is mainly through one large artery running in the mesentery, becomes interfered with. Again, in rarer cases, the inflammation is set up by the impaction of a solid mass of fæces or a foreign body in it. The inflammation may result in ulceration and perforation, or if the torsion is very acute in gangrene of the appendix. These conditions may require operative interference, and in cases of recurrent attacks of appendicitis it is generally advisable to remove this diverticulum of the bowel. In external hernia the ileum is the portion of bowel most frequently herniated. When a part of the large intestine is involved it is usually the cæcum, and this may occur even on the left side. In some few cases the vermiform appendix has been the part implicated in cases of strangulated hernia, and has given rise to serious symptoms of obstruction. Occasionally ulceration of the duodenal glands may occur in cases of burns, but is not a very common complication. The ulcer may perforate one of the large duodenal vessels and may cause death from hæmorrhage, or it may perforate the coats of the intestine and produce fatal acute peritonitis. The diameter of the large intestine gradually diminishes from the cæcum, which has the greatest diameter of any part of the bowel, to the point of junction of the sigmoid flexure with the rectum, at or a little below which point stricture most commonly occurs, and diminishes in frequency as one proceeds upwards to the cæcum. When distended by some obstruction low down, the outline of the large intestine can be defined throughout nearly the whole of its course—all, in fact, except the hepatic and splenic flexures, which are more deeply placed; the distension is most obvious in the two flanks and on the front of the abdomen just above the umbilicus. The cæcum, however, is that portion of the bowel which is, of all, most distended. It sometimes assumes enormous dimensions, and has been known to give way from the distension, causing fatal peritonitis. The hepatic flexure and the right extremity of the transverse colon is in close relationship with the liver, and abscess of this viscus sometimes bursts into the gut in this situation. The gall bladder may become adherent to the colon, and gall-stones may find their way through into the gut, where they may become impacted or may be discharged per anum. The mobility of the sigmoid flexure renders it more liable to become the seat of a volvulus or twist than any other part of the intestine. It generally occurs in patients who have been the subjects of habitual constipation, and in whom therefore the meso-sigmoid flexure is elongated. The gut at this part being loaded with fæces, from its weight falls over the gut below, and so gives rise to the twist.

The surgical anatomy of the rectum is of considerable importance. There may be congenital malformations due to arrest or imperfect development. Thus, there may be no inflection of the epiblast (see page 109), and consequently a complete absence of the anus; or the hind-gut may be imperfectly developed, and there may be an absence of the rectum, though the anus is developed; or the inflection of the epiblast may not communicate with the termination of the hind-gut from want of solution of continuity in the septum which in early fœtal life exists between the two. The mucous membrane is thick and but loosely connected to the muscular coat beneath, and thus favours prolapse, especially in children. The vessels of the rectum are arranged, as mentioned above, longitudinally, and are contained in the loose cellular tissue between the mucous and muscular coats, and receive no support from surrounding tissues, and this favours varicosity. Moreover, the veins, after running upwards in a longitudinal direction for about five inches in the sub-mucous tissue, pierce the muscular coats and are liable to become constricted at this spot by the contraction of the muscular wall of the gut. In addition to this there are no valves in the superior hæmorrhoidal veins, and the vessels of the rectum are placed in a dependent position, and are liable to be pressed upon and obstructed by hardened fæces. The anatomical arrangement, therefore, of the hæmorrhoidal vessels explains the great tendency to the occurrence of piles. Again, the presence of the Sphincter ani is of surgical importance, since it is the constant contraction of this muscle which prevents an ischio-rectal abscess from healing, and causes it to become a fistula. Also the reflex contraction of this muscle is the cause of the severe pain complained of in fissure of the anus. The relations of the peritoneum to the rectum are of importance in connection with the operation of removal of the lower end of the rectum for malignant disease. This membrane gradually

leaves the rectum as it descends into the pelvis; first leaving its posterior surface, then the sides, and then the anterior surface, to become reflected, in the male on to the posterior wall of the bladder, forming the recto-vesical pouch, and in the female on to the posterior wall of the vagina, forming Douglas's pouch. The recto-vesical pouch of peritoneum extends to within three and a half or four inches from the anus, so that it is not safe to remove more than three inches of the entire circumference of the bowel for fear of the risk of opening the peritoneum. When, however, the disease is confined to the posterior surface of the rectum, or extends farther in this direction, a greater amount of the posterior wall of the gut may be removed, as the peritoneum does not extend on this surface to a lower level than five inches from the margin of the anus. The recto-vaginal or Douglas's pouch in the female extends somewhat lower than the recto-vesical pouch of the male, and therefore it is necessary to remove a less length of the tube in this sex.* Of recent years, however, much more extensive operations have been done for the removal of cancer of the rectum, and in these the peritoneal cavity has necessarily been opened. If, in these cases, the opening is plugged with antiseptic wool until the operation is completed and then the edges of the wound in the peritoneum accurately brought together with sutures, no evil result appears to follow. For cases of cancer of the rectum which are too low to be reached by abdominal section, and too high to be removed by the ordinary operation from below, Kraske has devised an operation which goes by his name. The patient is placed on his right side and an incision is made from the second sacral spine to the anus. The soft parts are now separated from the back of the left side of the sacrum as far as its left margin and the greater and lesser sacro-sciatic ligaments are divided. A portion of the lateral mass of the sacrum, commencing on the left border at the level of the third posterior sacral foramen, and running downwards and inwards through the fourth foramen to the cornu, is now cut away with a chisel. The left side of the wound being now forcibly drawn outwards, the whole of the rectum is brought into view and the diseased portion can be removed, leaving the anal portion of the gut, if healthy. The two divided ends of the gut can then be approximated and sutured together in front, the posterior part being left open for drainage.

Upon introducing the finger into the rectum, the membranous portion of the urethra can be felt, if an instrument has been introduced into the bladder, exactly in the middle line; behind this the prostate gland can be recognised by its shape and hardness and any enlargement detected; behind the prostate the fluctuating wall of the bladder when full can be felt, and if thought desirable it can be tapped in this situation; on either side and behind the prostate the vesiculæ seminales can be readily felt, especially if enlarged by tuberculous disease. Behind, the coccyx is to be felt, and on the mucous membrane one or two of Houston's folds. The ischio-rectal fossæ can be explored on either side, with a view to ascertaining the presence of deep-seated collections of pus. Finally, it will be noted that the finger is firmly gripped by the sphincter for about an inch up the bowel. By gradual dilatation of the sphincter, the whole hand can be introduced into the rectum so as to reach the descending colon. This method of exploration is rarely, however, required for diagnostic purposes.

The colon frequently requires opening in cases of intestinal obstruction; the descending colon being usually the portion of bowel selected for this operation. The operation of colotomy may be performed either without opening the peritoneum, by an incision in the loin (lumbar colotomy), or by an opening through the peritoneum (inguinal colotomy). Lumbar colotomy is performed by placing the patient on the side opposite to the one to be operated on, with a firm pillow under the loin. A line is then drawn from the anterior superior to the posterior superior spine of the ilium, and the mid-point of this line (Heath) or half an inch behind the mid-point (Allingham) is taken, and a line drawn vertically upwards from it to the last rib. This line represents, with sufficient correctness, the position of the normal colon. An oblique incision four inches in length is now made midway between the last rib and the crest of the ilium, so that its centre bisects the vertical line, and the following parts successively divided: (1) The skin, superficial fascia, with cutaneous vessels and nerves and deep fascia. (2) The posterior fibres of the External oblique and anterior fibres of the Latissimus dorsi. (3) The Internal oblique. (4) The lumbar fascia and the external border of the Quadratus lumborum. The edges of the wound are now to be held apart with retractors, and the transversalis fascia will be exposed. This is to be opened with care, commencing at the posterior angle of the incision. If the bowel is distended, it will bulge into the wound, and no difficulty will be found in dealing with it. If, however, the gut is empty this bulging will not take place, and the colon will have to be sought for. The guides to it are the lower end of the kidney, which will be plainly felt, and the outer edge of the Quadratus lumborum. The bowel having been found, is to be drawn well up into the wound, and it may be opened at once and the margins of the opening stitched to the skin at the edge of the wound; or, if the case is not an urgent one, it may be retained in this position by two harelip pins passed through the muscular coat, the rest of the wound closed, and the bowel opened in three or four days, when adhesion of the bowel to the edges of the wound has taken place.

* Allingham says one inch less in the female.

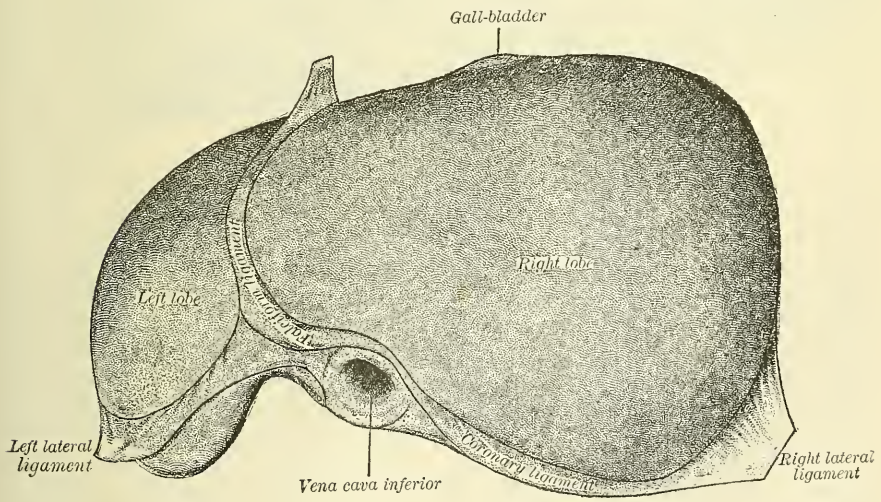
Inguinal colotomy is preferred by many surgeons in those cases where there is no urgent obstruction, and where, therefore, there is no necessity to open the bowel at once. The main reason for preferring this operation is that a spur-shaped process of the meso-colon can be formed which prevents any fæcal matter finding its way past the artificial anus, and becoming lodged on the diseased structures below. The sigmoid flexure being almost entirely surrounded by peritoneum, a coil can be drawn out of the wound and the greater part of its calibre removed, leaving the remainder attached to the meso-colon, which forms a spur, much the same as in an artificial anus caused by sloughing of the gut after a strangulated hernia, and this prevents any fæcal matter finding its way from the gut above the opening into that below. The operation is performed by making an incision two or three inches in length from a point one inch internal to the anterior superior spinous process of the ilium, parallel to Poupart's ligament. The various layers of abdominal muscles are cut through, and the peritoneum opened and sewn to the external skin. The sigmoid flexure is now sought for, and pulled out of the wound and fixed by passing a needle threaded with carbolised silk through the meso-colon close to the gut, and then through the abdominal wall. The intestine is now sewn to the skin all round, the sutures passing only through the serous and muscular coats. The wound is dressed, and on the second to the fourth day, according to the requirements of the case, the protruded coil of intestine is opened and removed with scissors.

The Liver

The **Liver** is a glandular organ of large size, intended mainly for the secretion of the bile, but effecting also important changes in certain constituents of the blood in their passage through the gland. It is situated in the right hypochondriac and epigastric regions, but in the child extends across the epigastrium into the left hypochondrium. It is the largest gland in the body, weighing from three to four pounds (from fifty to sixty ounces avoirdupois). It measures, in its transverse diameter, from ten to twelve inches; from six to seven in its antero-posterior; and is about three inches thick at the back part of the right lobe, which is the thickest part.

Its *upper* or *diaphragmatic surface* (fig. 614) is convex, directed upwards and forwards, smooth, covered by peritoneum except along a narrow line between

Fig. 614.—The liver. Upper surface. (Drawn from His' models.)

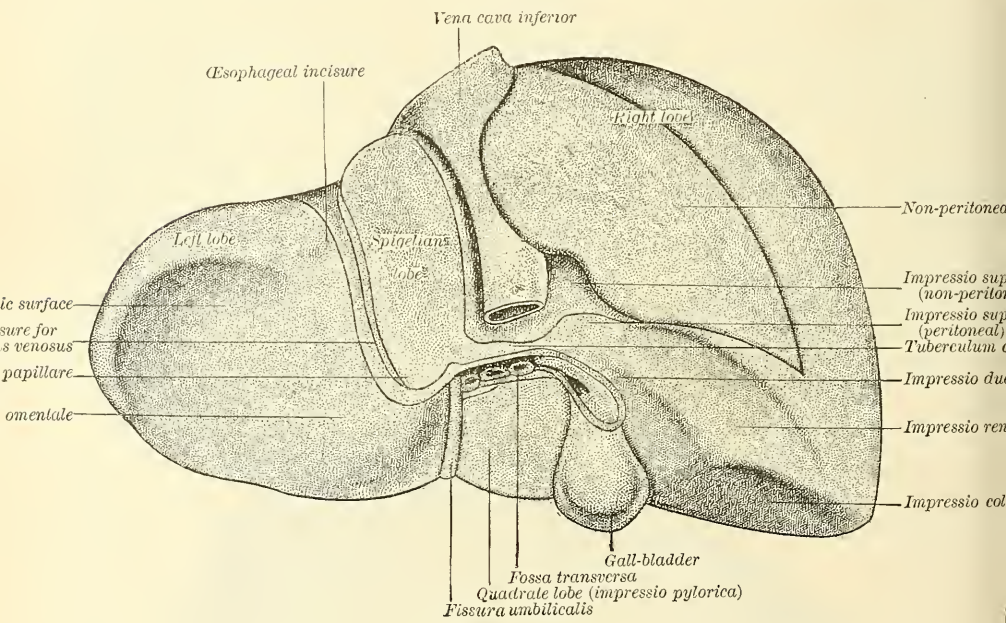


the two layers of the suspensory ligament. It is in relation with the under surface of the Diaphragm; and below, to a small extent, with the abdominal parietes. The surface is divided into two unequal lobes, the right and left; of these the right is much the larger and convex; the left smaller and more flat. The separation between the lobes is indicated by the line of attachment of a fold of peritoneum, the *suspensory* or *broad ligament*, and in front by a notch, the

umbilical notch, the termination of the umbilical fissure on the under surface. It is separated from the under surface in front by a sharp margin, in which, to the right of the umbilical notch, is an excavation, which corresponds to the fundus of the gall-bladder. Upon this surface is a shallow depression, corresponding to the heart.

Its *under* or *visceral surface* (fig. 615) is concave, directed downwards and backwards and to the left, and is in relation with the stomach and duodenum, the hepatic flexure of the colon, and the right kidney and suprarenal capsule. The surface is divided by a longitudinal fissure into a right and left lobe. It is invested by peritoneum over almost its entire surface; the only parts where this covering is absent are where the gall-bladder is attached to the liver and at the transverse fissure, where the two layers of the lesser omentum are separated from each other by the blood-vessels and duct of the viscus. The under surface of the left lobe presents behind and to the left a depression where it is moulded over the cardiac part of the stomach, and to the right and near the centre a

Fig. 615.—The liver. Posterior and inferior surface. (Drawn from His' models.)



rounded eminence, the *tuber omentale*, which fits into the concavity of the lesser curvature resting on the lesser omentum. The under surface of the right lobe is divided into two unequal portions by a fossa, which lodges the gall-bladder, the *fossa vesicalis*; the portion to the left, the smaller of the two, is somewhat oblong in shape, its antero-posterior diameter being greater than its transverse. It is known as the *quadrate lobe*, and is in relation with the pyloric end of the stomach and the first portion of the duodenum. The portion of the under surface of the right lobe to the right of the fossa vesicalis presents in front two shallow concave impressions, the one situated behind the other, and the two being separated by a ridge. The anterior of these two impressions, the *impressio colica*, is produced by the hepatic flexure of the colon; the posterior, the *impressio renalis*, being produced by the upper end of the right kidney. To the inner side of the latter impression is a third and slightly marked impression, lying between it and the neck of the gall-bladder. This is caused by the second portion of the duodenum, and is known as the *impressio duodenalis*. At the back part of the under surface of the right lobe is an impression for the right suprarenal capsule. This

is partly covered by peritoneum, and therefore belongs to the inferior surface of the liver; but in the rest of its extent is uncovered by peritoneum, and belongs to the posterior surface. It lies just to the right of the inferior vena cava. Finally, on this surface is the *caudate lobe*, a narrow strip of liver tissue which connects the right lobe to the Spigelian lobe.

The *posterior surface* is rounded and broad over the right lobe, but narrow on the left. Over the greater part of its extent it is not covered by peritoneum, but a small portion of this surface to the right is covered by this serous membrane. The uncovered portion is about three inches broad, and is in direct contact with the Diaphragm and posterior wall of the abdomen. It is marked off from the upper surface by the line of reflection of peritoneum from the under surface of the Diaphragm to the upper surface of the liver, constituting the anterior layer of the coronary and right lateral ligament of the liver. It is in the same way marked off from the under surface of the liver by the line of reflection of peritoneum from the posterior portion of the Diaphragm on to the liver, which forms the posterior layer of the coronary and right lateral ligaments. In its centre this posterior surface is deeply notched for the vertebral column and aorta, and to the right of this it is indented for the inferior vena cava, which is often partly embedded in its substance. Close to the right of this indentation is the portion of the impressio suprarenalis which belongs to the posterior surface (see above). To the left of the inferior vena cava is the Spigelian lobe, which lies between the fissure for the vena cava and the fissure for the ductus venosus. Below and in front it projects and forms part of the posterior boundary of the transverse fissure. Here, to the right, it is connected with the under surface of the right lobe of the liver by the caudate lobe, and to the left it presents a tubercle, the *tuber papillare*. It is opposite the tenth and eleventh dorsal vertebræ, and rests upon the aorta and crura of the Diaphragm. This lobe is nearly vertical in direction, and is directed backwards: it is longer from above downwards than from side to side, and is somewhat concave from side to side. On the posterior surface to the left of the Spigelian lobe is a groove indicating the position of the œsophageal orifice of the stomach.

The *anterior border* is thin and sharp, and marked opposite the attachment of the longitudinal ligament by a deep notch, and opposite the cartilage of the ninth rib by a second notch for the fundus of the gall-bladder. In adult males this border usually corresponds with the margin of the ribs; but in women and children it usually projects below the ribs.

The *right extremity of the liver* is thick and rounded, whilst the *left* is thin and flattened.

Ligaments.—The ligaments of the liver (fig. 614) are five in number, four being formed of folds of peritoneum; the fifth, the *ligamentum teres*, is a round fibrous cord, resulting from the obliteration of the umbilical vein. The ligaments are, the longitudinal, two lateral, coronary, and round.

The *longitudinal ligament* (broad, falciform, or suspensory ligament) is a broad and thin antero-posterior peritoneal fold, falciform in shape, its base being directed forwards, its apex backwards. It is attached by one margin to the under surface of the Diaphragm, and the posterior surface of the sheath of the right Rectus muscle as low down as the umbilicus; by its hepatic margin it extends from the notch on the anterior margin of the liver, as far back as its posterior surface. It consists of two layers of peritoneum closely united together. Its anterior free edge contains the round ligament between its layers.

The *lateral ligaments*, two in number, right and left, are triangular in shape. They are formed of two layers of peritoneum united, and extend from the sides of the Diaphragm to the extremities of the posterior surface of the organ. The left is the longer of the two, and lies in front of the œsophageal opening in the Diaphragm.

The *coronary ligament* connects the posterior surface of the liver to the Diaphragm. It is formed by the reflection of the peritoneum from the Diaphragm

on to the upper and lower margins of the posterior surface of the organ. The coronary ligament consists of two layers, which are continuous on each side with the lateral ligaments; and, in front, with the longitudinal ligament. Between the layers, a large oval space is left uncovered by peritoneum, and is connected to the Diaphragm by firm areolar tissue.

The *round ligament* is a fibrous cord resulting from the obliteration of the umbilical vein. It ascends from the umbilicus, in the anterior free margin of the longitudinal ligament, to the notch in the anterior border of the liver, from which it may be traced along the longitudinal fissure on the under surface of the liver as far back as the inferior vena cava.

Fissures (fig. 615).—Five fissures are seen upon the under and posterior surfaces of the liver, which serve to divide it into five lobes. They are, the umbilical fissure, the fissure of the ductus venosus, the transverse fissure, the fissure for the gall-bladder, and the fissure for the inferior vena cava. They are arranged in the form of the letter H; the left limb of the H is known as the longitudinal fissure; the anterior part contains the umbilical vein in the fœtus and its remains in the adult (the *round ligament*); it is known as the *umbilical* fissure; the posterior part, situated on the posterior surface of the liver, contains the ductus venosus, and is known as the *fissure of the ductus venosus*. The right limb of the H is formed in front by the *fissure for the gall-bladder* and behind by the *fissure for the inferior vena cava*; these two fissures are separated from each other by the caudate lobe. The connecting bar of the H is the *transverse* or *portal fissure*. It separates the quadrate lobe in front from the caudate and Spigelian lobe behind.

The *longitudinal fissure* is a deep groove, which extends from the notch on the anterior margin of the liver to the posterior surface of the organ. It separates the right and left lobes; the transverse fissure joins it, at right angles, about one-third from its posterior extremity, and divides it into two parts. The anterior half is called the *umbilical fissure*; it is deeper than the posterior part, and lodges the umbilical vein in the fœtus, or its remains (the round ligament) in the adult. This fissure is often partially bridged over by a prolongation of the hepatic substance, the *pons hepatis*.

The *fissure of the ductus venosus* is the back part of the longitudinal fissure, and is situated partly on the posterior surface of the liver; it is shorter and shallower than the anterior portion. It lies between the left lobe and the lobe of Spigelius. It lodges in the fœtus the ductus venosus, and in the adult a slender fibrous cord, the obliterated remains of that vessel.

The *transverse* or *portal fissure* is a short but deep fissure, about two inches in length, extending transversely across the under surface of the right lobe, nearer to its posterior surface than its anterior border. It joins, nearly at right angles, with the longitudinal fissure. It separates the quadrate lobe in front from the caudate and Spigelian lobe behind. By the older anatomists this fissure was considered the gateway (*porta*) of the liver; hence the large vein which enters at this point was called the *portal vein*. Besides this vein, the fissure transmits the hepatic artery and nerves, and the hepatic duct and lymphatics. At their entrance into the fissure, the hepatic duct lies in front and to the right, the hepatic artery to the left, and the portal vein behind and between the duct and artery.

The *fissure for the gall-bladder* (*fossa cystis fellee*) is a shallow, oblong fossa, placed on the under surface of the right lobe, parallel with the longitudinal fissure. It extends from the anterior free margin of the liver, which is notched for its reception, to near the right extremity of the transverse fissure.

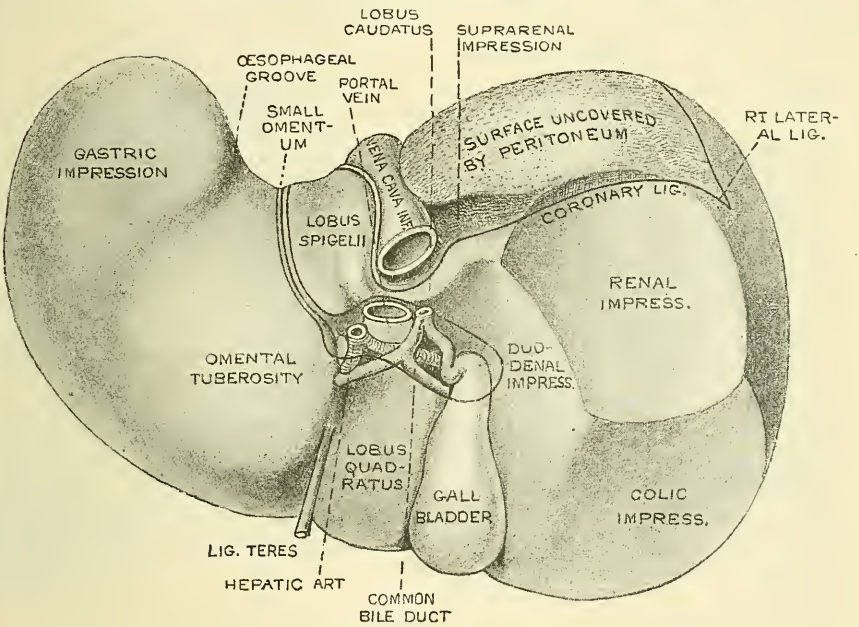
The *fissure for the inferior vena cava* is a short, deep fissure, occasionally a complete canal, from the substance of the liver uniting around the vena cava. It extends obliquely upwards from the lobus caudatus, which separates it from the transverse fissure on the posterior surface of the liver and separates the Spigelian from the right lobe. On slitting open the inferior vena cava which

is contained in it, a deep fossa is seen, at the bottom of which the hepatic veins communicate with this vessel.

Lobes.—The lobes of the liver, like the ligaments and fissures, are five in number—the right lobe, the left lobe, the lobus quadratus, the lobus Spigelii, and the lobus caudatus.

The *right lobe* is much larger than the left; the proportion between them being as six to one. It occupies the right hypochondrium, and is separated from the left lobe, on its upper surface, by the longitudinal ligament; on its under and posterior surfaces by the longitudinal fissure; and in front by a deep notch. It is of a quadrilateral form, its under surface being marked by three fissures—the transverse fissure, the fissure for the gall-bladder, and the fissure for the inferior vena cava; and by three shallow impressions, one in front (*impressio colica*), for the hepatic flexure of the colon; and one behind (*impressio renalis*), for the right kidney; and one internal, between the last-named and the gall-bladder (*impressio duodenalis*), for the second part of the duodenum.

Fig. 616.—Posterior and under surface of the liver. (From Ellis.)



The *left lobe* is smaller and more flattened than the right. It is situated in the epigastric region. Its upper surface is convex; its under surface is concave, and presents a shallow depression for the stomach (*gastric impression*). This is situated in front of the groove for the œsophagus, and is separated from the longitudinal fissure by a well-marked prominence, the *omental tuberosity*, which lies against the small omentum and lesser curvature of the stomach.

The *lobus quadratus*, or square lobe, is situated on the under surface of the right lobe, bounded in front by the free surface of the liver; behind by the transverse fissure; on the right, by the fissure for the gall-bladder; and on the left, by the umbilical fissure.

The *lobus Spigelii* projects perpendicularly from the posterior surface of the liver. It is bounded, in front, by the transverse fissure; on the right, by the fissure for the vena cava; and, on the left, by the fissure for the ductus venosus. Its left upper angle forms part of the groove for the œsophagus.

The *lobus caudatus*, or tailed lobe, is a small elevation of the hepatic substance, extending obliquely outwards, from the base of the lobus Spigelii to the under

surface of the right lobe. It is situated at the right extremity of the transverse fissure, and separates the fissure for the gall-bladder from the commencement of the fissure for the inferior vena cava.

Vessels.—The vessels connected with the liver are also five in number: they are, the hepatic artery, the portal vein, the hepatic vein, the hepatic duct, and the lymphatics.

The *hepatic artery* and *portal vein*, accompanied by numerous lymphatics and nerves, ascend to the transverse fissure, between the layers of the gastro-hepatic omentum. The *hepatic duct*, lying in company with them, descends from the transverse fissure between the layers of the same omentum. The relative position of the three structures is as follows:—The hepatic duct lies to the right, the hepatic artery to the left, and the portal vein behind and between the other two. These are enveloped in a loose areolar tissue, the capsule of Glisson, which accompanies the vessels in their course through the *portal canals*, in the interior of the organ.

The *hepatic veins* convey the blood from the liver. They commence in the substance of the liver, in the capillary terminations of the portal vein and hepatic artery; these tributaries, gradually uniting, usually form three large veins, which converge towards the posterior surface of the liver and open into the inferior vena cava, whilst that vessel is situated in the groove at the back part of this organ. Of these three veins, one from the right and another from the left lobe open obliquely into the vena cava: that from the middle of the organ and lobus Spigelii having a straight course.

The hepatic veins have very little cellular investment; what there is binds their parietes closely to the walls of the canals through which they run; so that, on a section of the organ, these veins remain widely open and solitary, and may be easily distinguished from the branches of the portal vein, which are more or less collapsed, and always accompanied by an artery and duct. The hepatic veins are destitute of valves.

The *lymphatics* are large and numerous, consisting of a deep and superficial set. They have been already described.

Nerves.—The nerves of the liver are derived from the hepatic plexus of the sympathetic, from the pneumogastric nerves, especially the left, and from the right phrenic.

Structure.—The substance of the liver is composed of lobules, held together by an extremely fine areolar tissue, and of the ramifications of the portal vein, hepatic duct, hepatic artery, hepatic veins, lymphatics, and nerves; the whole being invested by a serous and a fibrous coat.

The *serous coat* is derived from the peritoneum, and invests the greater part of the surface of the organ. It is intimately adherent to the fibrous coat.

The *fibrous coat* lies beneath the serous investment, and covers the entire surface of the organ. It is difficult of demonstration, excepting where the serous coat is deficient. At the transverse fissure it is continuous with the capsule of Glisson, and, on the surface of the organ, with the areolar tissue separating the lobules.

The *lobules* form the chief mass of the hepatic substance; they may be seen either on the surface of the organ, or by making a section through the gland. They are small granular bodies, about the size of a millet seed, measuring from one-twentieth to one-tenth of an inch in diameter. In the human subject their outline is very irregular; but in some of the lower animals (for example, the pig) they are well-defined, and, when divided transversely, have a polygonal outline. If divided longitudinally they are more or less foliated or oblong. The bases of the lobules are clustered round the smallest radicles (*sublobular*) of the hepatic veins, to which each is connected by means of a small branch which issues from the centre of the lobule (*intralobular*). The remaining part of the surface of each lobule is imperfectly isolated from the surrounding lobules by a thin stratum of

areolar tissue, in which is contained a plexus of vessels (the *interlobular plexus*) and ducts. In some animals, as the pig, the lobules are completely isolated one from another by this interlobular areolar tissue.

If one of the sublobular veins be laid open, the bases of the lobules may be seen through the thin wall of the vein on which they rest, arranged in the form of a tesselated pavement, the centre of each polygonal space presenting a minute aperture, the mouth of an intralobular vein (fig. 617).

Microscopic appearance.—Each lobule is composed of a mass of cells (*hepatic cells*), surrounded by a dense capillary plexus, composed of vessels which penetrate from the circumference to the centre of the lobule, and terminate in a single straight vein, which runs through its centre, to open at its base into one of the radicles of the hepatic vein. Between the cells are also the minute commencements of the bile-ducts. Therefore, in the lobule we have all the essentials of a secreting gland; that is to say: (1) *cells*, by which the secretion is formed; (2) *blood-vessels*, in close relation with the cells, containing the blood from which the secretion is derived; and (3) *ducts*, by which the secretion, when formed, is carried away. Each of these structures will have to be further considered.

Fig. 617.—Longitudinal section of an hepatic vein. (After Kiernan.)

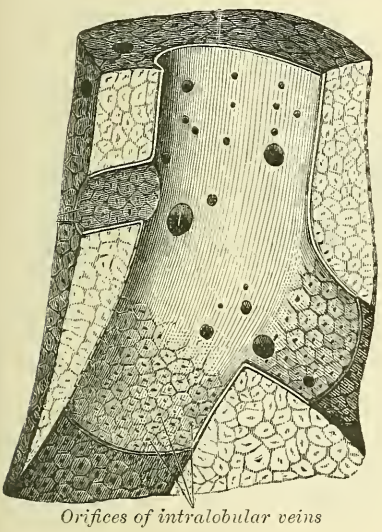


Fig. 618.—Longitudinal section of a small portal vein and canal. (After Kiernan.)

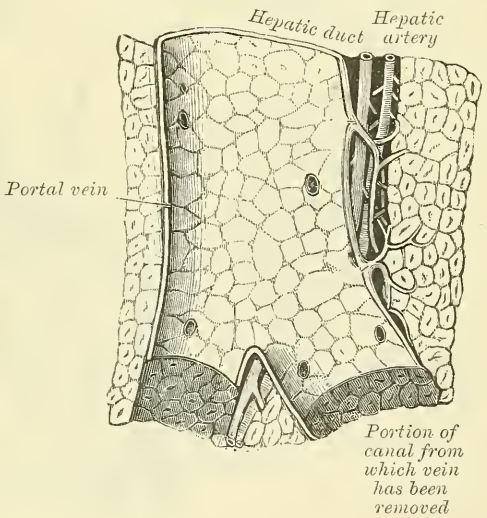


(1) The *hepatic cells* are of more or less spheroidal form; but may be rounded, flattened, or many-sided from mutual compression. They vary in size from the $\frac{1}{1000}$ to the $\frac{1}{2000}$ of an inch in diameter. They consist of a honeycomb network (Klein) without any cell-wall, and contain one or sometimes two distinct nuclei. In the nucleus is a highly refracting nucleolus with granules. Embedded in the honeycomb network are numerous yellow particles, the colouring-matter of the bile, and oil-globules. The cells adhere together by their surfaces so as to form rows, which radiate from the centre to the circumference of the lobules.* As stated above, they are the chief agents in the secretion of the bile.

(2) *The blood-vessels.*—The blood in the capillary plexus, around the liver-cells, is brought to the liver principally by the portal vein, but also to a certain

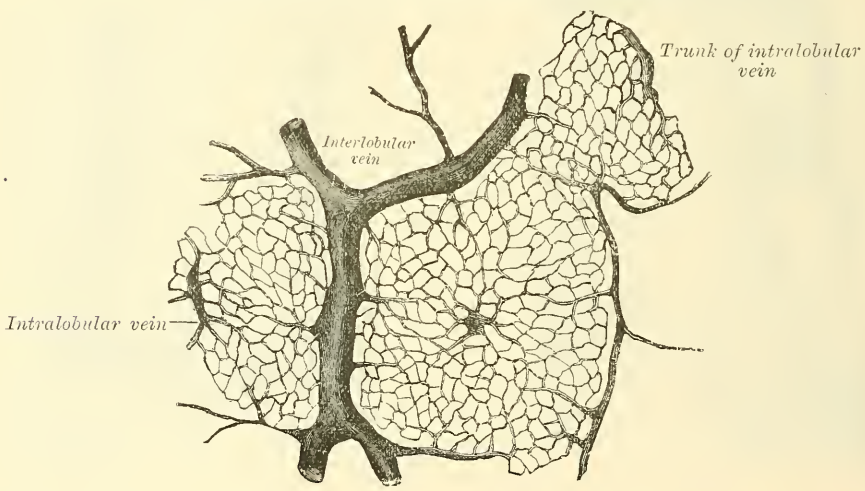
* Delépine states that there are evidences of the arrangement of these cells in the form of columns, which form tubes with narrow lumina branching from terminal bile ducts. This branching is evidenced by a divergence of the columns from lines extending between adjacent portal vessels. The columns of cells group round terminal bile ducts and not round the so-called intralobular veins. *Lancet*, vol. i. 1895, p. 1254.

extent by the hepatic artery. For the sake of clearness, the distribution of the blood derived from the hepatic artery may be considered first.

The *hepatic artery*, entering the liver at the transverse fissure with the portal vein and hepatic duct, ramifies with these vessels through the portal canals. It gives off *vaginal branches*, which ramify in the capsule of Glisson, and appear to be destined chiefly for the nutrition of the coats of the large vessels, the ducts, and the investing membranes of the liver. It also gives off *capsular branches* which reach the surface of the organ, terminating in its fibrous coat, in stellate plexuses. Finally it gives off *interlobular branches* which form a plexus on the outer side of each lobule, to supply its wall and the accompanying bile-ducts. From this, lobular branches enter the lobule and end in the capillary network between the cells. Some anatomists, however, doubt whether it transmits any blood directly to the capillary network.

The *portal vein* (fig. 618) also enters at the transverse fissure and runs through the portal canals, enclosed in Glisson's capsule, dividing into branches in its course, which finally break up into a plexus (the *interlobular plexus*) in the interlobular spaces between the lobules. In their course these branches receive the vaginal and capsular veins, corresponding to the vaginal and capsular branches of the hepatic artery (fig. 618). Thus it will be seen that all the blood carried to the liver by the portal vein and hepatic artery, except perhaps that

FIG. 619.—Horizontal section of liver (dog).



derived from the interlobular branches of the hepatic artery, directly or indirectly, finds its way into the interlobular plexus. From this plexus the blood is carried into the lobule by fine branches which pierce its wall, and then converge from the circumference to the centre of the lobule, forming a number of longitudinal vessels, which are connected by transverse or horizontal branches (fig. 619). In the interstices of the network of vessels thus formed are situated, as before said, the liver-cells; and here it is that, the blood being brought into intimate connection with the liver-cells, the bile is secreted. Arrived at the centre of the lobule, all these minute vessels empty themselves into one vein, of considerable size, which runs down the centre of the lobules from apex to base, and is called the *intralobular vein*. At the base of the lobule this vein opens directly into the *sublobular vein*, with which the lobule is connected, and which, as before mentioned, is a radicle of the hepatic vein. The sublobular veins, uniting into larger and larger trunks, end at last in the hepatic veins, which do not receive any intralobular veins. Finally, the hepatic veins, as mentioned at page 693, converge to form three large trunks which open into the inferior vena cava,

while that vessel is situated in the fissure appropriated to it at the back of the liver.

(3) *The ducts.*—Having shown how the blood is brought into intimate relation with the hepatic cells in order that the bile may be secreted, it remains now only to consider the way in which the secretion, having been formed, is carried away. Several views have prevailed as to the mode of origin of the hepatic ducts; it seems, however, to be clear that they commence by little passages which are formed between the cells, and which have been termed *intercellular biliary passages*, or *bile capillaries*. These passages are merely little channels or interspaces left between the contiguous surfaces of two cells, or in the angle where three or more liver-cells meet (fig. 620), and it seems doubtful whether there is any delicate membrane forming the wall of the space. The channels thus formed radiate to the circumference of the lobule, and, piercing its wall, form a plexus (*interlobular*) between the lobules. From this plexus ducts are derived which pass into the portal canals, become enclosed in Glisson's capsule, and, accompanying the portal vein and hepatic artery (fig. 621), join with other ducts to form two main trunks, which leave the liver at the transverse fissure, and by their union form the hepatic duct.

Fig. 620.—Section of liver.

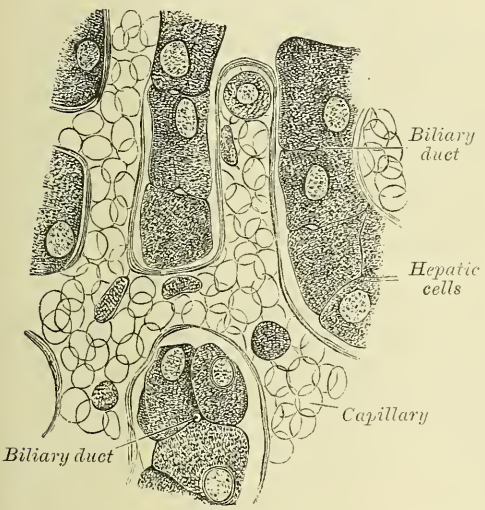


Fig. 621.—A transverse section of a small portal canal and its vessels. (After Kiernan.)

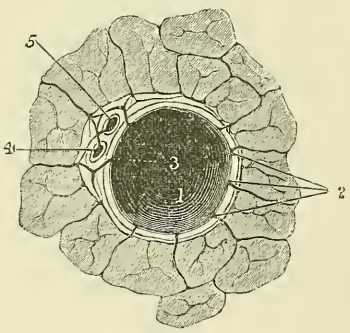


1. Portal vein. 2. Interlobular branches. 3. Vaginal branches. 4. Hepatic duct. 5. Hepatic artery.

Structure.—The coats of the smallest biliary ducts, which lie in the interlobular spaces, are a connective tissue coat, in which are muscle cells, arranged both circularly and longitudinally, and an epithelial layer, consisting of short columnar cells. In the larger ducts, which lie in the portal canals, there are a number of orifices disposed in two longitudinal rows, which were formerly regarded as the openings of mucous glands, but which are merely the orifices of tubular recesses. They occasionally anastomose, and from the sides of them saccular dilatations are given off.

Excretory Apparatus of the Liver

The excretory apparatus of the liver consists of (1) the *hepatic duct*, which, as we have seen, is formed by the junction of the two main ducts, which pass out of the liver at the transverse fissure, and are formed by the union of the bile capillaries; (2) the *gall-bladder*, which serves as a reservoir for the bile; (3) the *cystic-duct*, which is the duct of the gall-bladder; and (4) the common bile duct, formed by the junction of the hepatic and cystic ducts.

The hepatic duct.—Two main trunks of nearly equal size issue from the liver at the transverse fissure, one from the right, the other from the left lobe; these unite to form the hepatic duct, which then passes downwards and to the right for about an inch and a half, between the layers of the lesser omentum, where it joins at an acute angle with the cystic duct, and so forms the ductus communis choledochus. The hepatic duct, as it descends from the transverse fissure of the liver, between the two layers of the lesser omentum, lies in company with the hepatic artery and portal vein.

The **Gall-bladder** is the reservoir for the bile; it is a conical or pear-shaped musculo-membranous sac, lodged in a fossa on the under surface of the right lobe of the liver, and extending from near the right extremity of the transverse fissure to the anterior border of the organ. It is about four inches in length, one inch in breadth at its widest part, and holds from eight to ten drachms. It is divided into a fundus, body, and neck. The *fundus*, or broad extremity, is directed downwards, forwards, and to the right, and occasionally projects beyond the anterior border of the liver; the *body* and *neck* are directed upwards and backwards to the left. The upper surface of the gall-bladder is attached to the liver by connective tissue and vessels. The under surface is covered by peritoneum, which is reflected on to it from the surface of the liver. Occasionally the whole of the organ is invested by the serous membrane, and is then connected to the liver by a kind of mesentery.

Relations.—The *body of the gall-bladder* is in relation, by its upper surface, with the liver, to which it is connected by areolar tissue and vessels; by its under surface, with the first portion of the duodenum, occasionally the pyloric end of the stomach, and the hepatic flexure of the colon. The *fundus* is completely invested by peritoneum; it is in relation, in front, with the abdominal parietes, immediately below the ninth costal cartilage; behind, with the transverse arch of the colon. The *neck* is narrow, and curves upon itself like the letter S; at its point of connection with the cystic duct it presents a well-marked constriction.

When the gall-bladder is distended with bile or calculi, the fundus may be felt through the abdominal parietes, especially in an emaciated subject: the relations of this sac will also serve to explain the occasional occurrence of abdominal biliary fistulæ, through which biliary calculi may pass out, and of the passage of calculi from the gall-bladder into the stomach, duodenum, or colon, which occasionally happens.

Structure.—The gall-bladder consists of three coats—serous, fibrous and muscular, and mucous.

The *external* or *serous coat* is derived from the peritoneum; it completely invests the fundus, but covers the body and neck only on their under surface.

The *fibro-muscular coat* is a thin but strong layer, which forms the framework of the sac, consisting of dense fibrous tissue, which interlaces in all directions, and is mixed with plain muscular fibres, which are disposed chiefly in a longitudinal direction, a few running transversely.

The *internal* or *mucous coat* is loosely connected with the fibrous layer. It is generally tinged with a yellowish-brown colour, and is everywhere elevated into minute rugæ, by the union of which numerous meshes are formed; the depressed intervening spaces having a polygonal outline. The meshes are smaller at the fundus and neck, being most developed about the centre of the sac. Opposite the neck of the gall-bladder the mucous membrane projects inwards in the form of oblique ridges or folds, forming a sort of screw-like valve.

The mucous membrane is covered with columnar epithelium, and secretes an abundance of thick viscid mucus; it is continuous through the hepatic duct with the mucous membrane lining the ducts of the liver, and through the ductus communis choledochus with the mucous membrane of the alimentary canal.

The **cystic duct**, the smallest of the three biliary ducts, is about an inch and a half in length. It passes obliquely downwards and to the left from the neck

of the gall-bladder, and joins the hepatic duct to form the common duct. It lies in the gastro-hepatic omentum in front of the vena portæ, the hepatic artery lying to its left side. The mucous membrane lining its interior is thrown into a series of crescentic folds, from five to twelve in number, similar to those found in the neck of the gall-bladder. They project into the duct in regular succession, and are directed obliquely round the tube, presenting much the appearance of a continuous spiral valve. When the duct has been distended, the spaces between the folds are dilated, so as to give to its exterior a sacculated appearance.

The **ductus communis choledochus**, the largest of the three, is the common excretory duct of the liver and gall-bladder. It is about three inches in length, of the diameter of a goose-quill, and formed by the junction of the cystic and hepatic duct.

It descends along the right border of the lesser omentum behind the first portion of the duodenum, in front of the vena porta, and to the right of the hepatic artery; it then passes between the pancreas and descending portion of the duodenum, and, running for a short distance along the right side of the pancreatic duct, near its termination, passes, with it, obliquely between the mucous and muscular coats. The two ducts open by a common orifice upon the summit of a papilla, situated at the inner side of the descending portion of the duodenum, a little below its middle.

Structure.—The coats of the large biliary ducts are, an external or fibrous, and an internal or mucous. The fibrous coat is composed of strong fibro-areolar tissue, with a certain amount of muscular tissue, arranged, for the most part, in a circular manner around the duct. The mucous coat is continuous with the lining membrane of the hepatic ducts and gall-bladder, and also with that of the duodenum; and, like the mucous membrane of these structures, its epithelium is of the columnar variety. It is provided with numerous mucous glands, which are lobulated and open by minute orifices, scattered irregularly in the larger ducts. The coats of the smallest biliary ducts, which lie in the interlobular spaces, are a connective tissue coat, in which, according to Heidenhain, are muscle cells, arranged both circularly and longitudinally, and an epithelial layer, consisting of short columnar cells.

Surface Form.—The liver is situated in the right hypochondriac and the epigastric regions, and is moulded to the arch of the Diaphragm. In the greater part of its extent it lies under cover of the lower ribs and their cartilages, but in the epigastric region it comes in contact with the abdominal wall, in the subcostal angle. The *upper limit of the right lobe of the liver* may be defined by a line drawn from the articulation of the fifth right costal cartilage to the sternum horizontally outwards to a little below the nipple, and then inclined downwards to reach the seventh rib at the side of the chest. The *upper limit of the left lobe* may be defined by continuing this line to the left with an inclination downwards as it crosses the gladiolus, to a point about two inches to the left of the sternum on a level with the sixth left costal cartilage. The *lower limit of the liver* may be indicated by a line drawn half an inch below the lower border of the thorax on the right side as far as the ninth right costal cartilage, and thence obliquely upwards across the subcostal angle to the eighth left costal cartilage. A slight curved line with its convexity to the left from this point, i.e. the eighth left costal cartilage, to the termination of the line indicating the upper limit, will denote the left margin of the liver. The fundus of the gall-bladder approaches the surface behind the anterior extremity of the ninth costal cartilage, close to the outer margin of the right Rectus muscle.

It must be remembered that the liver is subject to considerable alterations in position, and the student should make himself acquainted with the different circumstances under which this occurs, as they are of importance in determining the existence of enlargement or other diseases of the organ.

Its position varies according to the posture of the body. In the erect position in the adult male, the edge of the liver projects about half an inch below the lower edge of the right costal cartilages, and its anterior border can be often felt in this situation if the abdominal wall is thin. In the supine position the liver gravitates backwards, and recedes above the lower margin of the ribs, and cannot then be detected by the finger. In the prone position it falls forward, and can then generally be felt in a patient with loose and lax abdominal walls. Its position varies also with the ascent or descent of the Diaphragm. In a deep inspiration the liver descends below the ribs; in expiration it is raised behind them. Again, in emphysema, where the lungs are distended, and the Diaphragm descends

very low, the liver is pushed down; in some other diseases, as phthisis, where the Diaphragm is much arched, the liver rises very high up. Pressure from without, as in tight-lacing, by compressing the lower part of the chest, displaces the liver considerably: its anterior edge often extending as low as the crest of the ilium; and its convex surface is often at the same time deeply indented from the pressure of the ribs. Again, its position varies greatly according to the greater or less distension of the stomach and intestines. When the intestines are empty, the liver descends in the abdomen; but when they are distended, it is pushed upwards. Its relations to surrounding organs may also be changed by the growth of tumours, or by collections of fluid in the thoracic or abdominal cavities.

Surgical Anatomy.—On account of its large size, its fixed position, and its friability, the liver is more frequently ruptured than any of the abdominal viscera. The rupture may vary considerably in extent, from a slight scratch to an extensive laceration completely through its substance, dividing it into two parts. Sometimes an internal rupture, without laceration of the peritoneal covering, takes place, and such injuries are most susceptible of repair; but small tears of the surface may also heal; when, however, the laceration is extensive, death usually takes place from hæmorrhage, on account of the fact that the hepatic veins are contained in rigid canals in the liver-substance and are unable to contract, and are moreover unprovided with valves. The liver may also be torn by the end of a broken rib perforating the Diaphragm. The liver may be injured by stabs or other punctured wounds, and when these are inflicted through the chest wall, both pleural and peritoneal cavities may be opened up, and both lung and liver be wounded. In cases of wound of the liver from the front, hernia of a part of this viscus may take place, but can generally easily be replaced. Abscess of the liver is of not unfrequent occurrence, and may open in many different ways on account of the relations of this viscus to other organs. Thus it has been known to burst into the lungs and the pus been coughed up, or into the stomach and the pus vomited; it may burst into the colon, or into the duodenum; or, by perforating the Diaphragm, it may empty itself into the pleural cavity. Frequently it makes its way forwards, and points on the anterior abdominal wall, and finally it may burst into the peritoneal or pericardiac cavities. Abscesses of the liver frequently require opening, and this should be done preferably by an incision in the right semilunar line, in two stages: the peritoneal cavity being opened and the liver over the summit of the abscess being stitched to the parietal peritoneum on the first occasion, and three or four days subsequently the abscess being evacuated. Hydatid cysts are more often found in the liver than in any other of the viscera. The reason of this is not far to seek. The embryo of the egg of the tænia echinococcus, being liberated in the stomach by the disintegration of its shell, bores its way through the gastric walls and usually enters a blood-vessel, and is carried by the blood-stream to the hepatic capillaries, where its onward course is arrested, and where it undergoes development into the fully formed hydatid.

When the *gall-bladder* is ruptured, or one of its main ducts, which may occur independently of laceration of the liver, the injury is necessarily fatal, from peritonitis caused by the extravasation of bile into the peritoneal cavity.

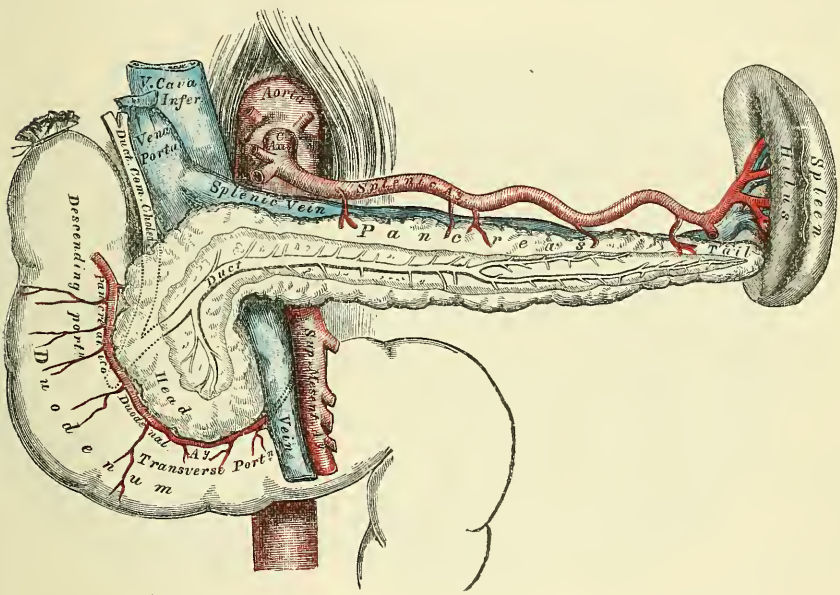
The gall-bladder may become distended with bile in cases of obstruction of its duct or the common bile duct, or from a collection of gall-stones within its interior, thus forming a large tumour. The swelling is pear-shaped, and projects downwards and forwards to the umbilicus. It moves with respiration, since it is attached to the liver. To relieve this condition, the gall-bladder must be opened and the gall-stones removed. The operation is performed by an incision, two or three inches long in the right semilunar line, commencing an inch below the costal margin. The peritoneal cavity is opened, and the tumour having been found, sponges are packed round it to protect the peritoneal cavity, and it is aspirated. When the contained fluid has been evacuated the flaccid bladder is drawn out of the abdominal wound and its wall incised to the extent of an inch; any gall-stones in the bladder are now removed and the interior of the sac sponged dry. If the case is one of obstruction of the duct, an attempt must be made to dislodge the stone by manipulation through the wall of the duct; or it may be crushed from without by carefully padded forceps; or it may be broken up by a needle introduced into the duct through the gall-bladder. After all obstruction has been removed, four courses are open to the surgeon: 1. The wound in the gall-bladder may be at once sewn up, the organ returned into the abdominal cavity and the external incision closed. 2. The edges of the incision in the gall-bladder may be sutured to the external wound, and a fistulous communication established between the gall-bladder and the exterior; this fistulous opening usually closes in the course of a few weeks. 3. The gall-bladder may be connected with the intestinal canal, preferably the duodenum, by means of a lateral anastomosis; this is known as cholecystenterostomy. 4. The gall-bladder may be completely removed.

The Pancreas

Dissection.—The pancreas may be exposed for dissection in three different ways: 1. By raising the liver, drawing down the stomach, and tearing through the gastro-hepatic omentum and the ascending layer of the transverse meso-colon. 2. By raising the stomach, the arch of the colon, and great omentum, and then dividing the inferior layer of the transverse meso-colon and raising the ascending layer of the transverse meso-colon. 3. By dividing the two layers of peritoneum, which descend from the great curvature of the stomach to form the great omentum; turning the stomach upwards, and then cutting through the ascending layer of the transverse meso-colon (see fig. 590, page 959).

The **Pancreas** (*παν-κρέας, all flesh*) is a compound racemose gland, analogous in its structure to the salivary glands, though softer and less compactly arranged than those organs. It is long and irregularly prismatic in shape, and has been compared to a human or a dog's tongue: its right extremity being broad, is called the *head*—this is connected to the main portion of the organ, the *body*, by a slight constriction, the *neck*; whilst its left extremity gradually tapers to form

Fig. 622.—The pancreas and its relations.



the *tail*. It is situated transversely across the posterior wall of the abdomen, at the back of the epigastric and left hypochondriac regions. Its length varies from six to eight inches, its breadth is an inch and a half, and its thickness from half an inch to an inch, being greater at its right extremity and along its upper border. Its weight varies from two to three and a half ounces, but it may reach six ounces.

The *right extremity* or *head of the pancreas* (fig. 622) is shaped like the head of a humerus, being elongated both above and below; it is flattened from before backwards, and is embraced by the concavity of the duodenum. The common bile duct descends behind, between the duodenum and pancreas; and the pancreatico-duodenal artery descends in front between the same parts.

The *neck of the pancreas* is about an inch long. It lies in front of the commencement of the vena porta, and is grooved on the right by the gastro-duodenal and superior pancreatico-duodenal arteries. The pylorus lies just above it.

The *body of the pancreas* is somewhat prismatic in shape, and has three surfaces: anterior, posterior, and inferior.

The *anterior surface* is somewhat concave, and is covered by the posterior surface of the stomach, which rests upon it.

The *posterior surface* is separated from the vertebral column by the aorta, the splenic vein, the left kidney and its vessels, the left suprarenal capsule, the pillars of the Diaphragm, and the origin of the superior mesenteric artery.

The *inferior surface* is narrow, and lies upon the duodenum-jejunal flexure and on some coils of the jejunum; its left extremity rests on the splenic flexure of the colon.

The *superior border* of the body is blunt and flat to the right; narrow and sharp to the left, near the tail. It commences to the right in a well marked prominence called the omental tuberosity; to the left of this it is in relation with the cœliac axis, from which the hepatic artery courses to the right just above the gland, whilst the splenic branch runs in a groove along this border to the left.

The *anterior border* is the position where the two layers of the transverse meso-colon separate: the one passing upwards in front of the anterior surface; the other passing backwards below the inferior surface.

The *lesser end* or *tail of the pancreas* is narrow; it extends to the left as far as the spleen, and is placed over the left kidney and suprarenal capsule.

Birmingham describes the body of the pancreas as projecting forwards as a prominent ridge into the abdominal cavity and forming a sort of shelf on which the stomach lies. He says: 'The portion of the pancreas to the left of the middle line has a very considerable antero-posterior thickness; as a result the anterior surface is of considerable extent, it looks strongly upwards and forms a large and important part of the shelf. As the pancreas extends to the left towards the spleen, it crosses the upper part of the kidney and is so moulded on to it that the top of the kidney forms an extension inwards and backwards of the upper surface of the pancreas and extends the bed in this direction. On the other hand, the extremity of the pancreas comes in contact with the spleen in such a way that the plane of its upper surface runs with little interruption upwards and backwards into the concave gastric surface of the spleen, which completes the bed behind and to the left, and running upwards, forms a partial cap for the wide end of the stomach' (see fig. 599).*

The **pancreatic duct**, called the **canal of Wirsung**, from its discoverer, extends transversely from left to right through the substance of the pancreas, nearer to its lower than its upper border, and lying nearer its anterior than its posterior surface. In order to expose it, the superficial portion of the gland must be removed. It commences by the junction of the small ducts of the lobules situated in the tail of the pancreas, and, running from right to left, it constantly receives the ducts of the various lobules composing the gland, and, considerably augmented in size, it leaves the head of the pancreas, and, turning obliquely downwards, backwards and to the right, it gets into relation with the common bile duct, lying to its left side, and passing very obliquely through the mucous and muscular coats of the duodenum, it terminates by an orifice common to it and the ductus communis choledochus upon the summit of an elevated papilla, situated at the inner side of the descending portion of the duodenum, a little below its middle.

Sometimes the pancreatic duct and ductus communis choledochus open separately into the duodenum. Occasionally there is an accessory duct, which is given off from the canal of Wirsung in the neck of the pancreas and passes horizontally to the right to open into the duodenum about an inch above the orifice of the main duct. This is known as the *ductus pancreaticus accessorius* or *ductus Santorini*.

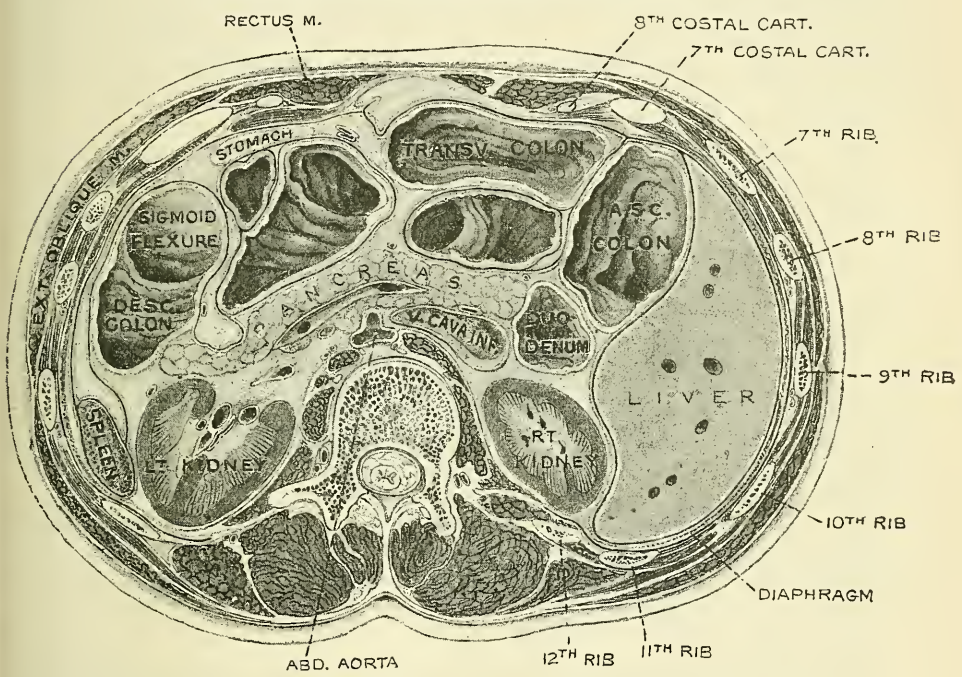
The pancreatic duct, near the duodenum, is about the size of an ordinary quill: its walls are thin, consisting of two coats, an external fibrous and an internal mucous; the latter is thin, smooth, and furnished near its termination with a few scattered follicles.

In **structure**, the pancreas resembles the salivary glands. It differs from them, however, in certain particulars, and is looser and softer in its texture. It is not

* *Journal of Anatomy and Physiology*, vol. xxxi. pt. 1, p. 102.

enclosed in a distinct capsule, but is surrounded by areolar tissue, which dips down into its interior, and connects together the various lobules of which it is composed. Each lobule, like the lobules of the salivary glands, consists of one of the ultimate ramifications of the main duct, terminating in a number of cæcal pouches or alveoli, which are tubular and somewhat convoluted. The minute ducts connected with the alveoli are narrow and lined with flattened cells. The alveoli are almost completely filled with secreting cells, so that scarcely any lumen is visible. In some animals those cells which occupy the centre of the alveolus are spindle-shaped, and are known as the *centro-acinar cells of Langerhans*. The true secreting cells which line the wall of alveolus are very characteristic. They are columnar in shape and present two zones ; an outer one clear and finely striated next the basement membrane, and an inner granular one next the lumen. During activity the granular zone occupies the greater part of the cell : before the cells are called into action, whilst in a condition of rest, the outer or

Fig. 623.—Transverse section through the middle of the first lumbar vertebra, showing the relations of the pancreas. (Braune.)



clear zone is the larger. In some secreting cells of the pancreas is a spherical mass, staining more easily than the rest of the cells ; this is termed the paranucleus, and is believed to be an extension from the nucleus. The connective tissue between the alveoli presents in certain parts collections of cells, which are termed *inter-alveolar cell-islets*.

Vessels and Nerves.—The *arteries of the pancreas* are derived from the splenic and the pancreatico-duodenal branches of the hepatic and the superior mesenteric. Its *veins* open into the splenic and superior mesenteric veins. Its *lymphatics* terminate in the lumbar glands. Its *nerves* are filaments from the splenic plexus.

Surface Form.—The pancreas lies in front of the first lumbar vertebra, and can sometimes be felt, in emaciated subjects, when the stomach and colon are empty, by making deep pressure in the middle line about three inches above the umbilicus.

Surgical Anatomy.—The pancreas presents but little of surgical importance. It is occasionally the seat of cancer, which usually affects the head or duodenal end, and therefore often speedily involves the common bile duct, leading to persistent jaundice.

Cysts are also occasionally found in it, which may present in the epigastric region, above and to the right of the umbilicus, and may require opening and draining. The fluid in them contains some of the elements of the pancreatic secretion, and is very irritating, so that, if allowed to come in contact with the skin of the abdominal wall, it is likely to produce intractable eczema. It has been said that the pancreas is the only abdominal viscus which has never been found in a hernial protrusion; but even this organ has been found, in company with other viscera, in rare cases of diaphragmatic hernia. The pancreas has been known to become invaginated into the intestine, and portions of the organ have sloughed off. In cases of excision of the pylorus great care must be exercised to avoid wounding the pancreas, as the escape of the pancreatic fluid may be attended with serious results. According to Billroth, it is likely, in consequence of its peptonising qualities, to dissolve the cicatrix of the stomach.

The Spleen

The **Spleen** belongs to that class of bodies which are known as *ductless glands*. It is probably related to the blood-vascular system, but in consequence of its anatomical relationship to the liver it is convenient to describe it in this place. It is situated principally in the left hypochondriac region, its upper and inner extremity extending into the epigastric region; lying between the fundus of the stomach and the Diaphragm. It is the largest of the ductless glands, and is of an oblong, flattened form, soft, of very brittle consistence, highly vascular, of a dark bluish-red colour, and situated in the left hypochondriac region, embracing the cardiac end of the stomach.

Relations.—The *external* or *phrenic surface* is convex, smooth, and is directed upwards, backwards and to the left, except at its upper end, where it is directed inwards. It is in relation with the under surface of the Diaphragm, which separates it from the ninth, tenth, and eleventh ribs of the left side and in part from the lower border of the left lung and pleura. The *internal surface* is concave, and divided by a ridge into an anterior or larger, and a posterior or smaller portion.

The *anterior portion* of the internal surface or *gastric surface*, which is directed forwards and inwards, is broad and concave, and is in contact with the posterior wall of the great end of the stomach; and below this with the tail of the pancreas. It presents near its inner border a long fissure, termed the *hilum*. This is pierced by several irregular apertures, for the entrance and exit of vessels and nerves.

The *posterior portion* of the internal surface or *renal surface* is directed inwards and downwards. It is flat, does not reach as high as the gastric surface, and is in relation with the outer surface of the left kidney and occasionally with the left suprarenal capsule.

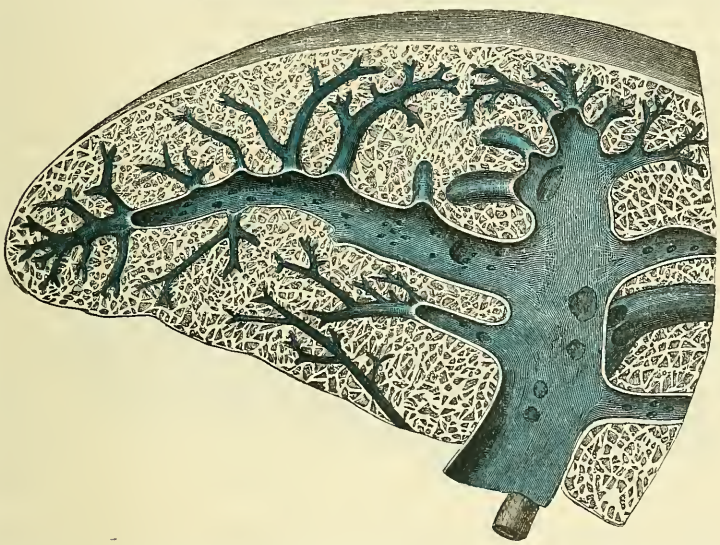
The *upper end*, thick and rounded, is directed inwards, towards the vertebral column, where it lies on a level with the tenth or eleventh dorsal vertebra. The *lower end*, sometimes termed the *basal surface*, is flat, triangular in shape, and rests upon the splenic flexure of the colon and the phreno-colic ligament, and generally is in contact with the tail of the pancreas. The *anterior* border is free, sharp and thin, and is often notched, especially below. It separates the phrenic from the internal surface. The *posterior* border is more rounded and blunter than the anterior. It separates the renal portion of the internal surface from the phrenic surface. It corresponds to the lower border of the eleventh rib and lies between the Diaphragm and left kidney. The *internal* border is the name sometimes given to the ridge which separates the renal and gastric portions of the internal surface.

The spleen is held in position by folds of peritoneum: one, the *suspensory ligament*, passes from the left crus of the Diaphragm to the so-called inner border of the spleen, from which it is reflected over the gastric and renal surfaces; a second, the *lieno-renal ligament*, which is formed by the layers of peritoneum forming the greater and lesser sacs, where they come into contact between the left kidney and the spleen. Between the two layers the splenic vessels pass (fig.

592); and a third, the *gastro-splenic omentum*, also formed of two layers, derived from the greater and lesser sacs respectively, where they meet between the spleen and stomach (fig. 592). Between these two layers run the vasa brevia of the splenic artery and vein. It is also supported by the phreno-colic ligament, upon which its lower end rests (see page 966).

The size and weight of the spleen are liable to very extreme variations at different periods of life, in different individuals, and in the same individual under different conditions. *In the adult*, in whom it attains its greatest size, it is usually about five inches in length, three or four inches in breadth, and an inch or an inch and a half in thickness, and weighs about seven ounces. *At birth*, its weight, in proportion to the entire body, is almost equal to what is observed in the adult, being as 1 to 350: whilst in the adult it varies from 1 to 320 and 400. *In old age*, the organ not only decreases in weight, but decreases considerably in proportion to the entire body, being as 1 to 700. The size of the spleen is increased during and after digestion, and varies considerably according to the state of nutrition of the body, being large in highly-fed, and small in starved animals. In intermittent and other fevers it becomes much enlarged, weighing occasionally from 18 to 20 pounds.

Fig. 624.—Transverse section of the spleen, showing the trabecular tissue and the splenic vein and its branches.



Frequently in the neighbourhood of the spleen, and especially in the gastro-splenic and great omenta, small nodules of splenic tissue may be found, either isolated or connected to the spleen by thin bands of splenic tissue. They are known as *supernumerary* or *accessory spleens*. They vary in size from a pea to a plum.

Structure.—The spleen is invested by two coats—an external serous, and an internal fibro-elastic coat.

The *external* or *serous coat* is derived from the peritoneum; it is thin, smooth, and in the human subject intimately adherent to the fibro-elastic coat. It invests the entire organ, except at the places of its reflection on to the stomach and Diaphragm and at the hilum.

The *fibro-elastic coat* forms the framework of the spleen. It invests the exterior of the organ, and at the hilum is reflected inwards upon the vessels in the form of vaginæ or sheaths. From these sheaths, as well as from the inner surface of the fibro-elastic coat, numerous small fibrous bands, *trabeculæ* (fig. 624), are given off in all directions; these uniting, constitute the areolar framework of the spleen. The framework of the spleen resembles, therefore, a sponge-like

material, consisting of a number of small spaces or *areolæ*, formed by the trabeculæ, which are given off from the inner surface of the capsule, or from the sheaths prolonged inwards on the blood-vessels. And in these spaces or areolæ is contained the *splenic pulp*.

The proper coat, the sheaths of the vessels and the trabeculæ, consist of a dense mesh of white and yellow elastic fibrous tissues, the latter considerably predominating. It is owing to the presence of this tissue that the spleen possesses a considerable amount of elasticity, which allows of the very great variations in size that it presents under certain circumstances. In addition to these constituents of this tunic, there is found in man a small amount of non-striped muscular fibre; and in some mammalia (e.g. dog, pig, and cat) a very considerable amount, so that the trabeculæ appear to consist chiefly of muscular tissue. It is probably owing to this structure that the spleen exhibits, when acted upon by the galvanic current, faint traces of contractility.

The *proper substance of the spleen* or *spleen pulp* is a soft mass of a dark reddish-brown colour, resembling grumous blood. When examined, by means of a thin section, under the microscope, it is found to consist of a number of branching cells, and of an intercellular substance The cells are connective-tissue corpuscles, and have been named the *sustentacular* or *supporting cells of the pulp*. The processes of these branching cells communicate with each other, thus forming a delicate reticulated tissue in the interior of the areolæ formed by the trabeculæ of the capsule. So that each primary space may be considered to be divided into a number of smaller spaces by the junction of these processes of the branching corpuscles. These secondary spaces contain blood, in which, however, the white corpuscles are found to be in larger proportion than they are in ordinary blood. The sustentacular cells are either small, uni-nucleated, or larger, multi-nucleated cells; they do not become deeply stained with carmine, like the cells of the Malpighian bodies, presently to be described (W. Müller), but like them they possess amœboid movements (Cohnheim). In many of them may be seen deep red or reddish-yellow granules of various sizes, which present the characters of the hæmatin of the blood. Sometimes, also, unchanged blood-discs are seen included in these cells, but more frequently blood-discs are found which are altered both in form and colour. In fact, blood-corpuscles in all stages of disintegration may be noticed to occur within them. Klein has recently pointed out that sometimes these cells, in the young spleen, contain a proliferating nucleus; that is to say, the nucleus is of large size, and presents a number of knob-like projections, as if small nuclei were budding from it by a process of gemmation. This observation is of importance, as it may explain one possible source of the colourless blood-corpuscles.

The interspaces or areolæ formed by the framework of the spleen are thus filled by a delicate reticulum of branched connective-tissue corpuscles, the interstices of which are occupied by blood, and in which the blood-vessels terminate in the manner now to be described.

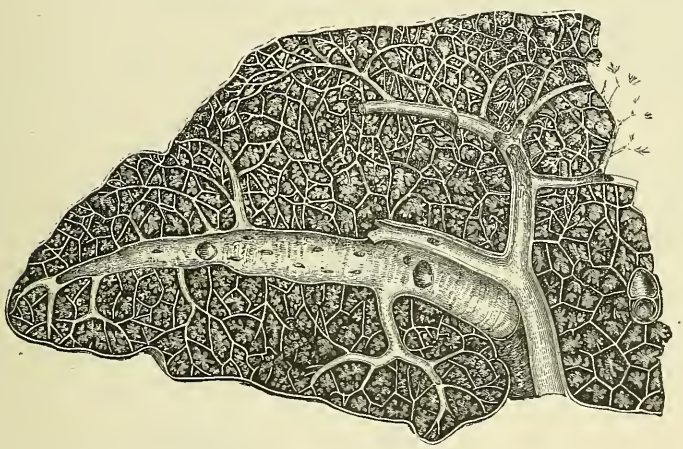
Blood-vessels of the Spleen.—The splenic artery is remarkable for its large size in proportion to the size of the organ, and also for its tortuous course. It divides into from four to six branches, which enter the hilum of the spleen and ramify throughout its substance (fig. 625), receiving sheaths from an involution of the external fibrous tissue. Similar sheaths also invest the nerves and veins.

Each branch runs in the transverse axis of the organ, from within outwards, diminishing in size during its transit, and giving off in its passage smaller branches, some of which pass to the anterior, others to the posterior part. These ultimately leave the trabecular sheaths, and terminate in the proper substance of the spleen in small tufts or pencils of minute arterioles, which open into the interstices of the reticulum formed by the branched sustentacular cells. Each of the larger branches of the artery supplies chiefly that region of the organ in which the branch ramifies, having no anastomosis with the majority of the other branches.

The *arterioles*, supported by the minute trabeculæ, traverse the pulp in all directions in bundles or pencilli of straight vessels. Their external coat, on leaving the trabecular sheaths, consists of ordinary connective tissue, but it gradually undergoes a transformation, becomes much thickened, and converted into a lymphoid material.* This change is effected by the conversion of the connective tissue into a cytogenous tissue; the bundles of connective tissue becoming looser and laxer, their fibrils more delicate, and containing in their interstices an abundance of lymph-corpuscles (W. Müller). This lymphoid material is supplied with blood by minute vessels derived from the artery with which they are in contact, and which terminates by breaking up into a network of capillary vessels.

The altered coat of the arterioles, consisting of lymphoid tissue, presents here and there thickenings of a spheroidal shape, the *Malpighian bodies of the spleen*. These bodies vary in size from about the $\frac{1}{100}$ of an inch to the $\frac{1}{25}$ of an inch in diameter. They are merely local expansions or hyperplasiæ of the lymphoid tissue, of which the external coat of the smaller arteries of the spleen is formed. They are most frequently found surrounding the arteriole, which thus seems to tunnel them, but occasionally they grow from one side of the vessel only, and present the appearance of a sessile bud growing from the arterial wall. Klein,

Fig. 625.—Transverse section of the human spleen, showing the distribution of the splenic artery and its branches.



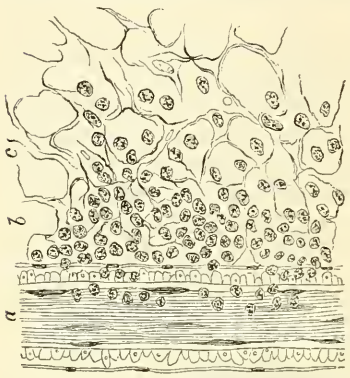
however, denies this, and says it is incorrect to describe the Malpighian bodies as isolated masses of adenoid tissue, but that they are always formed around an artery, though there is generally a greater amount on one side than the other, and that, therefore, in transverse sections, the artery, in the majority of cases, is found in an eccentric position. These bodies are visible to the naked eye on the surface of a fresh section of the organ, appearing as minute dots of a semi-opaque whitish colour in the dark substance of the pulp. In minute structure they resemble the adenoid tissue of lymphatic glands, consisting of a delicate reticulum, in the meshes of which lie ordinary lymphoid cells.

The reticulum of the tissue is made up of extremely delicate fibrils, and is comparatively open in the centre of the corpuscle, becoming closer at the periphery of the body. The cells which it encloses, like the supporting cells of the pulp, are possessed of amœboid movements, but when treated with carmine become deeply stained, and can thus easily be recognised from those of the pulp.

* According to Klein, it is the sheath of the small vessel which undergoes this transformation, and forms a 'solid mass of adenoid tissue which surrounds the vessel like a cylindrical sheath.'—*Atlas of Histology*, p. 424.

The arterioles terminate in capillaries, which traverse the pulp in all directions; their walls become much attenuated, lose their tubular character, and the cells of the lymphoid tissue of which they are composed become altered, presenting a branched appearance, and acquiring processes which are directly connected with the processes of the sustentacular cells of the pulp (fig. 627). In this manner the capillary vessels terminate, and the blood flowing through them finds its way into the interstices of the reticulated tissue formed by the branched connective-tissue corpuscles of the splenic pulp. Thus the blood passing through the spleen is brought into intimate relation with the elements of the pulp, and no doubt undergoes important changes.

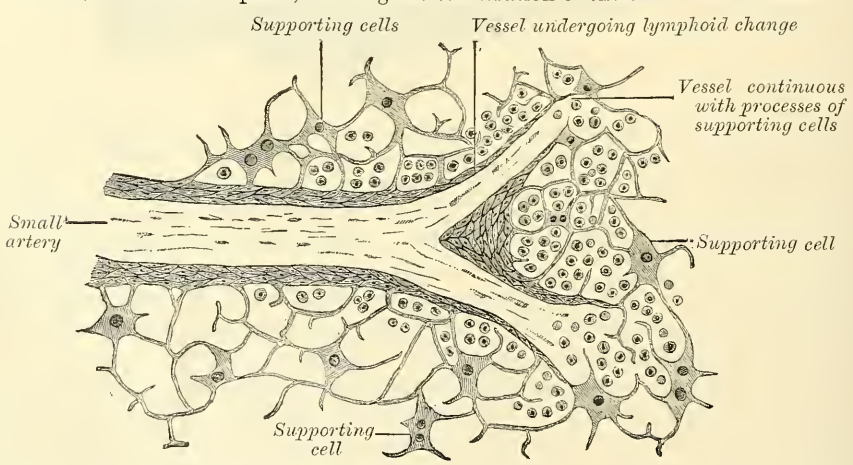
Fig. 626.—Part of a Malpighian capsule of the spleen of man. (Klein and Noble Smith.)



a. Arterial branch in longitudinal section. *b*. Adenoid tissue, still containing the lymph-corpuscles; only their nuclei are shown. *c*. Adenoid reticulum, the lymph-corpuscles accidentally removed.

After these changes have taken place the blood is collected from the interstices of the tissue by the rootlets of the veins, which commence much in the same way as the arteries terminate. Where a vein is about to commence the connective-tissue corpuscles of the pulp arrange themselves in rows, in such a way as to form an elongated space or sinus. They become changed in shape, being elongated and spindle-shaped, and overlap each other at their extremities. They thus form a sort of endothelial lining of the path or sinus, which is the radicle of a vein. On the outer surface of these cells are seen delicate transverse lines or markings, which are due to minute elastic fibrillæ arranged in a circular manner around the sinus. Thus the channel obtains a continuous external investment, and gradually becomes converted into a small vein, which after a time presents a coat of ordinary connective tissue, lined by a layer of fusiform epithelial cells, which are continuous with the supporting cells of the pulp. The smaller veins unite to form larger ones, which do not accompany the arteries,

Fig. 627.—Section of spleen, showing the termination of the small blood-vessels.



but soon enter the trabecular sheaths of the capsule, and by their junction form from four to six branches, which emerge from the hilum, and, uniting, form the splenic vein, the largest radicle of the vena porta.

The veins are remarkable for their numerous anastomoses, while the arteries hardly anastomose at all.

The lymphatics originate in two ways, i.e. from the sheaths of the arteries and in the trabeculæ. The former accompany the blood-vessels, the latter pass to the superficial lymphatic plexus which may be seen on the surface of the organ. The two sets communicate in the interior of the organ. They pass through the lymphatic glands at the hilum, and terminate in the thoracic duct.

The *nerves* are derived from branches of the right and left semilunar ganglia, and from the right pneumogastric nerve.

Surface Form.—The spleen is situated under cover of the ribs of the left side, being separated from them by the Diaphragm, and above by a small portion of the lower margin of the left lung and pleura. Its position corresponds to the ninth, tenth, and eleventh ribs. It is placed very obliquely. ' It is oblique in two directions, viz. from above downwards and outwards, and also from above downwards and forwards ' (Cunningham). ' Its highest and lowest points are on a level respectively with the ninth dorsal and first lumbar spines ; its inner end is distant about an inch and a half from the median plane of the body, and its outer end about reaches the mid-axillary line ' (Quain).

Surgical Anatomy.—Injury of the spleen is less common than that of the liver, on account of its protected situation and connections. It may be ruptured by direct or indirect violence ; torn by a broken rib ; or injured by a punctured or gunshot wound. When the organ is enlarged, the chance of rupture is increased. The great risk is hæmorrhage, owing to the vascularity of the organ, and the absence of a proper system of capillaries. The injury is not, however, necessarily fatal, and this would appear to be due, in a great measure, to the contractile power of its capsule, which narrows the wound and prevents the escape of blood. In cases where the diagnosis is clear and the symptoms indicate danger to life, laparotomy must be performed, and if the hæmorrhage cannot be stayed by ordinary surgical methods, the spleen must be removed. The spleen may become displaced, producing great pain from stretching of the vessels and nerves, and this may require removal of the organ. The spleen may become enormously enlarged in certain diseased conditions, such as ague, syphilis, valvular disease of the heart, or without any obtainable history of previous disease. It may also become enlarged in lymphadenoma, as a part of a general blood-disease. In these cases the tumour may sometimes fill the abdomen and extend into the pelvis, and may be mistaken for ovarian or uterine disease.

The spleen is sometimes the seat of cystic tumours, especially hydatids, and of abscess. These cases require treatment by incision and drainage ; and in abscess great care must be taken, if there are no adhesions between the spleen and abdominal cavity, to prevent the escape of any of the pus into the peritoneal cavity. If possible the operation should be performed in two stages, as in abscess of the liver. Sarcoma and carcinoma are occasionally found in the spleen, but very rarely as a primary disease.

Extirpation of the spleen has been performed for wounds or injuries, in floating spleen, in simple hypertrophy, and in leukæmic enlargement; but in these latter cases the operation is now regarded as unjustifiable, as every case in which it has been performed has terminated fatally. The incision is best made in the left semilunar line ; the spleen is isolated from its surroundings, and the pedicle transfixed and ligatured in two portions, before the tumour is turned out of the abdominal cavity, if this is possible, so as to avoid any traction on the pedicle, which may cause tearing of the splenic vein. In applying the ligature care must be taken not to include the tail of the pancreas, and in lifting out the organ to avoid rupturing the capsule.

THE THORAX

THE Thorax is a cone-shaped cavity, containing and protecting the heart, enclosed in its membranous bag, the *pericardium*; and the lungs, invested by the pleura. Its shape and boundaries have already been described (see page 210).

The cavity of the thorax.—The size of the cavity of the thorax does not correspond with its apparent size externally, because (1) the space enclosed by the lower ribs is occupied by some of the abdominal viscera; and (2) the cavity extends above the first rib into the neck. The size of the cavity of the thorax is constantly varying during life with the movements of the ribs and Diaphragm, and with the degree of distension of the abdominal viscera. From the collapsed state of the lungs in the dead body, it would appear as if the viscera only partly filled the cavity of the thorax, but during life there is no vacant space, that which is seen after death being filled up by the expanded lungs.

The upper opening of the thorax.—The parts which pass through the upper opening of the thorax are, from before backwards in the middle line, the Sterno-hyoid and Sterno-thyroid muscles, the remains of the thymus gland, the trachea, œsophagus, thoracic duct, and the Longus colli muscle of each side; at the sides, the innominate artery, the left common carotid and left subclavian arteries, the internal mammary and superior intercostal arteries, the right and left innominate veins, and the inferior thyroid veins, the pneumogastric, cardiac, phrenic, and sympathetic nerves, the anterior branch of the first dorsal nerve, and the recurrent laryngeal nerve of the left side. The apex of each lung, covered by the pleura, also projects through this aperture, a little above the margin of the first rib.

The **lower opening of the thorax** is wider transversely than from before backwards. It slopes obliquely downwards and backwards, so that the cavity of the thorax is much deeper behind than in front. The Diaphragm (see page 443) closes in the opening, forming the floor of the thorax. The floor is flatter at the centre than at the sides, and is higher on the right side than on the left, corresponding in the dead body to the upper border of the fifth costal cartilage on the former, and to the corresponding part of the sixth costal cartilage on the latter. From the highest point on each side the floor slopes suddenly downwards to the attachment of the Diaphragm to the ribs; this is more marked behind than in front, so that only a narrow space is left between it and the wall of the thorax.

The Pericardium

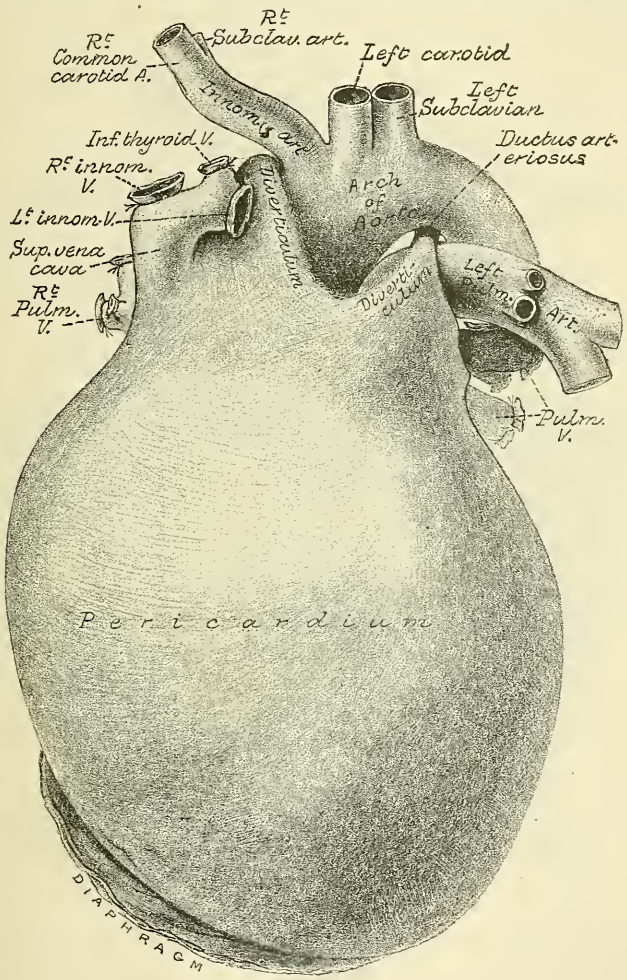
The **Pericardium** (figs. 628, 629) is a conical membranous sac, in which the heart and the commencement of the great vessels are contained. It is placed behind the sternum, and the cartilages of the third, fourth, fifth, sixth, and seventh ribs of the left side, in the interval between the pleuræ.

Its *apex* is directed upwards, and surrounds the great vessels about two inches above their origin from the base of the heart. Its *base* is attached to the central tendon and part of the adjoining muscular structure of the Diaphragm, extending a little farther to the left than to the right side. *In front* it is

separated from the sternum by the remains of the thymus gland above, and a little loose areolar tissue below; and is covered by the margins of the lungs, especially the left. *Behind*, it rests upon the bronchi, the œsophagus, and the descending aorta. *Laterally*, it is covered by the pleuræ; the phrenic nerve, with its accompanying vessels, descending between the two membranes on either side.

Structure of the Pericardium.—The pericardium is a fibro-serous membrane, and consists, therefore, of two layers, an external fibrous and an internal serous.

Fig. 628.—Pericardium, from in front. The sac has been distended with plaster. (From a preparation in the Museum of the Royal College of Surgeons.)

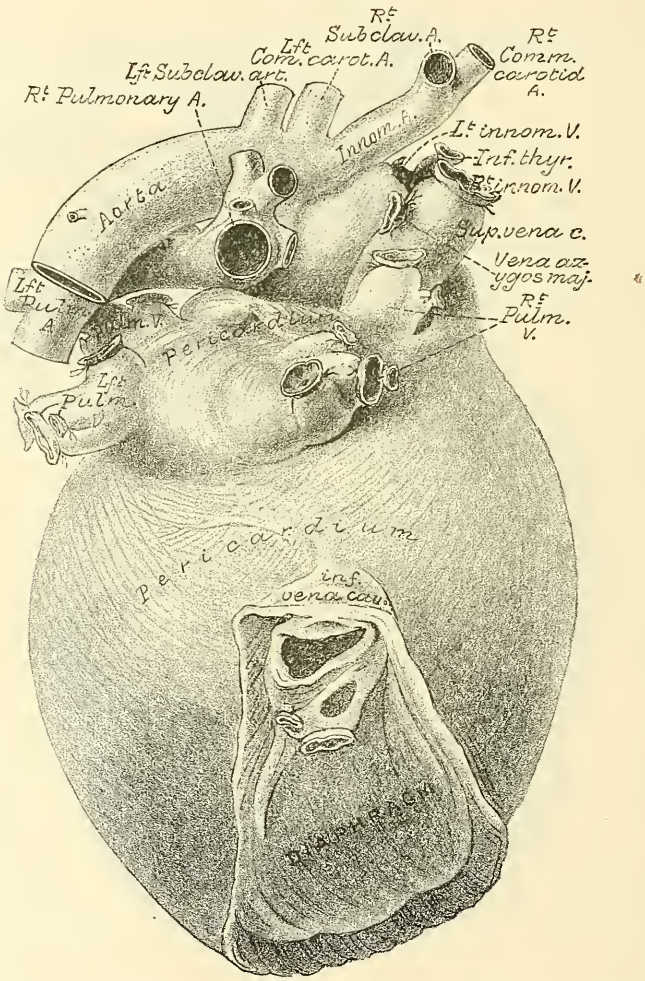


The *fibrous layer* is a strong, dense membrane. Above, it surrounds the great vessels arising from the base of the heart, on which it is continued in the form of tubular prolongations, which are gradually lost upon their external coat; the strongest being that which encloses the aorta. The pericardium may be traced, over these vessels, to become continuous with the deep layer of the cervical fascia. In front the pericardium is connected to the posterior surface of the sternum by two fibrous bands, the *superior* and *inferior sterno-pericardiac ligaments*; the upper passing to the manubrium, and the lower to the ensiform cartilage. On each side of the ascending aorta it sends upwards a diverticulum; the one on the left side, somewhat conical in shape, passes upwards and outwards, between

the arch of the aorta and the pulmonary artery, as far as the ductus arteriosus, where it terminates in a cæcal extremity which is attached by loose connective tissue to the obliterated duct (fig. 628). The one on the right side passes upwards and to the right, between the ascending aorta and vena cava superior, and also terminates in a cæcal extremity. Below, the fibrous layer is attached to the central tendon of the Diaphragm; and, on the left side, to its muscular fibres.

The vessels receiving fibrous prolongations from this membrane are, the aorta, the superior vena cava, the right and left pulmonary arteries, and the four

Fig. 629.—Pericardium, from behind. (From the same preparation as the preceding figure.)



pulmonary veins. As the inferior vena cava enters the pericardium through the central tendon of the Diaphragm, it receives no covering from the fibrous layer.

The *serous layer* invests the heart, and is then reflected on the inner surface of the pericardium. It consists, therefore, of a visceral and parietal portion. The former invests the surface of the heart, and the commencement of the great vessels, to the extent of an inch and a half from their origin; from these it is reflected upon the inner surface of the fibrous layer, lining, below, the upper surface of the central tendon of the Diaphragm. The serous membrane encloses the aorta and pulmonary artery in a single tube; but it only partially covers the

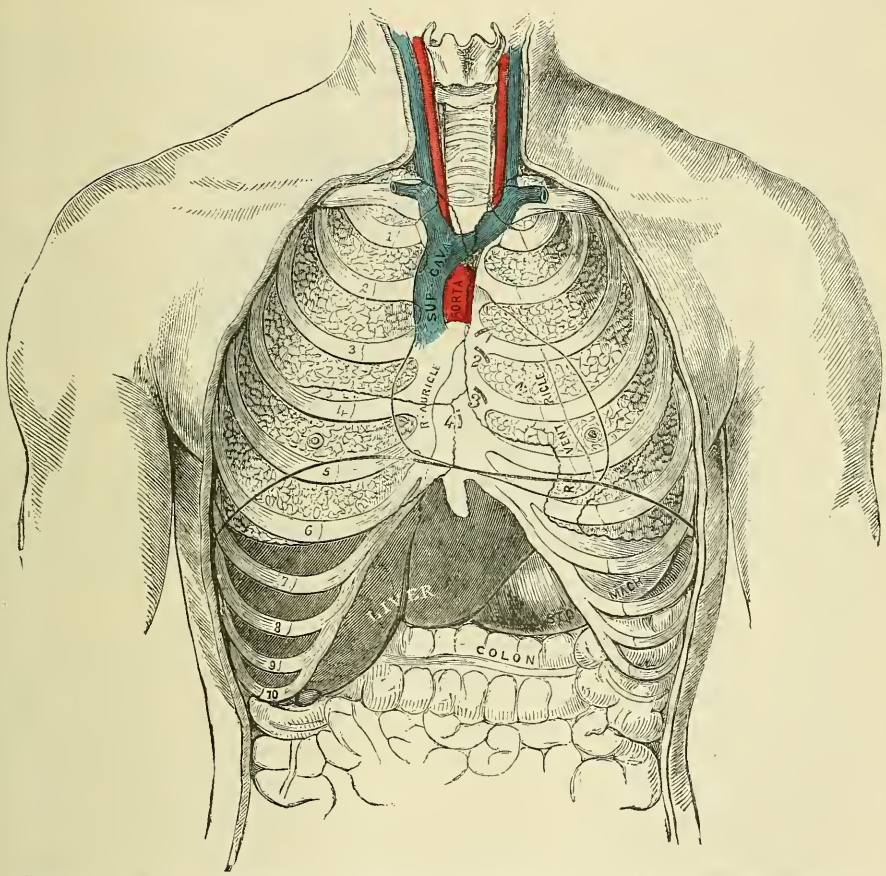
superior and inferior vena cava and the four pulmonary veins. Its inner surface is smooth and glistening, and secretes a thin fluid, which serves to facilitate the movements of the heart.

Arteries of the pericardium.—These are derived from the internal mammary, and its musculo-phrenic branch, and from the descending thoracic aorta.

Nerves of the pericardium.—These are branches from the vagus, the phrenic, and the sympathetic.

The vestigial fold of the pericardium.—Between the left pulmonary artery and the left pulmonary vein is a triangular reduplicature of the serous pericardium; it is known as the *vestigial fold of Marshall.* It is formed by the duplicature of

FIG. 630.—Front view of the thorax. The ribs and sternum are represented in relation to the lungs, heart, and other internal organs.



1. Pulmonary orifice. 2. Aortic orifice. 3. Left auriculo-ventricular orifice. 4. Right auriculo-ventricular orifice.

the serous layer over the remnant of the lower part of the left superior cava (duct of Cuvier), which, after birth, became obliterated, and remains as a fibrous band stretching from the left superior intercostal vein to the left auricle. The duplicature also contains some adipose tissue, vessels, and nerves.

Surgical Anatomy.—Paracentesis of the pericardium is sometimes required in cases of effusion into its cavity. The operation is best performed in the fifth intercostal space, one inch to the left of the sternum. The operation has been performed, however, in the fourth, sixth, and seventh spaces, and also on the right side of the sternum.

THE HEART

The **Heart** is a hollow muscular organ of a conical form, placed between the lungs, and enclosed in the cavity of the pericardium.

Position.—The heart is placed obliquely in the chest: the broad attached end, or base, is directed upwards, backwards, and to the right, and corresponds to the interval between the fifth and eighth dorsal vertebræ; the apex is directed downwards, forwards, and to the left, and corresponds to the space between the cartilage of the fifth and sixth ribs, three-quarters of an inch to the inner side, and an inch and a half below the left nipple. The heart is placed behind the lower two-thirds of the sternum, and projects farther into the left than into the right cavity of the chest, extending from the median line about three inches in the former direction, and only one and a half in the latter. The anterior surface of the heart is round and convex, directed upwards and forwards, and formed chiefly by the right ventricle and part of the left. Its posterior surface is flattened, and rests upon the Diaphragm, and is formed chiefly by the left ventricle. The right border is long, thin, and sharp; the left border short, but thick and round.

Size.—The heart, in the adult, measures five inches in length, three inches and a half in breadth in the broadest part, and two inches and a half in thickness. The prevalent weight, in the male, varies from ten to twelve ounces; in the female, from eight to ten: its proportions to the body being as 1 to 169 in males; 1 to 149 in females. The heart continues increasing in weight, and also in length, breadth, and thickness, up to an advanced period of life: this increase is more marked in men than in women.

Component Parts.—The heart is subdivided by a longitudinal muscular septum into two lateral halves, which are named respectively, from their position, right and left; and a transverse constriction subdivides each half of the organ into two cavities, the upper cavity on each side being called the *auricle*, the lower the *ventricle*. The right is the venous side of the heart, receiving into its auricle the dark venous blood from the entire body, by the superior and inferior vena cava, and coronary sinus. From the right auricle the blood passes into the right ventricle, and from the right ventricle, through the pulmonary artery, into the lungs. The blood, arterialised by its passage through the lungs, is returned to the left side of the heart by the pulmonary veins, which open into the left auricle; from the left auricle the blood passes into the left ventricle, and from the left ventricle is distributed, by the aorta and its subdivisions, through the entire body. This constitutes the circulation of the blood in the adult.

The division of the heart into four cavities is indicated by grooves upon its surface. The great transverse groove separating the auricles from the ventricles is called the *auriculo-ventricular groove*. It is deficient, in front, from being crossed by the root of the pulmonary artery. It contains the trunks of the nutrient vessels of the heart. The auricular portion occupies the base of the heart, and is subdivided into two cavities by a median septum. The two ventricles are also separated into a right and left, by two longitudinal furrows, the *interventricular grooves*, which are situated one on the anterior, the other on the posterior surface; these extend from the base of the ventricular portion to the apex of the organ; the former being situated nearer to the left border of the heart, and the latter to the right. It follows, therefore, that the right ventricle forms the greater portion of the anterior surface of the heart, and the left ventricle more of its posterior surface

Each of these cavities should now be separately examined.

To examine the interior of the right auricle, an incision should be made along its right border, from the entrance of the superior vena cava to that of the inferior. A second cut is to be made from the centre of this first incision to the tip of the auricular appendix, and the flaps raised.

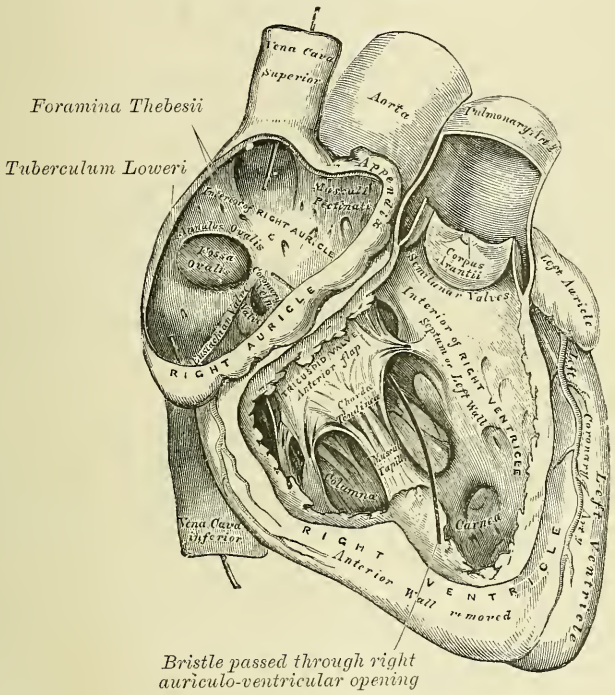
The **Right Auricle** is a little larger than the left, its walls somewhat thinner, measuring about one line; and its cavity is capable of containing about two ounces. It consists of two parts: a principal cavity, or *sinus venosus*, and an *appendix auriculæ*.

The *sinus* is the large quadrangular cavity, placed between the two venæ cavæ; its walls are extremely thin; it is connected below with the right ventricle, and internally with the left auricle, being free in the rest of its extent.

The *appendix auriculæ*, so called from its fancied resemblance to a dog's ear, is a small conical muscular pouch, the margins of which present a dentated edge. It projects from the sinus forwards and to the left side, overlapping the root of the aorta.

The internal surface of the right auricle is smooth, except in the appendix and adjacent part of the anterior wall of the sinus venosus, where it is thrown into parallel ridges.

Fig. 631.—The right auricle and ventricle laid open, the anterior walls of both being removed.



It presents the following parts for examination:

Openings { Superior cava. / Inferior cava. / Coronary sinus. / Foramina Thebesii. / Auriculo-ventricular. }

Valves { Eustachian. / Coronary. }

Relics of fœtal structure { Annulus ovalis. / Fossa ovalis. }

Musculi pectinati.

Tuberculum Loweri.

The *superior vena cava* returns the blood from the upper half of the body, and opens into the upper and back part of the auricle, the direction of its orifice being downwards and forwards.

The *inferior vena cava*, larger than the superior, returns the blood from the lower half of the body, and opens into the lowest part of the auricle, near the septum, the direction of its orifice being upwards and inwards. The direction of a current of blood through the superior vena cava would consequently be towards the auriculo-ventricular orifice; whilst the direction of the blood through the

inferior cava would be towards the auricular septum. This is the normal direction of the two currents in fœtal life.

The *tuberculum Loweri* is a small projection on the right wall of the auricle, between the two venæ cavæ. It is most distinct in the hearts of quadrupeds; in man it is scarcely visible. It was supposed by Lower to direct the blood from the superior cava towards the auriculo-ventricular opening.

The *coronary sinus* opens into the auricle, between the inferior vena cava and the auriculo-ventricular opening. It returns the blood from the substance of the heart, and is protected by a semicircular fold of the lining membrane of the auricle, the *coronary valve*. The sinus, before entering the auricle, is considerably dilated—nearly to the size of the end of the little finger. Its wall is partly muscular, and, at its junction with the great coronary vein, is somewhat constricted, and furnished with a valve, consisting of two unequal segments.

The *foramina Thebesii* are numerous minute apertures, the mouths of small veins (*venæ cordis minimæ*), which open on various parts of the inner surface of the auricle. They return the blood directly from the muscular substance of the heart. Some of these foramina are minute depressions in the walls of the heart, presenting a closed extremity.

The *auriculo-ventricular opening* is the large oval aperture of communication between the auricle and the ventricle, to be presently described.

The *Eustachian valve* is situated between the anterior margin of the inferior vena cava and the auriculo-ventricular orifice. It is semilunar in form, its convex margin being attached to the wall of the vein; its concave margin, which is free, terminating in two cornua, of which the left is attached to the anterior edge of the annulus ovalis; the right being lost on the wall of the auricle. The valve is formed by a duplicature of the lining membrane of the auricle, containing a few muscular fibres.

In the fœtus this valve is of large size, and serves to direct the blood from the inferior vena cava, through the foramen ovale, into the left auricle.

In the adult it is occasionally persistent, and may assist in preventing the reflux of blood into the inferior vena cava; more commonly it is small, and its free margin presents a cribriform or filamentous appearance; occasionally it is altogether wanting.

The *coronary valve* (valve of Thebesius) is a semicircular fold of the lining membrane of the auricle, protecting the orifice of the coronary sinus. It prevents the regurgitation of blood into the sinus during the contraction of the auricle. This valve is occasionally double.

The *fossa ovalis* is an oval depression, corresponding to the situation of the foramen ovale in the fœtus. It is situated at the lower part of the septum auricularum, above and to the left of the orifice of the inferior vena cava.

The *annulus ovalis* is the prominent oval margin of the foramen ovale. It is most distinct above, and at the sides; below, it is deficient. A small slit-like valvular opening is occasionally found, at the upper margin of the fossa ovalis, which leads upwards, beneath the annulus, into the left auricle, and is the remains of the aperture between the two auricles in the fœtus.

The *musculi pectinati* are small, prominent, muscular columns, which run across the inner surface of the appendix auriculæ and adjoining portion of the wall of the sinus. They have received the name *pectinati* from the fancied resemblance they bear to the teeth of a comb.

The **Right Ventricle** is triangular in form, and extends from the right auricle to near the apex of the heart. Its anterior or upper surface is rounded and convex, and forms the larger part of the front of the heart. Its under surface is flattened, rests upon the Diaphragm, and forms only a small part of the back of the heart. Its posterior wall is formed by the partition between the two ventricles, the *septum ventriculorum*, the surface of which is convex, and bulges into the cavity of the right ventricle. Its upper and inner angle is prolonged into a conical pouch, the *infundibulum*, or *conus arteriosus*, from which the pulmonary

artery rises. The walls of the right ventricle are thinner than those of the left, the proportion between them being as 1 to 3. The wall is thickest at the base, and gradually becomes thinner towards the apex. The cavity, which equals that of the left ventricle, is capable of containing about three fluid ounces.*

To examine the interior of the right ventricle, an incision should be made a little to the right of the anterior interventricular groove from the pulmonary artery to the apex of the heart, and should be carried up from thence a little to the right of the posterior interventricular groove, as far as the auriculo-ventricular opening.

The following parts present themselves for examination :

Openings { Auriculo-ventricular. / Opening of the pulmonary artery.
Valves { Tricuspid. / Semilunar.

And a muscular and tendinous apparatus connected with the tricuspid valve :

Columnæ carneæ. Chordæ tendineæ.

The *auriculo-ventricular orifice* is the large oval aperture of communication between the auricle and ventricle. It is situated at the base of the ventricle, near the right border of the heart. The opening is about an inch in diameter,† oval from side to side, surrounded by a fibrous ring, covered by the lining membrane of the heart, and rather larger than the corresponding aperture on the left side, being sufficiently large to admit the ends of four fingers. It is guarded by the tricuspid valve.

The *opening of the pulmonary artery* is circular in form, and situated at the summit of the conus arteriosus, close to the septum ventriculorum. It is placed on the left side of the auriculo-ventricular opening, upon the anterior aspect of the heart. Its orifice is guarded by the pulmonary semilunar valves.

The *tricuspid valve* consists of three segments of a triangular or trapezoidal shape, formed by a duplicature of the lining membrane of the heart, strengthened by a layer of fibrous tissue, and containing, according to Kürschner and Senac, muscular fibres. These segments are connected by their bases to the auriculo-ventricular orifice, and by their sides with one another, so as to form a continuous annular membrane, which is attached round the margin of the auriculo-ventricular opening, their free margins and ventricular surfaces affording attachment to a number of delicate tendinous cords, the *chordæ tendineæ*. The largest and most movable segment is placed towards the left side of the auriculo-ventricular opening, interposed between that opening and the pulmonary artery. Another segment corresponds to the front of the ventricle ; and a third to its posterior wall. The central part of each segment is thick and strong : the lateral margins are thin and indented. The chordæ tendineæ are connected with the adjacent margins of the principal segments of the valve, and are further attached to each segment in the following manner : 1. Three or four reach the attached margin of each segment, where they are continuous with the auriculo-ventricular tendinous ring. 2. Others, four to six in number, are attached to the

* Morrant Baker says that, 'taking the mean of various estimates, it may be inferred that each ventricle is able to contain four to six ounces of blood.'—Kirke's *Physiology*, 10th edition, p. 156.

† In the *Pathological Transactions*, vol. vi. p. 119, Dr. Peacock has given some careful researches upon the weight and dimensions of the heart in health and disease. He states, as the result of his investigations, that, in the healthy adult heart, the right auriculo-ventricular aperture has a mean circumference of 54·4 lines, or $4\frac{3}{4}\frac{9}{4}$ inches ; the left auriculo-ventricular aperture a mean circumference of 44·3 lines, or $3\frac{3}{4}\frac{2}{4}$ inches ; the pulmonic orifice of 40 lines, or $3\frac{1}{4}\frac{3}{4}$ inches ; and the aortic orifice of 35·5 lines, or $3\frac{4}{4}$ inches ; but the dimensions of the orifices varied greatly in different cases, the auriculo-ventricular aperture having a range of from 45 to 60 lines, and the others in the same proportion.

central thickened part of each segment. 3. The most numerous and finest are connected with the marginal portion of each segment.

The *columnæ carneæ* are the rounded muscular columns which project from nearly the whole of the inner surface of the ventricle, excepting near the opening of the pulmonary artery, where the wall becomes smooth. They may be classified, according to their mode of connection with the ventricle, into three sets. The first set merely form prominent ridges on the inner surface of the ventricle, being attached by their entire length on one side, as well as by their extremities. The second set are attached by their two extremities, but are free in the rest of their extent; whilst the third set (*musculi papillares*), three or four in number, are attached by one extremity to the wall of the heart, the opposite extremity giving attachment to the *chordæ tendineæ*.

The *semilunar valves*, three in number,* guard the orifice of the pulmonary artery. They consist of three semicircular folds, two anterior (right and left) and one posterior, formed by a duplicature of the lining membrane, strengthened by fibrous tissue. They are attached, by their convex margins, to the wall of the artery, at its junction with the ventricle, the straight border being free, and directed upwards in the course of the vessel, against the sides of which the valve-flaps are pressed during the passage of the blood along the artery. The free margin of each is somewhat thicker than the rest of the valve, is strengthened by a bundle of tendinous fibres, and presents, at its middle, a small projecting thickened nodule, called *corpus Arantii*.† From this nodule tendinous fibres radiate through the valve to its attached margin, and these fibres form a constituent part of its substance throughout its whole extent, excepting two narrow lunated portions, the *lunulæ*, placed on each side of the nodule immediately behind the free margin; here the valve is thin, and formed merely by the lining membrane. During the passage of the blood along the pulmonary artery these valves are pressed against the sides of the cylinder, and the course of the blood along the tube is uninterrupted; but during the ventricular diastole, when the current of blood along the pulmonary artery is checked, and partly thrown back by its elastic walls, these valves become immediately expanded, and effectually close the entrance of the tube. When the valves are closed, the lunated portions of each are brought into contact with one another by their opposed surfaces, the three corpora Arantii filling up the small triangular space that would be otherwise left by the approximation of the three semilunar valves.

Between the semilunar valves and the commencement of the pulmonary artery are three pouches or dilatations, one behind each valve. These are the pulmonary sinuses (*sinuses of Valsalva*). Similar sinuses exist between the semilunar valves and the commencement of the aorta; they are larger than the pulmonary sinuses. The blood, in its regurgitation towards the heart, finds its way into these sinuses, and so shuts down the valve-flaps.

In order to examine the interior of the left auricle, make an incision on the posterior surface of the auricle from the pulmonary veins on one side to those on the other, the incision being carried a little way into the vessels. Make another incision from the middle of the horizontal one to the appendix.

The **Left Auricle** is rather smaller than the right; its walls thicker, measuring

* The pulmonary semilunar valves have been found to be two in number instead of three (Dr. Hand, of St. Paul, Minn., in the *North-Western Med. and Surg. Journ.*, July 1873), and the same variety is more frequently noticed in the aortic semilunar valves.

† In former editions, as well as in other text-books on anatomy, these little nodules have been described as fibro-cartilaginous in structure. At my request, Dr. Le Cronier Lancaster, Demonstrator of Anatomy at St. George's Hospital, has investigated this subject, and reports that the 'corpora Arantii' appear to consist of bundles of interlacing connective-tissue fibres with branched connective-tissue cells, and some few elastic fibres. Occasionally a rounded cell, with indistinct capsule, resembling a cartilage cell, was seen; but there were not many of them. At the free edge of the corpus the structure is denser, there being a larger proportion of fibres to cells than in the central portion. He thinks the structure of the corpus should be put down as fibrous and not fibro-cartilaginous.

about one line and a half; it consists, like the right, of two parts, a principal cavity, or *sinus*, and an *appendix auriculæ*.

The *sinus* is cuboidal in form, and concealed, in front, by the pulmonary artery and aorta; internally, it is separated from the right auricle by the septum auricularum; behind, it receives on each side the pulmonary veins, being free in the rest of its extent.

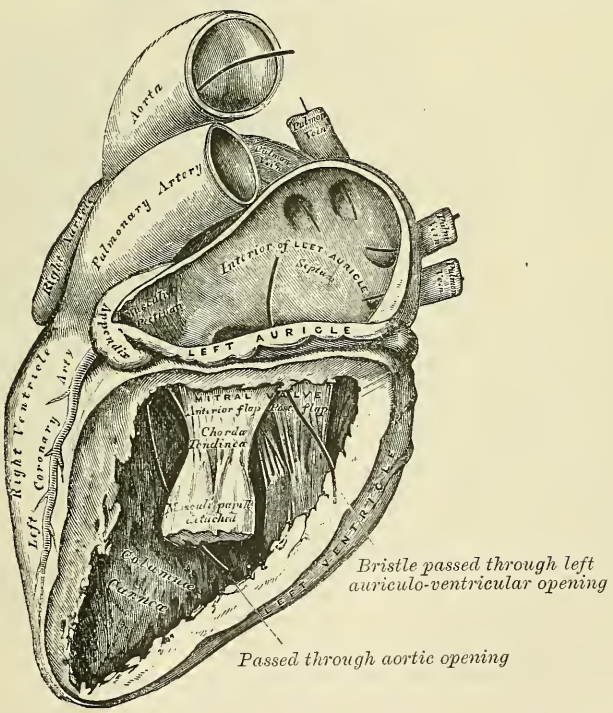
The *appendix auriculæ* is somewhat constricted at its junction with the auricle; it is longer, narrower, and more curved than that of the right side, and its margins more deeply indented, presenting a kind of foliated appearance. Its direction is forwards and towards the right side, overlapping the root of the pulmonary artery.

The following parts present themselves for examination:

The openings of the four pulmonary veins.
Auriculo-ventricular opening.
Musculi pectinati.

The *pulmonary veins*, four in number, open, two into the right, and two into the left side of the auricle. The two left veins frequently terminate by a common opening. They are not provided with valves.

Fig. 632.—The left auricle and ventricle laid open, the posterior walls of both being removed.



The *auriculo-ventricular opening* is the large oval aperture of communication between the auricle and ventricle. It is rather smaller than the corresponding opening on the opposite side (see note, page 1021).

The *musculi pectinati* are fewer in number and smaller than on the right side; they are confined to the inner surface of the appendix.

On the inner surface of the septum auricularum may be seen a lunated impression, bounded below by a crescentic ridge, the concavity of which is turned upwards. The depression is just above the fossa ovalis in the right auricle.

To examine the interior of the left ventricle, make an incision a little to the left of the anterior interventricular groove from the base to the apex of the heart, and carry it up from thence a little to the left of the posterior interventricular groove, nearly as far as the auriculo-ventricular groove.

The **Left Ventricle** is longer and more conical in shape than the right ventricle. It forms a small part of the left side of the anterior surface of the heart, and a considerable part of its posterior surface. It also forms the apex of the heart by its projection beyond the right ventricle. Its walls are much thicker than those of the right side, the proportion being as 3 to 1. They are also thickest in the broadest part of the ventricle, becoming gradually thinner towards the base, and also towards the apex, which is the thinnest part.

The following parts present themselves for examination:

Openings { Auriculo-ventricular. / Aortic. } Valves { Mitral. / Semilunar. }

Chordæ tendineæ. Columnæ carneæ.

The *auriculo-ventricular opening* is placed below and to the left of the aortic orifice. It is a little smaller than the corresponding aperture of the opposite side; and, like it, is broader in the transverse than in the antero-posterior diameter. It is surrounded by a dense fibrous ring, covered by the lining membrane of the heart, and guarded by the mitral valve.

The *aortic opening* is a circular aperture, in front and to the right side of the auriculo-ventricular, from which it is separated by one of the segments of the mitral valve. Its orifice is guarded by the semilunar valves.

The *mitral valve* is attached to the circumference of the auriculo-ventricular orifice in the same way that the tricuspid valve is on the opposite side. It is formed by a duplicature of the lining membrane, strengthened by fibrous tissue, and contains a few muscular fibres. It is larger in size, thicker, and altogether stronger than the tricuspid, and consists of two segments of unequal size. The larger segment is placed in front, between the auriculo-ventricular and aortic orifices, and is said to prevent the filling of the aorta during the distension of the ventricle. Two smaller segments are usually found at the angles of junction of the larger. The mitral valve-flaps are furnished with chordæ tendineæ, the mode of attachment of which is precisely similar to that of those on the right side; but they are thicker, stronger, and less numerous.

The *semilunar valves* surround the orifice of the aorta; two are posterior (right and left) and one anterior: they are similar in structure, and in their mode of attachment, to those of the pulmonary artery. They are, however, larger, thicker, and stronger than those of the right side; the lunulæ are more distinct, and the corpora Arantii larger and more prominent. Between each valve and the cylinder of the aorta is a deep depression, the *sinus aortici* (sinuses of Valsalva); they are larger than those of the root of the pulmonary artery.

The *columnæ carneæ* admit of a subdivision into three sets, like those upon the right side; but they are smaller, more numerous, and present a dense interlacement, especially at the apex, and upon the posterior wall. Those attached by one extremity only, the *musculi papillares*, are two in number, being connected one to the anterior, the other to the posterior wall; they are of large size, and terminate by free rounded extremities, from which the chordæ tendineæ arise.

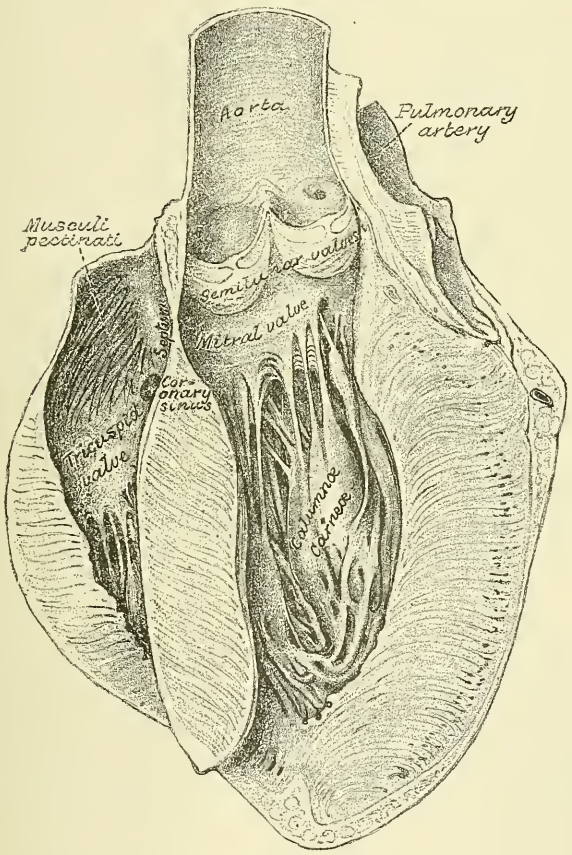
The septum between the two ventricles is thick, especially below (fig. 633). At its upper part it suddenly tapers off and becomes destitute of muscular fibres, consisting only of fibrous tissue, covered by two layers of endocardium; and on the right side also covered by one of the flaps of the tricuspid valve. It is continued upwards and forms the septum between the aortic vestibule and the right auricle. It is derived from the lower part of the aortic septum of the fœtus, and an abnormal communication may exist at this part owing to defective development of this septum.

The *Endocardium* is a thin membrane which lines the internal surface of the heart; it assists in forming the valves by its reduplications, and is continuous with the lining membrane of the great blood-vessels. It is a smooth, transparent membrane, giving to the inner surface of the heart its glistening appearance. It is more opaque on the left than on the right side of the heart, thicker in the auricles than in the ventricles, and thickest in the left auricle. It is thin on the musculi pectinati, and on the columnæ carneæ; but thicker on the smooth part of the auricular and ventricular walls, and on the tips of the musculi papillares.

Structure.—The heart consists of muscular fibres, and of fibrous rings which serve for their attachment.

The *fibrous rings* surround the auriculo-ventricular and arterial orifices: they are stronger upon the left than on the right side of the heart. The auriculo-

Fig. 633.—Section of the heart, showing the interauricular and interventricular septa.



ventricular rings serve for the attachment of the muscular fibres of the auricles and ventricles, and also for the mitral and tricuspid valves; the ring on the left side is closely connected, by its right margin, with the aortic arterial ring. Between these and the right auriculo-ventricular ring is a mass of fibrous tissue; and in some of the larger animals, as the ox and elephant, a nodule of bone.

The fibrous rings surrounding the arterial orifices serve for the attachment of the great vessels and semilunar valves. Each ring receives, by its ventricular margin, the attachment of the muscular fibres of the ventricles; its opposite margin presents three deep semicircular notches, within which the middle coat of the artery (which presents three convex semicircular segments) is firmly fixed; the attachment of the artery to its fibrous ring being strengthened by the

thin cellular coat and serous membrane externally, and by the endocardium within. It is opposite the margins of these semicircular notches, in the arterial rings, that the endocardium, by its reduplication, forms the semilunar valves, the fibrous structure of the ring being continued into each of the segments of the valve at this part. The middle coat of the artery in this situation is thin, and the sides of the vessel are dilated to form the sinuses of Valsalva.

The *muscular structure of the heart* consists of bands of fibres, which present an exceedingly intricate interlacement. They are of a deep red colour, and marked with transverse striæ (page 40).

The muscular fibres of the heart admit of a subdivision into two kinds, those of the auricles and those of the ventricles, which are quite independent of one another.

Fibres of the Auricles.—These are disposed in two layers—a superficial layer common to both cavities, and a deep layer proper to each. The *superficial fibres* are more distinct on the anterior surface of the auricles, across the bases of which they run in a transverse direction, forming a thin but incomplete layer. Some of these fibres pass into the septum auricularum. The *internal* or *deep fibres* proper to each auricle consist of two sets, looped and annular fibres. The *looped fibres* pass upwards over each auricle, being attached by their two extremities to the corresponding auriculo-ventricular rings, in front and behind. The *annular fibres* surround the whole extent of the appendices auricularum, and are continued upon the walls of the venæ cavæ and coronary sinus on the right side, and upon the pulmonary veins on the left side, at their connection with the heart. In the appendices they interlace with the longitudinal fibres.

Fibres of the Ventricles.—These are arranged in an exceedingly complex manner, and the accounts given by various anatomists differ considerably. This is probably due, partly, to the fact that the various layers of muscular fibre of which the heart is said to be composed are not independent, but their fibres are interlaced to a considerable extent, and therefore any separation into layers must be to a great extent artificial, and also no doubt partly due to the fact, pointed out by Henle, that there are varieties in the arrangement due to individual differences. If the epicardium (visceral layer of pericardium) and the subjacent fat is removed from a heart which has been subjected to prolonged boiling, so as to dissolve the connective tissues, the superficial fibres of the ventricles will be exposed. They will be seen to commence at the base of the heart, where they are attached to the tendinous rings around the orifices, and to pass obliquely downwards towards the apex, with a direction from right to left. At the apex the fibres turn suddenly inwards, into the interior of the ventricle, forming what is called the *vortex*. On the back of the heart it will be seen that the fibres pass continuously from one ventricle to the other over the interventricular groove; and the same thing will be noticed on the front of the heart at the upper and lower end of the anterior interventricular groove, but in the middle portion of this groove the fibres passing from one ventricle to the other are interrupted by fibres emerging from the septum along the groove; many of the superficial fibres pass in also at this groove to the septum. The vortex is produced, as stated above, by the sudden turning inwards of the superficial fibres in a peculiar spiral manner into the interior of the ventricle. Those fibres which descend on the posterior surface of the heart, enter the left ventricle at the vortex, and, ascending, form the posterior part of the inner layer of muscular fibres lining this cavity and the right (posterior) musculus papillaris; those fibres which descend on the front of the heart, to reach the apex, also pass, at the vortex, into the interior of the ventricle, where they form the remainder of the innermost layer of the ventricle and the left (anterior) musculus papillaris. The fibres forming the inner layer of the wall of the ventricle ascend to be attached to the fibrous rings around the orifices.

By dissection these superficial fibres may be removed as a thin stratum, and it will then be found that the ventricles are made up of oblique fibres, super-

imposed in layers one on the top of another, and assuming gradually a less oblique direction as they pass to the middle of the thickness of the ventricular wall, so that in the centre of the wall the fibres are transverse. Internal to this central transverse layer the fibres become oblique again, but in the opposite direction to the external ones. This division into distinct layers is, however, to a great extent artificial, as the fibres pass across from one layer to another, and have therefore to be divided in the dissection, and the change in the direction of the fibres is very gradual. These oblique fibres commence above at the fibrous rings at the base of the heart, and descending towards the apex they enter the septum near its lower end. In the septum the fibres which form the left ventricle may be traced in three directions. 1. Some pass upwards to be attached to the central mass of fibrous tissue. 2. Others pass through the septum to become continuous with the fibres of the right ventricle. 3. And the remainder pass through the septum to encircle the ventricle as annular fibres. Of the fibres of the right ventricle, some on entering the septum pass upwards to be attached to the central mass of fibrous tissue; some entering the septum from behind pass forwards to become continuous with the fibres on the anterior surface of the left ventricle; and others entering in front pass backwards to join the fibres on the posterior wall of the left ventricle. The septum therefore consists of three varieties of fibres: viz. annular fibres special to the left ventricle; ascending fibres, derived from both ventricles and ascending through the septum to the central fibro-cartilage; and decussating fibres derived from the anterior wall of one ventricle and passing to the posterior wall of the other ventricle, or from the posterior wall of the right ventricle and passing to the anterior wall of the left. In addition to these fibres, there are a considerable number which appear to encircle both ventricles and which pass across the septum without turning into it.

Vessels and Nerves.—The *arteries* supplying the heart are the left or anterior and right or posterior coronary (page 549).

The *veins* accompany the arteries, and terminate in the right auricle. They are, the anterior, posterior, left and right cardiac veins, the right or small, and the left or great, coronary sinuses and the venæ cordis minimæ (*venæ Thebesii*) (page 695).

The *lymphatics* terminate in the thoracic and right lymphatic ducts.

The *nerves* are derived from the cardiac plexuses, which are formed partly from the cranial nerves, and partly from the sympathetic. They are freely distributed both on the surface and in the substance of the heart, the separate filaments being furnished with small ganglia.

Surface Form.—In order to show the extent of the heart in relation to the front of the chest, draw a line from the lower border of the second left costal cartilage, one inch from the sternum, to the upper border of the third right costal cartilage, half an inch from the sternum. This represents the base line, or upper limit of the organ. Take a point an inch and a half below, and three-quarters of an inch internal to the left nipple, that is, about three and a half inches to the left of the median line of the body. This represents the apex of the heart. Draw a line from this apex point, with a slight convexity downwards, to the junction of the seventh right costal cartilage to the sternum. This represents the lower limit of the heart. Join the right extremity of the first line—that is, the base line—with the right extremity of this line—that is, to the seventh right chondro-sternal joint—with a slight curve outwards, so that it projects about an inch and a half from the middle line of the sternum. Lastly, join the left extremity of the base line and the apex point by a line curved slightly to the left.

The position of the various orifices is as follows: viz. the pulmonary orifice is situated in the upper angle formed by the articulation of the third left costal cartilage with the sternum; the aortic orifice is a little below and internal to this, behind the left border of the sternum, close to the articulation of the third left costal cartilage to this bone. The left auriculo-ventricular opening is behind the sternum, rather to the left of the median line and opposite the fourth costal cartilages. The right auriculo-ventricular opening is a little lower, opposite the fourth interspace and in the middle line of the body (fig. 630).

A portion of the area of the heart thus mapped out is uncovered by lung, and therefore gives a dull note on percussion; the remainder, being overlapped by the lung, gives a more or less resonant note. The former is known as the area of superficial cardiac

dulness; the latter, as the area of deep cardiac dulness. The area of superficial cardiac dulness is included between a line drawn from the centre of the sternum, on a level with the fourth costal cartilages, to the apex of the heart, and a line drawn from the same point down the lower third of the middle line of the sternum. Below, this area merges into the dulness which corresponds to the liver. Dr. Latham lays down the following rule as a sufficient practical guide for the definition of the portion of the heart which is uncovered by lung or pleura: 'Make a circle of two inches in diameter round a point midway between the nipple and the end of the sternum.'

Peculiarities in the Vascular System of the Fœtus

The chief peculiarities in the heart of the fœtus are the direct communication between the two auricles through the foramen ovale, and the large size of the Eustachian valve. There are also several minor peculiarities. Thus, the position of the heart is vertical until the fourth month, when it commences to assume an oblique direction. Its size is also very considerable as compared with the body, the proportion at the second month being 1 to 50; at birth it is as 1 to 120; whilst in the adult the average is about 1 to 160. At an early period of fœtal life the auricular portion of the heart is larger than the ventricular, the right auricle being more capacious than the left; but towards birth the ventricular portion becomes the larger. The thickness of both ventricles is, at first, about equal, but towards birth the left becomes much the thicker of the two.

The *foramen ovale* is situated at the lower and back part of the septum auricularum, forming a communication between the auricles. It remains as a free oval opening, from the time of the formation of the auricular septum (about the eighth week) until the middle period of fœtal life. About this period a fold grows up from the posterior wall of the auricle, to the left of the foramen ovale, and advances over the opening, so as to form a sort of valve, which allows the blood to pass only from the right to the left auricle, and not in the opposite direction.

The *Eustachian valve* is developed from the anterior border of the inferior vena cava at its entrance into the auricle. It is directed upwards on the left side of the opening of this vein, and serves to direct the blood from the inferior vena cava through the foramen ovale into the left auricle.

The peculiarities in the arterial system of the fœtus are the communication between the pulmonary artery and the descending aorta by means of the *ductus arteriosus*, and the communication between the internal iliac arteries and the placenta by means of the umbilical arteries.

The *ductus arteriosus* is a short tube, about half an inch in length at birth, and of the diameter of a goose-quill. In the early condition it forms the continuation of the pulmonary artery, and opens into the descending aorta, just below the origin of the left subclavian artery; and so conducts the chief part of the blood from the right ventricle into this vessel. When the branches of the pulmonary artery have become larger relatively to the ductus arteriosus, the latter is chiefly connected to the left pulmonary artery; and the fibrous cord, which is all that remains of the ductus arteriosus in later life, will be found to be attached to the root of that vessel.

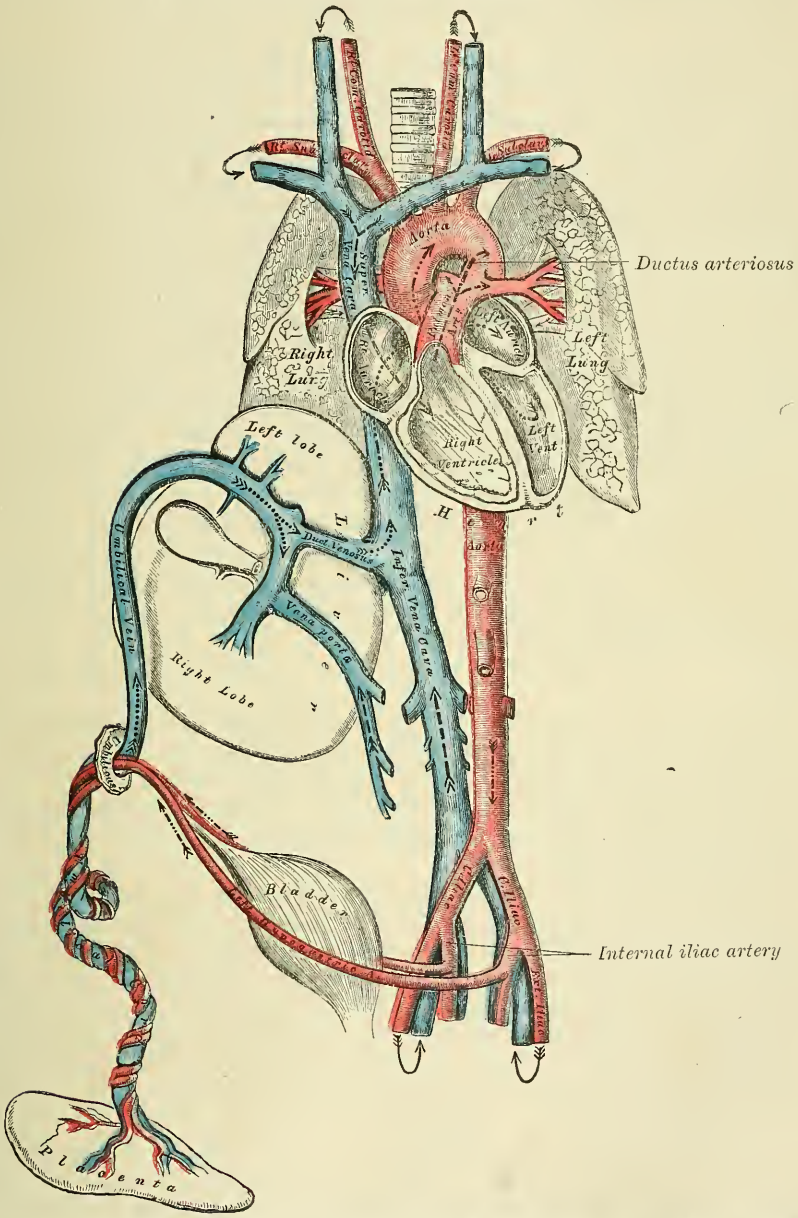
The *umbilical* or *hypogastric arteries* arise from the internal iliacs, in addition to the branches given off from those vessels in the adult. Ascending along the sides of the bladder to its fundus, they pass out of the abdomen at the umbilicus and are continued along the umbilical cord to the placenta, coiling round the umbilical vein. They return to the placenta the blood which has circulated in the system of the fœtus.

The peculiarity in the venous system of the fœtus is the communication established between the placenta and the liver and portal vein, through the umbilical vein; and the inferior vena cava through the ductus venosus.

Fœtal Circulation

The blood destined for the nutrition of the fœtus is carried from the placenta to the fœtus, along the umbilical cord, by the umbilical vein. The umbilical vein enters the abdomen at the umbilicus, and passes upwards along the free margin

Fig. 634.—Plan of the fœtal circulation.



In this plan the figured arrows represent the kind of blood, as well as the direction which it takes in the vessels. Thus—arterial blood is figured ≫·····→; venous blood, ≫– – – –→; mixed (arterial and venous) blood, ≫·—·—·→

of the suspensory ligament of the liver to the under surface of that organ, where it gives off two or three branches to the left lobe, one of which is of large size; and others to the lobus quadratus and lobulus Spigelii. At the transverse fissure it divides into two branches: of these, the larger is joined by the portal vein, and

enters the right lobe; the smaller branch continues onwards, under the name of the ductus venosus, and joins the left hepatic vein at the point of junction of that vessel with the inferior vena cava. The blood, therefore, which traverses the umbilical vein, reaches the inferior vena cava in three different ways. The greater quantity circulates through the liver with the portal venous blood, before entering the vena cava by the hepatic veins; some enters the liver directly, and is also returned to the inferior cava by the hepatic veins: the smaller quantity passes directly into the vena cava, by the junction of the ductus venosus with the left hepatic vein.

In the inferior cava, the blood carried by the ductus venosus and hepatic veins becomes mixed with that returning from the lower extremities and viscera of the abdomen. It enters the right auricle, and, guided by the Eustachian valve, passes through the foramen ovale into the left auricle, where it becomes mixed with a small quantity of blood returned from the lungs by the pulmonary veins. From the left auricle it passes into the left ventricle; and from the left ventricle into the aorta, by means of which it is distributed almost entirely to the head and upper extremities, a small quantity being probably carried into the descending aorta. From the head and upper extremities the blood is returned by the branches of the superior vena cava to the right auricle, where it becomes mixed with a small portion of the blood from the inferior cava. From the right auricle it descends over the Eustachian valve into the right ventricle; and from the right ventricle, passes into the pulmonary artery. The lungs of the fœtus being solid, and almost impervious, only a small quantity of the blood of the pulmonary artery is distributed to them, by the right and left pulmonary arteries, and is returned by the pulmonary veins to the left auricle: the greater part passes through the ductus arteriosus into the commencement of the descending aorta, where it becomes mixed with a small quantity of blood transmitted by the left ventricle into the aorta. Along this vessel it descends to supply the lower extremities and viscera of the abdomen and pelvis, the chief portion being, however, conveyed by the umbilical arteries to the placenta.

From the preceding account of the circulation of the blood in the fœtus, it will be seen—

1. That the placenta serves the double purpose of a respiratory and nutritive organ, receiving the venous blood from the fœtus, and returning it again re-oxygenated, and charged with additional nutritive material.

2. That nearly the whole of the blood of the umbilical vein traverses the liver before entering the inferior cava; hence the large size of this organ, especially at an early period of fœtal life.

3. That the right auricle is the point of meeting of a double current, the blood in the inferior cava being guided by the Eustachian valve into the left auricle, whilst that in the superior cava descends into the right ventricle. At an early period of fœtal life it is highly probable that the two streams are quite distinct; for the inferior cava opens almost directly into the left auricle, and the Eustachian valve would exclude the current along the vein from entering the right ventricle. At a later period, as the separation between the two auricles becomes more distinct, it seems probable that some mixture of the two streams must take place.

4. The blood carried from the placenta to the fœtus by the umbilical vein, mixed with the blood from the inferior cava, passes almost directly to the arch of the aorta, and is distributed by the branches of that vessel to the head and upper extremities: hence the large size and perfect development of those parts at birth.

5. The blood contained in the descending aorta, chiefly derived from that which has already circulated through the head and limbs, together with a small quantity from the left ventricle, is distributed to the lower extremities: hence the small size and imperfect development of these parts at birth.

Changes in the Vascular System at Birth

At birth, when respiration is established, an increased amount of blood from the pulmonary artery passes through the lungs, which now perform their office as respiratory organs, and, at the same time, the placental circulation is cut off. The foramen ovale becomes gradually closed by about the tenth day after birth: the valvular fold above mentioned becomes adherent to the margins of the foramen for the greater part of its circumference, but above a slit-like opening is left between the two auricles which sometimes remains persistent.

The *ductus arteriosus* begins to contract immediately after respiration is established, becomes completely closed from the fourth to the tenth day, and ultimately degenerates into an impervious cord, which serves to connect the left pulmonary artery to the descending aorta.

Of the *umbilical* or *hypogastric arteries*, the portion continued on to the bladder from the trunk of the corresponding internal iliac remains pervious, as the superior vesical artery; and the part between the fundus of the bladder and the umbilicus becomes obliterated between the second and fifth days after birth, and projects into the peritoneal sac, so as to form two of the fossæ of the peritoneum, spoken of in the section on the surgical anatomy of direct inguinal hernia.

The *umbilical vein* and *ductus venosus* become completely obliterated between the second and fifth days after birth, and ultimately dwindle to fibrous cords; the former becoming the round ligament of the liver, the latter the fibrous cord which, in the adult, may be traced along the fissure of the ductus venosus.

ORGANS OF VOICE AND RESPIRATION

The Larynx

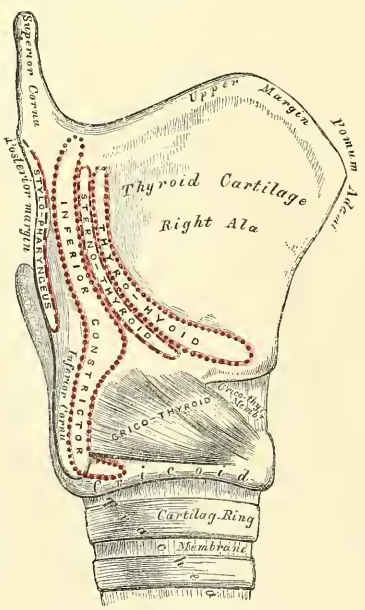
THE Larynx is the organ of voice, placed at the upper part of the air-passage. It is situated between the trachea and base of the tongue, at the upper and fore part of the neck, where it forms a considerable projection in the middle line. On either side of it lie the great vessels of the neck; behind, it forms part of the boundary of the pharynx, and is covered by the mucous membrane lining that cavity.

The larynx is broad above, where it presents the form of a triangular box, flattened behind and at the sides, and bounded in front by a prominent vertical ridge. Below, it is narrow and cylindrical. It is composed of cartilages, which are connected together by ligaments and moved by numerous muscles. It is lined by mucous membrane, which is continuous above with that lining the pharynx and below with that of the trachea.

The **Cartilages of the Larynx** are nine in number, three single, and three pairs:

Thyroid.	Two Arytenoid.
Cricoid.	Two Cornicula Laryngis.
Epiglottis.	Two Cuneiform.

Fig. 635.—Side view of the thyroid and cricoid cartilages.



The **Thyroid** (*θυρεός, a shield*) is the largest cartilage of the larynx. It consists of two lateral lamellæ or alæ, united at an acute angle in front, forming a vertical projection in the middle line which is prominent above, and called the *pomum Adami*. This projection is subcutaneous, more distinct in the male than in the female, and occasionally separated from the integument by a bursa mucosa.

Each lamella is quadrilateral in form. Its *outer surface* presents an oblique ridge, which passes downwards and forwards from a tubercle, situated near the root of the superior cornu, to the anterior part of the lower border. This ridge gives attachment to the Sterno-thyroid and Thyro-hyoid muscles, and the portion of cartilage included between it and the posterior border to part of the Inferior constrictor muscle.

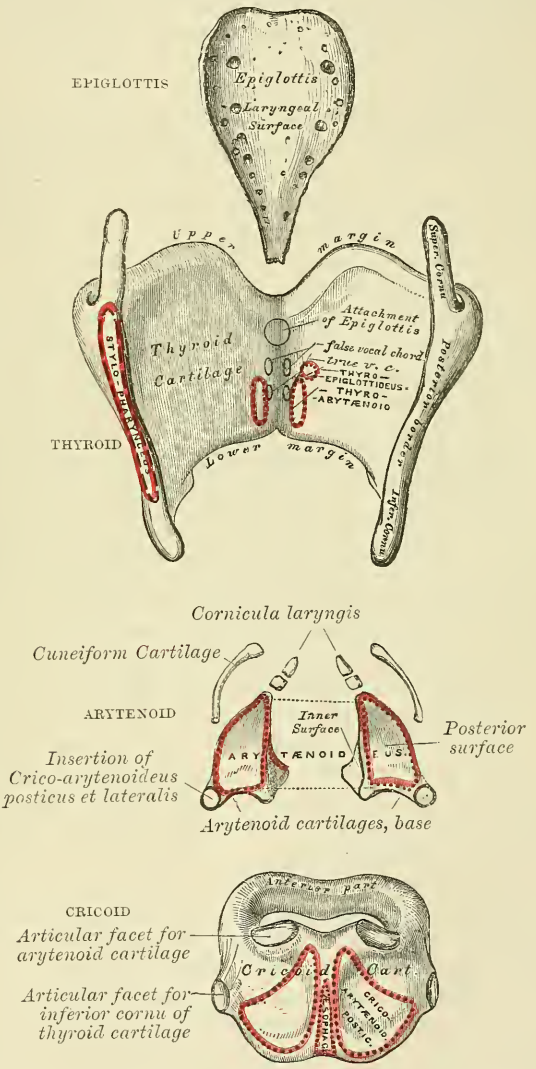
The *inner surface* of each ala is smooth, slightly concave, and covered by mucous membrane above and behind; but in front, in the receding angle formed by their junction, are attached the epiglottis, the true and false vocal cords, the Thyro-arytenoid and Thyro-epiglottidean muscles.

The *upper border of the thyroid cartilage* is sinuously curved, being concave at its posterior part, just in front of the superior cornu, then rising into a convex outline, which dips in front to form the sides of a notch, the *thyroid notch*, in the middle line, immediately above the pomum Adami. This border gives attachment throughout its whole extent to the thyro-hyoid membrane.

The *lower border* is nearly straight in front, but behind, close to the cornu, is concave. It is connected to the cricoid cartilage, in the median line, by the crico-thyroid membrane; and, on each side, by the Crico-thyroid muscle.

The *posterior borders*, thick and rounded, terminate, above, in the *superior cornua*; and, below, in the *inferior cornua*. The two superior cornua are long and narrow, directed upwards, backwards, and inwards; and terminate in a conical extremity, which gives attachment to the thyro-hyoid ligament. The two inferior cornua are short and thick; they pass downwards, with a slight inclination forwards and inwards, and present, on their inner surfaces, a small oval articular facet for articulation with the side of the cricoid cartilage. The posterior border receives the insertion of the Stylo-pharyngeus and Palato-pharyngeus muscles on each side.

Fig. 636.—The cartilages of the larynx. Posterior view.



The **Cricoid Cartilage** is so called from its resemblance to a signet ring (κρίκος, *a ring*). It is smaller, but thicker and stronger than the thyroid cartilage, and forms the lower and back part of the cavity of the larynx. It consists of two parts: a quadrate portion, situated behind, and a narrow ring or arch, one-fourth or one-fifth the depth of the posterior part, situated in front. The posterior square portion rapidly narrows at the sides of the cartilage, at the expense of the upper border, into the anterior portion.

Its *posterior portion* is very broad, both from side to side, and from above downwards; it presents, on its posterior surface, in the middle line a vertical ridge for the attachment of the longitudinal fibres of the œsophagus; and on either side a broad depression for the Crico-arytenoideus posticus muscle.

Its *anterior portion* is narrow and convex, affording attachment externally in front and at the sides to the Crico-thyroid muscles, and, behind, to part of the Inferior constrictor.

At the point of junction of the posterior quadrate portion with the rest of the cartilage is a small round elevation, for articulation with the inferior cornu of the thyroid cartilage.

The *lower border of the cricoid cartilage* is horizontal, and connected to the upper ring of the trachea by fibrous membrane.

Its *upper border* is directed obliquely upwards and backwards, owing to the great depth of its posterior surface. It gives attachment, in front, to the crico-thyroid membrane; at the sides, to part of the same membrane and to the lateral Crico-arytenoid muscle; behind, the highest point of the upper border is surmounted on each side by a smooth oval surface, for articulation with the arytenoid cartilage. Between the articular surfaces is a slight notch, for the attachment of part of the Arytenoideus muscle.

The *inner surface of the cricoid cartilage* is smooth, and lined by mucous membrane.

The **Arytenoid Cartilages** are so called from the resemblance they bear, when approximated, to the mouth of a pitcher (*ἀρύταινα, a pitcher*). They are two in number, and situated at the upper border of the cricoid cartilage, at the back of the larynx. Each cartilage is pyramidal in form, and presents for examination three surfaces, a base, and an apex.

The *posterior surface* is triangular, smooth, concave, and gives attachment to the Arytenoid muscle.

The *anterior* or *external surface* is somewhat convex and rough. It presents rather below its centre a transverse ridge, to the inner extremity of which is attached the false vocal cord, and to the outer part, as well as the surfaces above and below, is attached the Thyro-arytenoid muscle.

The *internal surface* is narrow, smooth, and flattened, covered by mucous membrane, and lies almost in apposition with the cartilage of the opposite side.

The *base* of each cartilage is broad, and presents a concave smooth surface, for articulation with the cricoid cartilage. Of its three angles, the *external* is short, rounded, and prominent; it projects backwards and outwards, and is termed the *muscular process*, from receiving the insertion of the Posterior and Lateral crico-arytenoid muscles. The *anterior angle*, also prominent, but more pointed, projects horizontally forwards, and gives attachment to the true vocal cord. This angle is called the *vocal process*.

The *apex* of each cartilage is pointed, curved backwards and inwards, and surmounted by a small conical-shaped, cartilaginous nodule, the *corniculum laryngis*.

The **cornicula laryngis** (*cartilages of Santorini*) are two small conical nodules, consisting of yellow fibro-cartilage, which articulate with the summit of the arytenoid cartilages and serve to prolong them backwards and inwards. To them are attached the aryteno-epiglottidean folds. They are sometimes united to the arytenoid cartilages.

The **cuneiform cartilages** (*cartilages of Wrisberg*) are two small, elongated, cartilaginous bodies, placed one on each side, in the fold of mucous membrane which extends from the apex of the arytenoid cartilage to the side of the epiglottis (*aryteno-epiglottidean fold*); they give rise to small whitish elevations on the inner surface of the mucous membrane, just in front of the arytenoid cartilages.

The **epiglottis** is a thin lamella of fibro-cartilage, of a yellowish colour, shaped like a leaf, and placed behind the tongue in front of the superior opening of the larynx. During respiration its direction is vertically upwards, its free extremity curving forwards towards the base of the tongue; but when the larynx is drawn up beneath the base of the tongue during deglutition, it is carried downwards and backwards, so as to completely close the opening of the larynx. Its free extremity is broad and rounded; its attached end is long and narrow, and connected to the receding angle between the two alæ of the thyroid cartilage, just below the median notch, by a long, narrow, ligamentous band, the *thyro-epiglottic ligament*. It is also connected to the posterior surface of the body of the hyoid bone by an elastic ligamentous band, the *hyo-epiglottic ligament*.

Its *anterior* or *lingual surface* is curved forwards towards the tongue, and covered at its upper part by mucous membrane, which is reflected on to the sides and base of the organ, forming a median and two lateral folds, the *glosso-epiglottidean ligaments.*

Its *posterior* or *laryngeal surface* is smooth, concave from side to side, concavo-convex from above downwards, and covered by mucous membrane; when this is removed. the surface of the cartilage is seen to be studded with a number of small mucous glands, which are lodged in little pits upon its surface. To its sides the aryteno-epiglottidean folds are attached.

Structure.—The cornicula laryngis, cuneiform cartilages, and epiglottis are composed of yellow fibro-cartilage, which shows little tendency to calcification; but the other cartilages resemble in structure the costal cartilages, becoming more or less calcified in old age.

Ligaments.—The ligaments of the larynx are *extrinsic*, i.e. those connecting the thyroid cartilage and epiglottis with the hyoid bone, and the cricoid cartilage with the trachea; and *intrinsic*, those which connect the several cartilages of the larynx to each other.

The ligaments connecting the thyroid cartilage with the hyoid bone are three in number—the thyro-hyoid membrane, and the two lateral thyro-hyoid ligaments.

The *thyro-hyoid membrane* is a broad, fibro-elastic, membranous layer, attached below to the upper border of the thyroid cartilage, and above to the upper border of the posterior surface of the hyoid bone, thus passing behind the posterior surface, and being separated from it by a synovial bursa. It is thicker in the middle line than at either side, in which situation it is pierced by the superior laryngeal vessels and nerve.

The *two lateral thyro-hyoid ligaments* are rounded, elastic cords, which pass between the superior cornua of the thyroid cartilage and the extremities of the greater cornua of the hyoid bone. A small cartilaginous nodule (*cartilago triticea*), sometimes bony, is frequently found in each.

The ligament connecting the epiglottis with the hyoid bone is the hyo-epiglottic. In addition to this extrinsic ligament, the epiglottis is connected to the tongue by the three glosso-epiglottidean folds of mucous membrane, which may also be considered as extrinsic ligaments of the epiglottis.

The *hyo-epiglottic ligament* is an elastic fibrous band, which extends from the anterior surface of the epiglottis, near its apex, to the upper border of the body of the hyoid bone.

The ligaments connecting the thyroid cartilage to the cricoid are also three in number—the crico-thyroid membrane, and the capsular ligaments.

The *crico-thyroid membrane* is composed mainly of yellow elastic tissue. It consists of three parts, a central, triangular portion and two lateral portions. The central part is thick and strong, narrow above and broadening out below. It connects together the contiguous margins of the thyroid and cricoid cartilages. It is convex, concealed on each side by the crico-thyroid muscle, but subcutaneous in the middle line; it is crossed horizontally by a small anastomotic arterial arch, formed by the junction of the two crico-thyroid arteries. The lateral portions are thinner and lie close under the mucous membrane of the larynx. They extend from the superior border of the cricoid cartilage to the inferior margin of the true vocal cords, with which it is closely united in front.

The lateral portions are lined internally by mucous membrane, and covered by the lateral Crico-arytenoid and Thyro-arytenoid muscles.

A *capsular ligament* encloses the articulation of the inferior cornu of the thyroid with the cricoid cartilage on each side. The articulation is lined by synovial membrane.

The ligaments connecting the arytenoid cartilages to the cricoid are two

capsular ligaments, and two *posterior crico-arytenoid ligaments*. The *capsular crico-arytenoid ligaments* are thin and loose capsules attached to the margin of the articular surfaces; they are lined internally by synovial membrane. The *posterior crico-arytenoid ligaments* extend from the cricoid to the inner and back part of the base of the arytenoid cartilage.

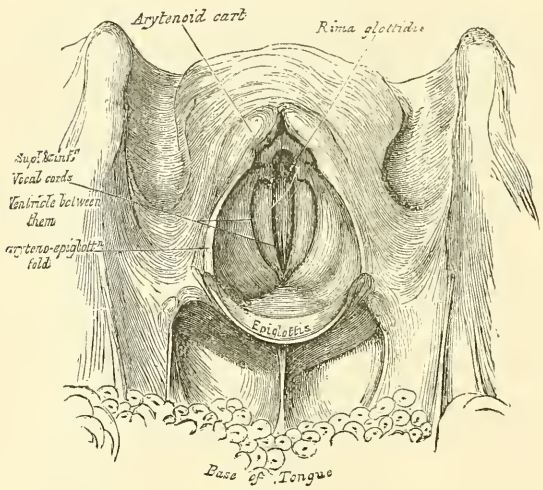
The ligament connecting the epiglottis with the thyroid cartilage is the thyro-epiglottic.

The *thyro-epiglottic ligament* is a long, slender, elastic cord which connects the apex of the epiglottis with the receding angle of the thyroid cartilage, immediately beneath the median notch, above the attachment of the vocal cords.

The *crico-tracheal ligament* connects the cricoid cartilage with the first ring of the trachea. It resembles the fibrous membrane which connects the cartilaginous rings of the trachea to each other.

Interior of the Larynx.—The *cavity of the larynx* extends from the superior aperture to the lower border of the cricoid cartilage. It is divided into two parts by the projection inwards of the vocal cords; between the two cords is a long and narrow triangular fissure or chink, the *rima glottidis*. The portion of the cavity of the larynx above the true vocal cords, sometimes called the *vestibule*, is broad and triangular in shape, and corresponds to the interval between the alæ of the thyroid cartilage; it contains the false vocal cords, and between these and the true vocal cords are the ventricles of the larynx. The portion below the true vocal cords is at first of an elliptical, and lower down of a circular form.

Fig. 637.—The larynx and adjacent parts, seen from above.



The *superior aperture of the larynx* (fig. 637) is a triangular or cordiform opening, wide in front, narrow behind, and sloping obliquely downwards and backwards. It is bounded, in front, by the epiglottis; behind, by the apices of the arytenoid cartilages, and the cornicula laryngis; and laterally, by a fold of mucous membrane, enclosing ligamentous and muscular fibres, stretched between the sides of the epiglottis and the apex of the arytenoid cartilages: these are the *aryteno-epiglottidean folds*, on the margins of which the cuneiform cartilages form more or less distinct whitish prominences.

The *rima glottidis* is the narrow fissure or chink between the inferior or true vocal cords. It is the narrowest part of the cavity of the larynx, and corresponds to the lower level of the arytenoid cartilages. Its length, in the male, measures rather less than an inch; its breadth, when dilated, varying at its widest part from a third to half an inch. In the female these measurements are less by two or three lines. The form of the rima glottidis varies. In its half-closed condition it is a narrow fissure, a little enlarged and rounded behind. In quiet breathing it is widely open, somewhat triangular, the base of the triangle directed backwards, and corresponding to the space between the separated arytenoid cartilages. In forcible expiration it is smaller than during inspiration. When sound is produced it is more narrowed, the margins of the arytenoid cartilages being brought into contact, and the edges of the vocal cords approximated and

made parallel, the degree of approximation and tension corresponding to the height of the note produced.*

The *superior* or *false vocal cords*, so called because they are not directly concerned in the production of the voice, are two folds of mucous membrane, enclosing a delicate narrow fibrous band, the *superior thyro-arytenoid ligament*. This ligament consists of a thin band of connective tissue, attached in front to the angle of the thyroid cartilage below the epiglottis, and behind to the anterior surface of the arytenoid cartilage. The lower border of this ligament, enclosed in mucous membrane, forms a free crescentic margin, which constitutes the upper boundary of the ventricle of the larynx.

The *inferior* or *true vocal cords*, so called from their being concerned in the production of sound, are two strong fibrous bands (*inferior thyro-arytenoid ligaments*), covered on their surface by a thin layer of mucous membrane. Each ligament consists of a band of yellow elastic tissue, attached in front to the depression between the two alæ of the thyroid cartilage, and behind to the anterior angle (vocal process) of the base of the arytenoid. Its lower border is continuous with the thin lateral part of the crico-thyroid membrane. Its upper border forms the lower boundary of the ventricle of the larynx. Externally, the Thyro-arytenoideus muscle lies parallel with it. It is covered internally by mucous membrane, which is extremely thin, and closely adherent to its surface.

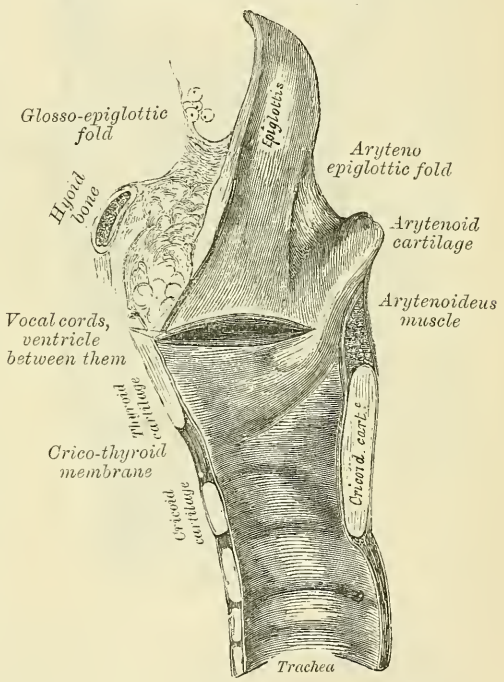


Fig. 638.—Vertical section of the larynx and upper part of the trachea.

The *ventricle of the larynx* is an oblong fossa, situated between the superior and inferior vocal cords on each side, and extending nearly their entire length. This fossa is bounded, above, by the free crescentic edge of the superior vocal cord; below, by the straight margin of the true vocal cord; externally, by the corresponding Thyro-arytenoideus muscle. The anterior part of the ventricle leads up by a narrow opening into a cæcal pouch of mucous membrane of variable size, called the *laryngeal pouch*.

The *sacculus laryngis*, or laryngeal pouch, is a membranous sac, placed between the superior vocal cord and the inner surface of the thyroid cartilage, occasionally extending as far as its upper border: it is conical in form, and curved slightly backwards. On the surface of its mucous membrane are the openings of sixty or seventy small follicular glands, which are lodged in the submucous areolar tissue. This sac is enclosed in a fibrous capsule, continuous below with the superior thyro-arytenoid ligament: its laryngeal surface is covered by the Aryteno-epiglottideus inferior muscle (*Compressor sacculi laryngis*, Hilton); whilst its exterior is covered by the Thyro-arytenoideus and Thyro-epiglottideus muscles. These muscles compress the sacculus laryngis, and discharge the secretion it contains upon the chordæ vocales, the surfaces of which it is intended to lubricate.

* On the shape of the rima glottidis, in the various conditions of breathing and speaking, see Czermak, *On the Laryngoscope*, translated for the *New Sydenham Society*.

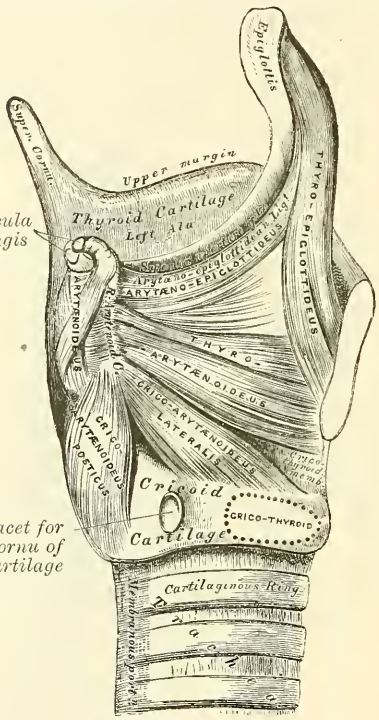
Muscles.—The intrinsic muscles of the larynx are eight in number, five of which are the muscles of the vocal cords and rima glottidis, and three are connected with the epiglottis.

The five muscles of the vocal cords and rima glottidis are—the

Crico-thyroid.	Arytenoideus.
Crico-arytenoideus posticus.	Thyro-arytenoideus.
Crico-arytenoideus lateralis.	

The *Crico-thyroid* is triangular in form, and situated at the fore part and side of the cricoid cartilage. It arises from the front and lateral part of the cricoid cartilage; its fibres diverge, passing obliquely upwards and outwards, to be inserted into the lower border of the thyroid cartilage, and into the anterior border of the lower cornua.

Fig. 639.—Muscles of larynx. Side view. Right ala of thyroid cartilage removed.



The inner borders of these two muscles are separated in the middle line by a triangular interval, occupied by the crico-thyroid membrane.

The *Crico-arytenoideus posticus* arises from the broad depression occupying each lateral half of the posterior surface of the cricoid cartilage; its fibres pass upwards and outwards, converging to be inserted into the outer angle of the base of the arytenoid cartilage (the muscular process). The upper fibres are nearly horizontal, the middle oblique, and the lower almost vertical.*

The *Crico-arytenoideus lateralis* is smaller than the preceding, and of an oblong form. It arises from the upper border of the side of the cricoid cartilage, and, passing obliquely upwards and backwards, is inserted into the muscular process of the arytenoid cartilage, in front of the preceding muscle.

The *Arytenoideus* is a single muscle, filling up the posterior concave surface of the arytenoid cartilages. It arises from the posterior surface and outer border of one arytenoid cartilage, and is inserted into the corresponding parts of the opposite cartilage. It consists of three planes of fibres, two oblique and one transverse. The *oblique fibres*, the most superficial, form two fasciculi, which pass from the base of one cartilage to the apex of the opposite one. The *transverse fibres*, the deepest and most numerous, pass transversely across between the two cartilages; hence the Arytenoideus was formerly considered as several muscles, under the name of *transversi* and *obliqui*. A few of the oblique fibres are occasionally continued round the outer margin of the cartilage, and blend with the Thyro-arytenoid or the Aryteno-epiglottideus muscle.

* Dr. Merkel, of Leipsic, has described a muscular slip which occasionally extends between the outer border of the posterior surface of the cricoid cartilage and the posterior margin of the inferior cornu of the thyroid; this he calls the 'Musculus kerato-cricoideus.' It is not found in every larynx, and when present exists usually only on one side, but is occasionally found on both sides. Sir Wm. Turner (*Edinburgh Medical Journal*, Feb. 1860) states that it is found in about one case in five. Its action is to fix the lower horn of the thyroid cartilage backwards and downwards, opposing in some measure the part of the Crico-thyroid muscle which is connected to the anterior margin of the horn.

The *Thyro-arytenoideus* is a broad, flat muscle, which lies parallel with the outer side of the true vocal cord. It arises in front from the lower half of the receding angle of the thyroid cartilage, and from the crico-thyroid membrane. Its fibres pass horizontally backwards and outwards, to be inserted into the base and anterior surface of the arytenoid cartilage. This muscle consists of two fasciculi.* The *inner* or *inferior portion*, the thicker, is inserted into the vocal process of the arytenoid cartilage, and into the adjacent portion of its anterior surface; it lies parallel with the true vocal cord, to which it is adherent. The *outer* or *superior fasciculus*, the thinner, is inserted into the anterior surface and outer border of the arytenoid cartilage above the preceding fibres; it lies on the outer side of the sacculus laryngis, immediately beneath the mucous membrane.†

The muscles of the epiglottis are, the

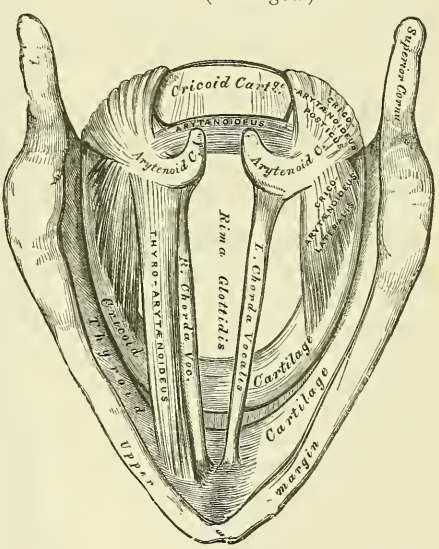
Thyro-epiglottideus. Aryteno-epiglottideus superior.
Aryteno-epiglottideus inferior.

The *Thyro-epiglottideus* is a delicate fasciculus, which arises from the inner surface of the thyroid cartilage, just external to the origin of the Thyro-arytenoid muscle, of which it is sometimes described as a part, and spreads out upon the outer surface of the sacculus laryngis: some of its fibres are lost in the aryteno-epiglottidean fold, whilst others are continued forwards to the margin of the epiglottis (*Depressor epiglottidis*).

The *Aryteno-epiglottideus superior* consists of a few delicate muscular fasciculi, which arise from the apex of the arytenoid cartilages, and become lost in the fold of mucous membrane extending between the arytenoid cartilage and side of the epiglottis (*aryteno-epiglottidean folds*).

The *Aryteno-epiglottideus inferior* (*Compressor sacculi laryngis*, Hilton) arises from the arytenoid cartilage, just above the attachment of the superior vocal cord; passing forwards and upwards, it spreads out upon the anterior surface of the epiglottis. This muscle is separated from the preceding by an indistinct areolar interval.‡

Fig. 640.—Interior of the larynx, seen from above. (Enlarged.)



Actions.—In considering the action of the muscles of the larynx, they may be conveniently divided into two groups, viz.: 1. Those which open and close the glottis. 2. Those which regulate the degree of tension of the vocal cords.

1. The muscles which open the glottis are the Crico-arytenoidei postici; and those which close it are the Arytenoideus and the Crico-arytenoidei laterales.

* Henle describes these two portions as separate muscles, under the names of External and Internal thyro-arytenoid.

† Luschka has described a small, but fairly constant muscle, as the *Arytenoideus rectus*. It is attached below to the posterior, concave surface of the arytenoid cartilage, beneath the Arytenoideus muscle, and passing upwards, emerges at the upper border of this muscle, and is inserted into the posterior surface of the cartilage of Santorini. (*Anatomy*, by Hyrtl, page 718.)

‡ Musculus triticeo-glossus. Bochdalek jun. (*Prager Vierteljahrsschrift*, 2nd part, 1866) describes a muscle hitherto entirely overlooked, except a brief statement in Henle's *Anatomy*, which arises from the nodule of cartilage (*corpus triticeum*) in the posterior thyro-hyoid ligament, and passes forwards and upwards to enter the tongue along with the Hyo-glossus muscle. He met with this muscle eight times in twenty-two subjects. It occurred in both sexes, sometimes on both sides, at others on one only.

2. The muscles which regulate the tension of the vocal cords are the Crico-thyroidei, which tense and elongate them; and the Thyro-arytenoidei, which relax and shorten them. The Thyro-epiglottideus is a depressor of the epiglottis, and the Aryteno-epiglottidei constrict the superior aperture of the larynx, compress the sacculi laryngis, and empty them of their contents.

The *Crico-arytenoidei postici* separate the chordæ vocales, and, consequently, open the glottis, by rotating the arytenoid cartilages outwards around a vertical axis passing through the crico-arytenoid joints; so that their anterior angles and the ligaments attached to them become widely separated, the vocal cords, at the same time, being made tense.

The *Crico-arytenoidei laterales* close the glottis, by rotating the arytenoid cartilages inwards, so as to approximate their anterior angles.

The *Arytenoideus muscles* approximate the arytenoid cartilages, and thus close the opening of the glottis, especially at its back part.

The *Crico-thyroid muscles* produce tension and elongation of the vocal cords. This is effected as follows:—The thyroid cartilage is fixed by the Thyro-hyoid muscles, then the Crico-thyroid muscles, when they act, draw upwards the front of the cricoid cartilage and so depress the posterior portion, which carries with it the arytenoid cartilages, and thus elongate the vocal cords.

The *Thyro-arytenoidei muscles*, consisting of two parts having different attachments and different directions, are rather complicated as regards their action. Their main use is to draw the arytenoid cartilages forwards towards the thyroid, and thus shorten and relax the vocal cords. But, owing to the connection of the inner portion with the vocal cord, this part, if acting separately, is supposed to modify its elasticity and tension, and the outer portion, being inserted into the outer part of the anterior surface of the arytenoid cartilage, may rotate it inwards, and thus narrow the rima glottidis by bringing the two cords together.

The *Thyro-epiglottidei* depress the epiglottis, and assist in compressing the sacculi laryngis. The Aryteno-epiglottideus superior constricts the superior aperture of the larynx, when it is drawn upwards, during deglutition, and the opening closed by the epiglottis. The Aryteno-epiglottideus inferior, together with some fibres of the Thyro arytenoidei, compress the sacculus laryngis.

The **Mucous Membrane of the Larynx** is continuous above with that lining the mouth and pharynx, and is prolonged through the trachea and bronchi into the lungs. It lines the posterior and upper part of the anterior surface of the epiglottis, to which it is closely adherent, and forms the aryteno-epiglottidean folds which encircle the superior aperture of the larynx. It lines the whole of the cavity of the larynx; forms, by its reduplication, the chief part of the superior, or false, vocal cord; and, from the ventricle, is continued into the sacculus laryngis. It is then reflected over the true vocal cords, where it is thin, and very intimately adherent; covers the inner surface of the crico-thyroid membrane and cricoid cartilage; and is ultimately continuous with the lining membrane of the trachea. It is covered with columnar ciliated epithelium below the superior vocal cord; but above this point the cilia are found only in front, as high as the middle of the epiglottis. In the rest of its extent the epithelium is of the squamous variety.

Glands.—The mucous membrane of the larynx is furnished with numerous muciparous glands, the orifices of which are found in nearly every part; they are very numerous upon the epiglottis, being lodged in little pits in its substance; they are also found in large numbers along the posterior margin of the aryteno-epiglottidean fold, in front of the arytenoid cartilages, where they are termed the *arytenoid glands*. They exist also in large numbers upon the inner surface of the sacculus laryngis. None are found on the vocal cords.

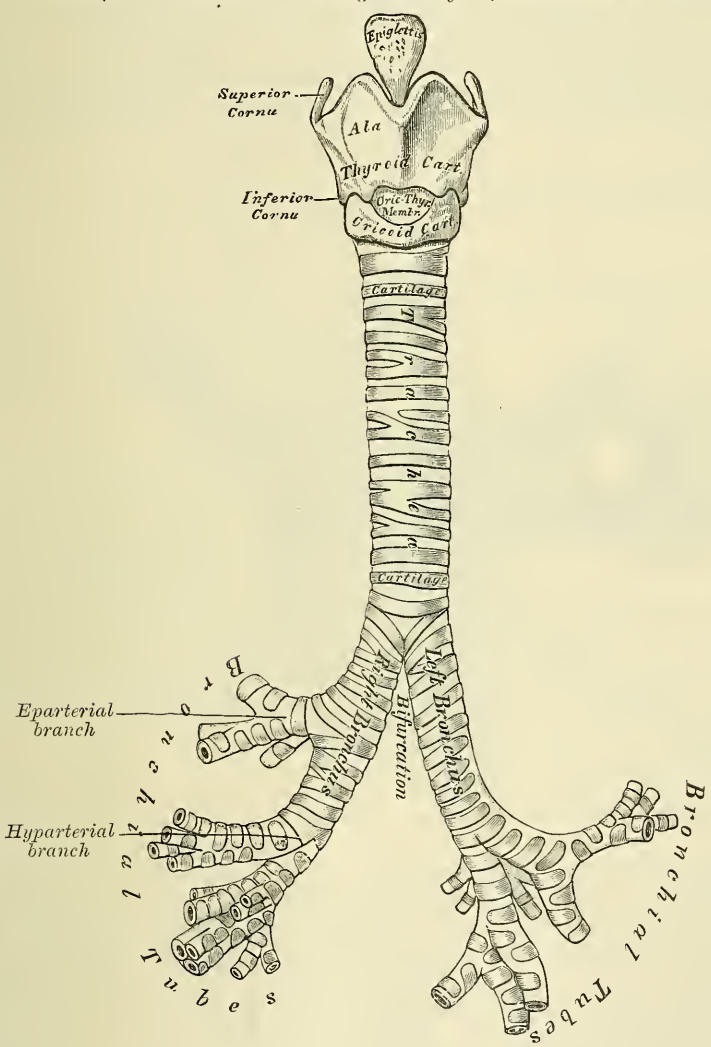
Vessels and Nerves.—The *arteries of the larynx* are the laryngeal branches derived from the superior and inferior thyroid. The *veins* accompany the arteries: those accompanying the superior laryngeal artery join the superior thyroid vein, which opens into the internal jugular vein; while those accompanying the inferior laryngeal artery join the inferior thyroid vein which opens into the innominate vein. The *lymphatics* terminate in the deep cervical glands. The *nerves* are the superior laryngeal, and the inferior or recurrent laryngeal branches of the pneumogastric nerves, joined by filaments from the sympathetic.

The superior laryngeal nerves supply the mucous membrane of the larynx and the Crico-thyroid muscles. The inferior laryngeal nerves supply the remaining muscles. The Arytenoid muscle is supplied by both nerves.

The Trachea (fig. 641)

The **trachea**, or **windpipe**, is a cartilaginous and membranous cylindrical tube, flattened posteriorly, which extends from the lower part of the larynx, on a level with the sixth cervical vertebra, to opposite the fourth, or sometimes the fifth,

Fig. 641.—Front view of cartilages of larynx; the trachea and bronchi.



dorsal, where it divides into the two bronchi, one for each lung. The trachea measures about four inches and a half in length; its diameter, from side to side, is from three-quarters of an inch to an inch, being always greater in the male than in the female.

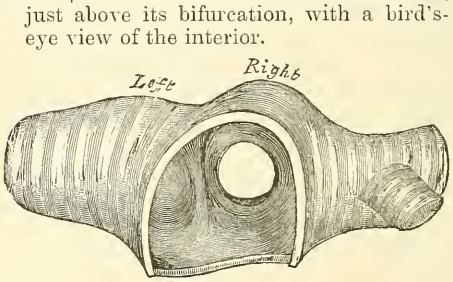
Relations.—The anterior surface of the trachea is convex, and covered *in the neck*, from above downwards, by the isthmus of the thyroid gland, the inferior thyroid veins, the arteria thyroidea ima (when that vessel exists), the Sterno-hyoid and Sterno-thyroid muscles, the cervical fascia, and, more superficially, by

the anastomosing branches between the anterior jugular veins; *in the thorax* it is covered from before backwards by the first piece of the sternum, the remains of the thymus gland, the left innominate vein, the arch of the aorta, the innominate and left carotid arteries, and the deep cardiac plexus. Posteriorly it is in relation with the œsophagus; laterally, *in the neck*, it is in relation with the common carotid arteries, the lateral lobes of the thyroid gland, the inferior thyroid arteries, and recurrent laryngeal nerves; and, *in the thorax*, it lies in the space between the pleuræ, having the pneumogastric nerve on each side of it.

The **Right Bronchus**, wider, shorter, and more horizontal in direction than the left, is about an inch in length, and enters the right lung, opposite the fifth dorsal vertebra. The vena azygos major arches over it, from behind; and the right pulmonary artery lies below, and then in front of it. About three-quarters of an inch from its commencement it gives off a branch to the upper lobe of the right lung. This is termed the *eparterial* branch, because it is given off above the right pulmonary artery. The bronchus now passes below the artery and is known as the *hyparterial* branch. It divides into two branches for the middle and lower lobes.

The **Left Bronchus** is smaller, longer, and more oblique than the right, being nearly two inches in length. It enters the root of the left lung, opposite the sixth dorsal vertebra, about an inch lower than the right bronchus. It passes beneath the arch of the aorta, crosses in front of the œsophagus, the thoracic duct and the descending aorta, and has the left pulmonary artery lying at first above, and then in front of it. If a transverse section is made across the trachea, a short distance above its point of bifurcation, and a bird's-eye view taken of its interior (fig. 642), the septum placed at the bottom of the trachea and separating the two bronchi will be seen to occupy the left of the median line, and the right bronchus appears to be a more direct continuation than the left, so that any solid body dropping into the trachea would naturally be directed towards the right bronchus. This tendency is aided by the larger size of the right tube as compared with its fellow. This fact serves to explain why a foreign body in the trachea more frequently falls into the right bronchus.*

FIG. 642.—Transverse section of the trachea, just above its bifurcation, with a bird's-eye view of the interior.



Structure.—The trachea is composed of imperfect cartilaginous rings, fibrous membrane, muscular fibres, longitudinal yellow elastic fibres, mucous membrane, and glands.

The **cartilages** vary from sixteen to twenty in number: each forms an imperfect ring, which surrounds about two-thirds of the cylinder of the trachea, being imperfect behind, where the tube is completed by fibrous membrane. The cartilages are placed horizontally above each other, separated by narrow membranous intervals. They measure about two lines in depth, and half a line in thickness. Their outer surfaces are flattened, but internally they are convex, from being thicker in the middle than at the margins. Two or more of the cartilages often unite, partially or completely, and are sometimes bifurcated at their extremities. They are highly elastic, but sometimes become calcified in advanced life. In the right bronchus the cartilages vary in number from six to eight; in the left, from nine to twelve. They are shorter and narrower than those of the trachea. The peculiar cartilages are the first and the last.

The *first cartilage* is broader than the rest, and sometimes divided at one end;

* Reigel asserts that the entry of a foreign body into the *left* bronchus is by no means so infrequent as is generally supposed. See also *Med.-Chir. Trans.* vol. lxxi. p. 121.

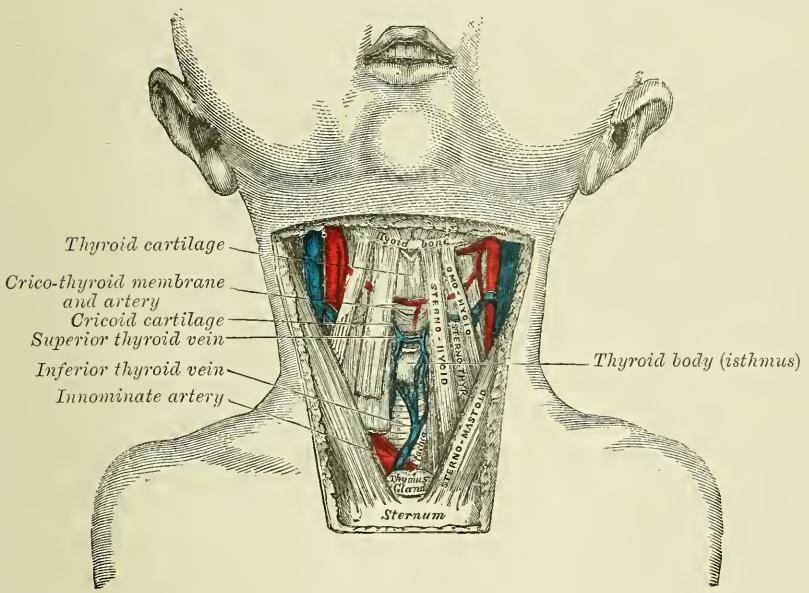
it is connected by fibrous membrane with the lower border of the cricoid cartilage, with which, or with the succeeding cartilage, it is sometimes blended.

The *last cartilage* is thick and broad in the middle, in consequence of its lower border being prolonged into a triangular hook-shaped process, which curves downwards and backwards between the two bronchi. It terminates on each side in an imperfect ring, which encloses the commencement of the bronchi. The cartilage above the last is somewhat broader than the rest at its centre.

The fibrous membrane.—The cartilages are enclosed in an elastic fibrous membrane, which forms a double layer ; one layer, the thicker of the two, passing over the outer surface of the ring, the other over the inner surface : at the upper and lower margins of the cartilages these two layers blend together to form a single membrane which connects the rings one with another. They are thus, as it were, embedded in the membrane. In the space behind, between the extremities of the rings, the membrane forms a single distinct layer.

The **muscular fibres** are disposed in two layers, longitudinal and transverse. The *longitudinal fibres* are the most external, and consist merely of a few scattered longitudinal bundles of fibres.

Fig. 643.—Surgical anatomy of laryngo-tracheal region. In the infant.



The *transverse fibres* (Trachealis muscle, Todd and Bowman), the most internal, form a thin layer, which extends transversely between the ends of the cartilages and the intervals between them at the posterior part of the trachea. The muscular fibres are of the unstriped variety.

The **elastic fibres** are found throughout the trachea, but are most abundant at the posterior part of the tube between the extremities of the rings, where they are collected into distinct longitudinal bundles, and are especially numerous about the bifurcation of the trachea. The fibres are contained in a loose submucous tissue, which contains numerous mucous glands.

The **Mucous membrane** is continuous above with that of the larynx, and below with that of the bronchi. Microscopically, it presents a well-marked basement membrane, supporting a layer of columnar ciliated epithelium, between the deeper ends of which are smaller round or elongated cells. It contains a large amount of lymphoid tissue and some tracheal glands.

The **Tracheal glands** are found in great abundance at the posterior part of the

trachea. They are small, flattened, ovoid bodies, placed upon the outer surface of the fibrous layer; each is furnished with an excretory duct, which pierces the fibrous and muscular layers, and opens on the surface of the mucous membrane. Some glands of smaller size are also found at the sides of the trachea, between the layers of fibrous tissue connecting the rings, and others immediately beneath the mucous coat. The secretion from these glands serves to lubricate the inner surface of the trachea.

Vessels and Nerves.—The trachea is supplied with blood by the inferior thyroid arteries. The *veins* terminate in the thyroid venous plexus. The *nerves* are derived from the pneumogastric and its recurrent branches, and from the sympathetic.

Surface Form.—In the middle line of the neck, some of the cartilages of the larynx can be readily distinguished. In the receding angle below the chin, the hyoid bone can easily be made out (see page 210), and a finger's breadth below it is the pomum Adami, the prominence between the upper borders of the two alæ of the thyroid cartilage. About an inch below this, in the middle line, is a depression corresponding to the crico-thyroid space, in which the operation of laryngotomy is performed. This depression is bounded below by a prominent arch, the anterior ring of the cricoid cartilage, below which the trachea can be felt, though it is only in the emaciated adult that the separate rings can be distinguished. The lower part of the trachea is not easily made out, for as it descends in the neck it takes a deeper position, and is farther removed from the surface. The level of the vocal cords corresponds to the middle of the anterior margin of the thyroid cartilage.

With the laryngoscope the following structures can be seen: The base of the tongue, and the upper surface of the epiglottis, with the glosso-epiglottic ligaments; the superior aperture of the larynx; bounded on either side by the aryteno-epiglottidean ligaments, in which may be seen two rounded eminences, corresponding to the cornicula and cuneiform cartilages. Beneath these the true and false vocal cords, with the ventricle between them. Still deeper, the cricoid cartilage and some of the anterior parts of the rings of the trachea, and sometimes, in deep inspiration, the bifurcation of the trachea.

Surgical Anatomy.—Foreign bodies often find their way into the air-passages. These may be either large soft substances, as a piece of meat, which may become lodged in the upper aperture of the larynx, or in the rima glottidis, and cause speedy suffocation unless rapidly got rid of, or unless an opening is made into the air-passages below, so as to enable the patient to breathe. Smaller bodies, frequently of a hard nature, such as cherry or plum stones, small pieces of bone, buttons, etc., may find their way through the rima glottidis into the trachea or bronchus, or may become lodged in the ventricle of the larynx. The dangers then depend not so much upon the mechanical obstruction as upon the spasm of the glottis which they excite from reflex irritation. When lodged in the ventricle of the larynx, they may produce very few symptoms beyond sudden loss of voice or alteration in the voice sounds, immediately following the inhalation of the foreign body. When, however, they are situated in the trachea, they are constantly striking against the vocal cords during expiratory efforts, and produce attacks of dyspnœa from spasm of the glottis. When lodged in the bronchus, they usually become fixed there, and, occluding the lumen of the tube, cause a loss of the respiratory murmur on the affected side, which is, as stated above, more often the right.

Beneath the mucous membrane of the upper part of the air-passages, there is a considerable amount of submucous tissue, which is liable to become much swollen from effusion in inflammatory affections, constituting the disease known as 'œdema of the glottis.' This effusion does not extend below the level of the vocal cords, on account of the fact that the mucous membrane is closely adherent to these structures, without the intervention of any submucous tissue. So that, in cases of this disease, in which it is necessary to open the air-passages to prevent suffocation, the operation of laryngotomy is sufficient.

Chronic laryngitis is an inflammation of the mucous glands of the larynx, which occurs in those who speak much in public, and is known as 'Clergyman's sore throat.' It is due to the dryness induced by the large amount of cold air drawn into the air-passages during prolonged speaking, which excites increased activity of the mucous glands to keep the parts moist, and this eventually terminates in inflammation of these structures.

Ulceration of the larynx may occur from syphilis, either superficial ulceration, or from the softening of a gumma; from tuberculous disease (laryngeal phthisis), or from malignant disease (epithelioma).

The air-passages may be opened in two different situations: through the crico-thyroid membrane (*laryngotomy*), or in some part of the trachea (*tracheotomy*); and to these some surgeons have added a third method, by opening the crico-thyroid membrane and dividing the cricoid cartilage with the upper ring of the trachea (*laryngo-tracheotomy*). The student should carefully consider the relative anatomy of the air-tube in each of these situations (fig. 643).

Laryngotomy is anatomically the simple operation; it can readily be performed, and should always be preferred when particular circumstances do not render the operation of tracheotomy absolutely necessary. The crico-thyroid membrane is very superficial, being covered only in the middle line by the skin, superficial fascia, and the deep fascia. On each side of the middle line it is also covered by the Sterno-hyoid and Sterno-thyroid muscles, which diverge slightly from each other at their upper parts, leaving a slight interval between them. On these muscles rests the anterior jugular vein. The only vessel of any importance in connection with this operation is the crico-thyroid artery, which crosses the crico-thyroid membrane, and which may be wounded, but rarely gives rise to any trouble. The operation is performed thus: the head being thrown back and steadied by an assistant, the finger is passed over the front of the neck, and the crico-thyroid depression felt for. A vertical incision is then made through the skin, in the middle line over this spot, and carried down though the fascia until the crico-thyroid membrane is exposed. A cross cut is then made through the membrane, close to the upper border of the cricoid cartilage, so as to avoid, if possible, the crico-thyroid artery, and a tracheotomy tube introduced. It has been recommended, as a more rapid way of performing the operation, to make a transverse instead of a longitudinal cut through the superficial structures, and thus to open at once the air-passages. It will be seen, however, that in operating in this way the anterior jugular veins would be in danger of being wounded.

Tracheotomy may be performed either above or below the isthmus of the thyroid body: or this structure may be divided and the trachea opened beneath it.

The isthmus of the thyroid gland usually crosses the second and third rings of the trachea; along its upper border is frequently to be found a large transverse communicating branch between the superior thyroid veins; and the isthmus itself is covered by a venous plexus, formed between the thyroid veins of the opposite sides. Theoretically, therefore, it is advisable to avoid dividing this structure in opening the trachea.

Above the isthmus the trachea is comparatively superficial, being covered by the skin, superficial fascia, deep fascia, Sterno-hyoid and Sterno-thyroid muscles, and a second layer of the deep fascia. which, attached above to the lower border of the hyoid bone, descends beneath the muscles to the thyroid body, where it divides into two layers and encloses the isthmus.

Below the isthmus the trachea lies much more deeply, and is covered by the Sterno-hyoid and the Sterno-thyroid muscles, and a quantity of loose areolar tissue, in which is a plexus of veins, some of them of large size; they converge to two trunks, the inferior thyroid veins, which descend on either side of the median line on the front of the trachea, and open into the innominate vein. In the infant the thymus gland ascends a variable distance along the front of the trachea; and opposite the episternal notch the windpipe is crossed by the left innominate vein. Occasionally also in young subjects the innominate artery crosses the tube obliquely above the level of the sternum. The thyroidea ima artery, when that vessel exists, passes from below upwards, along the front of the trachea.

From these observations it must be evident that the trachea can be more readily opened above, than below, the isthmus of the thyroid body.

Tracheotomy above the isthmus is performed thus: the patient should, if possible, be laid on his back on a table in a good light. A pillow is to be placed under the shoulders and the head thrown back and steadied by an assistant. The surgeon standing on the right side of his patient makes an incision from an inch and a half to two inches in length in the median line of the neck from the top of the cricoid cartilage. The incision must be made exactly in the middle line so as to avoid the anterior jugular veins, and after the superficial structures have been divided, the interval between the Sterno-hyoid muscles must be found, the raphé divided, and the muscles drawn apart. The lower border of the cricoid cartilage must now be felt for, and the upper part of the trachea exposed from this point downwards in the middle line. Bose has recommended that the layer of fascia in front of the trachea should be divided transversely at the level of the lower border of the cricoid cartilage, and, having been seized with a pair of forceps, pressed downwards with the handle of the scalpel. By this means the isthmus of the thyroid gland is depressed and is saved from all danger of being wounded, and the trachea cleanly exposed. The trachea is now transfixed with a sharp hook and drawn forwards in order to steady it, and is then opened by inserting the knife into it and dividing the two or three upper rings from below upwards. If the trachea is to be opened below the isthmus, the incision must be made from a little below the cricoid cartilage to the top of the sternum.

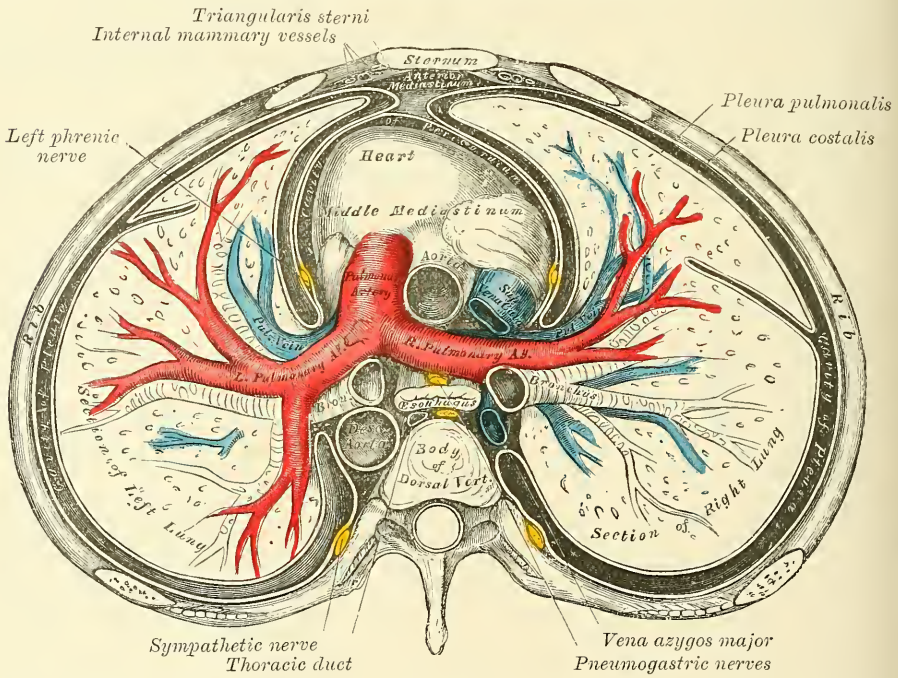
In the child the trachea is smaller, more deeply placed, and more movable than in the adult. In fat or short-necked people, or in those in whom the muscles of the neck are prominently developed, the trachea is more deeply placed than in the opposite conditions.

A portion of the larynx or the whole of it has been removed for malignant disease. The results which have been obtained from the removal of the whole of it have not been very satisfactory, and the cases in which the operation is justifiable are very few. It may be removed by a median incision through the soft parts; freeing the cartilages from the muscles and other structures in front; separating the larynx from the trachea below, and dissecting off the deeper structure from below upwards.

The Pleuræ

Each lung is invested, upon its external surface, by an exceedingly delicate serous membrane, the **pleura**, which encloses the organ as far as its root, and is then reflected upon the inner surface of the thorax. The portion of the serous membrane investing the surface of the lung and dipping into the fissures between its lobes, is called the *pleura pulmonalis* (visceral layer of pleura), while that which lines the inner surface of the chest is called the *pleura costalis* (parietal layer of pleura). The space between these two layers is called the *cavity of the pleura*, but it must be borne in mind that in the healthy condition the two layers are in contact and there is no real cavity, until the lung becomes collapsed and a separation of it from the wall of the chest takes place. Each pleura is therefore a shut sac, one occupying the right, the other the left half of the thorax; and they are perfectly separate, not communicating with each other.

Fig. 644.—A transverse section of the thorax, showing the relative position of the viscera, and the reflections of the pleuræ.



The two pleuræ do not meet in the middle line of the chest, excepting anteriorly opposite the second piece of the sternum; a space being left between them, which contains all the viscera of the thorax excepting the lungs; this is the *mediastinum*.

Reflections of the Pleura (fig. 644).—Commencing at the sternum, the pleura passes outwards, covers the costal cartilages, the inner surface of the ribs and Intercostal muscles, and at the back part of the thorax passes over the thoracic ganglia and their branches, and is reflected upon the sides of the bodies of the vertebræ, where it is separated by a narrow interval, the *posterior mediastinum*, from the opposite pleura. From the vertebral column the pleura passes to the side of the pericardium, which it covers to a slight extent; it then covers the back part of the root of the lung, from the lower border of which a triangular fold descends vertically by the side of the posterior mediastinum to the Diaphragm. This fold is the broad ligament of the lung, the *ligamentum latum pulmonis*, and serves to retain the lower part of that organ in position. *From the*

root, the pleura may be traced over the convex surface of the lung, the summit and base, and also over the sides of the fissures between the lobes on to its anterior surface and the front part of its root; from this it is reflected upon the side of the pericardium to the inner surface of the sternum. *Below*, it covers the upper surface of the Diaphragm and extends, in front, as low as the costal cartilage of the seventh rib; at the side of the chest, as low as the tenth rib on the left side, and the ninth on the right side; and behind, it reaches as low as the twelfth rib, and sometimes even beyond it, as low as the transverse process of the first lumbar vertebra. *Above*, its apex projects, in the form of a *cul-de-sac*, through the superior opening of the thorax into the neck, extending from one to two inches above the margin of the first rib, and receives the summit of the corresponding lung; this sac is strengthened, according to Dr. Sibson, by a dome-like expansion of fascia, attached in front to the posterior border of the first rib, and behind to the anterior border of the transverse process of the seventh cervical vertebra. This is covered and strengthened by a few spreading muscular fibres derived from the Scaleni muscles.

In the front of the chest, where the parietal layer of the pleura is reflected backwards to the pericardium, the two pleural sacs are in contact for a considerable extent. At the upper part of the chest, behind the manubrium, they are not in contact; the point of reflection being represented by a line drawn from the sterno-clavicular articulation to the mid-point of the junction of the manubrium to the body of the sternum. From this point the two pleuræ descend in close contact to the level of the fifth costal cartilage. Here the line of reflection on the right side is continued onwards in nearly a straight line to the lower end of the gladiolus and then turns outwards, whilst on the left side the line of reflection diverges outwards, so that opposite the seventh cartilage it about corresponds to the left border of this structure. It, however, always extends considerably further over the pericardium than the corresponding lung. The lower limit of the pleura is on a considerably lower level than the lower limit of the lung, but does not extend to the attachment of the Diaphragm.

The inner surface of the pleura is smooth, polished, and moistened by a serous fluid; its outer surface is intimately adherent to the surface of the lung, and to the pulmonary vessels as they emerge from the pericardium; it is also adherent to the upper surface of the Diaphragm: throughout the rest of its extent it is somewhat thicker, and may be separated from the adjacent parts with extreme facility.

The right pleural sac is shorter, wider, and reaches higher in the neck than the left.

Vessels and Nerves.—The *arteries of the pleura* are derived from the intercostal, the internal mammary, the musculo-phrenic, thymic, pericardiac, and bronchial. The *veins* correspond to the arteries. The *lymphatics* are very numerous. The *nerves* are derived from the phrenic and sympathetic (Luschka). Kölliker states that nerves accompany the ramification of the bronchial arteries in the pleura pulmonalis.

Surgical Anatomy.—In operations upon the kidney, it must be borne in mind that the pleura may sometimes extend below the level of the last rib, and may therefore be opened in these operations, especially when the last rib is removed in order to give more room.

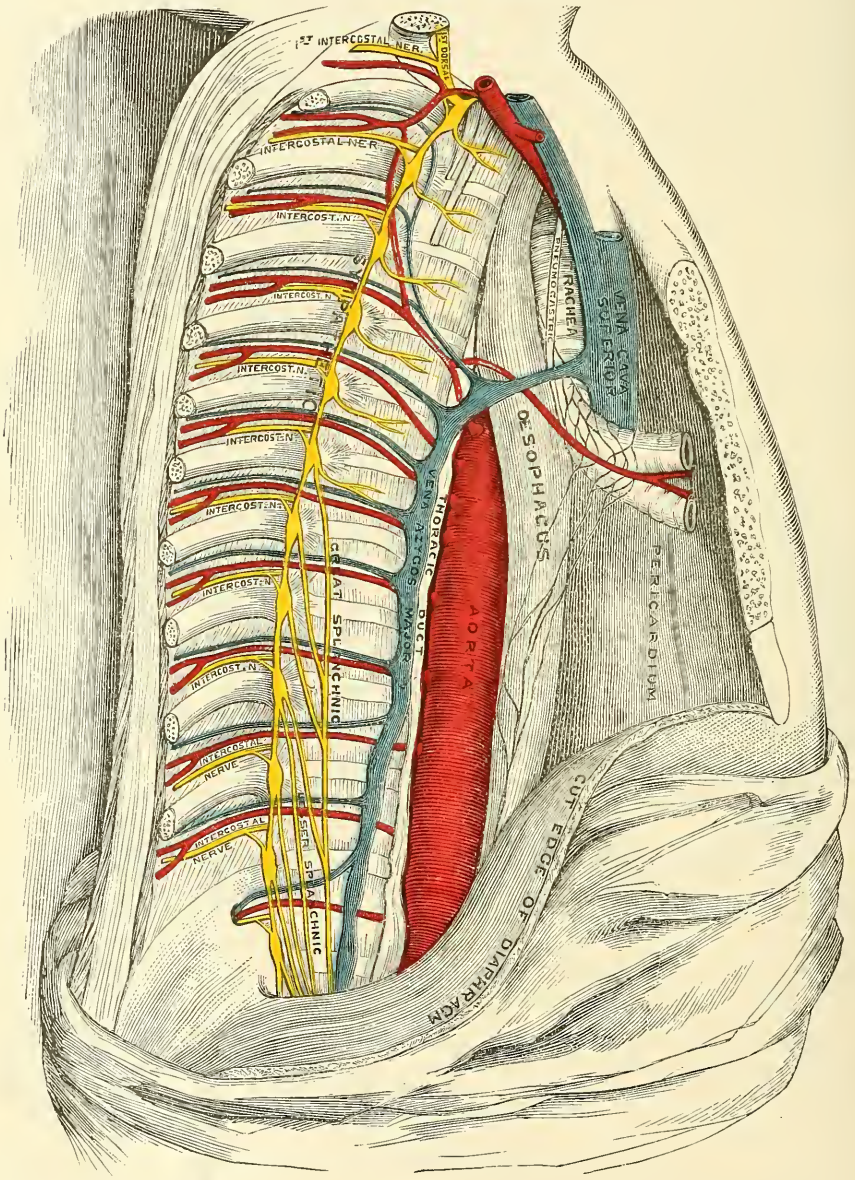
The Mediastinum

The **Mediastinum** is the space left in the median line of the chest by the non-approximation of the two pleuræ. It extends from the sternum in front to the spine behind, and contains all the viscera in the thorax excepting the lungs. The mediastinum may be divided for purposes of description into two parts: an upper portion, above the upper level of the pericardium, which is named the *Superior mediastinum* (Struthers); and a lower portion, below the upper level of the pericardium. This lower portion is again subdivided into three: that part

which contains the pericardium and its contents, the *middle mediastinum*; that part which is in front of the pericardium, the *anterior mediastinum*; and that part which is behind the pericardium, the *posterior mediastinum*.

The **superior mediastinum** is that portion of the interpleural space which lies above the upper level of the pericardium between the manubrium sterni in front, and the upper dorsal vertebræ behind. It is bounded below by a plane passing

Fig. 645.—The posterior mediastinum.



backwards from the junction of the manubrium and gladiolus sterni to the lower part of the body of the fourth dorsal vertebra. It contains the origins of the Sterno-hyoid and Sterno-thyroid muscles and the lower ends of the Longi colli muscles; the arch of the aorta; the innominate, the thoracic portion of the left carotid and subclavian arteries; the upper half of the superior vena cava and the innominate veins, and the left superior intercostal vein; the pneumogastric,

cardiac, phrenic, and left recurrent laryngeal nerves; the trachea, œsophagus, and thoracic duct; the remains of the thymus gland and some lymphatic glands.

The **anterior mediastinum** is bounded in front by the sternum, on each side by the pleura, and behind by the pericardium. It is very narrow, especially above, where the two pleural sacs are almost, if not quite, in contact, but widens out a little below, where the left pleura diverges somewhat from the middle line. It is therefore not parallel with the sternum, but directed from above obliquely downwards and to the left. It contains the origins of the Triangularis sterni muscles, and a quantity of loose areolar tissue, in which some lymphatic vessels are found ascending from the convex surface of the liver, and two or three lymphatic glands (anterior mediastinal glands).

The **middle mediastinum** is the broadest part of the interpleural space. It contains the heart, enclosed in the pericardium, the ascending aorta, the lower half of the superior vena cava, with the vena azygos major opening into it, the bifurcation of the trachea and the two bronchi, the pulmonary artery dividing into its two branches and the right and left pulmonary veins, the phrenic nerves, and some bronchial lymphatic glands.

The **posterior mediastinum** (fig. 645) is an irregular triangular space running parallel with the vertebral column; it is bounded in front by the pericardium and roots of the lungs, behind by the vertebral column from the lower border of the fourth dorsal vertebra, and on either side by the pleura. It contains the descending thoracic aorta, the greater and lesser azygos veins, the pneumogastric and splanchnic nerves, the œsophagus, thoracic duct, and some lymphatic glands.

The Lungs

The **Lungs** are the essential organs of respiration; they are two in number, placed one on each side of the chest, separated from each other by the heart and other contents of the mediastinum. Each lung is conical in shape, and presents for examination an apex, a base, two borders, and two surfaces (see fig. 647).

The *apex* forms a tapering cone which extends into the root of the neck, about an inch to an inch and a half above the level of the first rib.

The *base* is broad, concave, and rests upon the convex surface of the Diaphragm: its circumference is thin, and fits into the space between the lower ribs and the costal attachment of the Diaphragm, extending lower down externally and behind than in front.

The *external* or *thoracic surface* is smooth, convex, of considerable extent, and corresponds to the form of the cavity of the chest, being deeper behind than in front.

The *inner surface* is concave. It presents, in front, a depression corresponding to the convex surface of the pericardium; and behind, a deep fissure (the hilum pulmonis), which gives attachment to the root of the lung.

The *posterior border* is rounded and broad, and is received into the deep concavity on either side of the spinal column. It is much longer than the anterior border, and projects, below, between the ribs and the Diaphragm.

The *anterior border* is thin and sharp, and overlaps the front of the pericardium.

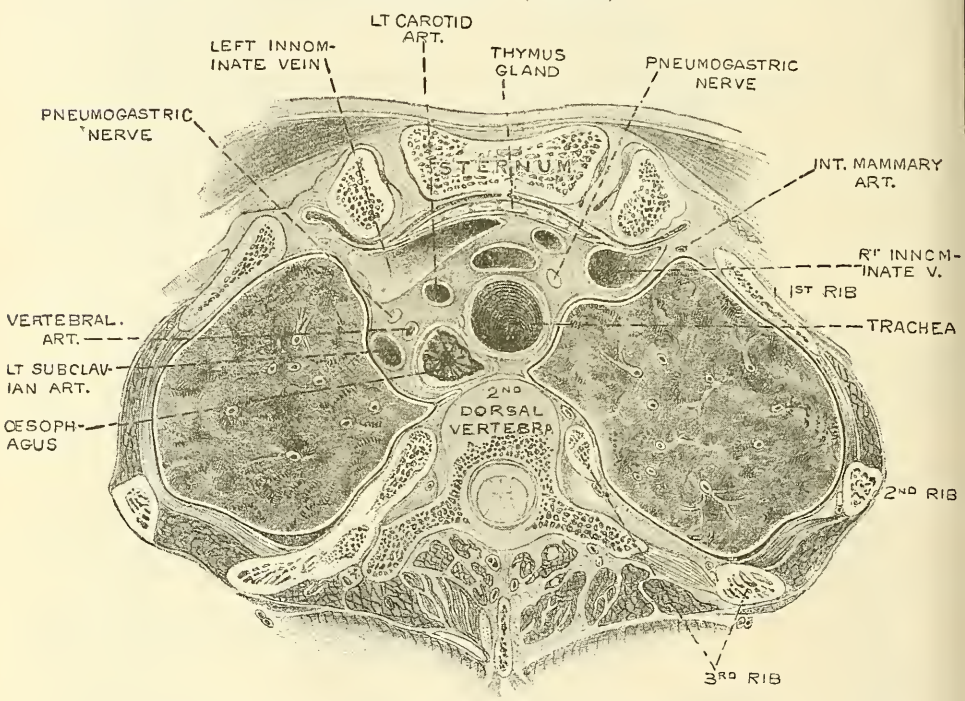
Each lung is divided into two lobes, an upper and lower, by a long and deep fissure, which extends from the upper part of the posterior border of the organ, about three inches from its apex, downwards and forwards to the lower part of its anterior border. This fissure penetrates nearly to the root. In the right lung the upper lobe is partially subdivided by a second and shorter fissure, which extends from the middle of the preceding, forwards and upwards, to the anterior margin of the organ, marking off a small triangular portion, the middle lobe.

The *right lung* is the larger and heavier; it is broader than the left, owing to the inclination of the heart to the left side; it is also shorter by an inch, in

consequence of the Diaphragm rising higher on the right side to accommodate the liver.

The roots of the lungs.—A little above the middle of the inner surface of each lung, and nearer its posterior than its anterior border, is its root, by which the lung is connected to the heart and the trachea. The root is formed by the bronchial tube, the pulmonary artery, the pulmonary veins, the bronchial arteries and veins, the pulmonary plexus of nerves, lymphatics, bronchial glands, and areolar tissue, all of which are enclosed by a reflection of the pleura. The root of the right lung lies behind the superior vena cava and ascending portion of the aorta, and below the vena azygos major. That of the left lung passes beneath the arch of the aorta, and in front of the descending aorta; the phrenic nerve and the anterior pulmonary plexus lie in front of each, and the pneumogastric and posterior pulmonary plexus behind each.

Fig. 646.—Transverse section through the upper margin of the third dorsal vertebra. (Braune.)



The chief structures composing the root of each lung are arranged in a similar manner from before backwards on both sides—viz.: the pulmonary veins most anterior; the pulmonary artery in the middle; and the bronchus, together with the bronchial vessels, behind. From above downwards, on the two sides, their arrangement differs, thus:

On the right side their position is—bronchus, pulmonary artery, pulmonary veins; but on the left side their position is—pulmonary artery, bronchus, pulmonary veins; this is accounted for by the bronchus being placed on a lower level on the left than on the right side, in order that it may pass under the arch of the aorta.

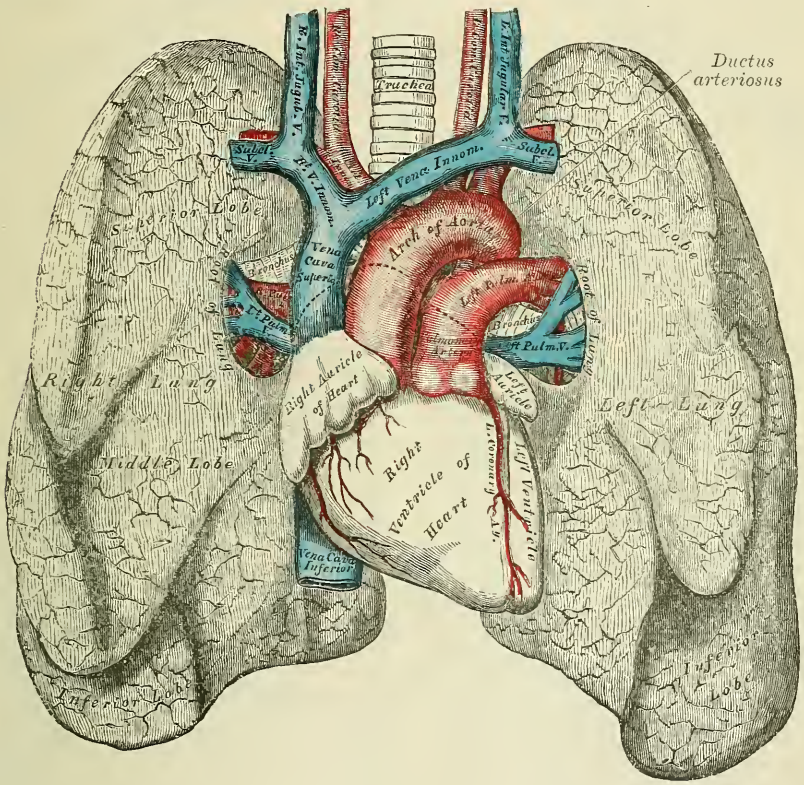
The *weight* of both lungs together is about forty-two ounces, the right lung being two ounces heavier than the left; but much variation is met with according to the amount of blood or serous fluid they may contain. The lungs are heavier in the male than in the female, their proportion to the body being, in the former, as 1 to 37, in the latter as 1 to 43. The specific gravity of the lung-tissue varies from 0·345 to 0·746, water being 1,000.

The *colour* of the lungs at birth is a pinkish-white; in adult life, a dark slate-colour, mottled in patches; and as age advances, this mottling assumes a black colour. The colouring matter consists of granules of a carbonaceous substance deposited in the areolar tissue near the surface of the organ. It increases in quantity as age advances, and is more abundant in males than in females. The posterior border of the lung is usually darker than the anterior.

The *surface* of the lung is smooth, shining, and marked out into numerous polyhedral spaces, indicating the lobules of the organ: the area of each of these spaces is crossed by numerous lighter lines.

The *substance* of the lung is of a light, porous, spongy texture; it floats in water, and crepitates when handled, owing to the presence of air in the tissue;

Fig. 647.—Front view of the heart and lungs.



it is also highly elastic; hence the collapsed state of these organs when they are removed from the closed cavity of the thorax.

Structure.—The lungs are composed of an external serous coat, a subserous areolar tissue, and the pulmonary substance or parenchyma.

The *serous coat* is derived from the pleura; it is thin, transparent, and invests the entire organ as far as the root.

The *subserous areolar tissue* contains a large proportion of elastic fibres; it invests the entire surface of the lung, and extends inwards between the lobules.

The *parenchyma* is composed of lobules, which, although closely connected together by an interlobular areolar tissue, are quite distinct from one another, and may be teased asunder without much difficulty in the fœtus. The lobules vary in size: those on the surface are large, of pyramidal form, the base turned towards the surface; those in the interior smaller, and of various forms. Each lobule is composed of one of the ramifications of a bronchial tube and its

terminal air-cells, and of the ramifications of the pulmonary and bronchial vessels, lymphatics and nerves; all of these structures being connected together by areolar tissue.

The *bronchus*, upon entering the substance of the lung, divides and subdivides bipinnately throughout the entire organ. Sometimes three branches arise together, and occasionally small lateral branches are given off from the sides of a main trunk. Each of the smaller subdivisions of the bronchi enters a pulmonary lobule, and is termed a *lobular bronchial tube* or *bronchiole*. Its wall now begins to present irregular dilatations, *air-cells* or *alveoli*, at first sparingly and on one side of the tube only, but as it proceeds onwards these dilatations become more numerous and surround the tube on all sides, so that it loses its cylindrical character. The bronchiole now becomes enlarged, and is termed the *atrium* or *alveolar passage*; from it are given off, on all sides, ramifications, called *infundibula*, which are closely beset in all directions by *alveoli* or *air-cells*. Within the lungs the bronchial tubes are circular, not flattened, and present certain peculiarities of structure.

Changes in the structure of the bronchi in the lungs.—1. *In the lobes of the lungs.*—In the lobes of the lungs the following changes take place. The *cartilages* are not imperfect rings, but consist of thin laminæ, of varied form and size, scattered irregularly along the sides of the tube, being most distinct at the points of division of the bronchi. They may be traced into tubes, the diameter of which is only one-fourth of a line. Beyond this point the tubes are wholly membranous. The fibrous coat and the longitudinal elastic fibres are continued into the smallest ramifications of the bronchi. The muscular coat is disposed in the form of a continuous layer of annular fibres, which may be traced upon the smallest bronchial tubes, and consists of the unstriped variety of muscular tissue. The mucous membrane lines the bronchi and its ramifications throughout, and is covered with columnar ciliated epithelium.

2. *In the lobules of the lung.*—In the lobular bronchial tubes and in the infundibula the following changes take place. The muscular tissue begins to disappear, so that in the infundibula there is scarcely a trace of it. The longitudinal elastic fibres begin to break up, so that in the infundibula they form an interlacement around the mouths of the air-cells which spring from it. The epithelium becomes non-ciliated and flattened. This occurs gradually; thus, in the lobular bronchial tubes, patches of non-ciliated flattened epithelium may be found scattered amongst the columnar ciliated epithelium; then these patches of non-ciliated flattened epithelium become more and more numerous, until in the infundibula and air-cells all the epithelium is of the non-ciliated pavement variety. In addition to these flattened cells, there are small polygonal granular cells in the air-sacs in clusters of two or three, between the others.

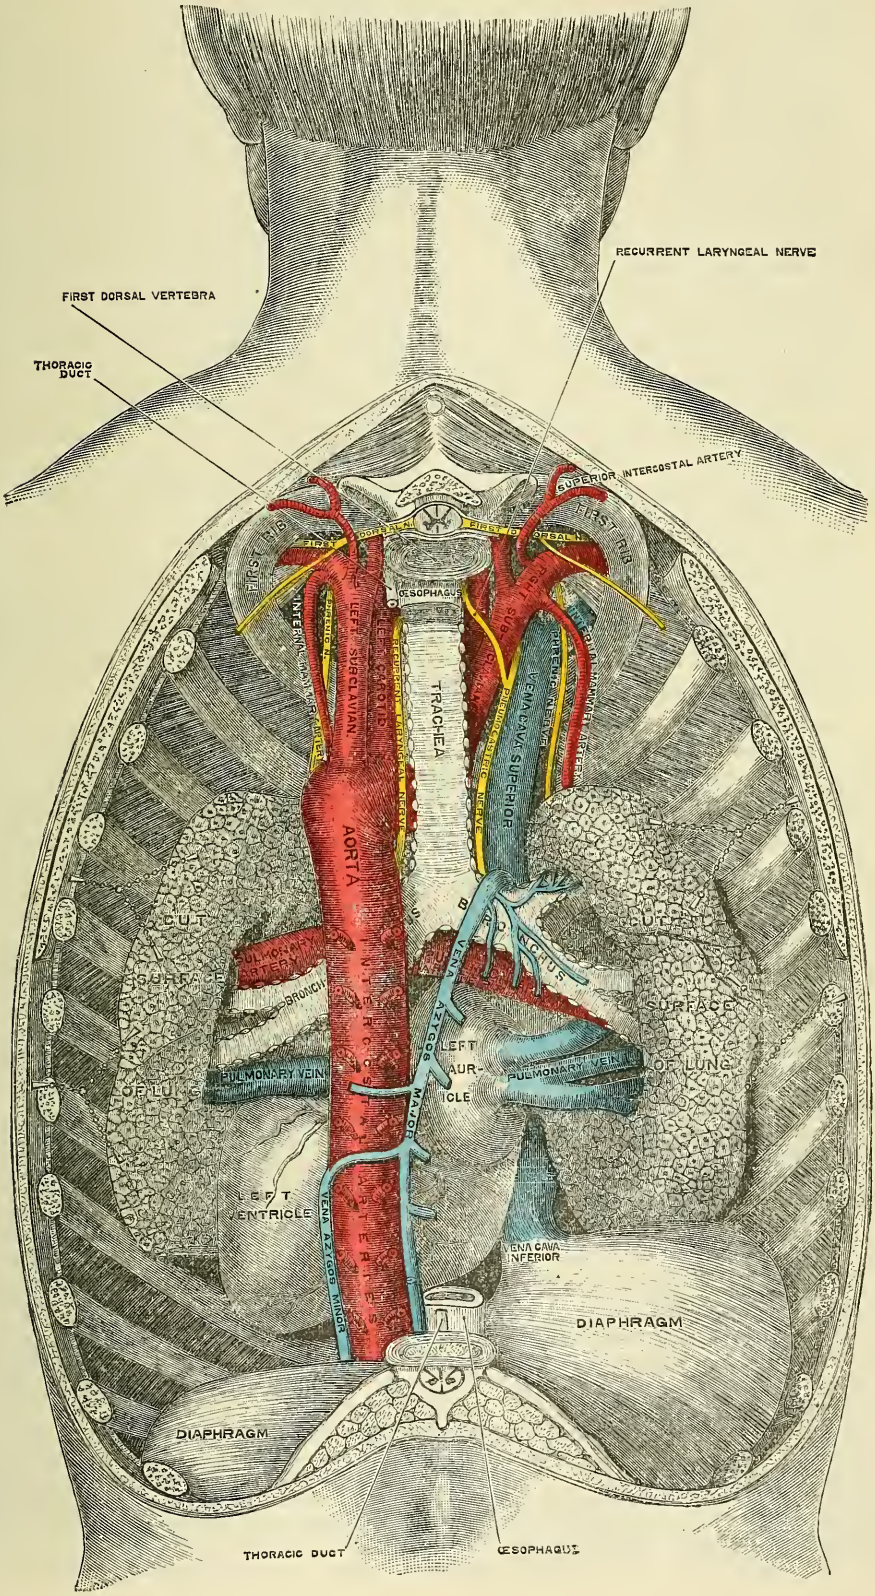
The air-cells are small, polyhedral, alveolar recesses composed of a fibrillated connective tissue, and surrounded by a few involuntary muscular and elastic fibres. In their walls are granular, rounded, amœboid cells, often containing carbonaceous particles. The air-cells are well seen on the surface of the lung, and vary from $\frac{1}{200}$th to $\frac{1}{70}$th of an inch in diameter; being largest on the surface at the thin borders and at the apex, and smallest in the interior.

The *pulmonary artery* conveys the venous blood to the lungs; it divides into branches which accompany the bronchial tubes, and terminates in a dense capillary network, upon the walls of the intercellular passages and air-cells. In the lung, the branches of the pulmonary artery are usually above and in front of a bronchial tube, the vein below.

The *pulmonary capillaries* form plexuses which lie immediately beneath the mucous membrane, in the walls and septa of the air-cells, and of the infundibula. In the septa between the air-cells the capillary network forms a single layer. The capillaries form a very minute network, the meshes of which are smaller than the vessels themselves; * their walls are also exceedingly thin. The arteries

* The meshes are only 0·002‴ to 0·008‴ in width, while the vessels are 0·003‴ to 0·005‴. Kölliker, *Human Microscopic Anatomy.*

Fig. 648.—The roots of the lungs and posterior pulmonary plexus, seen from behind.



of neighbouring lobules are independent of each other, but the veins freely anastomose together.

The *pulmonary veins* commence in the pulmonary capillaries, the radicles coalescing into larger branches, which accompany the arteries and return the oxygenated blood to the left auricle of the heart.

The *bronchial arteries* supply blood for the nutrition of the lung: they are derived from the thoracic aorta, and, accompanying the bronchial tubes, are distributed to the bronchial glands, and upon the walls of the larger bronchial tubes and pulmonary vessels. Those supplying the bronchial tubes form a capillary plexus in the muscular coat, from which branches are given off to form a second plexus in the mucous coat. This plexus communicates with branches of the pulmonary artery, and empties itself into the pulmonary vein. Others are distributed in the interlobular areolar tissue, and terminate partly in the deep, partly in the superficial, bronchial veins. Lastly, some ramify upon the surface of the lung, beneath the pleura, where they form a capillary network.

The *bronchial vein* is formed at the root of the lung, receiving superficial and deep veins corresponding to branches of the bronchial artery. It does not, however, receive all the blood supplied by the artery, as some of it passes into the pulmonary vein. It terminates on the right side in the vena azygos major, and on the left side in the superior intercostal vein.

The **lymphatics** consist of a superficial and deep set: they terminate at the root of the lung, in the bronchial glands.

Nerves.—The lungs are supplied from the anterior and posterior pulmonary plexuses, formed chiefly by branches from the sympathetic and pneumogastric. The filaments from these plexuses accompany the bronchial tubes, upon which they are lost. Small ganglia are found upon these nerves.

Surface Form.—The apex of the lung is situated in the neck, behind the interval between the two heads of origin of the Sterno-mastoid. The height to which it rises above the clavicle varies very considerably, but is generally about one inch. It may, however, extend as much as an inch and a half or an inch and three-quarters, or, on the other hand, it may scarcely project above the level of this bone. In order to mark out the anterior margin of the lung, a line is to be drawn from the apex point, one inch above the level of the clavicle, and rather nearer the posterior than the anterior border of the Sterno-mastoid muscle, downwards and inwards across the sterno-clavicular articulation and first piece of the sternum until it meets, or almost meets, its fellow of the other side opposite the articulation of the manubrium and gladiolus. From this point the two lines are to be drawn downwards, one on either side of the mesial line and close to it, as far as the level of the articulation of the fourth costal cartilages to the sternum. From here the two lines diverge, the left is to be drawn at first passing outwards with a slight inclination downwards, and then taking a bend downwards with a slight inclination outwards to the apex of the heart, and thence to the sixth costo-chondral articulation. The direction of the anterior border of this part of the left lung is denoted with sufficient accuracy by a curved line, with its convexity directed upwards and outwards from the articulation of the fourth right costal cartilage of the sternum to the fifth intercostal space, an inch and a half below, and three-quarters of an inch internal to the left nipple. The continuation of the anterior border of the right lung is marked by a prolongation of its line from the level of the fourth costal cartilages vertically downwards as far as the sixth, when it slopes off along the line of the sixth costal cartilage to its articulation with the rib.

The lower border of the lung is marked out by a slightly curved line, with its convexity downwards from the articulation of the sixth costal cartilage to its rib to the spinous process of the tenth dorsal vertebra. If vertical lines are drawn downwards from the nipple, the mid-axillary line and the apex of the scapula, while the arms are raised from the sides, they should intersect this convex line, the first at the sixth, the second at the eighth, and the third at the tenth rib. It will thus be seen that the pleura (see page 1047) extends farther down than the lung, so that it may be wounded, and a wound pass through its cavity into the Diaphragm, and even injure the abdominal viscera, without the lung being involved.

The posterior border of the lung is indicated by a line drawn from the level of the spinous process of the seventh cervical vertebra, down either side of the spine, corresponding to the costo-vertebral joints as low as the spinous process of the tenth dorsal vertebra. The trachea bifurcates opposite the spinous process of the fourth dorsal vertebra, and from this point the two bronchi are directed outwards, the right one almost horizontally, the left with a considerable inclination downwards.

The position of the great fissure in the right lung may be indicated by a line drawn

from the fourth dorsal vertebra round the side of the chest to the anterior margin of the lung opposite the seventh rib, and the smaller or secondary fissure by a line drawn from the preceding where it bisects the mid-axillary line to the junction of the fourth costal cartilage to the sternum. The great fissure in the left lung is a little higher, extending from the third dorsal vertebra round the side of the chest to reach the anterior margin of the lung opposite the sixth costal cartilage.

Surgical Anatomy.—The lungs may be wounded or torn in three ways. (1) By compression of the chest, without any injury to the ribs. (2) By a fractured rib penetrating the lung. (3) By stabs, gunshot wounds, etc.

The first form, where the lung is ruptured by external compression without any fracture of the ribs, is very rare, and usually occurs in young children, and affects the root of the lung, i.e. the most fixed part, and thus, implicating the great vessels, is frequently fatal. It would seem *a priori* a most unusual injury, and its exact mode of causation is difficult to interpret. The probable explanation is that immediately before the compression is applied a deep inspiration is taken and the lungs are fully inflated; owing then to spasm of the glottis at the moment of compression, the air is unable to escape from the lung, which is not able to recede, and consequently gives way.

In the second variety, when the wound in the lung is produced by the penetration of a broken rib, both the pleura costalis and pulmonalis must necessarily be injured, and consequently the air taken into the wounded air-cells may find its way through these wounds into the cellular tissue of the parietes of the chest. This it may do without collecting in the pleural cavity; the two layers of the pleura are so intimately in contact that the air passes straight through from the wounded lung into the subcutaneous tissue. Emphysema constitutes therefore the most important sign of injury to the lung in cases of fracture of the ribs. Pneumothorax, or air in the pleural cavity, is much more likely to occur in injuries to the lung of the third variety, that is to say, from external wounds, from stabs, gunshot injuries and such like, in which case air passes either from the wound of the lung or from the external wound into the cavity of the pleura during the respiratory movements. In these cases there is generally no emphysema of the subcutaneous tissue unless the external wound is small and valvular, so that the air is drawn into the wound during inspiration, and then forced into the cellular tissue around during expiration because it cannot escape from the external wound. Occasionally in wounds of the parietes of the chest no air finds its way into the cavity of the pleura, because the lung at the time of the accident protrudes through the wound and blocks the opening. This occurs where the wound is large, and constitutes one form of *hernia* of the lung. Another form of hernia of the lung occurs, though very rarely, after wounds of the chest wall, when the wound has healed and the cicatrix subsequently yields from the pressure of the viscus behind. It forms a globular, elastic, crepitating swelling, which enlarges during expiratory efforts, falls in during inspiration, and disappears on holding the breath.

The Thyroid Gland

The **thyroid gland** bears much resemblance in structure to other glandular organs, and was formerly classified together with the thymus, suprarenal capsules, and spleen, under the head of *ductless glands*, since when fully developed it has no excretory duct. From its situation in connection with the trachea and larynx, the thyroid body is usually described with those organs, although it takes no part in the function of respiration. It is situated at the upper part of the trachea, and consists of two lateral lobes, placed one on each side of that tube, and connected together by a narrow transverse portion, the *isthmus*.

Its *anterior surface* is convex, and covered by the Sterno-hyoid, Sterno-thyroid, and Omo-hyoid muscles.

Its *lateral surfaces*, also convex, lie in contact with the sheath of the common carotid artery and are overlapped by the Sterno-mastoid muscle.

Its *posterior surface* is concave, and embraces the trachea and larynx. The posterior borders of the gland extend as far back as the lower part of the pharynx, and on the left side to the œsophagus.

The thyroid varies in weight from one to two ounces. It is larger in females than in males, and becomes slightly increased in size during menstruation. Each lobe is somewhat conical in shape, about two inches in length, and three-quarters of an inch to an inch and a quarter in breadth, the right lobe being the larger of the two.

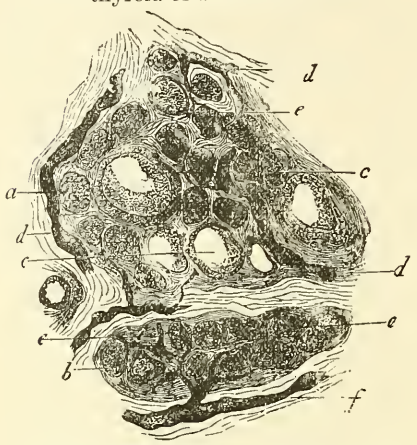
The *isthmus* connects the lower third of the two lateral lobes; it measures about half an inch in breadth, and the same in depth, and usually covers the

second and third rings of the trachea. Its situation presents, however, many variations, a point of importance in the operation of tracheotomy. Sometimes the isthmus is altogether wanting.

A third lobe, of conical shape, called the *pyramid*, occasionally arises from the upper part of the isthmus, or from the adjacent portion of either lobe, but most commonly the left, and ascends as high as the hyoid bone. It is occasionally quite detached, or divided into two parts, or altogether wanting.

A few muscular bands are occasionally found attached, above, to the body of the hyoid bone, and below to the isthmus of the gland, or its pyramidal process. These form a muscle, which was named by Sömmerring the *Levator glandulæ thyroideæ*.

Fig. 649.—Two lobules from the thyroid of an infant.



a. Small glandular vesicles with their cells. *b*. The same with incipient colloid metamorphosis, more strongly marked at *c*. *d*. Coarse lymph-canals. *e*. Fine radicles of the same. *f*. An efferent vessel of considerable size.

Structure.—The thyroid body is invested by a thin capsule of connective tissue, which projects into its substance and imperfectly divides it into masses of irregular form and size. When the organ is cut into, it is of a brownish-red colour, and is seen to be made up of a number of closed vesicles, containing a yellow glairy fluid, and separated from each other by intermediate connective tissue.

According to Dr. Baber, who has recently published some important observations on the minute structure of the thyroid,* the vesicles of the thyroid of the adult animal are generally closed cavities; but in some young animals (e.g. young dogs) the vesicles are more or less tubular and branched. This appearance he supposes to be due to the mode of growth of the gland, and merely indicating that an increase in the number of vesicles is taking place. Each vesicle is lined by a single layer of epithelium, the cells of which, though differing somewhat in shape in different animals, have always a tendency to assume a columnar form. Between the epithelial cells exists a delicate reticulum. The vesicles are of various sizes and shapes, and contain as a normal product a viscid, homogeneous, semi-fluid, slightly yellowish material, which frequently contains blood; the red corpuscles of which are found in it in various stages of disintegration and decolorisation, the yellow tinge being probably due to the hæmoglobin, which is thus set free from the coloured corpuscles. Baber has also described in the thyroid gland of the dog large round cells ('parenchymatous cells'), each provided with a single oval-shaped nucleus, which migrate into the interior of the gland-vesicles.

The capillary blood-vessels form a dense plexus in the connective tissue around the vesicles, between the epithelium of the vesicles and the endothelium of the lymph-spaces, which latter surround a greater or smaller part of the circumference of the vesicle. These lymph-spaces empty themselves into lymphatic vessels, which run in the interlobular connective tissue, not uncommonly surrounding the arteries which they accompany, and communicate with a network in the capsule of the gland. Baber has found in the lymphatics of the thyroid a viscid material which is morphologically identical with the normal constituent of the vesicle.

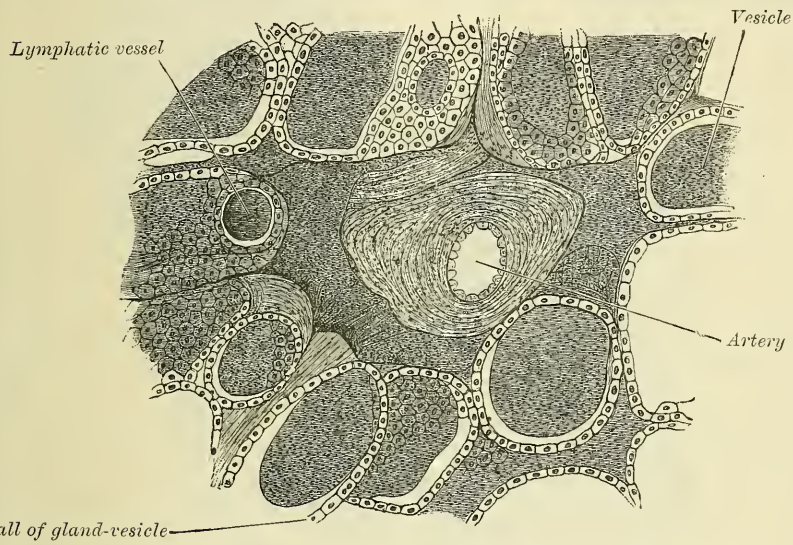
Vessels and Nerves.—The *arteries* supplying the thyroid are the superior and inferior thyroid, and sometimes an additional branch (thyroidea media, or ima) from the innominate artery, or the arch of the aorta, which ascends upon the

* 'Researches on the Minute Structure of the Thyroid Gland,' *Phil. Trans.* part iii. 1881.

front of the trachea. The arteries are remarkable for their large size and frequent anastomoses. The *veins* form a plexus on the surface of the gland, and on the front of the trachea, from which arise the superior, middle, and inferior thyroid veins; the two former terminating in the internal jugular, the latter in the innominate vein. The *lymphatics* are numerous, of large size, and terminate in the thoracic and right lymphatic ducts. The *nerves* are derived from the middle and inferior cervical ganglia of the sympathetic.

Surgical Anatomy.—The thyroid gland is subject to enlargement, which is called goitre. This may be due to hypertrophy of any of the constituents of the gland. The simplest (parenchymatous goitre) is due to an enlargement of the follicles. The *fibroid* is due to increase of the interstitial connective tissue. The *cystic* is that form in which one or more large cysts are formed from dilatation and possibly coalescence of adjacent follicles. The *pulsating goitre* is where the vascular changes predominate over the

FIG. 650.—Minute structure of thyroid. From a transverse section of the thyroid of a dog. (Semi-diagrammatic.) (Baber.)



parenchymatous, and the vessels of the gland are especially enlarged. Finally, there is *exophthalmic goitre* (Graves's disease), where there is great vascularity and often pulsation accompanied by exophthalmos, palpitation, and rapid pulse.

For the relief of these growths various operations have been resorted to: such as injection of tincture of iodine or perchloride of iron, especially applicable to the cystic form of the disease; ligature of the thyroid arteries; excision of the isthmus; and extirpation of the whole or a part of the gland. This latter operation is one of difficulty, and when the entire gland has been removed the operation has been followed by a condition resembling myxœdema. In removing the organ great care must be taken to avoid tearing the capsule, as if this happens the gland-tissue bleeds profusely. The thyroid arteries should be ligatured before an attempt is made to remove the mass, and in ligaturing the inferior thyroid the position of the recurrent laryngeal nerve must be borne in mind, so as not to include it in the ligature.

THE THYMUS GLAND

The **thymus gland** presents much resemblance in structure to other glandular organs, and is another of the organs which used formerly to be denominated *ductless glands*.

The thymus gland is a temporary organ, attaining its full size at the end of the second year, when it ceases to grow, and gradually dwindles, until at puberty it has almost disappeared. If examined when its growth is most active, it will be found to consist of two lateral lobes placed in close contact along the middle line, situated partly in the superior mediastinum, partly in the neck, and extending

from the fourth costal cartilage upwards, as high as the lower border of the thyroid gland. It is covered by the sternum, and by the origins of the Sterno-hyoid and Sterno-thyroid muscles. Below, it rests upon the pericardium, being separated from the arch of the aorta and great vessels by a layer of fascia. In the neck it lies on the front and sides of the trachea, behind the Sterno-hyoid and Sterno-thyroid muscles. The two lobes generally differ in size; they are occasionally united, so as to form a single mass; and sometimes separated by an intermediate lobe. The thymus is of a pinkish-grey colour, soft, and lobulated on its surfaces. It is about two inches in length, one and a half in breadth below, and about three or four lines in thickness. At birth it weighs about half an ounce.

Structure.—Each lateral lobe is composed of numerous lobules, held together by delicate areolar tissue; the entire gland being enclosed in an investing capsule of a similar but denser structure. The primary lobules vary in size from a pin's head to a small pea, and are made up of a number of small nodules or follicles, which are irregular in shape and are more or less fused together, especially

Fig. 651.—Minute structure of thymus gland.

Larger. *d*. Larger, with oil-globules, from the ox. *e*, *f*. Cells completely filled with fat, at *f* without a nucleus. *g*, *h*. Concentric bodies. *g*. An encapsulated nucleated cell. *h*. A composite structure of a similar nature.

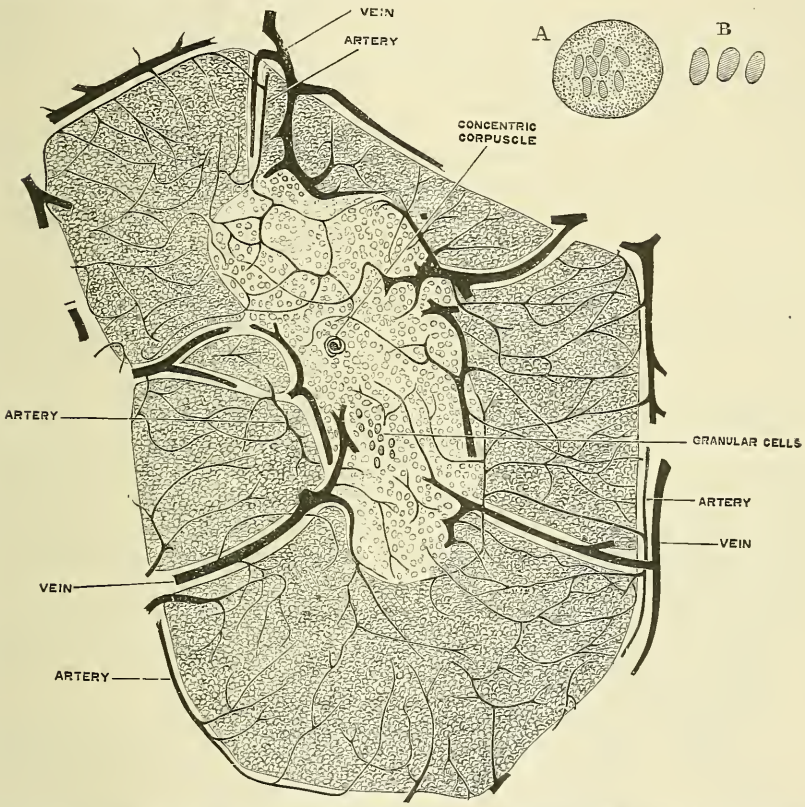
towards the interior of the gland. According to Watney, each follicle consists of a medullary and cortical portion, which differ in many essential particulars from each other. The *cortical portion* is mainly composed of lymphoid cells, supported by a delicate reticulum. In addition to this reticulum, of which traces only are found in the medullary portion, there is also a network of finely branched cells, which is continuous with a similar network in the medullary portion. This network forms an adventitia to the blood-vessels. In the *medullary portion* there are but few lymphoid cells, but there are, especially towards the centre, granular cells and concentric corpuscles. The granular cells are rounded or flask-shaped masses, attached (often by fibrillated extremities) to blood-vessels and to newly formed connective tissue. The concentric corpuscles are composed of a central mass, consisting of one or more granular cells, and of a capsule which is formed of epithelioid cells, which are continuous with the branched cells forming the network mentioned above.

Each follicle is surrounded by a capillary plexus, from which vessels pass into the interior, and radiate from the periphery towards the centre, and form a second

zone just within the margin of the medullary portion. In the centre of the medulla there are very few vessels, and they are of minute size.

Dr. Watney has recently made the important observation that hæmoglobin is found in the thymus, either in cysts or in cells situated near to, or forming part of, the concentric corpuscles. This hæmoglobin varies from granules to masses exactly resembling coloured blood-corpuscles, oval in the bird, reptile, and fish; circular in all mammals, except in the camel. Dr. Watney has also discovered, in the lymph issuing from the thymus, similar cells to those found in the gland, and, like them, containing hæmoglobin, either in the form of granules or masses.

FIG. 652.—Minute structure of thymus gland. Follicle of injected thymus from calf, four days old, slightly diagrammatic, magnified about 50 diameters. The large vessels are disposed in two rings, one of which surrounds the follicle, the other lies just within the margin of the medulla. (Watney.)



A and B. From thymus of camel, examined without addition of any reagent. Magnified about 400 diameters. A. Large colourless cell, containing small oval masses of hæmoglobin. Similar cells are found in the lymph-glands, spleen, and medulla of bone. B. Coloured blood-corpuscles.

From these facts he arrives at the physiological conclusion that the thymus is one source of the coloured blood-corpuscles.

Vessels and Nerves.—The *arteries* supplying the thymus are derived from the internal mammary, and from the superior and inferior thyroid. The *veins* terminate in the left innominate vein, and in the thyroid veins. The *lymphatics* are of large size, arise in the substance of the gland, and are said to terminate in the internal jugular vein. The *nerves* are exceedingly minute; they are derived from the pneumogastric and sympathetic. Branches from the descendens hypoglossi and phrenic reach the investing capsule, but do not penetrate into the substance of the gland.

THE URINARY ORGANS

THE KIDNEYS

THE Kidneys, two in number, are situated in the back part of the abdomen, and are for the purpose of separating from the blood certain materials which, when dissolved in a quantity of water, also separated from the blood by the kidneys, constitute the urine.

They are placed in the loins, one on each side of the vertebral column, behind the peritoneum, and surrounded by a mass of fat and loose areolar tissue. Their upper extremity is on a level with the upper border of the twelfth dorsal vertebra, their lower extremity on a level with the third lumbar. The right kidney is usually on a slightly lower level than the left, probably on account of the vicinity of the liver.

The kidneys rest on the lower part of the Diaphragm and the fascia covering the Quadratus lumborum and the Psoas magnus muscles. The right one is covered in front by the right lobe of the liver, the descending portion of the duodenum, and hepatic flexure of the colon ; the left one has in front the fundus of the stomach, the tail of the pancreas, and the descending colon.

Each kidney is about four inches in length, two to two and a half in breadth, and rather more than one inch in thickness. The left is somewhat longer, though narrower, than the right. The weight of the kidney in the adult male varies from $4\frac{1}{2}$ ounces to 6 ounces, in the adult female from 4 to $5\frac{1}{2}$ ounces. The combined weight of the two kidneys in proportion to the body is about 1 in 240.

The kidney has a characteristic form. It is flattened on its sides, and presents at one part of its circumference a hollow. It is larger at its upper than its lower extremity. It presents for examination two surfaces, two borders, and an upper and lower extremity.

Its *anterior surface* is convex, looks forwards and outwards, and is partially covered by peritoneum. The upper part of this surface on the right side is in contact with the under surface of the right lobe of the liver, on which it produces a slight concave impression, the *impressio renalis* (page 994) ; below this, the descending portion of the duodenum, and the hepatic flexure of the colon are connected to this surface by a quantity of loose areolar tissue. On the left side, the upper part of the anterior surface of the kidney is in contact with the under surface of the stomach, and below this with the left extremity of the pancreas, whilst the lower part is connected to the descending colon by loose areolar tissue.

The kidneys are partly covered in front by peritoneum and partly uncovered. On the right kidney, the *hepatic area*, that is to say that portion of the kidney which produces the renal impression on the liver, is covered by peritoneum, which therefore separates the kidney from the liver ; the *duodenal* and *colic areas* are not peritoneal, and these structures are connected to the kidney by loose connective tissue ; at the lower and inner extremity is a small area, the *meso-colic area*, which is covered by a layer of peritoneum of the greater sac and by the colic vessels. On the left kidney, the *gastric area* is covered by the peritoneum of the lesser sac ; the *pancreatic* and *colic areas* are non-peritoneal ; whilst as on

the right side, at the lower and inner extremity is an area, *meso-colic*, which is covered by the peritoneum of the greater sac and by the colic vessels.

The *posterior surface* is flatter than the anterior, and is embedded in areolar tissue, which separates it from the Diaphragm, and from the anterior lamella of the lumbar fascia covering the Quadratus lumborum muscle, and internally from the fascia covering the Psoas magnus muscle. The last dorsal, the ilio-inguinal and the ilio-hypogastric nerves are also in relation with this surface.

The *external border* is convex, and is directed outwards and backwards, towards the postero-lateral wall of the abdomen. On the left side it is in contact, at its upper part, with the spleen.

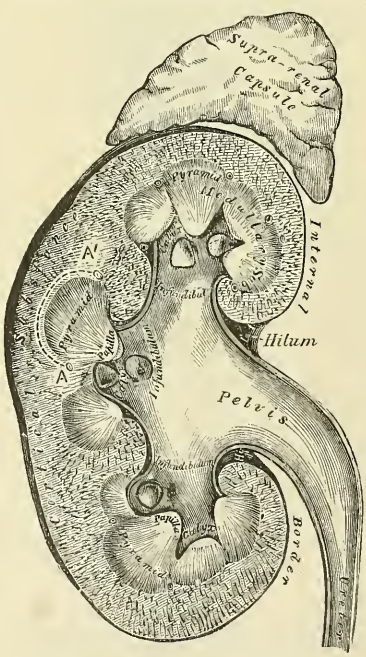
The *internal border* is concave, and is directed forwards and a little downwards. It presents a deep longitudinal fissure, bounded by a prominent overhanging anterior and posterior lip. This fissure is named the *hilum*, and allows of the passage of the vessels, nerves, and ureter into and out of the kidney.

The *superior extremity*, directed slightly inwards as well as upwards, is thick and rounded, and is surmounted by the suprarenal capsule, which covers also a small portion of the anterior surface.

The *inferior extremity*, directed a little outwards, as well as downwards, is smaller and thinner than the superior. It extends to within two inches of the crest of the ilium.

At the hilum of the kidney the relative position of the main structures passing into and out of the kidney is as follows:—the vein is in front, the artery in the middle, and the duct or ureter behind and towards the lower part. By a knowledge of these relations, the student may distinguish between the right and left kidney. The kidney is to be laid on the table, before the student, on its posterior surface, with its lower extremity towards the observer—that is to say, with the ureter *behind* and *below* the other vessels; the hilum will then be directed to the side to which the kidney belongs.

Fig. 653.—Vertical section of kidney.



General Structure of the Kidney.—The kidney is surrounded by a distinct investment of fibrous tissue, which forms a firm, smooth covering to the organ. It closely invests it, but can be easily stripped off, in doing which, however, numerous fine processes of connective tissue and small blood-vessels are torn through. Beneath this coat, a thin wide-meshed network of unstriped muscular fibre forms an incomplete covering to the organ. When the fibrous coat is stripped off, the surface of the kidney is found to be smooth and even, and of a deep red colour.

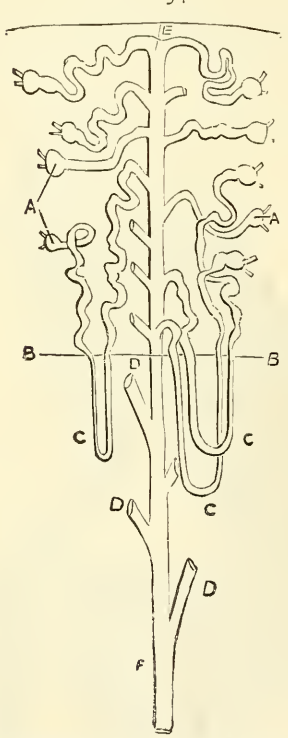
In infants, fissures extending for some depth may be seen on the surface of the organ, a remnant of the lobular construction of the gland. The kidney is dense in texture, but is easily lacerable by mechanical force. In order to obtain a knowledge of the structure of the gland, a vertical section must be made from its convex to its concave border, and the loose tissue and fat removed from around the vessels and the excretory duct (fig. 653). It will be then seen that the kidney consists of a central cavity, surrounded at all parts but one by the proper kidney-substance. This central cavity is called the *sinus*, and is lined by a

prolongation of the fibrous coat of the kidney, which enters through a longitudinal fissure, the *hilum* (before mentioned), which is situated at that part of the cavity which is not surrounded by kidney-structure. Through this fissure the blood-vessels of the kidney and its excretory duct pass, and therefore these structures, upon entering the kidney, are contained within the sinus. The excretory duct, or *ureter*, after entering, dilates into a wide, funnel-shaped sac, named the *pelvis*. This divides into two or three tubular divisions, which subdivide into several short, truncated branches, named *calices* or *infundibula*, all of which are contained in the central cavity of the kidney. The blood-vessels of the kidney, after passing through the hilum, are contained in the sinus or central cavity, lying between its lining membrane and the excretory apparatus before entering the kidney-substance.

This central cavity, as before mentioned, is surrounded on all sides, except at the hilum, by the substance of the kidney, which is at once seen to consist of two parts, viz. of an external, granular, investing part, which is called the *cortical portion*; and of an internal part, the *medullary portion*, made up of a number of dark-coloured pyramidal masses, with their bases resting on the cortical part, and their apices converging towards the centre, where they form prominent papillæ, which project into the interior of the calices.

The cortical substance is of a bright reddish-brown colour, soft, granular, and easily lacerable. It is found everywhere immediately beneath the capsule, and is seen to extend in an arched form over the base of each medullary pyramid. The part separating the sides of any two pyramids through which the arteries and nerves enter, and the veins and lymphatics emerge from the kidney, is called a *cortical column* or *column of Bertini* (A A′, fig. 653); whilst that portion which stretches from one cortical column to the next, and intervenes between the base of the pyramid and the capsule (which is marked by the dotted line, extending from A to A′ in fig. 653), is called a *cortical arch*, the depth of which varies from a third to half an inch.

Fig. 654.



A A. Malpighian bodies. B B. Margin of medullary structure. C C C. Loops of Henle. D D D. Straight tubes cut off. E. Commencing straight tubes. F. Termination of straight tube.

The *medullary substance*, as before said, is seen to consist of pale red-coloured, striated, conical masses, the *pyramids of Malpighi*; the number of which, varying from eight to eighteen, correspond to the number of lobes of which the organ in the fœtal state is composed. The base of each pyramid is surrounded by a cortical arch and directed towards the circumference of the kidney; the sides are contiguous with the cortical columns; whilst the apex, known as the *papilla* or *mammilla* of the kidney, projects into one of the calices of the ureter.

These two parts, *cortical* and *medullary*, so dissimilar in appearance, are very similar in structure, being made up of urinary tubes and blood-vessels, united and bound together by a connecting matrix or stroma.

Minute Anatomy.—The *tubuli uriniferi*, of which the kidney is for the most part made up, commence in the cortical portion of the kidney, and, after pursuing a very circuitous course through the cortical and medullary parts of the kidney, finally terminate at the apices of the Malpighian pyramids by open mouths (fig. 654), so that the fluid which they

contain is emptied into the dilated extremity of the ureter contained in the sinus of the kidney. If the surface of one of the papillæ is examined with a lens, it will be seen to be studded over with a number of small depressions from sixteen to twenty in number, and in a fresh kidney, upon pressure being made, fluid will be seen to exude from these depressions. They are the orifices of the tubuli uriniferi, which terminate in this situation. They commence in the cortical portion of the kidney as the *Malpighian bodies*, which are small rounded masses, varying in size, but of an average of about $\frac{1}{120}$ of an inch in diameter. They are of a deep red colour, and are found only in the cortical portion of the kidney. Each of these little bodies is composed of two parts: a central glomerulus of vessels, called a *Malpighian tuft*; and a membranous envelope, the *Malpighian capsule*, or *capsule of Bowman*, which latter is a small pouch-like commencement of a uriniferous tubule.

The *Malpighian tuft*, or vascular glomerulus, is a network of convoluted capillary blood-vessels, held together by scanty connective tissue and grouped into from two to five lobules. This capillary network is derived from a small arterial twig, the *afferent vessel*, which pierces the wall of the capsule, generally at a point opposite that at which the latter is connected with the tube; and the

Fig. 655.—Minute structure of kidney.

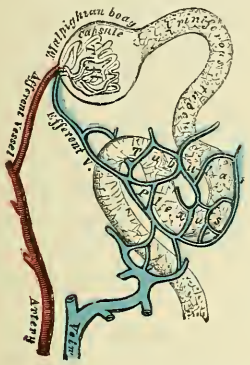


Fig. 656.—Malpighian body.

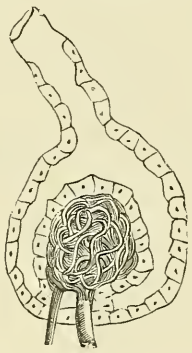


resulting vein, the *efferent vessel*, emerges from the capsule at the same point. The afferent vessel is usually the larger of the two (fig. 655). The *Malpighian*, or *Bowman's capsule*, which surrounds the glomerulus, is formed of a hyaline membrane, supported by a small amount of connective tissue, which is continuous with the connective tissue of the tube. It is lined on its inner surface by a layer of squamous epithelial cells, which are reflected from the lining membrane on to the glomerulus, at the point of entrance or exit of the afferent and efferent vessels. The whole surface of the glomerulus is covered with a continuous layer of the same cells, on a delicate supporting membrane, which with the cells dips in between the lobules of the glomerulus, closely surrounding them (fig. 656). Thus between the glomerulus and the capsule a space is left, forming a cavity lined by a continuous layer of cells, which varies in size according to the state of secretion and the amount of fluid present in it. The cells, as above stated, are squamous in the adult, but in the fœtus and young subject they are polyhedral or even columnar.

The *tubuli uriniferi*, commencing in the Malpighian bodies, in their course present many changes in shape and direction, and are contained partly in the medullary and partly in the cortical portions of the organ. At their junction with the Malpighian capsule they present a somewhat constricted portion, which is termed the *neck*. Beyond this the tube becomes convoluted, and pursues a considerable course in the cortical structure, constituting the *proximal convoluted tube*. After a time the convolutions disappear, and the tube approaches the medullary portion of the kidney in a more or less spiral manner. This section of

the tube has been called the *spiral tube of Schachowa*. Throughout this portion of their course the tubuli uriniferi have been contained entirely in the cortical structure, and have presented a pretty uniform calibre. They now enter the medullary portion, suddenly become much smaller, quite straight in direction, and dip down for a variable depth into the pyramids, constituting the *descending limb of Henle's loop*. Bending on themselves, they form a kind of loop, the *loop of Henle*, and re-ascending, they become suddenly enlarged and again spiral in direction, forming the *ascending limb of Henle's loop*, and re-enter the cortical structure. This portion of the tube does not present a uniform calibre, but becomes narrower as it ascends, and irregular in outline. As a narrow tube it enters the cortex and ascends for a short distance, when it again becomes dilated, irregular, and angular. This section is termed the *irregular tubule*; it terminates in a convoluted tube, which exactly resembles the proximal convoluted tubule, and is called the *distal convoluted tubule*. This again terminates in a narrow *curved tube*, which enters the straight or collecting tube.

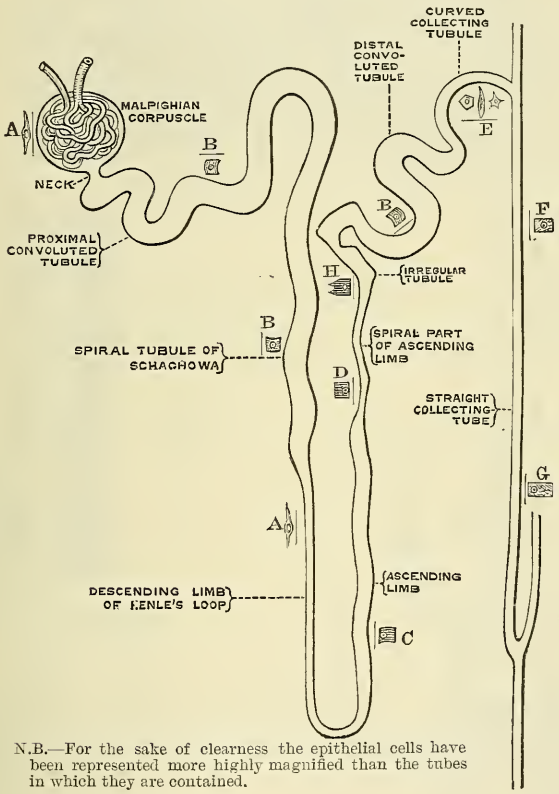
Each *straight*, otherwise called a *collecting* or *receiving tube*, commences by a small orifice on the summit of one of the papillæ, thus opening and discharging its contents into the interior of one of the calices. Traced into the substance of the pyramid, these tubes are found to run from apex to base, dividing dichotomously in their course and slightly diverging from each other. Thus dividing and subdividing, they reach the base of the pyramid, and enter the cortical structure greatly increased in number. Upon entering the cortical portion they continue a straight course for a variable distance, and are arranged in groups, called *medullary rays*, several of these groups corresponding to a single pyramid. The tubes in the centre of the group are the longest, and reach almost to the surface of the kidney, while the external ones are shorter, and advance only a short distance into the cortex. In consequence of this arrangement the cortical portion presents a number of conical masses, the apices of which reach the periphery of the organ, and the bases are applied to the medullary portion. These are termed the *pyramids of Ferrein*. As they run through the cortical portion, the straight tubes receive on either side the curved extremity of the convoluted tubes, which, as stated above, commence at the Malpighian bodies.

It will be seen from the above description that there is a continuous series of tubes from their commencement in the Malpighian bodies, to their termination at the orifices on the apices of the pyramids of Malpighi; and that the urine, the secretion of which commences in the capsule, finds its way through these tubes into the calices of the kidney, and so into the ureter. Commencing at the capsule, the tube first presents a narrow constricted portion (1) the *neck*. 2. It forms a wide convoluted tube, the *proximal convoluted tube*. 3. It becomes spiral, the *spiral tubule of Schachowa*. 4. It enters the medullary structure as a narrow, straight tube, the *descending limb of Henle's loop*. 5. Forming a loop and becoming dilated, it ascends somewhat spirally and, gradually diminishing in calibre, again enters the cortical structure, the *ascending limb of Henle's loop*. 6. It now becomes irregular and angular in outline, the *irregular tubule*. 7. It then becomes convoluted, the *distal convoluted tubule*. 8. Diminishing in size, it forms a curve, the *curved tubule*. 9. Finally it joins a straight tube, the *straight collecting tube*, which is continued downwards through the medullary substance to open at the apex of a pyramid.

The Tubuli Uriniferi: their Structure.—The tubuli uriniferi consist of basement membrane lined with epithelium. The epithelium varies considerably in different sections of the uriniferous tubes. In the neck the epithelium is continuous with that lining the Malpighian capsule, and like it consists of flattened cells with an oval nucleus (fig. 657, A). The cells are, however, very indistinct and difficult to trace, and the tube has here the appearance of a simple basement membrane unlined by epithelium. In the proximal convoluted tubule and the spiral tubule of Schachowa the epithelium is polyhedral in shape, the sides of the cells not being straight, but fitting into each other, and in some animals so fused

together that it is impossible to make out the lines of junction. In the human kidney the cells often present an angular projection of the surface next the basement membrane. These cells are made up of more or less rod-like fibres, which rest by one extremity on the basement membrane, whilst the other projects towards the lumen of the tube. This gives to the cells the appearance of distinct striation (Heidenhain) (fig. 657, B). In the descending limb of Henle's loop the epithelium resembles that found in the Malpighian capsule and the commencement of the tube, consisting of flat transparent epithelial plates with an oval nucleus (figs. 657, A; 658). In the ascending limb, on the other hand, the cells partake more of the character of those described as existing in the proximal convoluted tubule, being polyhedral in shape, and presenting the same appearance of striation. The nucleus, however, is not situated in the centre of the cell, but near the lumen

FIG. 657.—Uriniferous tube.



N.B.—For the sake of clearness the epithelial cells have been represented more highly magnified than the tubes in which they are contained.

(fig. 657, C). After the ascending limb of Henle's loop becomes narrower upon entering the cortical structure, the striation appears to be confined to the outer part of the cell; at all events it is much more distinct in this situation; the nucleus, which appears flattened and angular, being still situated near the lumen (fig. 657, D). In the irregular tubule, the cells undergo a still further change, becoming very angular, and presenting thick bright rods or markings, which render the striation much more distinct than in any other section of the urinary tubules (fig. 657, H). In the distal convoluted tubule the epithelium appears to be somewhat similar to that which has been described as existing in the proximal convoluted tubule, but presents a peculiar refractive appearance (fig. 657, B). In the curved tubule, just before its entrance into the straight collecting tube, the epithelium varies greatly as regards the shape of the cells, some being angular with short processes, others spindle-shaped, others polyhedral (fig. 657, E).

In the straight tubes the epithelium is more or less columnar: in its papillary portion the cells are distinctly columnar and transparent (figs. 659, 660); but as the tube approaches the cortex the cells are less uniform in shape; some are polyhedral, and others angular with short processes (fig. 657, F and G).

The Renal Blood-vessels.—The kidney is plentifully supplied with blood by the renal artery, a large offset of the abdominal aorta. Previously to entering the kidney, each artery divides into four or five branches, which are distributed to its substance. At the hilum these branches lie between the renal vein and ureter, the vein being in front, the ureter behind. Each vessel gives off some small branches to the suprarenal capsules, the ureter, and the surrounding cellular tissue and muscles. Frequently there is a second renal artery, which is given off from the abdominal aorta at a lower level, and supplies the lower portion of the kidney. It is termed the *inferior renal artery*. The branches of the renal artery, whilst in the sinus, give off a few twigs for the nutrition of the surrounding tissues, and terminate in the *arteriæ propriæ renales*, which enter the kidney proper in the columns of Bertini. Two of these pass to each pyramid of Malpighi, and run along its sides for its entire length, giving off as they

advance the afferent vessels of the Malpighian bodies in the columns. Having arrived at the bases of the pyramids, they make a bend in their course, so as to lie between the bases of the pyramids and the cortical arches, where they break up into two distinct sets of branches devoted to the supply of the remaining portions of the kidney.

The *first set*, the *interlobular arteries* (figs. 661, 662, B), are given off at right angles from the side of the arteriæ propriæ renales looking towards the cortical substance, and passing directly outwards between the pyramids of Ferrein they reach the capsule, where they terminate in the capillary network of this part. In their outward course they give off lateral branches; these are the *afferent vessels* for the Malpighian bodies (see page 1063), and, having pierced the capsule, end in the Malpighian tufts. From each tuft the corresponding renal efferent arises, and, having made its egress from the capsule near to the point where the afferent vessel entered, breaks up into a number of branches, which form a dense *venous plexus* around the adjacent urinary tubes (fig. 661).

The *second set of branches* from the arteriæ propriæ renales are for the supply of the medullary pyramids, which they enter at their bases; and, passing straight

* From the *Handbook for the Physiological Laboratory*.

through their substance to their apices, terminate in the venous plexuses found in that situation. They are called the *arteriolæ rectæ* (figs. 661, 662, F).

The *renal veins* arise from *three sources*—the veins beneath the capsule, the plexuses around the tubuli contorti in the cortical arches, and the plexuses

situated at the apices of the pyramids of Malpighi. The veins beneath the capsule are stellate in arrangement, and are derived from the capillary network of the capsule, into which the terminal branches of the interlobular arteries break up. These join to form the *venæ interlobulares*, which pass inwards

between the pyramids of Ferrein, receive branches from the plexuses around the tubuli contorti, and, having arrived at the bases of the Malpighian pyramids, join with the venæ rectæ, next to be described (figs. 661, 662, *b*).

The *venæ rectæ* are branches from the plexuses at the apices of the medullary

pyramids, formed by the terminations of the arteriolæ rectæ. They pass outwards in a straight course between the tubes of the medullary structure, and joining, as above stated, the venæ interlobulares, form the proper renal veins (figs. 661, 662, *f*).

These vessels, *venæ propriæ renales*, accompany the arteries of the same name, running along the entire length of the sides of the pyramids; and, having received in their course the efferent vessels from the Malpighian bodies in the cortical structure adjacent, quit the kidney substance to enter the sinus. In this cavity they inosculate with the corresponding veins from the outer pyramids to form the *renal vein*, which emerges from the kidney at the hilum and opens into the inferior vena cava; the left being longer than the right, from having to cross in front of the abdominal aorta.

Nerves of the Kidney.—The nerves of the kidney, although small, are about fifteen in number. They have small ganglia developed upon them, and are derived from the renal plexus, which is formed by branches from the solar plexus, the lower and outer part of the semilunar ganglion and aortic plexus, and from the lesser and smallest splanchnic nerves. They communicate with the spermatic plexus, a circumstance which may explain the occurrence of pain in the testicle in affections of the kidney. So far as they have been traced, they seem to accompany the renal artery and its branches, but their exact mode of termination is not known.

The *lymphatics* consist of a superficial and deep set which terminate in the lumbar glands.

Connective tissue, or *intertubular stroma*.—Although the tubules and vessels are closely packed, a certain small amount of connective tissue, continuous with the capsule, binds them firmly together. This tissue was first described by Goodsir, and subsequently by Bowman. Ludwig and Zawarykin have observed distinct fibres passing around the Malpighian bodies; and Henle has seen them between the straight tubes composing the medullary structure.

Surface Form.—The kidneys, being situated at the back part of the abdominal cavity and deeply placed, cannot be felt unless enlarged or misplaced. They are situated on the confines of the epigastric and umbilical regions internally, with the hypochondriac and lumbar regions externally. The left is somewhat higher than the right. According to Morris, the position of the kidney may be thus defined: *Anteriorly.* '1. A horizontal line through the umbilicus is below the lower edge of each kidney. 2. A vertical line carried upwards to the costal arch from the middle of Poupart's ligament has one third of the kidney to its outer side, and two thirds to its inner side. i.e. between this line and the median line of the body.' In adopting these lines it must be borne in mind that the axes of the kidneys are not vertical, but oblique, and if continued upwards would meet about the ninth dorsal vertebra. *Posteriorly.* The upper end of the left kidney would be defined by a line drawn horizontally outwards from the spinous process of the eleventh dorsal vertebra, and its lower end by a point two inches above the iliac crest. The right kidney would be half to three-quarters of an inch lower. Morris lays down the following rules for indicating the position of the kidney on the posterior surface of the body: '1. A line parallel with, and one inch from, the spine between the lower edge of the tip of the spinous process of the eleventh dorsal vertebra, and the lower edge of the spinous process of the third lumbar vertebra. 2. A line from the top of this first line outwards at right angles to it for $2\frac{3}{4}$ inches. 3. A line from the lower end of the first transversely outwards for $2\frac{3}{4}$ inches. 4. A line parallel to the first, and connecting the outer extremities of the second and third lines just described.'

The hilum of the kidney lies about two inches from the middle line of the back at the level of the spinous process of the first lumbar vertebra.

Surgical Anatomy.—The kidney is embedded in a large quantity of loose fatty tissue, and is only partially covered by peritoneum; hence rupture of this organ is not nearly so serious an accident as rupture of the liver or spleen, since the extravasation of blood and urine which follows is outside the peritoneal cavity. Occasionally the kidney may be bruised by blows in the loin, or by being compressed between the lower ribs and the ilium when the body is violently bent forwards. This is followed by a little transient hæmaturia, which, however, speedily passes off. Occasionally, when rupture involves the pelvis of the kidney or the commencement of the ureter, this duct may become blocked, and hydro-nephrosis follow.

The loose cellular tissue around the kidney may be the seat of suppuration, constituting *perinephritic abscess*. This may be due to injury, to disease of the kidney itself, or to extension of inflammation from neighbouring parts. The abscess may burst into the pleura, constituting empyema; into the colon or bladder; or may point externally in the groin or loin. Tumours of the kidney, of which perhaps sarcoma, in children, is the most common, may be recognised by their position and fixity; by the resonant colon lying in front of it; by their not moving with respiration; and by their rounded outline not presenting a notched anterior margin like the spleen, with which they are most likely to be confounded. The examination of the kidney should be bimanual; that is to say, one hand should be placed in the flank and firm pressure made forwards, while the other hand is buried in the abdominal wall, over the situation of the organ. Manipulation of the kidney frequently produces a peculiar sickening sensation, with sometimes faintness.

The kidney is mainly held in position by the mass of fatty matter in which it is embedded. If this fatty matter is loose or lax or is absorbed, the kidney may become movable and may give rise to great pain. This condition occurs, therefore, in badly nourished people, or in those who have become emaciated from any cause, and is more common in women than in men. It must not be confounded with the *floating kidney*: this is a congenital condition due to the development of a meso-nephron, which permits the organ to move more or less freely. The two conditions cannot, however, be distinguished until the abdomen is opened or the kidney explored from the loin.

The kidney has, of late years, been frequently the seat of surgical interference. It may be exposed for exploration or the evacuation of pus (nephrotomy); it may be incised for the removal of stone (nephro-lithotomy); it may be sutured when movable or floating (nephroraphy); or it may be removed (nephrectomy).

The kidney may be exposed either by a lumbar or abdominal incision. The lumbar operation is the one which is generally adopted, unless in cases of very large tumours, or of wandering kidneys, with a loose meso-nephron, on account of the advantages which it possesses of not opening the peritoneum, and affording admirable drainage. It may be performed either by an oblique, a vertical, or a transverse incision. Perhaps the preferable, as affording the best means for exploring the whole surface of the kidney, is an incision from the tip of the last rib, backwards to the edge of the Erector spinæ. This incision must not be quite parallel to the rib, but its posterior end must be at least three-quarters of an inch below it, lest the pleura be wounded. This cut is quite sufficient for an exploration of the organ. Should it require removal, a vertical incision can be made downwards to the crest of the ilium, along the outer border of the Quadratus lumborum. The structures divided are, the skin, the superficial fascia with the cutaneous nerves, the deep fascia, the posterior border of the External oblique muscle of the abdomen, and the outer border of the Latissimus dorsi; the Internal oblique and the posterior aponeurosis of the Transversalis muscle; the outer border of the Quadratus lumborum, and the deep layer of the lumbar fascia, and the transversalis fascia. The fatty tissue around the kidney is now exposed to view and must be separated by the fingers, or a director, in order to reach the kidney.

The abdominal operation is best performed by an incision in the linea semilunaris on the side of the kidney to be removed, as recommended by Langenbuch. The incision is made of varying length according to the size of the kidney; its mid-point should be on a level with the umbilicus. The abdominal cavity is opened. The intestines are then held aside, and the outer layer of the meso-colon opened, so that the fingers can be introduced behind the peritoneum and the renal vessels sought for. These are then to be ligatured: if tied separately, care must be taken to ligature the artery first. The kidney must now be enucleated, and the vessels and ureter divided, and the latter tied, or if thought necessary stitched to the edge of the wound.

The Ureters

The **Ureters** are the two tubes which conduct the urine from the kidneys into the bladder. They commence within the sinus of the kidney, by a number of short truncated branches, the *calices* or *infundibula*, which unite, either directly or indirectly, to form a dilated pouch, the *pelvis*, from which the ureter, after passing through the hilum of the kidney, descends to the bladder. The *calices*

are cup-like tubes encircling the apices of the Malpighian pyramids; but inasmuch as one calyx may include two or even more papillæ, their number is generally less than the pyramids themselves, the former being from seven to thirteen, whilst the latter vary from eight to eighteen. These calices converge into two or three tubular divisions, which by their junction form the *pelvis*, or dilated portion of the ureter. The portion last mentioned, where the pelvis merges into the ureter proper, is found opposite the spinous process of the first lumbar vertebra, in which situation it is accessible behind the peritoneum (see fig. 610, page 985).

The *ureter proper* is a cylindrical, membranous tube, about sixteen inches in length, and of the diameter of a goose-quill, extending from the pelvis of the kidney to the bladder. Its course is obliquely downwards and inwards through the lumbar region into the cavity of the pelvis, where it passes downwards, forwards, and inwards across that cavity to the base of the bladder, into which it then opens by a constricted orifice, after having passed obliquely for nearly an inch between its muscular and mucous coats.

Relations.—In its course it rests upon the Psoas muscle, being covered by the peritoneum, and crossed obliquely, from within outwards, by the spermatic vessels; the right ureter lying close to the outer side of the inferior vena cava. Opposite the first piece of the sacrum it crosses either the common or external iliac artery, lying behind the ileum on the *right* side and the sigmoid flexure of the colon on the *left*. In the pelvis it enters the posterior false ligament of the bladder, below the obliterated hypogastric artery, the vas deferens in the male passing between it and the bladder. In the female the ureter passes along the sides and cervix of the uterus and upper part of the vagina. At the base of the bladder it is situated about two inches from its fellow: lying, in the male, about an inch and a half behind the orifice of the urethra, at the posterior angle of the trigone.

Structure.—The *ureter* is composed of three coats—a fibrous, muscular, and mucous.

The *fibrous coat* is the same throughout the entire length of the duct, being continuous at one end with the capsule of the kidney at the floor of the sinus; whilst at the other it is lost in the fibrous structure of the bladder.

In the pelvis of the kidney the muscular coat consists of two layers, longitudinal and circular; the longitudinal fibres become lost upon the sides of the papillæ at the extremities of the calices; the circular fibres may be traced surrounding the medullary structure in the same situation. In the ureter proper the muscular fibres are very distinct, and are arranged in three layers—an external longitudinal, a middle circular, and an internal layer, less distinct than the other two, but having a general longitudinal direction. According to Kölliker, this internal layer is only found in the neighbourhood of the bladder.

The *mucous coat* is smooth, and presents a few longitudinal folds which become effaced by distension. It is continuous with the mucous membrane of the bladder below, whilst it is prolonged over the papillæ of the kidney above. Its epithelium is of a peculiar character, and resembles that found in the bladder. It is known by the name of 'transitional' epithelium (see fig. 13, page 15). It consists of several layers of cells, of which the innermost—that is to say, the cells in contact with the urine—are quadrilateral in shape, with a concave margin on their outer surface, into which fits the rounded end of the cells of the second layer. These, the intermediate cells, more or less resemble columnar epithelium, and are pear-shaped, with a rounded internal extremity which fits into the concavity of the cells of the first layer, and a narrow external extremity which is wedged in between the cells of the third layer. The external or third layer consists of conical or oval cells varying in number in different parts, and presenting processes which extend down into the basement membrane.

The *arteries* supplying the ureter are branches from the renal, spermatic, internal iliac, and inferior vesical.

The *nerves* are derived from the inferior mesenteric, spermatic, and pelvic plexuses.

Suprarenal Capsules

The **Suprarenal Capsules** were formerly classified together with the spleen, thymus, and thyroid, under the head of 'ductless glands,' as they have no excretory duct. They are two small flattened globular bodies, of a yellowish colour, situated at the back part of the abdomen, behind the peritoneum, and immediately in front of the upper part of each kidney; hence their name. The right one is somewhat triangular in shape, bearing a resemblance to a cocked hat; the left is more semilunar, and usually larger and higher than the right. They vary in size in different individuals, being sometimes so small as to be scarcely detected: their usual size is from an inch and a quarter to nearly two inches in length, rather less in width, and from two to three lines in thickness. Their average weight is about a drachm each.

Fig. 664.—Vertical section of the suprarenal capsule. (From Elberth, in Stricker's 'Manual.')

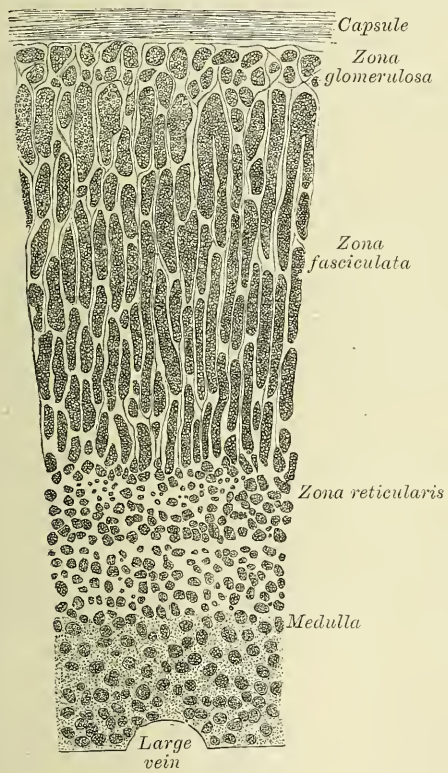

Fig. 665.—Minute structure of suprarenal capsule.

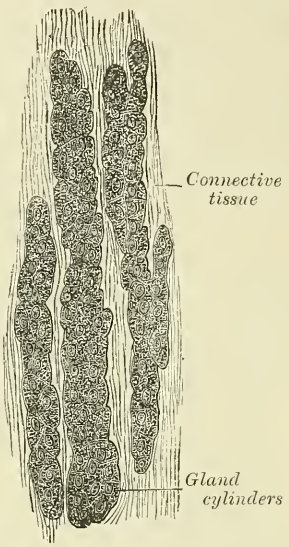

Fig. 666.—Minute structure of suprarenal capsule.

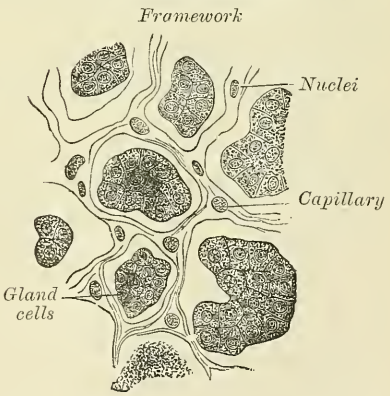


Relations.—The relations of the suprarenal capsules differ on the two sides of the body. The *right suprarenal* is roughly triangular in shape, its angles pointing upwards, downwards, and outwards. It presents two surfaces for examination, an anterior and posterior. The *anterior surface* presents two areas, separated by a furrow: one area, occupying about one third of the whole surface, is situated above and internally; it is depressed, uncovered by peritoneum, and is in contact in front with the under surface of the right lobe of the liver, and

along its inner border with the inferior vena cava (Rolleston); the remaining area is elevated, and is divided into a non-peritoneal portion, in contact with the hepatic flexure of the duodenum, and a portion covered by the peritoneum forming the hepato-renal fold. The *posterior surface*, in like manner, is divided into two areas separated by a ridge, which corresponds to the depression on the anterior surface, and which fits into the groove between the kidney and the right crus of the Diaphragm; of these areas, the inner one rests on the right crus of the Diaphragm, and the outer on the upper, inner, and anterior part of the right kidney. The *left suprarenal* is crescentic in shape, and presents an inner border which is convex, and an outer which is concave; its upper border is pointed, and its lower rounded. Its *anterior surface* presents two areas: an upper one, covered by the peritoneum forming the lesser sac, which separates it from the cardiac end of the stomach and to a small extent from the superior extremity of the spleen; and a lower one, which is in contact with the pancreas and splenic artery, and is therefore not in contact with the peritoneum. Its *posterior surface* presents a vertical ridge, which divides it into two areas. The ridge lies in the sulcus between the kidney and crus of the Diaphragm, whilst the area on either side of it lies on these parts respectively; the outer area, which is thin, resting on the kidney, and the inner and smaller area resting on the left crus of the Diaphragm. The surface of the suprarenal gland is surrounded by areolar tissue containing much fat, and closely invested by a thin fibrous coat, which is difficult to remove, on account of the numerous fibrous processes and vessels which enter the organ through the furrows on its anterior surface and base.

Small accessory suprarenals are often to be found in the connective tissue around the suprarenals. The smaller of these, on section, show a uniform surface, but in some of the larger a distinct medulla can be made out.

Structure.—On making a perpendicular section, the gland is seen to consist of two substances—external or cortical, and internal or medullary. The former, which constitutes the chief part of the organ, is of a deep yellow colour. The medullary substance is soft, pulpy, and of a dark brown or black colour, whence the name *atrabiliary capsules* formerly given to these organs. In the centre is often seen a space, not natural, but formed by the breaking down after death of the medullary substance.

The **cortical portion** consists chiefly of narrow columnar masses, placed perpendicularly to the surface. This arrangement is due to the disposition of the capsule, which sends into the interior of the gland processes, passing in vertically and communicating with each other by transverse bands, so as to form spaces which open into each other. These spaces are of slight depth near the surface of the organ, so that there the section somewhat resembles a net; this is termed the *zona glomerulosa*; but they become much deeper or longer further in, so as to resemble pipes or tubes placed endwise, the *zona fasciculata*. Still deeper down, near the medullary part, the spaces become again of small extent; this is named the *zona reticularis*. These processes, or trabeculæ, derived from the capsule and forming the framework of the spaces, are composed of fibrous connective tissue, with longitudinal bundles of unstriped muscular fibres. Within the interior of the spaces are contained groups of polyhedral cells, which are finely granular in appearance, and contain a spherical nucleus, and not unfrequently fat molecules. These groups of cells do not entirely fill the spaces in which they are contained, but between them and the trabeculæ of the framework is a channel, which is believed to be a lymph path or sinus, and which communicates with certain passages between the cells composing the group. The lymph path is supposed to open into a plexus of efferent lymphatic vessels which are contained in the capsule.

In the **medullary portion**, the fibrous stroma seems to be collected together into a much closer arrangement, and forms bundles of connective tissue which are loosely applied to the large plexus of veins of which this part of the organ

mainly consists. In the interstices lie a number of cells compared by Frey to those of columnar epithelium. They are coarsely granular, do not contain any fat molecules, and some of them are branched. Luschka has affirmed that these branches are connected with the nerve-fibres of a very intricate plexus which is found in the medulla: this statement has not been verified by other observers, for the tissue of the medullary substance is less easy to make out than that of the cortical, owing to its rapid decomposition.

The numerous arteries which enter the suprarenal bodies, from the sources mentioned below, penetrate the cortical part of the gland, where they break up into capillaries in the fibrous septa, and these converge to the very numerous veins of the medullary portion, which are collected together into the suprarenal vein, which usually emerges as a single vessel from the centre of the gland.

The *arteries* supplying the suprarenal capsules are numerous and of large size; they are derived from the aorta, the phrenic, and the renal; they subdivide into numerous minute branches previous to entering the substance of the gland.

The *suprarenal vein* returns the blood from the medullary venous plexus, and receives several branches from the cortical substance; it opens on the right side into the inferior vena cava, on the left side into the renal vein.

The *lymphatics* terminate in the lumbar glands.

The *nerves* are exceedingly numerous: they are found chiefly, if not entirely, in the medulla, and are derived from the solar and renal plexuses, and, according to Bergmann, from the phrenic and pneumogastric nerves. They have numerous small ganglia developed upon them, from which circumstance the organ has been conjectured to have some function in connection with the sympathetic nervous system.

THE PELVIS

The **cavity of the pelvis** is that part of the general abdominal cavity which is below the level of the linea ilio-pectinea and the promontory of the sacrum.

Boundaries.—It is bounded, behind, by the sacrum, the coccyx, the Pyriformis muscle, and the great sacro-sciatic ligaments; in front and at the sides, by the ossa pubis and ischia, covered by the Obturator muscles; above, it communicates with the cavity of the abdomen; and below, the outlet is closed by the triangular ligament, the Levatores ani and Coccygei muscles, and the visceral layer of the pelvic fascia, which is reflected from the wall of the pelvis on to the viscera.

Contents.—The viscera contained in this cavity are the urinary bladder, the rectum, some of the generative organs peculiar to each sex, and some convolutions of the small intestines: they are partially covered by the peritoneum, and supplied with blood-vessels, lymphatics and nerves.

The Bladder

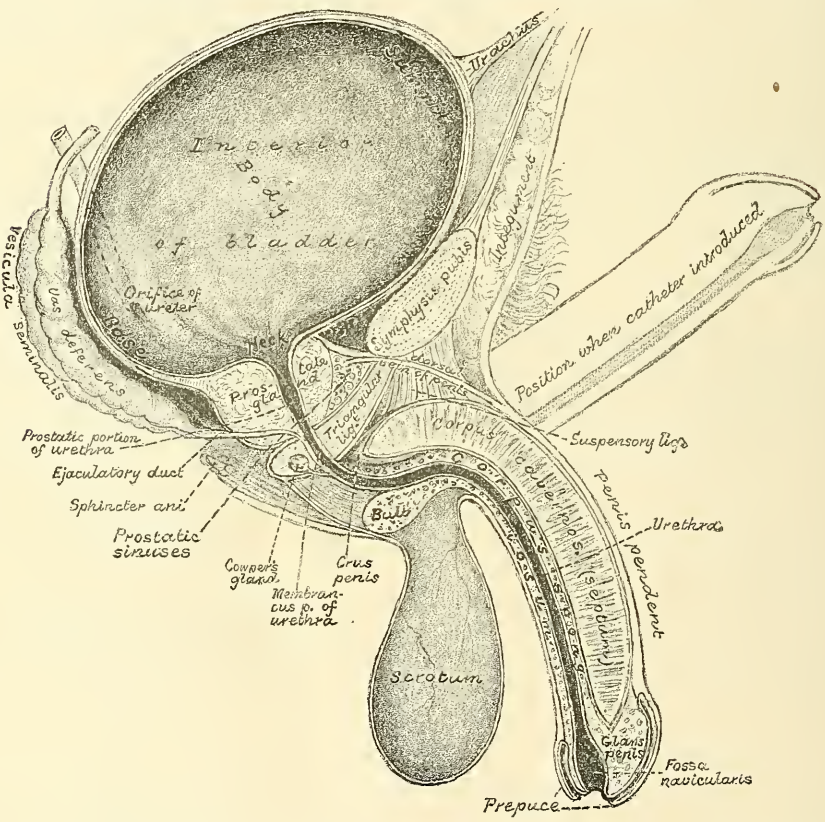
The **bladder** is the reservoir for the urine. It is a musculo-membranous sac, situated in the pelvis, behind the pubes, and in front of the rectum in the male; the cervix uteri and vagina intervening between it and that intestine in the female. The shape, position, and relations of the bladder are greatly influenced by age, sex, and the degree of distension of the organ. *During infancy* it is conical in shape, and projects above the upper border of the ossa pubis into the hypogastric region. *In the adult*, when quite empty and contracted, it is cup-shaped and on vertical median section its cavity, with the adjacent portion of the urethra, presents a Y-shaped cleft, the stem of the Y corresponding to the urethra. It is placed deeply in the pelvis, flattened from before backwards, and reaches as high as the upper border of the symphysis pubis. When slightly distended, it has a rounded form, and is still contained within the pelvic cavity; and when greatly distended it is ovoid in shape, rising into the abdominal cavity, and often extending nearly as high as the umbilicus. It is larger in its vertical diameter than

from side to side, and its long axis is directed from above obliquely downwards and backwards, in a line directed from some point between the symphysis pubis and umbilicus (according to its distension) to the end of the coccyx. The bladder, when distended, is slightly curved forwards towards the anterior wall of the abdomen, so as to be more convex behind than in front. In the female it is larger in the transverse than in the vertical diameter, and its capacity is said to be greater than in the male.* When moderately distended, it measures about five inches in length, and three inches across, and the ordinary amount which it contains is about a pint.

The bladder is divided for purposes of description into a superior, an antero-inferior, a posterior and two lateral surfaces.

The **superior** or **abdominal surface** is entirely free, and is covered throughout by peritoneum. It looks almost directly upwards into the abdominal cavity and

Fig. 667.—Vertical section of bladder, penis, and urethra.



is in relation with the small intestine and sometimes with the sigmoid flexure, and in the female, with the uterus. To its summit is attached the *urachus*.

The **urachus** is the obliterated remains of a tubular canal which exists in the embryo, and connects the cavity of the bladder with a membranous sac placed external to the abdomen, opposite the umbilicus, called the *allantois*. It passes upwards, from the apex of the bladder between the transversalis fascia and peritoneum, to the umbilicus, becoming thinner as it ascends. It is composed of fibrous tissue, mixed with plain muscular fibres. On each side of it is placed a fibrous cord, the obliterated portion of the hypogastric artery, which, passing

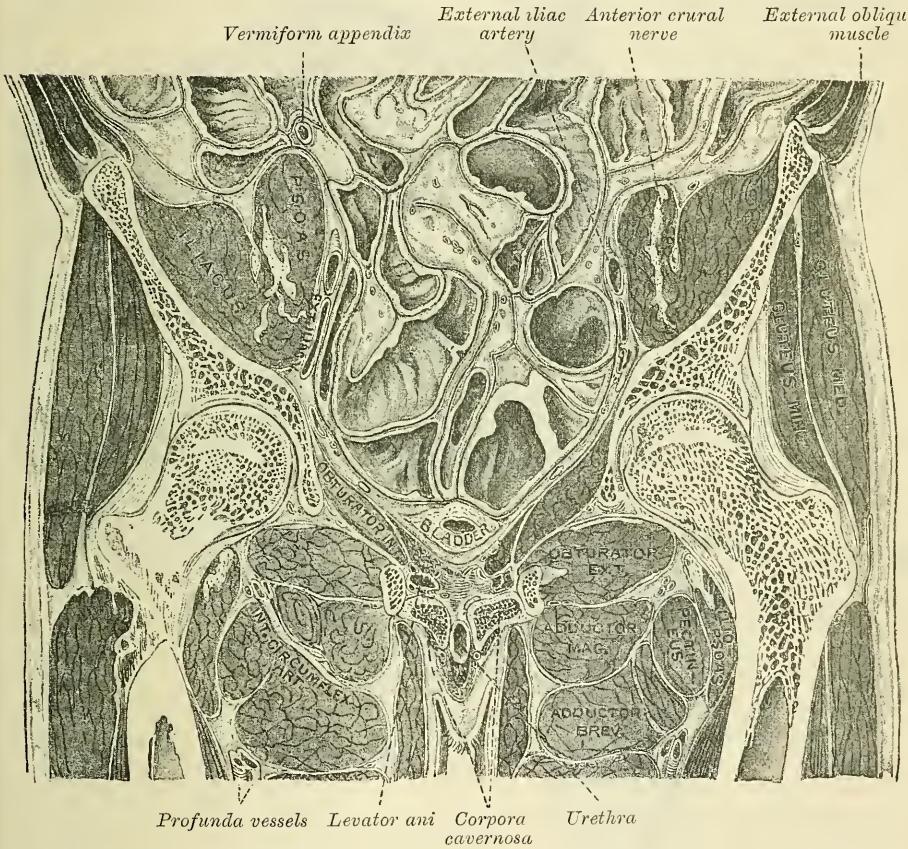
* According to Henle, the bladder is considerably smaller in the female than in the male.

upwards from the side of the bladder, approaches the urachus above its summit. In the infant, at birth, it is occasionally found pervious, so that the urine escapes at the umbilicus, and calculi have been found in its canal.

The **antero-inferior** or **pubic surface** is entirely uncovered by peritoneum, and looks downwards and forwards to the symphysis pubis, to which it is connected by loose cellular tissue. It is also in relation with the anterior part of the Levatores ani and Obturatores interni, and, when distended, with the anterior wall of the abdomen. It is covered by recto-vesical fascia, and at its lower part is attached by two strong bands of this fascia, the *anterior true ligaments*, to the back of the pubic bones.

The **posterior** or **rectal surface** is partly covered by peritoneum and partly uncovered. The upper portion to within about an inch and a half of the prostate

Fig. 668.—Frontal section of the lower part of the abdomen. Viewed from the front. (Braune.)



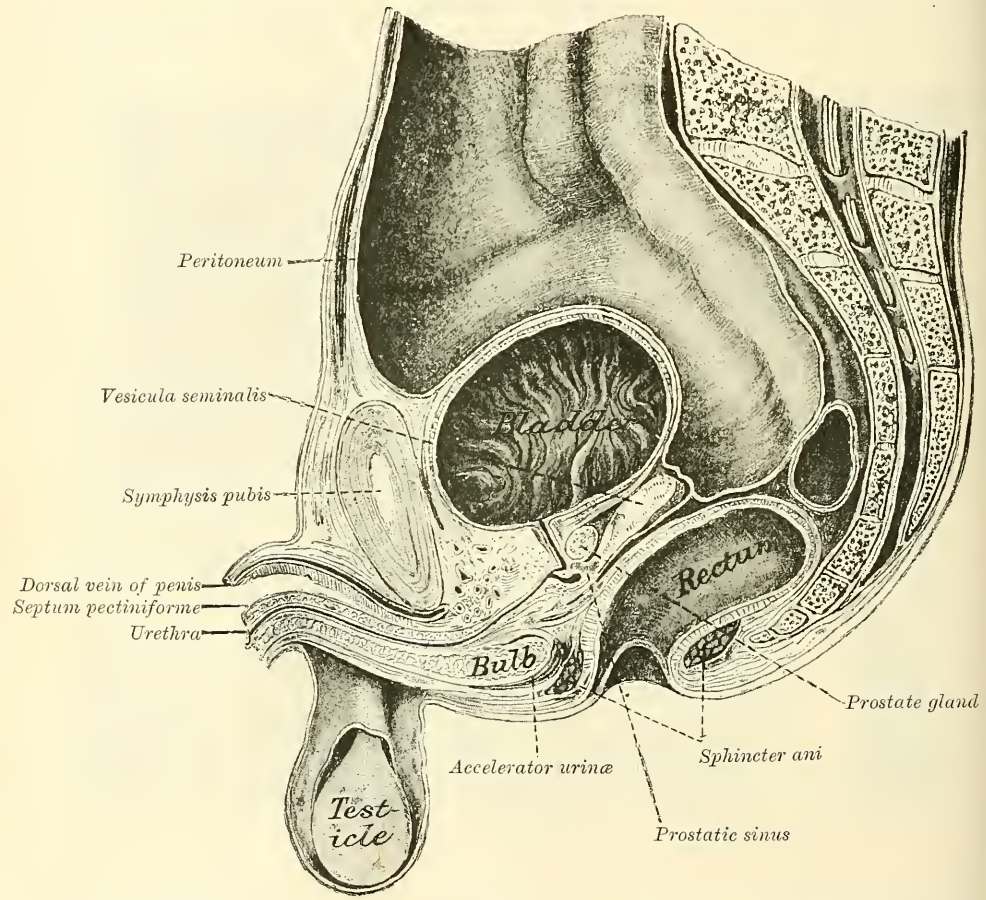
in the male is covered by the recto-vesical pouch of peritoneum; in the female to a similar extent by the utero-vesical pouch. The lower part is in direct contact with the anterior wall of the rectum and the vesiculæ seminales and vasa deferentia in the male.

The portion of the bladder in relation with the rectum corresponds to a triangular space bounded, in front, by the prostate gland; behind, by the recto-vesical fold of the peritoneum; and on each side, by the vesicula seminalis and vas deferens. It is separated from direct contact with the rectum by the recto-vesical fascia. When the bladder is very full, the peritoneal fold is raised with it, and the distance between its reflection and the anus is about four inches; but this distance is much diminished when the bladder is empty and contracted. *In*

the female, the base of the bladder lies in contact with the lower part of the cervix uteri, is adherent to the anterior wall of the vagina, and separated from the upper part of the anterior surface of the cervix uteri by a fold of the peritoneum.

The **lateral surfaces** are covered behind and above by peritoneum, which extends as low as the level of the obliterated hypogastric artery; below and in front of this, these surfaces are uncovered by peritoneum, and are separated from the Levatores ani muscles and walls of the pelvis by a quantity of loose areolar tissue containing fat. In front this surface is connected to the recto-vesical fascia by a broad expansion on either side, the *lateral true ligaments*. Separating these ligaments and the anterior true ligaments from the peritoneum is a space containing a considerable amount of loose cellular tissue. It is known as the *cavum*

Fig. 669.—Vertical median section of the male pelvis. (Henle.)



Retzii. The vas deferens crosses the hinder part of the lateral surface obliquely, and is itself crossed by the ureter, which enters the bladder at the junction of the posterior and lateral surfaces, about two inches above the prostate.

The, so-called, *neck* (*cervix*) *of the bladder* is the point of commencement of the urethra; there is, however, no tapering part, which would constitute a true neck, but the bladder suddenly contracts to the opening of the urethra. In the male its direction is oblique in the erect posture, and it is surrounded by the prostate gland. In the female its direction is obliquely downwards and forwards.

Ligaments.—The bladder is retained in its place by ligaments, which are divided into true and false. The true ligaments are five in number: two anterior, two

lateral, and the urachus. The false ligaments, also five in number, are formed by folds of the peritoneum.

The *anterior ligaments* (*pubo-prostatic*) extend from the back of the ossa pubis, one on each side of the symphysis, to the front of the neck of the bladder, over the upper surface of the prostate gland. These ligaments are formed by the recto-vesical fascia, and contain a few muscular fibres prolonged from the bladder.

The *lateral ligaments*, also formed by the recto-vesical fascia, are broader and thinner than the preceding. They are attached to the lateral parts of the prostate, and to the sides of the base of the bladder.

The *urachus* is the fibro-muscular cord already mentioned, extending between the summit of the bladder and the umbilicus. It is broad below, at its attachment to the bladder, and becomes narrower as it ascends.

The *false ligaments of the bladder* are two posterior, two lateral, and one superior.

The *two posterior* pass forwards, in the male, from the sides of the rectum; in the female, from the sides of the uterus, to the posterior and lateral aspect of the bladder: they form the lateral boundaries of the recto-vesical fold of the

Fig. 670.—Superficial layer of the epithelium of the bladder. Composed of polyhedral cells of various sizes, each with one, two, or three nuclei. (Klein and Noble Smith.)

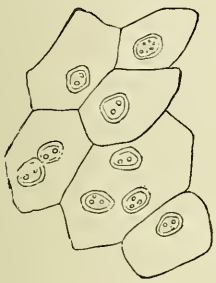


Fig. 671.—Deep layers of epithelium of bladder, showing large club-shaped cells above, and smaller, more spindle-shaped cells below—each with an oval nucleus. (Klein and Noble Smith.)

peritoneum, and contain the obliterated hypogastric arteries, and the ureters, together with vessels and nerves.

The *two lateral ligaments* are reflections of the peritoneum, from the iliac fossæ to the sides of the bladder.

The *superior ligament* (*ligamentum suspensorium*) is the prominent fold of peritoneum extending from the summit of the bladder to the umbilicus. It covers the urachus and the obliterated hypogastric arteries.

Structure.—The bladder is composed of four coats—serous, muscular, submucous, and mucous.

The *serous coat* is partial, and derived from the peritoneum. It invests the superior surface and the upper part of the posterior and lateral surfaces, and is reflected from them on to the abdominal and pelvic walls.

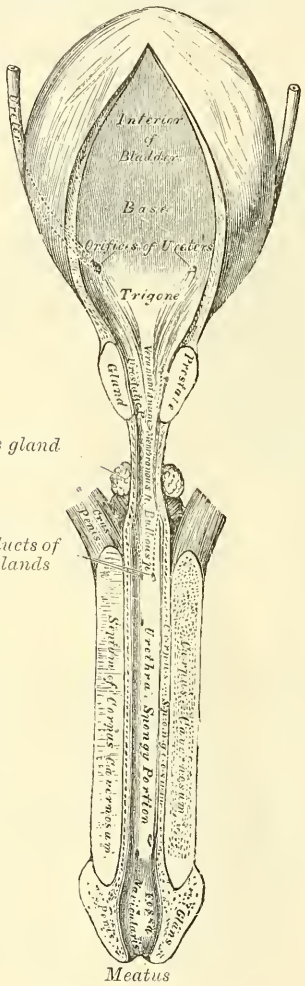
The *muscular coat* consists of three layers of unstriped muscular fibre: an external layer, composed of fibres having for the most part a longitudinal arrangement; a middle layer, in which the fibres are arranged, more or less, in a circular manner; and an internal layer, in which the fibres have a general longitudinal arrangement.

The *fibres of the external longitudinal layer* arise from the posterior surface of the body of the os pubis in both sexes (*musculi pubo-vesicalis*), and in the male from the adjacent part of the prostate gland and its capsule. They pass, in a more or less longitudinal manner, up the anterior surface of the bladder, over its apex, and then descend along its posterior surface to its base, where they become attached to the prostate in the male, and to the front of the vagina in the female.

At the sides of the bladder the fibres are arranged obliquely and intersect one another. This layer has been named the *detrusor urinæ muscle*.

The fibres of the *middle circular layer* are very thinly and irregularly scattered on the body of the organ, and though to some extent placed transversely to the long axis of the bladder, are for the most part arranged obliquely. Towards the lower part of the bladder, round the cervix and commencement of the urethra, they are disposed in a thick circular layer, forming the *sphincter vesicæ*, which is continuous with the muscular fibres of the prostate gland.

Fig. 672.—The bladder and urethra laid open. Seen from above.



The *internal longitudinal layer* is thin, and its fasciculi have a reticular arrangement, but with a tendency to assume for the most part a longitudinal direction.

Two bands of oblique fibres, originating behind the orifices of the ureters, converge to the back part of the prostate gland, and are inserted, by means of a fibrous process, into the middle lobe of that organ. They are the *muscles of the ureters*, described by Sir C. Bell, who supposed that during the contraction of the bladder they serve to retain the oblique direction of the ureters, and so prevent the reflux of the urine into them.

The *submucous coat* consists of a layer of areolar tissue, connecting together the muscular and mucous coats, and intimately united to the latter.

The *mucous coat* is thin, smooth, and of a pale rose colour. It is continuous through the ureters with the lining membrane of the uriniferous tubes, and below with that of the urethra. It is connected loosely to the muscular coat by a layer of areolar tissue, excepting at the trigone, where its adhesion is more close. The epithelium covering it is of the transitional variety, consisting of a superficial layer of polyhedral, flattened cells, each with one, two, or three nuclei; beneath these, a stratum of large club-shaped cells, with the narrow extremity directed downwards and wedged in between smaller spindle-shaped cells, containing an oval nucleus (figs. 602, 603).

Objects seen on the inner surface.—Upon the inner surface of the bladder are seen the orifices of the ureters, the trigone, and the commencement of the urethra.

The orifices of the ureters.—These are situated at the base of the trigone, being distant from each other about two inches; they are about an inch and a half from the base of the prostate and the commencement of the urethra.

The *trigonum vesicæ*, or *trigone vesical*, is a triangular smooth surface with the apex directed forwards, situated at the base of the bladder immediately behind the urethral orifice. It is paler in colour than the rest of the mucous membrane, and never presents any rugæ, even in the collapsed condition of the organ, owing to its intimate adhesion to the subjacent tissue. It is bounded at

each posterior angle by the orifices of the ureters, which are placed nearly two inches from each other, and about an inch and a half behind the orifice of the urethra, which forms the anterior angle of the trigone. Projecting from the lower and anterior part of the bladder, and reaching to the orifice of the urethra, is a slight elevation of mucous membrane, called the *uvula vesicæ*. It is formed by a thickening of the submucous tissue.

The *arteries* supplying the bladder are the superior, middle, and inferior vesical in the male, with additional branches from the uterine and vaginal in the female. They are all derived from the anterior trunk of the internal iliac. The obturator and sciatic arteries also supply small visceral branches to the bladder.

The *veins* form a complicated plexus round the neck, sides, and base of the bladder, and terminate in the internal iliac vein.

The *lymphatics* accompany the blood-vessels, passing through the glands surrounding them.

The *nerves* are derived from the pelvic plexus of the sympathetic and from the third and the fourth sacral nerves; the former supplying the upper part of the organ, the latter its base and neck. According to F. Darwin the sympathetic fibres have ganglia connected with them, which send branches to the vessels and muscular coat.

Surface Form.—The surface form of the bladder varies with its degree of distension and under other circumstances. In the young child it is represented by a conical figure, the apex of which, even when the viscus is empty, is situated in the hypogastric region, about an inch above the level of the symphysis pubis. In the adult, when the bladder is empty, its apex does not reach above the level of the upper border of the symphysis pubis, and the whole organ is situated in the pelvis; the neck, in the male, corresponding to a line drawn horizontally backwards, through the symphysis a little below its middle. As the bladder becomes distended it gradually rises out of the pelvis into the abdomen and forms a swelling in the hypogastric region, which is perceptible to the hand, as well as to percussion. In extreme distension it reaches into the umbilical region. Under these circumstances it is closely applied to the abdominal wall, without the intervention of peritoneum, so that it can be tapped by an opening in the middle line just above the symphysis pubis, without any fear of wounding the serous membrane. When the rectum is distended, the prostatic portion of the urethra is elongated and the bladder lifted out of the pelvis and the peritoneum pushed upwards. Advantage is taken of this in performing the operation of suprapubic cystotomy. The rectum is distended by an indiarubber bag, which is introduced into this cavity empty, and then filled with ten or twelve ounces of water. If now the bladder is injected with about half a pint of some antiseptic fluid, it will appear above the pubes plainly perceptible to the sight and touch. The peritoneum will be pushed out of the way, and an incision three inches long may be made in the linea alba from the symphysis pubis upwards without any great risk of wounding the peritoneum.

When distended the bladder can be felt in the male, from the rectum, behind the prostate, and fluctuation can be perceived by a bimanual examination, one finger being introduced into the rectum and the distended bladder tapped on the front of the abdomen with the finger of the other hand. This portion of the bladder, that is, the portion felt in the rectum by the finger, is also uncovered by peritoneum, and the bladder may here be punctured from the rectum, in the middle line, without risk of wounding the serous membrane.

Surgical Anatomy.—A defect of development, in which the bladder is implicated, is known under the name of *extroversion of the bladder*. In this condition the lower part of the abdominal wall and the anterior wall of the bladder are wanting, so that the posterior surface of the bladder presents on the abdominal surface, and is pushed forwards by the pressure of the viscera within the abdomen, forming a red vascular tumour, on which the openings of the ureters are visible. The penis, except the glans, is rudimentary and is cleft on its dorsal surface, exposing the floor of the urethra, a condition known as *epispadias*. The pelvic bones are also arrested in development (see page 271).

The bladder may be ruptured by violence applied to the abdominal wall, when the viscus is distended, without any injury to the bony pelvis, or it may be torn in cases of fracture of the pelvis. The rupture may be either intraperitoneal or extraperitoneal, that is, may implicate the superior surface of the bladder in the former case, or one of the other surfaces in the latter. Rupture of the antero-inferior surface alone is, however, very rare. Until recently intraperitoneal rupture was uniformly fatal, but now abdominal section and suturing the rent with Lembert's suture is resorted to, with a very considerable amount of success. The sutures are inserted only through the peritoneal and muscular coats in such a way as to bring the serous surfaces at the margins of the wound into apposition, and one is

inserted just beyond each end of the wound. The bladder should be tested as to whether it is water-tight before closing the external wound.

The muscular coat of the bladder undergoes hypertrophy in cases in which there is any obstruction to the flow of urine. Under these circumstances the bundles of which the muscular coat consists become much increased in size, and, interlacing in all directions, give rise to what is known as the *fasciculated bladder*. Between these bundles of muscular fibres the mucous membrane may bulge out, forming sacculi, constituting the *sacculated bladder*, and in these little pouches phosphatic concretions may collect, forming *encysted calculi*. The mucous membrane is very loose and lax, except over the trigone, to allow of the distension of the viscus.

Various forms of tumour have been found springing from the wall of the bladder. The innocent tumours are the papilloma and the mucous polypus arising from the mucous membrane; the fibrous, from the submucous tissue; and the myoma, originating in the muscular tissue; and, very rarely, dermoid tumours, the exact origin of which it is difficult to explain. Of the malignant tumours, epithelioma is the most common, but sarcomata are occasionally found in the bladder of children.

Puncture of the bladder may be performed either above the symphysis pubis or through the rectum, in both cases without wounding the peritoneum. The former plan is generally to be preferred, since in puncture by the rectum a permanent fistula may be left from abscess forming between the rectum and the bladder; or pelvic cellulitis may be set up; moreover, it is exceedingly inconvenient to keep a cannula in the rectum. In some cases, in performing this operation the recto-vesical pouch of peritoneum has been wounded, inducing fatal peritonitis. The operation, therefore, has been almost completely abandoned.

The Male Urethra

The **urethra in the male** extends from the neck of the bladder to the meatus urinarius. It presents a double curve in the flaccid state of the penis, but in the erect state it forms only a single curve, the concavity of which is directed upwards (fig. 667). Its length varies from eight to nine inches; and it is divided into three portions, the *prostatic*, *membranous*, and *spongy*, the structure and relations of which are essentially different. Except during the passage of the urine or semen, the urethra is a mere transverse cleft or slit, with its upper and under surfaces in contact. At the orifice of the urethra at the end of the penis, the slit is vertical, and in the prostatic portion somewhat arched.

The **Prostatic portion** is the widest and most dilatable part of the canal. It passes through the prostate gland, from its base to the apex, lying nearer its upper than its lower surface. It is about an inch and a quarter in length; the form of the canal is spindle-shaped, being wider in the middle than at either extremity, and narrowest in front, where it joins the membranous portion. A transverse section of the canal as it lies in the prostate is horseshoe in shape, the convexity being directed upwards (fig. 673).

Upon the floor of the canal is a narrow longitudinal ridge, the *verumontanum*, or *caput gallinaginis*, formed by an elevation of the mucous membrane and its subjacent tissue. It is eight or nine lines in length, and a line and a half in height; and contains, according to Kobelt, muscular and erectile tissues. When distended, it may serve to prevent the passage of the semen backwards into the bladder. On each side of the verumontanum is a slightly depressed fossa, the *prostatic sinus*, the floor of which is perforated by numerous apertures, the *orifices of the prostatic ducts*; the ducts of the middle lobe opening behind the verumontanum. At the fore part of the verumontanum, in the middle line, is a depression, the *sinus pocularis* (*vesicula prostatica*); and upon or within its margins are the slit-like openings of the ejaculatory ducts. The sinus pocularis forms a *cul-de-sac* about a quarter of an inch in length, which runs upwards and backwards in the substance of the prostate beneath the middle lobe; its prominent upper wall partly forms the verumontanum. Its walls are composed of fibrous tissue, muscular fibres, and mucous membrane; and numerous small glands open on its inner surface. It has been called by Weber, who discovered it, the *uterus masculinus*, from its being developed from the united ends of the rudimentary Müllerian ducts, and therefore homologous with the uterus in the female.

The **Membranous portion of the urethra** extends between the apex of the prostate and the bulb of the corpus spongiosum. It is the narrowest part of the canal (excepting the orifice), and measures three-quarters of an inch along its upper, and half an inch along its lower surface, in consequence of the bulb projecting backwards beneath it. Its anterior concave surface is placed about an inch beneath the pubic arch, from which it is separated by the dorsal vessels and nerves of the penis, and some muscular fibres. Its posterior convex surface is separated from the rectum by a triangular space, which constitutes the perinæum. The membranous portion of the urethra perforates both the inferior and superior layers of the deep perineal fascia, and receives an investment from them. As it pierces the superior layer, the fibres around the opening are prolonged backwards over the posterior part of the membranous portion of the urethra, and as it pierces the inferior layer a similar prolongation takes place in the opposite direction, investing the anterior part of the membranous portion. It is also surrounded by the Compressor urethræ muscle.

The **Spongy portion** is the longest part of the urethra, and is contained in the corpus spongiosum. It is about six inches in length, and extends from the termination of the membranous portion to the meatus urinarius. Commencing just in front of the triangular ligament, it inclines downwards for a short distance; it then ascends for about half its length, and then, in the flaccid condition of the penis, it bends suddenly downwards. It is narrow, and of uniform size in the body of the penis, measuring about a quarter of an inch in diameter; being dilated behind, within the bulb; and again anteriorly within the glans penis, where it forms the *fossa navicularis*.

The *Bulbous portion* is a name given, in some descriptions of the urethra, to the posterior part of the spongy portion contained within the bulb.

The *meatus urinarius* is the most contracted part of the urethra; it is a vertical slit, about three lines in length, bounded on each side by two small labia.

The inner surface of the lining membrane of the urethra, especially on the floor of the spongy portion, presents the orifices of numerous mucous glands and follicles situated in the submucous tissue, and named the *glands of Littré*. They vary in size, and their orifices are directed forwards, so that they may easily intercept the point of a catheter in its passage along the canal. One of these lacunæ, larger than the rest, is situated on the upper surface of the fossa navicularis, about an inch and a half from the orifice; it is called the *lacuna magna*. Into the bulbous portion are found opening the ducts of Cowper's glands.

Structure.—The urethra is composed of a continuous mucous membrane, supported by a submucous tissue which connects it with the various structures through which it passes.

The *mucous coat* forms part of the genito-urinary mucous membrane. It is continuous with the mucous membrane of the bladder, ureters, and kidneys; externally, with the integument covering the glans penis; and is prolonged into the ducts of the glands which open into the urethra, viz. Cowper's glands and the prostate gland; and into the vasa deferentia and vesiculæ seminales, through the ejaculatory ducts. In the spongy and membranous portions the mucous membrane is arranged in longitudinal folds when the organ is contracted. Small papillæ are found upon it, near the orifice; and its epithelial lining is of the columnar variety, excepting near the meatus, where it is squamous.

The *submucous tissue* consists of a vascular erectile layer; outside which is a layer of unstriped muscular fibres, arranged in a circular direction, which separates the mucous membrane and submucous tissue from the tissue of the corpus spongiosum.

Surgical Anatomy.—The urethra may be ruptured by the patient falling astride of any hard substance and striking his perinæum, so that the urethra is crushed against the pubic arch. Bleeding will at once take place from the urethra, and this, together with the

bruising in the perinæum and the history of the accident, will at once point to the nature of the injury.

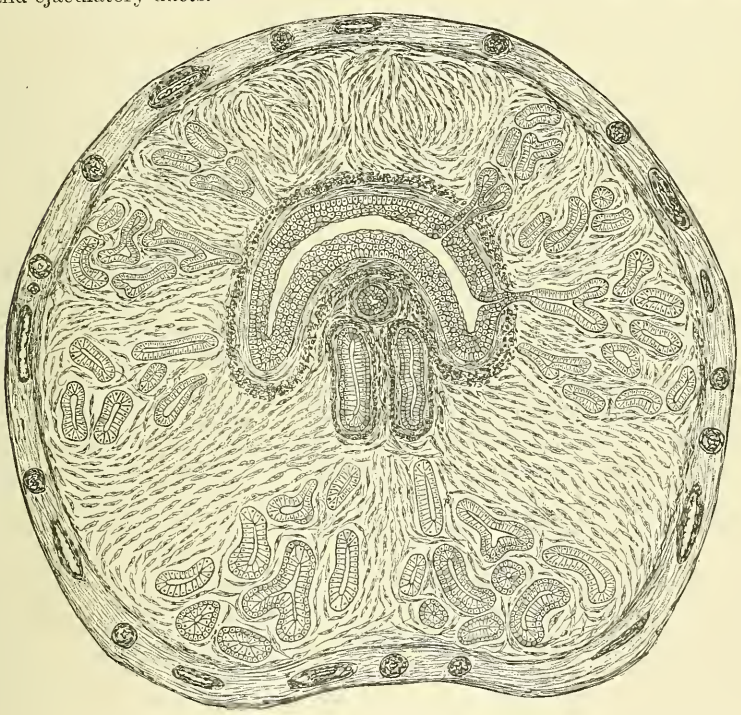
The surgical anatomy of the urethra is of considerable importance, in connection with the passage of instruments into the bladder. Otis was the first to point out that the urethra is capable of great dilatability, so that, excepting through the external meatus, an instrument corresponding to 18 English gauge (29 French) can usually be passed without damage. The orifice of the urethra is not so dilatable and therefore frequently requires slitting. A recognition of this dilatability caused Bigelow to very considerably modify the operation of lithotrity and introduce that of litholapaxy. In passing catheters, especially fine ones, the point of the instrument should be kept as far as possible along the upper wall of the canal, as it is otherwise very liable to enter one of the lacunæ. Stricture of the urethra is a disease of very common occurrence, and is generally situated in the spongy portion of the urethra, most commonly in the bulbous portion, just in front of the membranous urethra, but in a very considerable number of cases in the penile or ante-scrotal part of the canal.

MALE ORGANS OF GENERATION

The Prostate Gland

THE **Prostate Gland** (*προΐστημι, to stand before*) is a pale, firm, glandular body, which is placed immediately in front of the neck of the bladder and around the commencement of the urethra. It is placed in the pelvic cavity, behind and below the symphysis pubis, posterior to the deep perineal fascia, and rests upon

Fig. 673—Transverse section of the prostate gland; showing the urethra, with the eminence of the caput gallinaginis; beneath it the sinus pocularis and ejaculatory ducts.



the rectum, through which it may be distinctly felt, especially when enlarged. In shape and size it resembles a chestnut.

Its *base* is directed upwards and backwards towards the neck of the bladder.

Its *apex* is directed downwards and forwards to the deep perineal fascia, which it touches.

Its *posterior surface* is smooth, marked by a slight longitudinal furrow, and rests on the rectum, to which it is connected by dense areolar tissue.

Its *anterior surface* is convex, and placed about three-quarters of an inch below the pubic symphysis, from which it is separated by a plexus of veins and a quantity of loose fat. It is connected to the pubic bone on either side by the pubo-prostatic ligaments.

The *lateral surfaces* are prominent, and are covered by the Levatores ani muscles.

It measures about an inch and a half in its transverse diameter at the base, an inch in its antero-posterior diameter, and an inch and a quarter in its vertical diameter. Its weight is about four and a half drachms. It is held in its position by the anterior ligaments of the bladder (*pubo-prostatic*); by the posterior layer of the deep perineal fascia, which invests the commencement of the membranous portion of the urethra and prostate gland; and by the anterior portion of the Levator ani muscle (*levator prostatæ*), which passes down on each side from the symphysis pubis and anterior ligament of the bladder to the sides of the prostate.

The prostate consists of two lateral lobes and a middle lobe.

The *two lateral lobes* are of equal size, separated by a deep notch behind, and by a slight furrow upon their anterior and posterior surfaces, which indicates the bilobed condition of the organ in some animals.

The third, or *middle lobe*, is a small transverse band, occasionally a rounded or triangular prominence, placed between the two lateral lobes, at the posterior part of the organ. It lies immediately beneath the neck of the bladder, behind the commencement of the urethra, and above and between the ejaculatory ducts. Its existence is not constant; but it is occasionally found at an early period of life, as well as in adults, and in old age.

The prostate gland is perforated by the urethra and the ejaculatory ducts. The urethra usually lies about one-third nearer its anterior than its posterior surface; occasionally, the prostate surrounds only the lower three-fourths of this tube, and more rarely the urethra runs through the lower instead of the upper part of the gland. The ejaculatory ducts pass forwards obliquely through the lower part of the prostate, and open into the prostatic portion of the urethra.

Structure.—The prostate is enclosed in a thin but firm fibrous capsule, distinct from that derived from the posterior layer of the deep perineal fascia, and separated from it by a plexus of veins. Its substance is of a pale reddish-grey colour, of great density, and not easily torn. It consists of glandular substance and muscular tissue.

The muscular tissue, according to Kölliker, constitutes the proper stroma of the prostate: the connective tissue being very scanty, and simply forming thin trabeculæ between the muscular fibres, in which the vessels and nerves of the gland ramify. The muscular tissue is arranged as follows: immediately beneath the fibrous capsule is a dense layer, which forms an investing sheath for the gland; secondly, around the urethra, as it lies in the prostate, is another dense layer of circular fibres, continuous behind with the internal layer of the muscular coat of the bladder, and in front blending with the fibres surrounding the membranous portion of the urethra. Between these two layers, strong bands of muscular tissue, which decussate freely, form meshes in which the glandular structure of the organ is embedded. In that part of the gland which is situated in front of the urethra the muscular tissue is especially dense, and there is here little or no gland tissue; while in that part which is behind the urethra the muscular tissue presents a wide-meshed structure, which is densest at the base of the gland—that is, near the bladder—becoming looser and more sponge-like towards the apex of the organ.

The *glandular substance* is composed of numerous follicular pouches, opening into elongated canals, which join to form from twelve to twenty small excretory ducts. The follicles are connected together by areolar tissue, supported by prolongations from the fibrous capsule and muscular stroma, and enclosed in a delicate capillary plexus. The epithelium lining of both the canals and the terminal vesicles is of the columnar variety. The prostatic ducts open into the floor of the prostatic portion of the urethra.

Vessels and Nerves.—The *arteries* supplying the prostate are derived from the

internal pudic, vesical, and hæmorrhoidal. Its *veins* form a plexus around the sides and base of the gland; they receive in front the dorsal vein of the penis, and terminate in the internal iliac vein. The *nerves* are derived from the pelvic plexus.

Surgical Anatomy.—The relation of the prostate to the rectum should be noted: by means of the finger introduced into the gut, the surgeon detects enlargement or other disease of this organ; he can feel the apex of the gland, which is the guide to Cock's operation for stricture; he is enabled also by the same means to direct the point of a catheter, when its introduction is attended with difficulty either from injury or disease of the membranous or prostatic portions of the urethra. When the finger is introduced into the bowel, the surgeon may, in some cases, especially in boys, learn the position, as well as the size and weight, of a calculus in the bladder; and in the operation for its removal, if, as is not unfrequently the case, it should be lodged behind an enlarged prostate, it may be displaced from its position by pressing upwards the base of the bladder from the rectum. The prostate gland is occasionally the seat of suppuration, either due to injury, gonorrhœa, or tuberculous disease. The gland is enveloped in a dense unyielding capsule which determines the course of the abscess, and also explains the great pain which is present in the acute form of the disease. The abscess most frequently bursts into the urethra, the direction in which there is least resistance, but may occasionally burst into the rectum, or more rarely in the perinæum. In advanced life the prostate sometimes becomes considerably enlarged and projects into the bladder so as to impede the passage of the urine. According to Dr. Messer's researches, conducted at Greenwich Hospital, it would seem that such obstruction exists in 20 per cent. of all men over sixty years of age. In some cases the enlargement affects principally the lateral lobes, which may undergo considerable enlargement without causing much inconvenience. In other cases it would seem that the middle lobe enlarges most, and even a small enlargement of this lobe may act injuriously, by forming a sort of valve over the urethral orifice, preventing the passage of the urine, and the more the patient strains, the more completely will it block the opening into the urethra. In consequence of the enlargement of the prostate, a pouch is formed at the base of the bladder behind the projection, in which water collects, and cannot be entirely expelled. It becomes decomposed and ammoniacal, and leads to cystitis. For this condition 'prostatectomy' is sometimes done. The bladder is opened by an incision above the symphysis pubis, the mucous membrane incised, and the enlarged and projecting middle lobe enucleated.

Cowper's Glands

Cowper's Glands are two small rounded and somewhat lobulated bodies, of a yellow colour, about the size of peas, placed behind the fore part of the membranous portion of the urethra, between the two layers of the deep perineal fascia. They lie close above the bulb, and are enclosed by the transverse fibres of the Compressor urethræ muscle. Their existence is said to be constant: they gradually diminish in size as age advances.

Structure.—Each gland consists of several lobules, held together by a fibrous investment. Each lobule consists of a number of acini, lined by columnar epithelial cells, opening into one duct, which, joining with the ducts of other lobules outside the gland, form a single excretory duct. The excretory duct of each gland, nearly an inch in length, passes obliquely forwards beneath the mucous membrane, and opens by a minute orifice on the floor of the bulbous portion of the urethra. Their existence is said to be constant; they gradually diminish in size as age advances.

The Penis

The **Penis** consists of a root, body, and extremity or *glans penis*.

The *root* is firmly connected to the rami of the os pubis and ischium by two strong tapering fibrous processes, the *crura*; and to the front of the symphysis pubis by the *suspensory ligament*, a strong band of fibrous tissue which passes downwards from the front of the symphysis pubis to the upper surface of the root of the penis, where it blends with the fascial sheath of the organ.

The *extremity*, or *glans penis*, presents the form of an obtuse cone, flattened from above downwards. At its summit is a vertical fissure, the orifice of the urethra (*meatus urinarius*). The base of the glans forms a rounded projecting

border, the *corona glandis*; and behind the corona is a deep constriction, the *cervix*. Upon both of these parts, numerous small sebaceous glands are found the *glandulæ Tysonii odoriferæ*. They secrete a sebaceous matter of very peculiar odour, which probably contains caseine, and becomes easily decomposed.

The *body of the penis* is the part between the root and extremity. In the flaccid condition of the organ it is cylindrical, but when erect has a triangular prismatic form with rounded angles, the broadest side being turned upwards, and called the *dorsum*. The body is covered by integument, and contains in its interior a large portion of the urethra. The integument covering the penis is remarkable for its thinness, its dark colour, its looseness of connection with the deeper parts of the organ, and its containing no adipose tissue. At the root of the penis, the integument is continuous with that upon the pubes and scrotum: and at the neck of the glans it leaves the surface, and becomes folded upon itself to form the *prepuce*.

The internal layer of the prepuce is attached behind to the cervix, and approaches in character to a mucous membrane; from the cervix it is reflected over the glans penis, and at the meatus urinarius is continuous with the mucous lining of the urethra.

The mucous membrane covering the glans penis contains no sebaceous glands; but projecting from its free surface are a number of small, highly sensitive papillæ. At the back part of the meatus urinarius a fold of mucous membrane passes backwards to the bottom of a depressed raphé, where it is continuous with the prepuce; this fold is termed the *frænum præputii*.

Structure of the Penis.—The penis is composed of a mass of erectile tissue, enclosed in three cylindrical fibrous compartments. Of these, two, the *corpora cavernosa*, are placed side by side along the upper part of the organ; the third, or *corpus spongiosum*, encloses the urethra, and is placed below.

The **Corpora Cavernosa** form the chief part of the body of the penis. They consist of two fibrous cylindrical tubes, placed side by side, and intimately connected along the median line for their anterior three-fourths, whilst at their back part they separate from each other to form the *crura*, which are two strong tapering fibrous processes firmly connected to the rami of the os pubis and ischium. Each crus commences by a blunt pointed process in front of the tuberosity of the ischium; and, before its junction with its fellow to form the body of the penis, it presents a slight enlargement, named by Kobelt the *bulb of the corpus cavernosum*. Just beyond this point they become constricted, and retain an equal diameter to their anterior extremity, where they form a single rounded end, which is received into a fossa in the base of the glans penis. A median groove on the upper surface lodges the dorsal vein of the penis, and the groove on the under surface receives the corpus spongiosum. The root of the penis is connected to the symphysis pubis by the suspensory ligament.

Structure.—The corpora cavernosa are surrounded by a strong fibrous envelope, consisting of two sets of fibres: the one, longitudinal in direction, being common to the two corpora cavernosa, and investing them in a common covering; the other, internal, being circular in direction, and being proper to each corpus cavernosum. The internal circular fibres by their junction at one part form an incomplete partition or septum between the two bodies.

The *septum* between the two corpora cavernosa forms an imperfect partition; it is thick and complete behind, but in front it is incomplete, and consists of a number of vertical bands, which are arranged like the teeth of a comb, whence the name which it has received, *septum pectiniforme*. These bands extend between the dorsal and the urethral surface of the corpora cavernosa. This fibrous investment is extremely dense, of considerable thickness, and consists of bundles of shining white fibres, with an admixture of well-developed elastic fibres, so that it is possessed of great elasticity.

From the internal surface of the fibrous envelope, as well as from the sides of the septum, are given off a number of bands or cords, which cross the interior of

the corpora cavernosa in all directions, subdividing them into a number of separate compartments, and giving the entire structure a spongy appearance. These bands and cords are called *trabeculæ*, and consist of white fibrous tissue, elastic fibres, and plain muscular fibres. In them are contained numerous arteries and nerves.

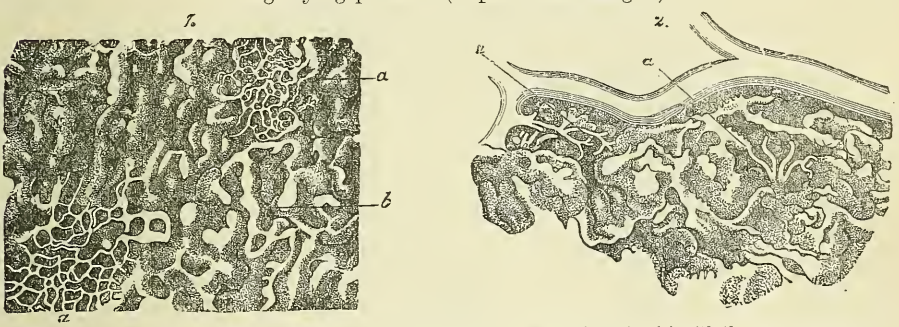
The component fibres of which the trabeculæ are composed are larger and stronger round the circumference than at the centre of the corpora cavernosa; they are also thicker behind than in front. The interspaces, on the contrary, are larger at the centre than at the circumference, their long diameter being directed transversely; they are largest anteriorly. They are occupied by venous blood, and are lined by a layer of flattened cells similar to the endothelial lining of veins.

The whole of the structure of the corpora cavernosa, contained within the fibrous sheath, consists therefore of a sponge-like tissue of areolar spaces, freely communicating with each other and filled with venous blood. The spaces may therefore be regarded as large cavernous veins.

The arteries bringing the blood to these spaces are the arteries of the corpora cavernosa and branches from the dorsal artery of the penis, which perforate the fibrous capsule, along the upper surface, especially near the fore part of the organ.

These arteries on entering the cavernous structure divide into branches, which are supported and enclosed by the trabeculæ. Some of these terminate in a

Fig. 674.—From the peripheral portion of the corpus cavernosum penis under a low magnifying power. (Copied from Langer.)



1. *a*. Capillary network. *b*. Cavernous spaces. 2. Connection of the arterial twigs (*a*) with the cavernous spaces.

capillary network, the branches of which open directly into the cavernous spaces; others assume a tendril-like appearance, and form convoluted and somewhat dilated vessels, which were named by Müller, *helicine arteries*. They project into the spaces, and from them are given off small capillary branches to supply the trabecular structure. They are bound down in the spaces by fine fibrous processes, and are more abundant in the back part of the corpora cavernosa (fig. 674).

The blood from the cavernous spaces is returned by a series of vessels, some of which emerge in considerable numbers from the base of the glans penis and converge on the dorsum of the organ to form the dorsal vein; others pass out on the upper surface of the corpora cavernosa and join the dorsal vein; some emerge from the under surface of the corpora cavernosa and, receiving branches from the corpus spongiosum, wind round the sides of the penis to terminate in the dorsal vein; but the greater number pass out at the root of the penis, and join the prostatic plexus.

The **Corpus Spongiosum** encloses the urethra, and is situated in the groove on the under surface of the corpora cavernosa. It commences posteriorly in front of the deep perineal fascia, between the diverging crura of the corpora cavernosa, where it forms a rounded enlargement, the *bulb*; and terminates, anteriorly, in

another expansion, the *glans penis*, which overlaps the anterior rounded extremity of the corpora cavernosa. The central portion, or body of the corpus spongiosum, is cylindrical, and tapers slightly from behind forwards.

The *bulb* varies in size in different subjects; it receives a fibrous investment from the anterior layer of the deep perineal fascia, and is surrounded by the Accelerator urinæ muscle. The urethra enters the bulb nearer its upper than its lower surface, being surrounded by a layer of erectile tissue, a thin prolongation of which is continued backwards round the membranous and prostatic portions of the canal to the neck of the bladder, lying between the two layers of muscular tissue. The portion of the bulb below the urethra presents a partial division into two lobes, being marked externally by a linear raphé, whilst internally there projects inwards, for a short distance, a thin fibrous septum, more distinct in early life.

Structure.—The corpus spongiosum consists of a strong fibrous envelope, enclosing a trabecular structure, which contains in its meshes erectile tissue. The fibrous envelope is thinner, whiter in colour, and more elastic than that of the corpora cavernosa. The trabeculæ are delicate, uniform in size, and the meshes between them small: their long diameter, for the most part, corresponding with that of the penis. The external envelope or outer coat of the corpus spongiosum is formed partly of unstriped muscular fibre, and a layer of the same tissue immediately surrounds the canal of the urethra.

The *lymphatics of the penis* consist of a superficial and deep set; the former are derived from a dense network on the skin of the glans and prepuce and from the mucous membrane of the urethra, and terminate in the superficial inguinal glands; the latter emerge from the corpora cavernosa and corpus spongiosum, and, passing beneath the pubic arch, join the deep lymphatics of the pelvis.

The *nerves* are derived from the internal pudic nerve and the pelvic plexus. On the glans and bulb some filaments of the cutaneous nerves have Pacinian bodies connected with them, and, according to Krause, many of them terminate in a peculiar form of end-bulb (see p. 48).

Surgical Anatomy.—The penis occasionally requires removal for malignant disease. Usually, removal of the ante-scrotal portion is all that is necessary, but sometimes it is requisite to remove the whole organ from its attachment to the rami of the ossa pubes and ischia. The former operation is performed either by cutting off the whole of the anterior part of the penis with one sweep of the knife; or, what is better, cutting through the corpora cavernosa from the dorsum, and then separating the corpus spongiosum from them, dividing it at a level nearer the glans penis. The mucous membrane of the urethra is then slit up, and the edges of the flap attached to the external skin, in order to prevent contraction of the orifice, which would otherwise take place. The vessels which require ligature are the two dorsal arteries of the penis, the arteries of the corpora cavernosa, and the artery of the septum. When the entire organ requires removal, the patient is placed in the lithotomy position, and an incision is made round the root of the penis, and carried down the median line of the scrotum as far as the perinæum. The two halves of the scrotum are then separated from each other, and a catheter having been introduced into the bladder as a guide, the membranous portion of the urethra in front of the triangular ligament is separated from the corpora cavernosa and divided, the catheter having been withdrawn, just behind the bulb. The suspensory ligament is now severed, and the crura separated from the bone with a periosteum scraper, and the whole penis removed. The membranous portion of the urethra, which has not been removed, is now to be attached to the skin at the posterior extremity of the incision in the perinæum. The remainder of the wound is to be brought together, free drainage being provided for.

The Testes and their Coverings (fig. 675)

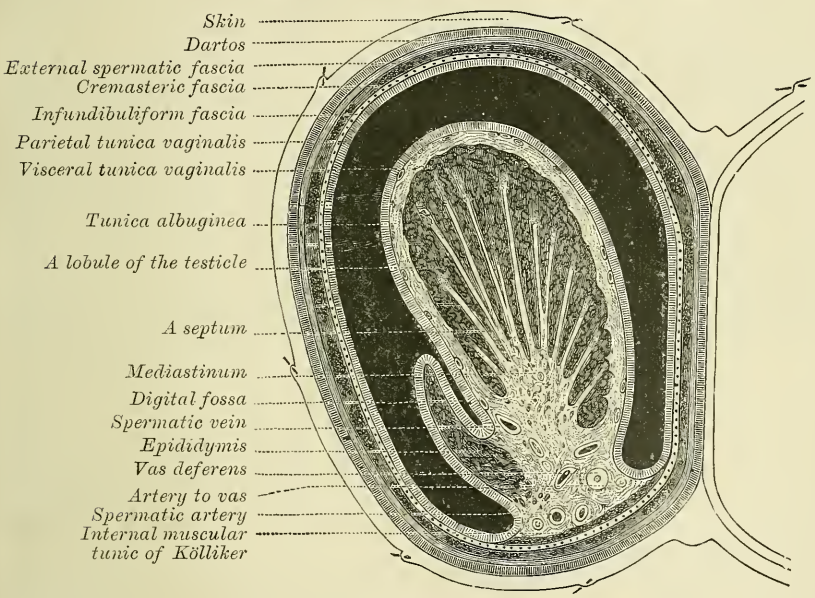
The **Testes** are two small glandular organs, which produce the spermatozoa; they are situated in the scrotum, being suspended by the spermatic cords. At an early period of fœtal life the testes are contained in the abdominal cavity, behind the peritoneum. Before birth they descend to the inguinal canal, along which they pass with the spermatic cord, and, emerging at the external abdominal ring, they descend into the scrotum, becoming invested in their course by numerous

coverings derived from the serous, muscular, and fibrous layers of the abdominal parietes, as well as by the scrotum. The coverings of the testis are—the

Skin, Dartos } Scrotum.
Intercolumnar, or External spermatic fascia.
Cremasteric fascia.
Infundibuliform, or Fascia propria (Internal spermatic fascia).
Tunica vaginalis.

The **scrotum** is a cutaneous pouch which contains the testes and part of the spermatic cords. It is divided into two lateral halves by a median line, or *raphé*, which is continued forwards to the under surface of the penis, and backwards along the middle line of the perinæum to the anus. Of these two lateral portions the left is longer than the right, and corresponds with the greater length of the spermatic cord on the left side. Its external aspect varies under different circumstances:

Fig. 675.—Transverse section through the left side of the scrotum and the left testicle. The sac of the tunica vaginalis represented in a distended condition. (Delépine.)



thus, under the influence of warmth, and in old and debilitated persons, it becomes elongated and flaccid; but, under the influence of cold, and in the young and robust, it is short, corrugated, and closely applied to the testes.

The scrotum consists of two layers, the integument and the dartos.

The **integument** is very thin, of a brownish colour, and generally thrown into folds or rugæ. It is provided with sebaceous follicles, the secretion of which has a peculiar odour, and is beset with thinly scattered, crisp hairs, the roots of which are seen through the skin.

The **dartos** is a thin layer of loose reddish tissue, endowed with contractility: it forms the proper tunic of the scrotum, is continuous, around the base of the scrotum, with the two layers of the superficial fascia of the groin and perinæum, and sends inwards a distinct septum, *septum scroti*, which divides it into two cavities for the two testes, the septum extending between the raphé and the under surface of the penis, as far as its root.

The dartos is closely united to the skin externally, but connected with the subjacent parts by delicate areolar tissue, upon which it glides with the greatest

facility. The dartos is very vascular, and consists of a loose areolar tissue, containing unstriped muscular fibre, but no fat. Its contractility is slow, and excited by cold and mechanical stimuli, but not by electricity.

The **intercolumnar fascia** is a thin membrane, derived from the margin of the pillars of the external abdominal ring, during the descent of the testis in the fœtus, which is prolonged downwards around the surface of the cord and testis. It is separated from the dartos by loose areolar tissue, which allows of considerable movement of the latter upon it, but is intimately connected with the succeeding layers.

The **cremasteric fascia** consists of scattered bundles of muscular fibres (*Cremaster muscle*), connected together into a continuous covering by intermediate areolar tissue. The muscular fibres are derived from the lower border of the Internal oblique muscle, during the descent of the testis.

The **infundibuliform fascia** is a thin membranous layer, which loosely invests the surface of the cord. It is a continuation downwards of the fascia transversalis. Beneath it is a quantity of loose connective tissue which connects this layer of fascia with the spermatic cord and posterior part of the testicle. This connective tissue is continuous above with the sub-serous areolar tissue of the abdomen. These two layers, the infundibuliform fascia and the tissue beneath it, are known collectively as the *fascia propria*.

The **tunica vaginalis** is described with the proper covering of the testis.

Vessels and nerves.—The *arteries* supplying the coverings of the testis are: the superficial and deep external pudic, from the femoral; the superficial perineal branch of the internal pudic; and the cremasteric branch from the epigastric. The *veins* follow the course of the corresponding arteries. The *lymphatics* terminate in the inguinal glands. The *nerves* are the ilio-inguinal branch of the lumbar plexus, the two superficial perineal branches of the internal pudic nerve, the inferior pudendal branch of the small sciatic nerve, and the genital branch of the genito-crural nerve.

The **spermatic cord** extends from the internal abdominal ring, where the structures of which it is composed converge, to the back part of the testicle. In the abdominal wall the cord passes obliquely along the inguinal canal, lying at first beneath the Internal oblique, and upon the fascia transversalis; but nearer the pubes, it rests upon Poupart's ligament, having the aponeurosis of the External oblique in front of it, and the conjoined tendon behind it. It then escapes at the external ring, and descends nearly vertically into the scrotum. The left cord is rather longer than the right, consequently the left testis hangs somewhat lower than its fellow.

Structure of the spermatic cord.—The spermatic cord is composed of arteries, veins, lymphatics, nerves, and the excretory duct of the testicle. These structures are connected together by areolar tissue, and invested by the fasciæ brought down by the testicle in its descent.

The *arteries of the cord* are: the spermatic, from the aorta; the artery of the vas deferens, from the superior vesical; and the cremasteric, from the deep epigastric.

The *spermatic artery*, a branch of the abdominal aorta, escapes from the abdomen at the internal or deep abdominal ring, and accompanies the other constituents of the spermatic cord along the inguinal canal and through the external abdominal ring into the scrotum. It then descends to the testicle, and, becoming tortuous, divides into several branches, two or three of which accompany the vas deferens and supply the epididymis, anastomosing with the artery of the vas deferens: others pierce the back of the tunica albuginea and supply the substance of the testis.

The *cremasteric artery* is a branch of the deep epigastric artery. It accompanies the spermatic cord and supplies the Cremaster muscle and other coverings of the cord, anastomosing with the spermatic artery.

The *artery of the vas deferens*, a branch of the superior vesical, is a long

slender vessel, which accompanies the vas deferens, ramifying upon the coats of that duct, and anastomosing with the spermatic artery near the testis.

The spermatic veins emerge from the back of the testis, and receive tributaries from the epididymis; they unite and form a convoluted plexus (*plexus pampiniformis*), which forms the chief mass of the cord; the vessels composing this plexus are very numerous, and ascend along the cord in front of the vas deferens; below the external or superficial abdominal ring they unite to form three or four veins, which pass along the spermatic canal, and, entering the abdomen through the internal or deep abdominal ring, coalesce to form two veins. These again unite to form a single vein, which opens on the right side into the inferior vena cava, at an acute angle, and on the left side into the renal vein at a right angle.

The *lymphatic vessels* terminate in the lumbar glands.

The *nerves* are the spermatic plexus from the sympathetic, joined by filaments from the pelvic plexus which accompany the artery of the vas deferens.

Surgical Anatomy.—The scrotum forms an admirable covering for the protection of the testicle. This body, lying suspended and loose in the cavity of the scrotum and surrounded by a serous membrane, is capable of great mobility, and can therefore easily slip about within the scrotum, and thus avoid injuries from blows or squeezes. The skin of the scrotum is very elastic and capable of great distension, and on account of the looseness and amount of subcutaneous tissue, the scrotum becomes greatly enlarged in cases of œdema, to which this part is especially liable on account of its dependent position. The scrotum is frequently the seat of epithelioma; this is no doubt due to the rugæ on its surface, which favour the lodgment of dirt, and this, causing irritation, is the exciting cause of the disease, which is especially common in chimney-sweeps from the lodgment of soot. The scrotum is also the part most frequently affected by elephantiasis.

On account of the looseness of the subcutaneous tissue, considerable extravasations of blood may take place from very slight injuries. It is therefore generally recommended never to apply leeches to the scrotum, since they may lead to considerable ecchymosis, but rather to puncture one or more of the superficial veins of the scrotum in cases where local blood-letting from this part is judged to be desirable. The muscular fibre in the dartos causes contraction and considerable diminution in the size of a wound of the scrotum, as after the operation of castration, and is of assistance in keeping the edges together, and covering the exposed parts.

The Testes

The **testes** are suspended in the scrotum by the spermatic cords. As the left spermatic cord is rather longer than the right one, the left testicle hangs somewhat lower than its fellow. Each gland is of an oval form, compressed laterally, and having an oblique position in the scrotum; the upper extremity being directed forwards and a little outwards; the lower, backwards and a little inwards; the anterior convex border looks forwards and downwards; the posterior or straight border, to which the cord is attached, backwards and upwards.

The anterior and lateral surfaces, as well as both extremities of the organ, are convex, free, smooth, and invested by the tunica vaginalis. The posterior border, to which the cord is attached, receives only a partial investment from that membrane. Lying upon the outer edge of this posterior border is a long, narrow, flattened body, named, from its relation to the testis, the epididymis (δίδυμος, testis). It consists of a central portion, or *body*, an upper enlarged extremity, the *globus major*, or head; and a lower pointed extremity, the tail, or *globus minor*. The globus major is intimately connected with the upper end of the testicle by means of its efferent ducts; and the globus minor is connected with its lower end by cellular tissue, and a reflection of the tunica vaginalis. The outer surface and upper and lower ends of the epididymis are free and covered by serous membrane; the body is also completely invested by it, excepting along its posterior border. The epididymis is connected to the back of the testis by a fold of the serous membrane. Attached to the upper end of the testis, or to the epididymis, are one or more small pedunculated bodies. One of them is pretty constantly found between the globus major of the epididymis and the testicle,

and is believed to be the remains of the upper extremity of the Müllerian duct (page 114). It is termed the *hydatid of Morgagni*. When the testicle is removed from the body, the position of the vas deferens, on the posterior surface of the testicle and inner side of the epididymis, marks the side to which the gland has belonged.

Size and weight.—The average dimensions of this gland are from one and a half to two inches in length, an inch in breadth, and an inch and a quarter in the antero-posterior diameter; and the weight varies from six to eight drachms, the left testicle being a little the larger.

The testis is invested by three tunics, the tunica vaginalis, tunica albuginea, and tunica vasculosa.

The **tunica vaginalis** is the serous covering of the testis. It is a pouch of serous membrane, derived from the peritoneum during the descent of the testis in the fœtus from the abdomen into the scrotum. After its descent, that portion of the pouch which extends from the internal ring to near the upper part of the gland becomes obliterated, the lower portion remaining as a shut sac, which invests the outer surface of the testis, and is reflected on to the internal surface of the scrotum; hence it may be described as consisting of a visceral and parietal portion.

The *visceral portion* (*tunica vaginalis propria*) covers the outer surface of the testis, as well as the epididymis, connecting the latter to the testis by means of a distinct fold. From the posterior border of the gland it is reflected on to the internal surface of the scrotum.

The *parietal portion of the serous membrane* (*tunica vaginalis reflexa*) is far more extensive than the visceral portion, extending upwards for some distance in front, and on the inner side of the cord, and reaching below the testis. The inner surface of the tunica vaginalis is free, smooth, and covered by a layer of endothelial cells. The interval between the visceral and parietal layers of this membrane constitutes the cavity of the tunica vaginalis.

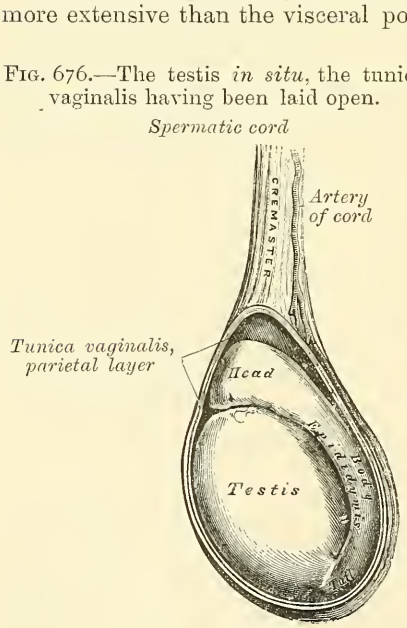


Fig. 676.—The testis *in situ*, the tunica vaginalis having been laid open.

The obliterated portion of the pouch may generally be seen as a fibro-cellular thread lying in the loose areolar tissue around the spermatic cord; sometimes this may be traced as a distinct band from the upper end of the inguinal canal, where it is connected with the peritoneum, down to the tunica vaginalis; sometimes it gradually becomes lost on the spermatic cord. Occasionally no trace of it can be detected. In some cases it happens that the pouch of peritoneum does not become obliterated, but the sac of the peritoneum communicates with the tunica vaginalis. This may give rise to one of the varieties of oblique inguinal hernia (page 1126). Or in other cases the pouch may contract, but not become entirely obliterated; it then forms a minute canal leading from the peritoneum to the tunica vaginalis.*

The **tunica albuginea** is the fibrous covering of the testis. It is a dense

* It is recorded that in the post-mortem examination of Sir Astley Cooper, this minute canal was found on both sides of the body. Sir Astley Cooper states that when a student he suffered from inguinal hernia; probably this was of the congenital variety, and the canal found after death was the remains of the one down which the hernia travelled.—*Lancet*, vol. ii. 1824, p. 116.

fibrous membrane, of a bluish-white colour, composed of bundles of white fibrous tissue, which interlace in every direction. Its outer surface is covered by the tunica vaginalis, except along its posterior border, at the points of attachment of the epididymis; hence the tunica albuginea is usually considered as a fibro-serous membrane, like the pericardium. This membrane surrounds the glandular structure of the testicle, and, at its posterior border, is reflected into the interior of the gland, forming an incomplete vertical septum, called the *mediastinum testis* (*corpus Highmorianum*).

The *mediastinum testis* extends from the upper, nearly to the lower border of the gland, and is wider above than below. From the front and sides of this septum numerous slender fibrous cords and imperfect septa (*trabeculæ*) are given off, which radiate towards the surface of the organ, and are attached to the inner surface of the tunica albuginea. They therefore divide the interior of the organ into a number of incomplete spaces, which are somewhat cone-shaped, being broad at their bases at the surface of the gland, and becoming narrower as they converge to the mediastinum. The mediastinum supports the vessels and ducts of the testis in their passage to and from the substance of the gland.

The **tunica vasculosa** (*pia mater testis*) is the vascular layer of the testis, consisting of a plexus of blood-vessels, held together by delicate areolar tissue. It covers the inner surface of the tunica albuginea and the different septa in the interior of the gland, and therefore forms an internal investment to all the spaces of which the gland is composed.

Structure.—The glandular structure of the testis consists of numerous lobules (*lobuli testis*). Their number, in a single testis, is estimated by Berres at 250, and by Krause at 400. They differ in size according to their position, those in the middle of the gland being larger and longer. The lobules are conical in shape, the base being directed towards the circumference of the organ, the apex towards the mediastinum. Each lobule is contained in one of the intervals between the fibrous cords and vascular processes which extend between the mediastinum testis and the tunica albuginea, and consists of from one to three, or more, minute convoluted tubes, the *tubuli seminiferi*. The tubes may be separately unravelled, by careful dissection under water, and may be seen to commence either by free cæcal ends, or by anastomotic loops. The total number of tubes is considered by Monro to be about 300, and the length of each about sixteen feet; by Lauth, their number is estimated at 840, and their average length two feet and a quarter. Their diameter varies from $\frac{1}{200}$ to $\frac{1}{150}$ of an inch. The tubuli are pale in colour in early life, but in old age they acquire a deep yellow tinge, from containing much fatty matter. Each tube consists of a basement layer, formed of epithelioid cells united edge to edge, outside which are other layers of flattened cells arranged in interrupted laminæ, which give to the tube an appearance of striation in cross section. The cells of the outer layers gradually pass into the interstitial tissue. Within the basement membrane are epithelial cells arranged in several irregular layers, which are not always clearly separate, but which may be arranged in three different groups. Amongst these cells may be seen the *spermatozoa* in different stages of development. 1. Lining the basement membrane and forming the outer zone is a layer of cubical cells, with small nuclei; these are known as the *lining cells* or *spermatogonia*. The nucleus of some of them may be seen to be in the process of indirect division (*karyokinesis*, page 10), and in consequence of this daughter cells are formed, which constitute the second zone. 2. Within this first layer is to be seen a number of larger cells with clear nuclei, arranged in two or three layers; these are the *intermediate* or *spermatogenic cells*. Embedded between them are clusters of developing spermatozoa, whose tails project into the lumen of the tube. Most of these cells are in a condition of karyokinetic division, and the cells which result from this division are converted into the next layer, or *spermatoblasts*, by further division. 3. The third layer of cells is the *spermatoblast*, from which the spermatozoa originate. They are ill-defined granular masses of

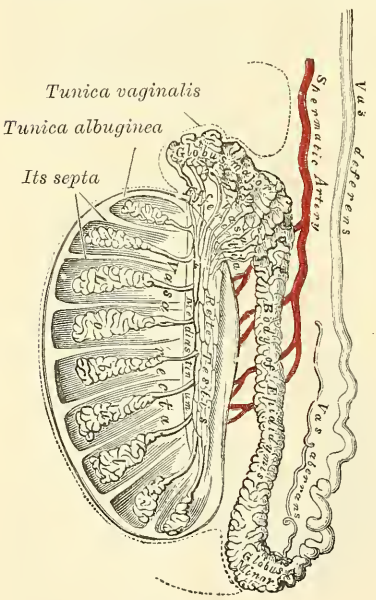
protoplasm, of an elongated form, with a nucleus, which becomes the head of the newly-forming spermatozoa. As development proceeds, the nuclear extremity penetrates between the cells of the intermediate layer and becomes connected with some of the cells of the outermost layer, which become elongated to receive them. When development is almost complete, the spermatozoa begin to travel inwards again towards the lumen of the tube, their connection with the cell of the outer layer becoming stretched and converted into an attenuated thread. Eventually, when they are fully developed, they may be seen forming a zone of contiguous spermatozoa next to the lumen of the tube, with their tails projecting into it; and finally detachment of the head takes place, and they are set free into the interior of the tube.

The tubules are enclosed in a delicate plexus of capillary vessels, and are held together by an intertubular connective tissue, which presents large interstitial spaces lined by endothelium, which are believed to be the rootlets of the lymphatic vessels of the testis.

In the apices of the lobules, the tubuli become less convoluted, assume a nearly straight course, and unite together to form from twenty to thirty larger ducts, of about $\frac{1}{50}$ of an inch in diameter, and these, from their straight course, are called *vasa recta*.

The *vasa recta* enter the fibrous tissue of the mediastinum, and pass upwards and backwards, forming, in their ascent, a close network of anastomosing tubes which are merely channels in the fibrous stroma, lined by flattened epithelium and having no proper walls; this constitutes the *rete testis*. At the upper end of the mediastinum, the vessels of the rete testis terminate in from twelve to fifteen or twenty ducts, the *vasa efferentia*: they perforate the tunica albuginea, and carry the seminal fluid from the testis to the epididymis. Their course is at first straight, they then become enlarged, and exceedingly convoluted, and form a series of conical masses, the *coni vasculosi*, which, together constitute the globus major of the epididymis. Each cone consists of a single convoluted duct, from six to eight inches in length, the diameter of which gradually decreases from the testis to the epididymis. Opposite the bases of the cones the efferent vessels open at narrow intervals into a single duct, which constitutes, by its complex convolutions, the body and globus minor of the epididymis. When the convolutions of this tube are unravelled, it measures upwards of twenty feet in length, and increases in breadth and thickness as it approaches the vas deferens. The convolutions are held together by fine areolar tissue, and by bands of fibrous tissue.

Fig. 677.—Vertical section of the testicle, to show the arrangement of the ducts.



The vasa recta are of smaller diameter than the seminal tubes, and have very thin parietes. They, like the channels of the rete testis, are lined by a single layer of flattened epithelium. The vasa efferentia and the tube of the epididymis have walls of considerable thickness, on account of the presence in them of muscular tissue, which is principally arranged in a circular manner. These tubes are lined by columnar ciliated epithelium.

The **vas deferens**, the excretory duct of the testis, is the continuation of the epididymis. Commencing at the lower part of the globus minor, it ascends along

the posterior surface of the testis and inner side of the epididymis, and along the back part of the spermatic cord, through the spermatic canal to the internal or deep abdominal ring. From the ring it curves round the outer side of the epigastric artery, crosses the external iliac vessels, and descends into the pelvis at the side of the bladder; it arches backwards and downwards to its base, crossing over the obliterated hypogastric artery, and to the inner side of the ureter. At the base of the bladder it lies between that viscus and the rectum, running along the inner border of the vesicula seminalis. In this situation it becomes enlarged and sacculated, forming the *ampulla*; and then, becoming narrowed at the base of the prostate, unites with the duct of the vesicula seminalis to form the ejaculatory duct. The vas deferens presents a hard and cord-like sensation to the fingers; it is about two feet in length, of cylindrical form, and about a line and a quarter in diameter. Its walls are dense, measuring one-third of a line; and its canal is extremely small, measuring about half a line.

Structure.—The vas deferens consists of three coats: 1. An external, or cellular coat. 2. A muscular coat, which in the greater part of the tube consists of two layers of unstriped muscular fibre: an outer, longitudinal in direction, and an inner, circular; but in addition to these, at the commencement of the vas deferens, there is a third layer, consisting of longitudinal fibres, placed internal to the circular stratum, between it and the mucous membrane. 3. An internal, or mucous coat, which is pale, and arranged in longitudinal folds; its epithelial covering is of the columnar variety.

A long narrow tube, the *vas aberrans of Haller*, is occasionally found connected with the lower part of the canal of the epididymis, or with the commencement of the vas deferens. It extends up into the cord for about two or three inches, where it terminates by a blind extremity, which is occasionally bifurcated. Its length varies from an inch and a half to fourteen inches, and sometimes it becomes dilated towards its extremity; more commonly it retains the same diameter throughout. Its structure is similar to that of the vas deferens. Occasionally it is found unconnected with the epididymis.

Surgical Anatomy.—The testicle frequently requires removal for malignant disease; in tuberculous disease, to prevent systemic infection; in cystic disease; in cases of large hernia testis, and in some instances of incompletely descended or misplaced testicles. The operation of castration has also been, during the last few years, performed for enlargement of the prostate; for it has been found that removal of the testicles is followed by very rapid and often considerable diminution in the size of the prostate. The operation is, however, one of severity, and is frequently followed by death in these cases, performed, as is necessarily the case, in old men. Reginald Harrison has proposed to substitute for it excision of a portion of the vasa deferentia. The operation of castration is a comparatively simple one. An incision is made from the external ring to the bottom of the scrotum, into the tunica vaginalis. The coverings are shelled off the organ, and the mesorchium, stretching between the back of the testicle and the scrotum, divided. The cord is then isolated, and an aneurism needle, armed with a double ligature, passed under it, as high as is thought necessary, and the cord tied in two places, and divided between the ligatures. Sometimes, in cases of malignant disease, it is desirable to open the inguinal canal and tie the cord as near the internal abdominal ring as possible.

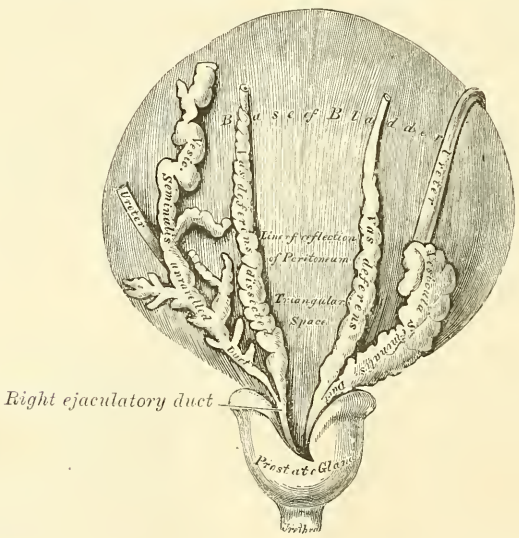
Vesiculæ Seminales

The **seminal vesicles** are two lobulated membranous pouches, placed between the base of the bladder and the rectum, serving as reservoirs for the semen, and secreting a fluid to be added to the secretion of the testicles. Each sac is somewhat pyramidal in form, the broad end being directed backwards, and the narrow end forwards towards the prostate. They measure about two and a half inches in length, about five lines in breadth, and two or three lines in thickness. They vary, however, in size, not only in different individuals, but also in the same individual on the two sides. Their *upper surface* is in contact with the base of the bladder, extending from near the termination of the ureters to the base of the prostate gland. Their *under surface* rests upon the rectum, from which they

are separated by the recto-vesical fascia. Their *posterior extremities* diverge from each other. Their *anterior extremities* are pointed, and converge towards the base of the prostate gland, where each joins with the corresponding vas deferens to form the ejaculatory duct. Along the inner margin of each vesicula runs the enlarged and convoluted vas deferens. The inner border of the vesiculæ, and the corresponding vas deferens form the lateral boundaries of a triangular space, limited behind by the recto-vesical peritoneal fold; the portion of the bladder included in this space rests on the rectum, and corresponds with the trigonum vesicæ in its interior.

Each vesicula consists of a single tube, coiled upon itself, and giving off several irregular cæcal diverticula: the separate coils, as well as the diverticula, being connected together by fibrous tissue. When uncoiled, this tube is about the diameter of a quill, and varies in length from four to six inches; it terminates posteriorly in a *cul-de-sac*; its anterior extremity becomes constricted into a narrow straight duct, which joins on its inner side with the corresponding vas deferens, and forms the ejaculatory duct.

Fig. 678.—Base of the bladder, with the vasa deferentia and vesiculæ seminales.



The **ejaculatory ducts**, two in number, one on each side, are formed by the junction of the ducts of the vesiculæ seminales with the vasa deferentia. Each duct is about three-quarters of an inch in length; it commences at the base of the prostate, and runs forwards and downwards in a canal in its substance, and along the side of the sinus pocularis, to terminate by a separate slit-like orifice close to or just within the margins of the sinus. The ducts diminish in size, and converge towards their termination.

Structure.—The vesiculæ seminales are composed of three coats: an *external* or *fibro-cellular*; a *middle* or *muscular coat*, which is thinner than in the vas deferens, arranged in two layers, an outer, longitudinal, and inner, circular; an *internal* or *mucous coat*, which is pale, of a whitish-brown colour, and presents a delicate reticular structure, like that seen in the gall-bladder, but the meshes are finer. The epithelium is columnar.

The coats of the ejaculatory ducts are extremely thin. They are: an *outer fibrous layer*, which is almost entirely lost after their entrance into the prostate; a *layer of muscular fibres*, consisting of an outer thin circular and an inner longitudinal layer, and the *mucous membrane*, forming the only constituents of the tubes.

Vessels and nerves.—The *arteries* supplying the vesiculæ seminales are derived

from the middle and inferior vesical and middle hæmorrhoidal. The *veins* and *lymphatics* accompany the arteries. The *nerves* are derived from the pelvic plexus.

Surgical Anatomy.—The vesiculæ seminales are often the seat of an extension of the disease in cases of tuberculous disease of the testicle, and should always be examined from the rectum before coming to a decision with regard to castration in this affection.

Descent of the Testes

The testes, at an early period of fœtal life, are placed at the back part of the abdominal cavity, behind the peritoneum; in front, and a little below the kidneys. The anterior surface and sides are invested by peritoneum. At about the third month of intra-uterine life a peculiar structure, the *gubernaculum testis*, makes its appearance. This structure is at first a slender band which extends from the situation of the internal ring, to the epididymis and body of the testicle, and is then continued upwards in front of the kidney towards the Diaphragm. As development advances, the peritoneum covering the testicle encloses it and forms a mesentery, the *mesorchium*, which also encloses the gubernaculum and forms two folds, one above the testicle, and the other below it. The one above the testicle is the *plica vascularis*, and contains ultimately the spermatic vessels; the one below, the *plica gubernatrix*, contains the lower part of the gubernaculum, which has now grown into a thick cord; it terminates below at the internal ring in a tube of peritoneum, the *processus vaginalis*, which protrudes itself down the inguinal canal. The lower part of the gubernaculum by the fifth month has become a thick cord, whilst the upper part has disappeared. The lower part can now be seen to consist of a central core of unstriped muscle-fibre, and outside this of a firm layer of striped elements connected, behind the peritoneum, with the abdominal wall. Later on, about the sixth month, the lower end of the gubernaculum can be traced into the inguinal canal, extending to the pubes, and, at a later period, to the bottom of the scrotum. The fold of peritoneum, constituting the processus vaginalis, projects itself downwards into the inguinal canal, forming a gradually elongating depression or *cul-de-sac*, which eventually reaches the bottom of the scrotum, and into this the testicle is drawn by the growth of the body of the fœtus, for the gubernaculum does not grow commensurately with the growth of other parts, and therefore the testicle, being attached by the gubernaculum to the bottom of the scrotum, is prevented from rising as the body grows, and is drawn first into the inguinal canal and eventually into the scrotum. By the eighth month, the testicle has reached the scrotum, preceded by the lengthened pouch of peritoneum, the processus vaginalis, which communicates by its upper extremity with the peritoneal cavity. Just before birth the upper part of the pouch usually becomes closed, and this obliteration extends gradually downwards to within a short distance of the testis. The process of peritoneum surrounding the testis, which is now entirely cut off from the general peritoneal cavity, constitutes the *tunica vaginalis*.*

In the female, a small cord, corresponding to the gubernaculum in the male, descends to the inguinal region, and ultimately forms the round ligament of the uterus. A pouch of peritoneum accompanies it along the inguinal canal, analogous to the processus vaginalis in the male: it is called the *canal of Nuck*.

Surgical Anatomy.—Abnormalities in the formation and in the descent of the testicle may occur. The testicle may fail to be developed; or the testicle may be fully developed, and the vas deferens may be undeveloped in whole or part; or again, both testicle and vas deferens may be fully developed, but the duct may not become connected to the gland. The testicle may fail in its descent, or it may descend into some abnormal position. Thus it may be retained in the position where it was primarily developed, below the kidney; or it may descend to the internal abdominal ring, but fail to pass through this opening; it may be retained in the inguinal canal, which is perhaps the

* The obliteration of the process of peritoneum which accompanies the cord, and is hence called the *funicular process*, is often incomplete. See section on Inguinal Hernia.

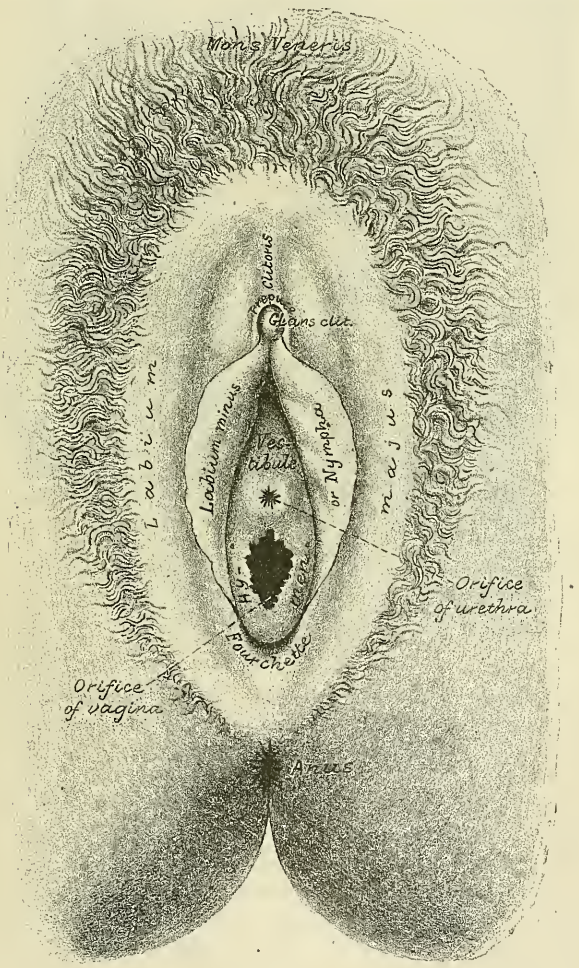
most common position; or it may pass through the external abdominal ring and remain just outside it, failing to pass to the bottom of the scrotum. On the other hand, it may get into some abnormal position: it may pass the scrotum and reach the perinæum, or it may fail to enter the inguinal canal, and may find its way through the femoral ring into the crural canal, and present itself on the thigh at the saphenous opening. There is still a third class of cases of abnormality of the testicle, where the organ has descended in due course into the scrotum, but is malplaced. The most common form of this is where the testicle is *inverted*; that is to say, the organ is rotated so that the epididymis is connected to the front of the scrotum, and the body, surrounded by the tunica vaginalis, is directed backwards. In these cases the vas deferens is to be felt in the front of the cord. The condition is of importance in connection with hydrocele and hæmatocele, and the position of the testicle should always be carefully ascertained before performing any operation for these affections. Again, more rarely, the testicle may be *reversed*. This is a condition in which the top of the testicle, indicated by the globus major of the epididymis, is at the bottom of the scrotum, and the vas deferens comes off from the summit of the organ.

FEMALE ORGANS OF GENERATION

EXTERNAL ORGANS

THE **external organs of generation in the female** are: the mons Veneris; the labia majora and minora, the clitoris, the meatus urinarius, and the orifice of the vagina. The term 'vulva' or 'pudendum,' as generally applied, includes all these parts.

FIG. 679.—The vulva. External female organs of generation

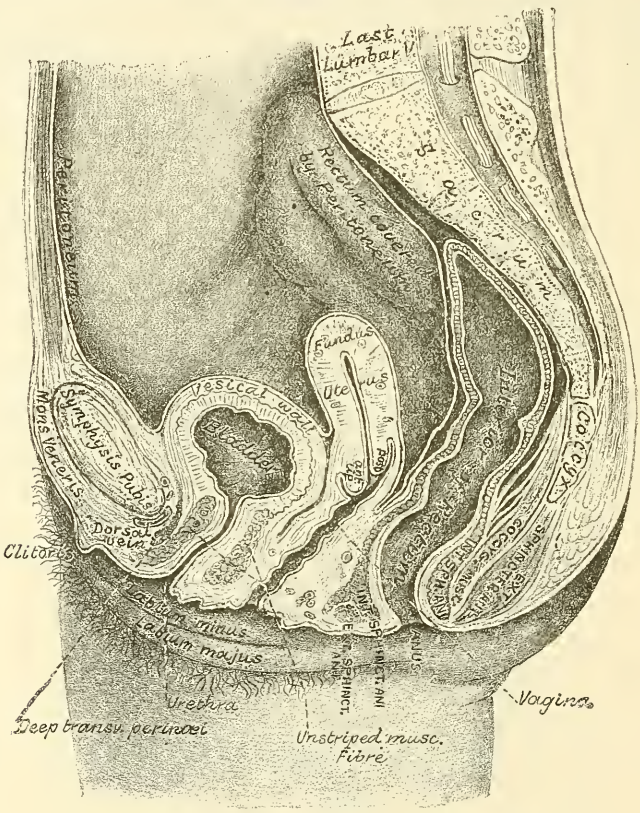


The **mons Veneris** is the rounded eminence in front of the pubic symphysis formed by a collection of fatty tissue beneath the integument. It surmounts the vulva, and becomes covered with hair at the time of puberty.

The **labia majora** are two prominent longitudinal cutaneous folds, extending

downwards from the mons Veneris to the anterior boundary of the perinæum, and enclosing the common urino-sexual opening. Each labium has two surfaces, an outer, which is pigmented and covered with strong, crisp hairs; and an inner, which is smooth and is beset with large sebaceous follicles and is continuous with the genito-urinary mucous tract; and between the two a considerable quantity of areolar tissue, fat, and a tissue resembling the dartos of the scrotum, besides vessels, nerves, and glands. The labia are thicker in front, where they form by their meeting the *anterior commissure*. Posteriorly they are not really joined, but appear to become lost in the neighbouring integument, terminating close to, and nearly parallel with each other. Together with the connecting skin between them, they form the posterior commissure, or posterior boundary of the vulval orifice.

Fig. 680.—Vertical median section of the female pelvis.



The interval between the posterior commissure and the anus, about an inch to an inch and a quarter in length, constitutes the perinæum. The *fourchette* is the anterior edge of the perinæum, and between it and the hymen is a depression, the *fossa navicularis*. The labia correspond to the scrotum in the male.

The **labia minora**, or **nymphæ**, are two small cutaneous folds, situated within the labia majora, and extending from the clitoris obliquely downwards, outwards and backwards for about an inch and a half on each side of the orifice of the vagina, between which and the labia majora they are lost. Anteriorly, the two labia minora meet, and form the *frænum of the clitoris*. The prepuce of the clitoris, passing backwards on each side, is inserted, as it were, into the labia minora, but is not actually a part of them. The nymphæ are really modified skin. Their internal surfaces have numerous sebaceous follicles.

The **clitoris** is an erectile structure, analogous to the corpora cavernosa of the penis. It is situated beneath the anterior commissure, partially hidden between

the anterior extremities of the labia minora. It is connected to the rami of the os pubis and ischium on each side by a crus; the body is short and concealed beneath the labia; the free extremity, or *glans clitoridis*, is a small rounded tubercle, consisting of spongy erectile tissue, and highly sensitive. It is provided, like the penis, with a suspensory ligament, and with two small muscles, the Erectores clitoridis, which are inserted into the crura of the clitoris. The clitoris consists of two corpora cavernosa, composed of erectile tissue enclosed in a dense layer of fibrous membrane, united together along their inner surfaces by an incomplete fibrous pectiniform septum.

Between the clitoris and the entrance of the vagina is a triangular smooth surface, bounded on each side by the nymphæ; this is the *vestibule*.

The orifice of the urethra (**meatus urinarius**) is situated at the back part of the vestibule, about an inch below the clitoris, and near the margin of the vagina, surrounded by a prominent elevation of the mucous membrane. Below the meatus urinarius is the orifice of the vagina, more or less closed in the virgin by a membranous fold, the *hymen*.

The **hymen** is a membranous fold which closes to a greater or less extent the opening of the vagina. It varies much in shape. Its commonest form is that of a ring, generally broadest posteriorly: sometimes it is represented by a semilunar fold, with its concave margin turned towards the pubes. A complete septum stretched across the lower part of the vaginal orifice is called 'imperforate hymen.' Occasionally it is cribriform, or its free margin forms a membranous fringe, or it may be entirely absent. It may persist after copulation, so that it cannot be considered as a test of virginity. After parturition, the small rounded elevations known as the *carunculæ myrtiformes* are found as the remains of the hymen.

Glands of Bartholin.—On each side of the commencement of the vagina, and behind the hymen, is a round or oblong body, of a reddish-yellow colour, and of the size of a horse-bean, analogous to Cowper's gland in the male. It is called the *gland of Bartholin*. Each gland opens by means of a long single duct, on each side, external to the hymen.

Bulbi vestibuli.—Extending from the clitoris, along either side of the vestibule, and lying a little behind the nymphæ, are two large oblong masses, about an inch in length, consisting of a plexus of veins, enclosed in a thin layer of fibrous membrane. These bodies are narrow in front, rounded below, and are connected with the crura of the clitoris and rami of the pubes: they are termed by Kobelt the *bulbi vestibuli*; and he considers them analogous to the bulb of the corpus spongiosum in the male. Immediately in front of these bodies is a smaller venous plexus, continuous with the bulbi vestibuli behind and the glans clitoridis in front: it is called by Kobelt the *pars intermedia*, and is considered by him as analogous to that part of the body of the corpus spongiosum which immediately succeeds the bulb.

Relations of the Bladder

The **bladder** is situated at the anterior part of the pelvis. It is in relation, *in front*, with the symphysis pubis; *behind*, with the utero-vesical pouch of peritoneum which separates it from the body of the uterus; its *base* lies in contact with the connective tissue in front of the cervix and upper part of the vagina. *Laterally*, is the recto-vesical fascia. The bladder is said by some anatomists to be larger in the female than in the male. At any rate it does not rise above the symphysis pubis till more distended than in the male, but this is perhaps owing to the more capacious pelvis rather than to its being of actually larger size.

The Urethra

The **urethra** is a narrow membranous canal, about an inch and a half in length, extending from the neck of the bladder to the meatus urinarius. It is

placed beneath the symphysis pubis, embedded in the anterior wall of the vagina; and its direction is obliquely downwards and forwards, its course being slightly curved, the concavity directed forwards and upwards. Its diameter when undilated is about a quarter of an inch. The urethra perforates the triangular ligament, precisely as in the male.

Structure.—The urethra consists of three coats: muscular, erectile, and mucous.

The *muscular coat* is continuous with that of the bladder; it extends the whole length of the tube, and consists of a circular stratum of muscular fibres. In addition to this, between the two layers of the triangular ligament, the female urethra is surrounded by the Compressor urethræ, as in the male.

A *thin layer of spongy erectile tissue*, containing a plexus of large veins, intermixed with bundles of unstriped muscular fibre, lies immediately beneath the mucous coat.

The *mucous coat* is pale, continuous externally with that of the vulva, and internally with that of the bladder. It is thrown into longitudinal folds, one of which, placed along the floor of the canal, resembles the verumontanum in the male urethra. It is lined by laminated epithelium, which becomes transitional near the bladder. Its external orifice is surrounded by a few mucous follicles.

The urethra, from not being surrounded by dense resisting structures, as in the male, admits of considerable dilatation, which enables the surgeon to remove, with considerable facility, calculi, or other foreign bodies, from the cavity of the bladder.

The Rectum

The **rectum** is more capacious and less curved in the female than in the male.

The *first portion* extends from the left sacro-iliac symphysis to the middle of the sacrum. Its connections are similar to those in the male.

The *second portion* extends to the tip of the coccyx. It is covered in front by the peritoneum for a short distance, at its upper part: it is in relation with the posterior wall of the vagina.

The *third portion* curves backwards from the vagina to the anus, leaving a space which corresponds on the surface of the body to the perinæum. Its extremity is surrounded by the Sphincter muscles, and its sides are supported by the Levatores ani.

INTERNAL ORGANS

The **internal organs of generation** are: the vagina, the uterus and its appendages, the Fallopian tubes, the ovaries and their ligaments, and the round ligaments.

The **vagina** extends from the vulva to the uterus. It is situated in the cavity of the pelvis, behind the bladder, and in front of the rectum. Its direction is curved upwards and backwards, at first in the line of the outlet, and afterwards in that of the axis of the cavity of the pelvis. Its walls are ordinarily in contact, and its usual shape on transverse section is that of an H, the transverse limb being slightly curved forwards or backwards, whilst the lateral limbs are somewhat convex towards the median line. Its length is about two inches along its anterior wall, and two and three-quarter inches along its posterior wall. It is constricted at its commencement, and becomes dilated medially, and narrowed near its uterine extremity; it surrounds the vaginal portion of the cervix uteri, a short distance from the os, its attachment extending higher up on the posterior than on the anterior wall of the uterus.

Relations.—Its *anterior surface* is in relation with the base of the bladder, and with the urethra. Its *posterior surface* is connected for the lower three-fourths of its extent to the anterior wall of the rectum, the upper fourth being separated from that tube by the recto-vaginal fold of peritoneum, which forms a

cul-de-sac between the vagina and rectum. Its sides give attachment superiorly to the broad ligaments, and inferiorly to the Levatores ani muscles and recto-vesical fascia.

Structure.—The vagina consists of an internal mucous lining, of a muscular coat, and between the two of a layer of erectile tissue.

The *mucous membrane* is continuous above with that lining the uterus. Its inner surface presents, along the anterior and posterior walls, a longitudinal ridge or raphé, called the *columns of the vagina*, and numerous transverse ridges or rugæ, extending outwards from the raphé on either side. These rugæ are divided by furrows of variable depth, giving to the mucous membrane the appearance of being studded over with conical projections or papillæ; they are most numerous near the orifice of the vagina, especially in females before parturition. The epithelium covering the mucous membrane is of the squamous variety. The submucous tissue is very loose, and contains numerous large veins, which by their anastomoses form a plexus, together with smooth muscular fibres derived from the muscular coat; it is regarded by Gussenbauer as an erectile tissue. It contains a number of mucous crypts, but no true glands.

The *muscular coat* consists of two layers: an external longitudinal, which is far the stronger, and an internal circular layer. The longitudinal fibres are continuous with the superficial muscular fibres of the uterus. The strongest fasciculi are those attached to the recto-vesical fascia on each side. The two layers are not distinctly separable from each other, but are connected by oblique decussating fasciculi, which pass from the one layer to the other. In addition to this, the vagina at its lower end is surrounded by a band of striped muscular fibres, the *sphincter vaginæ* (see page 465).

External to the muscular coat is a layer of connective tissue, containing a large plexus of blood-vessels.

The *erectile tissue* consists of a layer of loose connective tissue, situated between the mucous membrane and the muscular coat; embedded in it is a plexus of large veins, and numerous bundles of unstriped muscular fibres, derived from the circular muscular layer. The arrangement of the veins is similar to that found in other erectile tissues.

The Uterus

The **uterus** is the organ of gestation, receiving the fecundated ovum in its cavity, retaining and supporting it during the development of the fœtus, and becoming the principal agent in its expulsion at the time of parturition.

In the virgin state it is pear-shaped, flattened from before backwards, and situated in the cavity of the pelvis, between the bladder and the rectum; it is retained in its position by the round and broad ligaments on each side, and projects into the upper end of the vagina below. Its upper end, or base, is directed upwards and forwards; its lower end, or apex, downwards and backwards, in the line of the axis of the inlet of the pelvis. It therefore forms an angle with the vagina, since the direction of the vagina corresponds to the axis of the cavity and outlet of the pelvis. The uterus measures about three inches in length, two in breadth at its upper part, and nearly an inch in thickness, and it weighs from an ounce to an ounce and a half.

It consists of two parts: (1) the *body*, with its upper broad extremity, the *fundus*; and (2) the *cervix*, or *neck*, which is partly above the vagina, and partly in the vagina. The fundus is placed on a line below the level of the brim of the pelvis, being directed forwards behind the upper portion of the anterior pelvic wall.

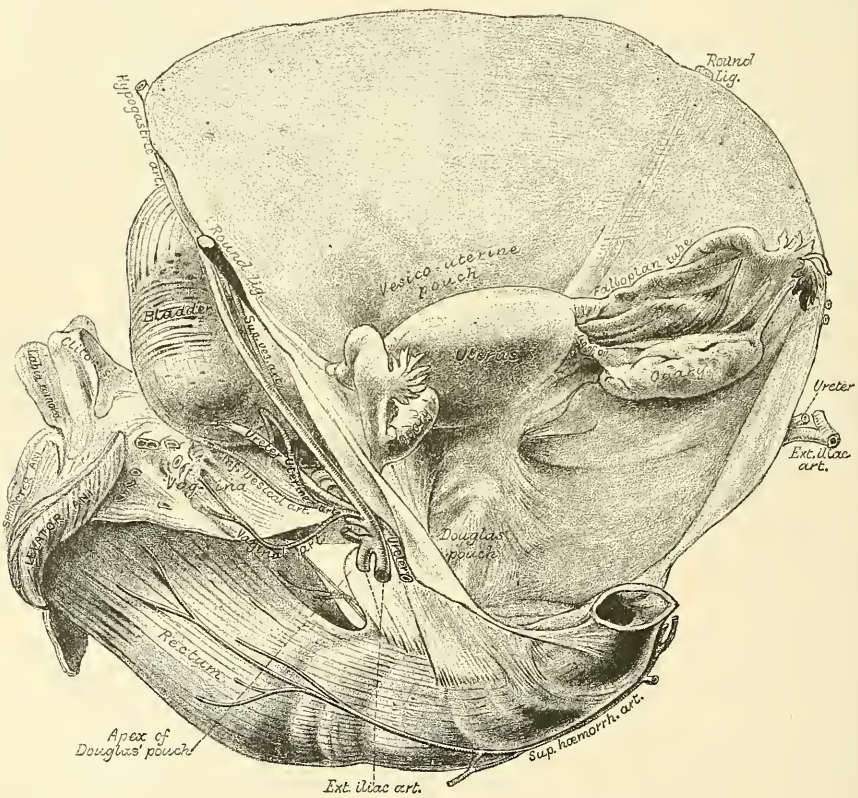
The division between the body and cervix is indicated externally by a slight constriction, and by the reflection of the peritoneum from the anterior surface of the uterus on to the bladder, and internally by a narrowing of the canal, called the *internal os*.

The *body* gradually narrows from the fundus to the neck. Its anterior surface is flattened, covered by peritoneum in the upper three-fourths of its extent, and separated from the bladder by the utero-vesical pouch. Its *posterior surface* is convex transversely, covered by peritoneum throughout, and separated from the rectum by some convolutions of the intestine. Its *lateral margins* are concave, and give attachment to the Fallopian tube above, the round ligament below and in front of this, and the ligament of the ovary behind and between both of these structures.

The *cervix* is the lower constricted segment of the uterus; around its circumference is attached the upper end of the vagina, which extends upwards a greater distance behind than in front.

The supravaginal portion is not covered by peritoneum in front; a pad of cellular tissue is interposed between it and the bladder. Behind, the peritoneum

Fig. 681.—Douglas's pouch. (From a preparation in the Museum of the Royal College of Surgeons.)



is extended over it. The vaginal portion is the rounded lower end projecting into the vagina. On its surface is a small aperture, the *os uteri*, generally circular in shape, but sometimes oval, or almost linear. The margin of the opening is, in the absence of past parturition or disease, quite smooth.

Ligaments.—The ligaments of the uterus are eight in number: one anterior; one posterior; two lateral or broad; two sacro-uterine—all these being formed of peritoneum; and, lastly, two round ligaments.

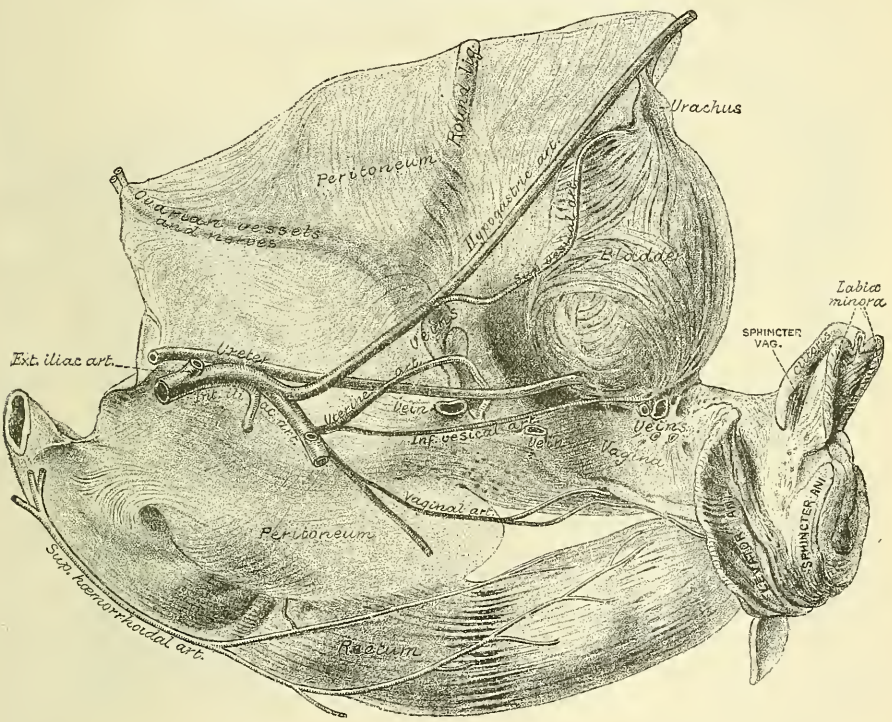
The *anterior ligament* (vesico-uterine) is reflected on to the bladder from the front of the uterus, at the junction of the supravaginal cervix and body.

The *posterior ligament* (recto-uterine) passes from the posterior wall of the uterus over the upper fourth of the vagina, and thence on to the rectum and sacrum. It thus forms a pouch called *Douglas's pouch* (fig. 681), the boundaries

of which are, in front, the posterior wall of the uterus, the supravaginal cervix, and the upper fourth of the vagina; behind, the rectum and sacrum; above, the small intestine; and laterally, the sacro-uterine ligaments.

The *two lateral* or *broad ligaments* pass from the sides of the uterus to the lateral walls of the pelvis, forming a septum across the pelvis, which divides that cavity into two portions. In the anterior part are contained the bladder, urethra, and vagina; in the posterior part, the rectum. Between the two layers of each broad ligament are contained: (1) the Fallopian tubes superiorly; (2) the round ligament; (3) the ovary and its ligament; (4) the parovarium, or organ of Rosenmüller; (5) connective tissue; and (6) unstriped muscular fibre. The Fallopian tube is contained in a special fold of the broad ligament, which is attached to the part of the ligament near the ovary, and is known by the

FIG. 682.—Side view of the female pelvic organs. (From a preparation in the Museum of the Royal College of Surgeons.)



name of the *meso-salpinx*. Between the fimbriated extremity of the tube and the lower attachment of the broad ligament is a concave rounded margin called the *infundibulo-pelvic ligament* (fig. 684).

The *sacro-uterine ligaments* pass from the second and third bones of the sacrum, downwards and forwards, to be attached one on each side of the uterus at the junction of the supravaginal cervix and the body, this point corresponding internally to the position of the os internum.

The *round ligament* will be described in the sequel.

The **cavity of the uterus** is small in comparison with the size of the organ: that portion of the cavity which corresponds to the body is triangular, flattened from before backwards, so that its walls are closely approximated, and having its base directed upwards towards the fundus. At each superior angle is a funnel-shaped cavity, which constitutes the remains of the division of the body of the uterus into two cornua; and at the bottom of each cavity is the minute orifice of the Fallopian tube. At the inferior angle of the uterine cavity is a small

constricted opening, the internal orifice (*ostium internum*), which leads into the cavity of the cervix.

The **cavity of the cervix** is somewhat fusiform, flattened from before backwards, broader at the middle than at either extremity, and communicates, below, with the vagina. The wall of the canal presents, anteriorly and posteriorly, a longitudinal column, from which proceed a number of small oblique columns, giving the appearance of branches from the stem of a tree; and hence the name *arbor vitæ uterina* applied to it. These folds usually become very indistinct after the first labour.

Structure.—The uterus is composed of three coats: an external serous coat, a middle or muscular, and an internal mucous coat.

The *serous coat* is derived from the peritoneum; it invests the fundus and the whole of the posterior surface of the body of the uterus; but only the upper three-fourths of its anterior surface. In the lower fourth of the posterior surface the peritoneum, though covering the uterus, is not closely connected with it, being separated from it by a layer of loose cellular tissue and some large veins.

The *muscular coat* forms the chief bulk of the substance of the uterus. In the unimpregnated state it is dense, firm, of a greyish colour, and cuts almost like cartilage. It is thick opposite the middle of the body and fundus, and thin at the orifices of the Fallopian tubes. It consists of bundles of unstriped muscular fibres, disposed in layers, intermixed with areolar tissue, blood-vessels, lymphatic vessels, and nerves. In the impregnated state the muscular tissue becomes more prominently developed, and is disposed in three layers—external, middle, and internal.

The external layer is placed beneath the peritoneum, disposed as a thin plane on the anterior and posterior surfaces. It consists of fibres, which pass transversely across the fundus, and, converging at each superior angle of the uterus, are continued on to the Fallopian tube, the round ligament, and the ligament of the ovary: some passing at each side into the broad ligament, and others running backwards from the cervix into the sacro-uterine ligaments.

The middle layer of fibres, which is thickest, presents no regularity in its arrangement, being disposed longitudinally, obliquely, and transversely. It contains most blood-vessels.

The internal or deep layer consists of circular fibres arranged in the form of two hollow cones, the apices of which surround the orifices of the Fallopian tubes, their bases intermingling with one another on the middle of the body of the uterus. At the internal os these circular fibres form a distinct sphincter.

The *mucous membrane* is thin, smooth, and closely adherent to the subjacent tissue. It is continuous, through the fimbriated extremity of the Fallopian tubes, with the peritoneum; and, through the os uteri, with the lining of the vagina.

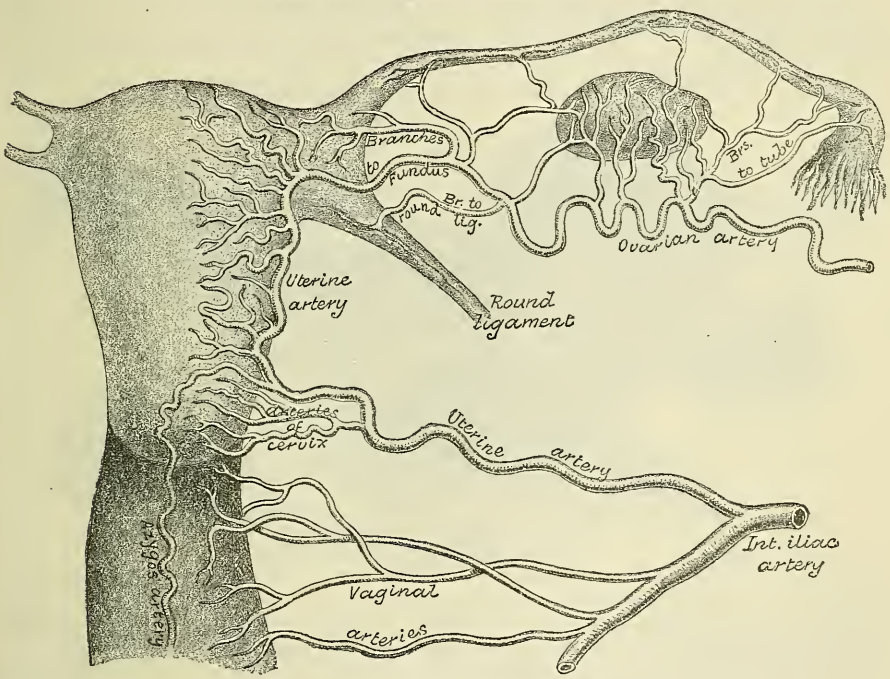
In the body of the uterus it is smooth, soft, of a pale red colour, lined by columnar ciliated epithelium, and presents, when viewed with a lens, the orifices of numerous tubular follicles arranged perpendicularly to the surface. It is unprovided with any submucosa, but is intimately connected with the innermost layer of the muscular coat, which by some anatomists is regarded as the muscularis mucosæ. In structure the corium differs from ordinary mucous membrane, consisting of an embryonic nucleated and highly cellular form of connective tissue in which run numerous large lymphatics. In it are the tube-like *uterine glands*, which are of small size in the unimpregnated uterus, but shortly after impregnation become enlarged, elongated, presenting a contorted or waved appearance towards their closed extremities, which reaches into the muscularis, and may be single or bifid. They consist of a delicate membrane, lined by an epithelium, which becomes ciliated towards the orifices. In the impregnated uterus the epithelium loses its ciliated character, is thicker and tougher, and is provided with a submucous layer of areolar tissue.

In the cervix the mucous membrane is sharply differentiated from that of the uterine cavity. It is thrown into numerous transverse folds, which are arranged

along an anterior and posterior longitudinal raphé, presenting an appearance which has received the name of *arbor vitæ*. In the upper two-thirds of the canal, the mucous membrane is provided with numerous deep glandular follicles, which secrete a clear viscid alkaline mucus; and in addition, extending through the whole length of the canal, are a variable number of little cysts, presumably follicles, which have become occluded and distended with retained secretion. They are called the *ovula Nabothi*. The mucous membrane covering the lower half of the cervical canal presents numerous papillæ. The epithelium of the upper two-thirds is cylindrical and ciliated, but below this it loses its cilia, and gradually changes to squamous epithelium close to the external os.

Vessels and nerves.—The *arteries of the uterus* are the uterine, from the internal iliac; and the ovarian, from the aorta. They are remarkable for their tortuous course in the substance of the organ, and for their frequent anastomoses. The termination of the ovarian artery meets the termination of the uterine

Fig. 683.—The arteries of the internal organs of generation of the female, seen from behind. (After Hyrtl.)



artery, and forms an anastomotic trunk from which branches are given off to supply the uterus, their disposition being, as shown by Sir John Williams, circular. The *veins* are of large size, and correspond with the arteries. In the impregnated uterus these vessels are termed the *uterine sinuses*, consisting of the lining membrane of the veins adhering to the walls of canals channelled through the substance of the uterus. They terminate in the uterine plexuses. The *lymphatics* of the body terminate in the lumbar glands, those of the cervix in the pelvic glands. The *nerves* are derived from the inferior hypogastric and ovarian plexuses, and from the third and fourth sacral nerves.

The form, size, and situation of the uterus vary at different periods of life and under different circumstances.

In the fœtus the uterus is contained in the abdominal cavity, projecting beyond the brim of the pelvis. The cervix is considerably larger than the body.

At puberty the uterus is pyriform in shape, and weighs from eight to ten drachms. It has descended into the pelvis, the fundus being just below the level of the brim of this cavity. The arbor vitæ is distinct, and extends to the upper part of the cavity of the organ.

During menstruation the organ is enlarged, and more vascular, its surfaces rounder; the os externum is rounded, its labia swollen, and the lining membrane of the body thickened, softer, and of a darker colour. According to Sir J. Williams, at each recurrence of menstruation a molecular disintegration of the mucous membrane takes place, which leads to its complete removal, only the bases of the glands embedded in the muscle being left. At the cessation of menstruation, by a proliferation of the remaining structures a fresh mucous membrane is formed.

During pregnancy the uterus becomes enormously enlarged, and in the ninth month reaches the epigastric region. The increase in size is partly due to growth of pre-existing muscle, and partly to development of new fibres.

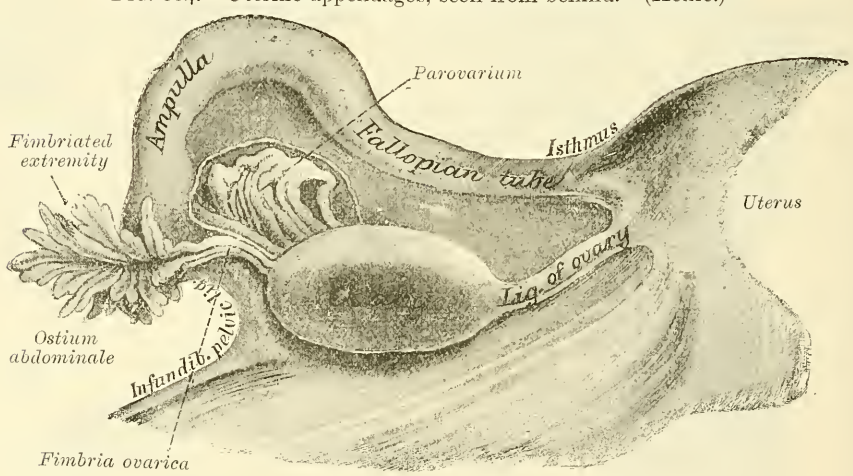
After parturition the uterus nearly regains its usual size, weighing about an ounce and a half; but its cavity is larger than in the virgin state; the external orifice is more marked; its edges present a fissured surface; its vessels are tortuous; and its muscular layers are more defined.

In old age the uterus becomes atrophied, and paler and denser in texture; a more distinct constriction separates the body and cervix. The ostium internum and, occasionally, the vaginal orifice often become obliterated, and its labia almost entirely disappear.

Appendages of the Uterus

The **appendages of the uterus** are the Fallopian tubes, the ovaries and their ligaments, and the round ligaments. They are placed in the following order: in

Fig. 684.—Uterine appendages, seen from behind. (Henle.)



front is the round ligament; the Fallopian tube occupies the upper margin of the broad ligament; the ovary and its ligament are behind and below both.

The **Fallopian tubes**, or **oviducts**, convey the ova from the ovaries to the cavity of the uterus. They are two in number, one on each side, situated in the upper margin of the broad ligament, extending from each superior angle of the uterus to the side of the pelvis. Each tube is about four inches in length; and is described as consisting of three portions: (1) the *isthmus*, or inner constricted half; (2) the *ampulla*, or outer dilated portion, which curves over the ovary; and (3) the *infundibulum* with its *ostium abdominale*, surrounded by fimbriæ, one of which is attached to the ovary, the *fimbria ovarica*. The general direction of the Fallopian tube is outwards, backwards, and downwards. The uterine opening is minute, and will only admit a fine bristle; the abdominal opening is comparatively much larger. In connection with the fimbriæ of the Fallopian tube, or with the broad ligament close to them, there is frequently one or more small vesicles, floating on a long stalk of peritoneum. These are termed the *hydatids of Morgagni*.

Structure.—The Fallopian tube consists of three coats: serous, muscular, and mucous.

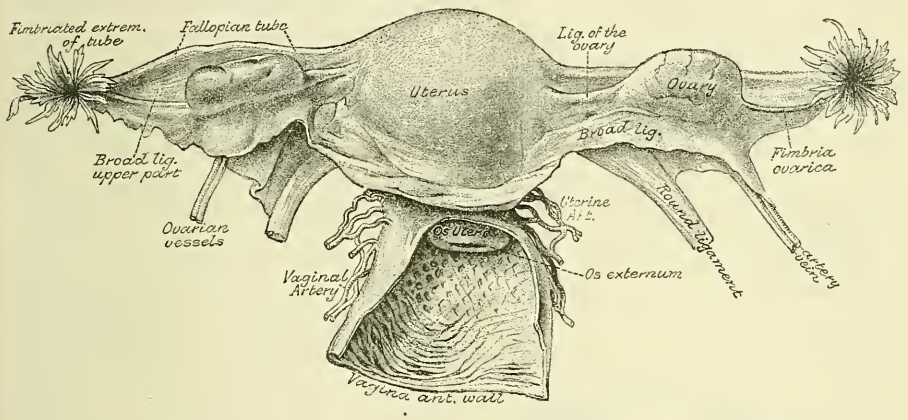
The *external* or *serous coat* is peritoneal.

The *middle* or *muscular coat* consists of an external longitudinal and an internal circular layer of muscular fibres continuous with those of the uterus.

The *internal* or *mucous coat* is continuous with the mucous lining of the uterus, and, at the free extremity of the tube, with the peritoneum. It is thrown into longitudinal folds, which in the outer, larger part of the tube, or ampulla, are much more extensive than in the narrow canal of the isthmus. The lining epithelium is columnar ciliated. This form of epithelium is also found on the inner surface of the fimbriæ; while on the outer or serous surfaces of these processes the epithelium gradually merges into the endothelium of the peritoneum.

The **ovaries** (*testes muliebres*, Galen) are analogous to the testes in the male. They are oval-shaped bodies, of an elongated form, flattened from above downwards, situated one on each side of the uterus, in the posterior part of the broad ligament behind and below the Fallopian tubes. Each ovary is connected, by its anterior straight margin, to the broad ligament; by its lower extremity, to the

FIG. 685.—The uterus and its appendages. Posterior view. The parts have been somewhat displaced from their proper position in the preparation of the specimen; thus the right ovary has been raised above the Fallopian tube, and the fimbriated extremities of the tubes have been turned upwards and outwards. (From a preparation in the Museum of the Royal College of Surgeons.)



uterus by a proper ligament, the *ligament of the ovary*; and by its upper end to the fimbriated extremity of the Fallopian tube by the ovarian fimbria; its mesial and lateral surfaces and posterior convex border are free. The ovaries are of a greyish-pink colour, and present either a smooth or puckered, uneven surface. They are each about an inch and a half in length, three-quarters of an inch in width, and about a third of an inch thick; and weigh from one to two drachms.

The exact position of the ovary has been the subject of considerable difference of opinion, and writers differ much as to what is to be regarded as the normal position. The fact appears to be that it is differently placed in different individuals. Hasse has described it as being situated with its long axis transverse, or almost transverse, to the pelvic cavity. Schultze, on the other hand, believes that its long axis is antero-posterior. Kölliker asserts that the truth lies between these two views, and that the ovary is placed obliquely in the pelvis, its long axis lying parallel to the external iliac vessels, with its surface directed inwards and outwards, and its convex free border upwards. His has made some important observations on this subject, and his views are largely accepted. He teaches that the uterus rarely lies symmetrically in the middle of the pelvic cavity, but is generally inclined to one or other side, most frequently to the left, in the proportion of three to two. The position of the two ovaries varies according to the inclination of the uterus. When the uterus is inclined to the left, the ovary of this side lies with its long axis vertical and with one side closely applied to the

outer wall of the pelvis; while the ovary of the opposite side, being dragged upon by the inclination of the uterus, lies obliquely, its outer extremity being retained in close apposition to the side of the pelvis by the infundibulo-pelvic ligament (page 1105). When, on the other hand, the uterus is inclined to the right, the position of the two ovaries is exactly reversed, the right being vertical and the left oblique. In whichever position the ovary is placed, the Fallopian tube forms a loop around it, the uterine half ascending obliquely over it, and the outer half, including the dilated extremity, descending and bulging freely behind it. From this extremity the fimbriæ pass upwards on to the ovary and closely embrace it.

Structure.—The ovary consists of a number of Graafian vesicles, embedded in the meshes of a stroma or framework, and invested by a serous covering derived from the peritoneum.

Serous Covering.—Though the investing membrane of the ovary is derived from the peritoneum, it differs essentially from that structure, inasmuch as its epithelium consists of a single layer of columnar cells, instead of the flattened endothelial cells on other parts of the membrane; this has been termed the *germinal epithelium of Waldeyer*, and gives to the surface of the ovary a dull grey aspect instead of the shining smoothness of serous membranes generally.

Stroma.—The stroma is a peculiar soft tissue, abundantly supplied with blood-vessels, consisting for the most part of spindle-shaped cells, with a small amount of ordinary connective tissue. These cells have been regarded by some anatomists as unstriped muscle cells, which, indeed, they most resemble (His); by others as connective-tissue cells (Waldeyer, Henle, and Kölliker). On the surface of the organ this tissue is much condensed, and forms a layer composed of short connective-tissue fibres, with fusiform cells between them. This was formerly regarded as a distinct fibrous covering, and was termed the *tunica albuginea*, but is nothing more than a condensed layer of the stroma of the ovary.

Graafian vesicles.—Upon making a section of an ovary, numerous round transparent vesicles of various sizes are to be seen; they are the *Graafian vesicles*, the ovisacs containing the ova. Immediately beneath the superficial covering is a layer of stroma, in which are a large number of minute vesicles, of uniform size, about $\frac{1}{100}$ of an inch in diameter. These are

Fig. 686.—Section of the ovary. (After Schrön.)

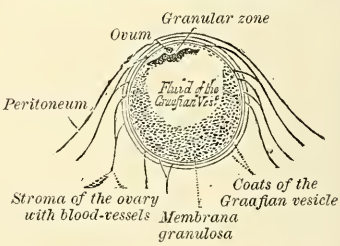
Fig. 687.—Section of the Graafian vesicle. (After Von Baer.)



the Graafian vesicles in their earliest condition, and the layer where they are found has been termed the *cortical layer*. They are especially numerous in the ovary of the young child. After puberty, and during the whole of the child-bearing period, large and mature, or almost mature, Graafian vesicles are also found in the cortical layer in small numbers, and also ‘corpora lutea,’ the remains of vesicles which have burst and are undergoing atrophy and absorption. Beneath

this superficial stratum, other large and more mature Graafian vesicles are found embedded in the ovarian stroma. These increase in size as they recede from the surface towards a highly vascular stroma in the centre of the organ, termed the *medullary substance* (*zona vasculosa*, Waldeyer). This stroma forms the tissue of the hilum by which the ovary is attached, and through which the blood-vessels enter: it does not contain any Graafian vesicles.

The larger *Graafian vesicles* consist of an external fibro-vascular coat, connected with the surrounding stroma of the ovary by a network of blood-vessels; and an internal coat, named *ovicapsule*, which is lined by a layer of nucleated cells, called the *membrana granulosa*. The fluid contained in the interior of the vesicles is transparent and albuminous, and in it is suspended the ovum. In that part of the mature Graafian vesicle which is nearest the surface of the ovary, the cells of the membrana granulosa are collected into a mass which projects into the cavity of the vesicle. This is termed the *discus proligerus*, and in this the ovum is embedded.*

The ova are formed from the germ-epithelium on the surface of the ovary: the cells become enlarged and involuted, forming little depressions on the surface of the ovary. As they sink deeper into the tissue they become enclosed by the outgrowth of processes from the stroma of the ovary, and, becoming surrounded, their connection with the surface is cut off, and the germ-epithelium forming the involution is contained in a cavity, the future Graafian follicle. The germ-cell or cells now form the ovum; the cell-wall forms the vitelline membrane; the nucleus, the germinal area; and a nucleolus, which soon appears, the germinal spot. A clear homogeneous protoplasm is formed within the cell, constituting the yelk, and thus the primordial ovum is developed. According to Dr. Foulis, the cells of the membrana granulosa are formed out of the nuclei of the fibro-cellular stroma of the ovary.†

The development and maturation of the Graafian vesicles and ova continue uninterruptedly from puberty to the end of the fruitful period of woman's life, while their formation commences before birth. Before puberty the ovaries are small, the Graafian vesicles contained in them are disposed in a comparatively thick layer in the cortical substance; here they present the appearance of a large number of minute closed vesicles, constituting the early condition of the Graafian vesicle; many, however, never attain full development, but shrink and disappear, their ova being incapable of impregnation. At puberty the ovaries enlarge, are more vascular, the Graafian vesicles are developed in greater abundance, and their ova are capable of fecundation.

Discharge of the ovum.—The Graafian vesicles, after gradually approaching the surface of the ovary, burst: the ovum and fluid contents of the vesicles are liberated, and escape on the exterior of the ovary, passing thence into the Fallopian tube.‡

In the fœtus, the ovaries are situated, like the testes, in the lumbar region, near the kidneys. They may be distinguished from those bodies at an early period by their elongated and flattened form, and by their position, which is at first oblique and then nearly transverse. They gradually descend into the pelvis.

Lying above the ovary in the broad ligament between it and the Fallopian tube is the *organ of Rosenmüller*, called also the *parovarium*. This is the remnant of a fœtal structure, the development of which has been described at a former page (page 114). In the adult it consists of a few closed convoluted tubes, lined with epithelium, which converge towards the ovary at one end and at the other are united by a longitudinal tube, the *epoophoron* or *duct of Gartner*. This duct terminates in a bulbous enlargement (see fig. 111). The parovarium is connected at its uterine extremity with the remains of the Wolffian duct.

* For a description of the ovum, see page 72.

† *Proceedings of the Royal Society of Edinburgh*, April 1875.

‡ This is effected either by application of the tube to the ovary, or by a curling upwards of the fimbriated extremity, so that the ovum is caught as it falls.

The **ligament of the ovary** is a rounded cord, which extends from each superior angle of the uterus to the inner extremity of the ovary; it consists of fibrous tissue and a few muscular fibres derived from the uterus.

The **round ligaments** are two rounded cords between four and five inches in length, situated between the layers of the broad ligament in front of and below the Fallopian tube. Commencing on each side at the superior angle of the uterus, this ligament passes forwards, upwards, and outwards through the internal abdominal ring, along the inguinal canal to the labia majora, in which it becomes lost. The round ligament consists principally of muscular tissue, prolonged from the uterus; also of some fibrous and areolar tissue, besides blood-vessels and nerves, enclosed in a duplicature of peritoneum, which, in the fœtus, is prolonged in the form of a tubular process for a short distance into the inguinal canal. This process is called the *canal of Nuck*. It is generally obliterated in the adult, but sometimes remains pervious even in advanced life. It is analogous to the peritoneal pouch which accompanies the descent of the testis.

Vessels and nerves.—The *arteries of the ovaries and Fallopian tubes* are the ovarian from the aorta. They enter the attached border, or hilum, of the ovary. The *veins* follow the course of the arteries; they form a plexus near the ovary, the *pampiniform plexus*. The *nerves* are derived from the inferior hypogastric or pelvic plexus, and from the ovarian plexus, the Fallopian tube receiving a branch from one of the uterine nerves.

Mammary Glands

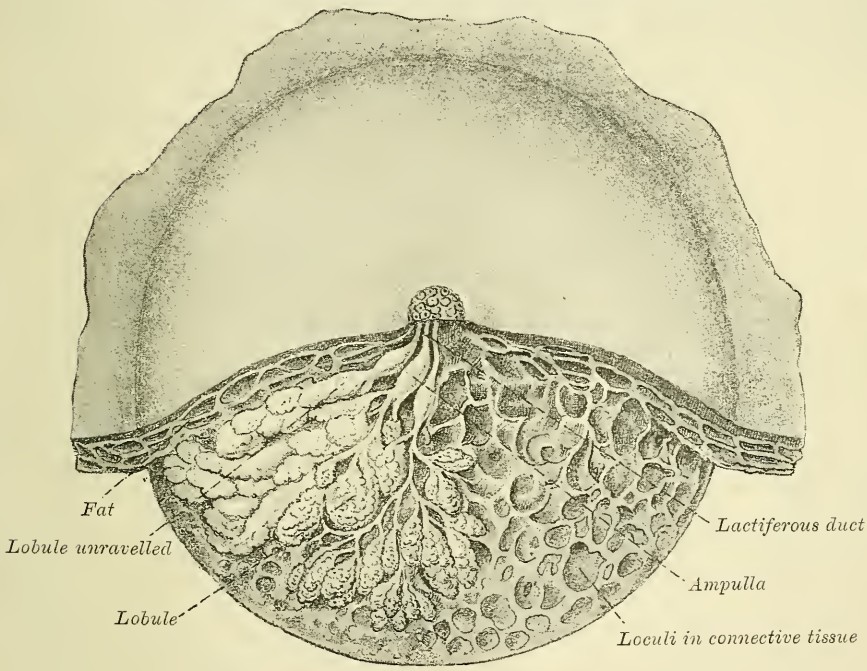
The **mammæ**, or breasts, are accessory glands of the generative system, which secrete the milk. They exist in the male as well as in the female; but in the former only in the rudimentary state, unless their growth is excited by peculiar circumstances. In the female they are two large hemispherical eminences situated towards the lateral aspect of the pectoral region, corresponding to the intervals between the third and sixth or seventh ribs, and extending from the side of the sternum to the axilla. Their weight and dimensions differ at different periods of life, and in different individuals. Before puberty they are of small size, but enlarge as the generative organs become more completely developed. They increase during pregnancy, and especially after delivery, and become atrophied in old age. The left mamma is generally a little larger than the right. Their base is nearly circular, flattened, or slightly concave, and has its long diameter directed upwards and outwards towards the axilla; they are separated from the Pectoral muscles by a layer of fascia. The outer surface of the mamma is convex, and presents, just below the centre, a small conical prominence, the nipple (*mammilla*). The surface of the nipple is dark-coloured, and surrounded by an areola having a coloured tint. In the virgin the areola is of a delicate rosy hue; about the second month after impregnation it enlarges and acquires a darker tinge, which increases as pregnancy advances, becoming in some cases of a dark brown, or even black colour. This colour diminishes as soon as lactation is over, but is never entirely lost throughout life. These changes in the colour of the areola are of importance in forming a conclusion in a case of suspected first pregnancy.

The **nipple** is a cylindrical or conical eminence, capable of undergoing a sort of erection from mechanical excitement, a change mainly due to the contraction of its muscular fibres. It is of a pink or brownish hue, its surface wrinkled and provided with papillæ; and it is perforated by numerous orifices, the apertures of the lactiferous ducts. Near the base of the nipple, and upon the surface of the areola, are numerous sebaceous glands, which become much enlarged during lactation, and present the appearance of small tubercles beneath the skin. These glands secrete a peculiar fatty substance, which serves as a protection to the integument of the nipple during the act of sucking. The nipple consists of numerous vessels, intermixed with plain muscular fibres which are principally

arranged in a circular manner around the base: some few fibres radiating from base to apex.

Structure.—The mamma consists of gland-tissue; of fibrous tissue, connecting its lobes; and of fatty tissue in the intervals between the lobes. The gland-tissue, when freed from fibrous tissue and fat, is of a pale reddish colour, firm in texture, circular in form, flattened from before backwards, thicker in the centre than at the circumference, and presenting several inequalities on its surface, especially in front. It consists of numerous lobes, and these are composed of lobules, connected together by areolar tissue, blood-vessels, and ducts. The smallest lobules consist of a cluster of rounded alveoli, which open into the smallest branches of the lactiferous ducts; these ducts uniting form larger ducts, which terminate in a single canal, corresponding with one of the chief subdivisions of the gland. The number of excretory ducts varies from fifteen to twenty; they are termed the *tubuli lactiferi*, or *galactophori*. They converge towards the

FIG. 688.—Dissection of the lower half of the female breast during the period of lactation. (From Luschka.)



areola, beneath which they form dilatations, or *ampullæ*, which serve as reservoirs for the milk, and, at the base of the nipple, become contracted, and pursue a straight course to its summit, perforating it by separate orifices considerably narrower than the ducts themselves. The ducts are composed of areolar tissue, with longitudinal and transverse elastic fibres, and longitudinal muscular fibres: their mucous lining is continuous, at the point of the nipple, with the integument. The epithelium of the mammary gland differs according to the state of activity of the organ. In the gland of a woman who is not pregnant or suckling, the alveoli are very small and solid, being filled with a mass of granular polyhedral cells. During pregnancy the alveoli enlarge, and the cells undergo rapid multiplication. At the commencement of lactation, the cells in the centre of the alveolus undergo fatty degeneration, and are eliminated in the first milk, as *colostrum corpuscles*. The peripheral cells of the alveolus remain, and form a single layer of granular, short columnar cells, with a spherical nucleus, lining the limiting membrana propria. These cells during the state of

activity of the gland, are capable of forming, in their interior, oil-globules, which are then ejected into the lumen of the alveolus, and constitute the milk-globules.

The *fibrous tissue* invests the entire surface of the breast, and sends down septa between its lobes, connecting them together.

The *fatty tissue* surrounds the surface of the gland, and occupies the interval between its lobes. It usually exists in considerable abundance, and determines the form and size of the gland. There is no fat immediately beneath the areola and nipple.

Vessels and nerves.—The *arteries* supplying the mammæ are derived from the thoracic branches of the axillary, the intercostals, and internal mammary. The *veins* describe an anastomotic circle round the base of the nipple, called by Haller the *circulus venosus*. From this, large branches transmit the blood to the circumference of the gland, and end in the axillary and internal mammary veins. The *lymphatics*, for the most part, run along the lower border of the Pectoralis major to the axillary glands; some few, from the inner side of the breast, perforate the intercostal spaces and empty themselves into the anterior mediastinal glands. The *nerves* are derived from the anterior and lateral cutaneous nerves of the thorax.

THE SURGICAL ANATOMY OF INGUINAL HERNIA

Dissection (fig. 689).—For dissection of the parts concerned in inguinal hernia, a male subject, free from fat, should always be selected. The body should be placed in the supine position, the abdomen and pelvis raised by means of blocks placed beneath them, and the lower extremities rotated outwards, so as to make the parts as tense as possible. If the abdominal walls are flaccid, the cavity of the abdomen should be inflated by an aperture through the umbilicus. An incision should be made along the middle line, from the umbilicus to the symphysis pubis, and continued along the front of the scrotum; and a second incision, from the anterior superior spine of the ilium to just below the umbilicus. These incisions should divide the integument; and the triangular-shaped flap included between them should be reflected downwards and outwards, when the superficial fascia will be exposed.

The superficial fascia of the abdomen.—This, over the greater part of the abdominal wall, consists of a single layer of fascia, which contains a variable amount of fat; but as it approaches the groin it is easily divisible into two layers, between which are found the superficial vessels and nerves and the superficial inguinal lymphatic glands.

The *superficial layer* is thick, areolar in texture, containing adipose tissue in its meshes, the quantity of which varies in different subjects. Below it passes over Poupart's ligament, and is continuous with the outer layer of the superficial fascia of the thigh. In the male, this fascia is continued over the penis and over the outer surface of the cord to the scrotum, where it helps to form the dartos. As it passes to the penis and over the cord to the scrotum it changes its character, becoming thin, destitute of adipose tissue, and of a pale, reddish colour; and in the scrotum it acquires some involuntary muscular fibres. From the scrotum it may be traced backwards, to be continuous with the superficial fascia of the perinæum. In the female this fascia is continued into the labia majora.

The *hypogastric branch of the ilio-hypogastric nerve* perforates the aponeurosis of the External oblique muscle about an inch above and a little to the outer side of the external abdominal ring, and is distributed to the integument of the hypogastric region.

The *ilio-inguinal nerve* escapes at the external abdominal ring, and is distributed to the integument of the upper and inner part of the thigh; to the scrotum in the male and to the labium in the female.

The *superficial epigastric artery* arises from the femoral about half an inch below Poupart's ligament, and, passing through the saphenous opening in the fascia lata, ascends on to the abdomen, in the superficial fascia covering the External oblique muscle, nearly as high as the umbilicus. It distributes branches to the superficial inguinal lymphatic glands, the superficial fascia, and the integument, anastomosing with branches of the deep epigastric and internal mammary arteries.

The *superficial circumflex iliac artery*, the smallest of the cutaneous branches, arises close to the preceding, and, piercing the fascia lata, runs outwards, parallel with Poupart's ligament, as far as the crest of the ilium, dividing into branches which supply the superficial inguinal lymphatic glands, the superficial fascia and

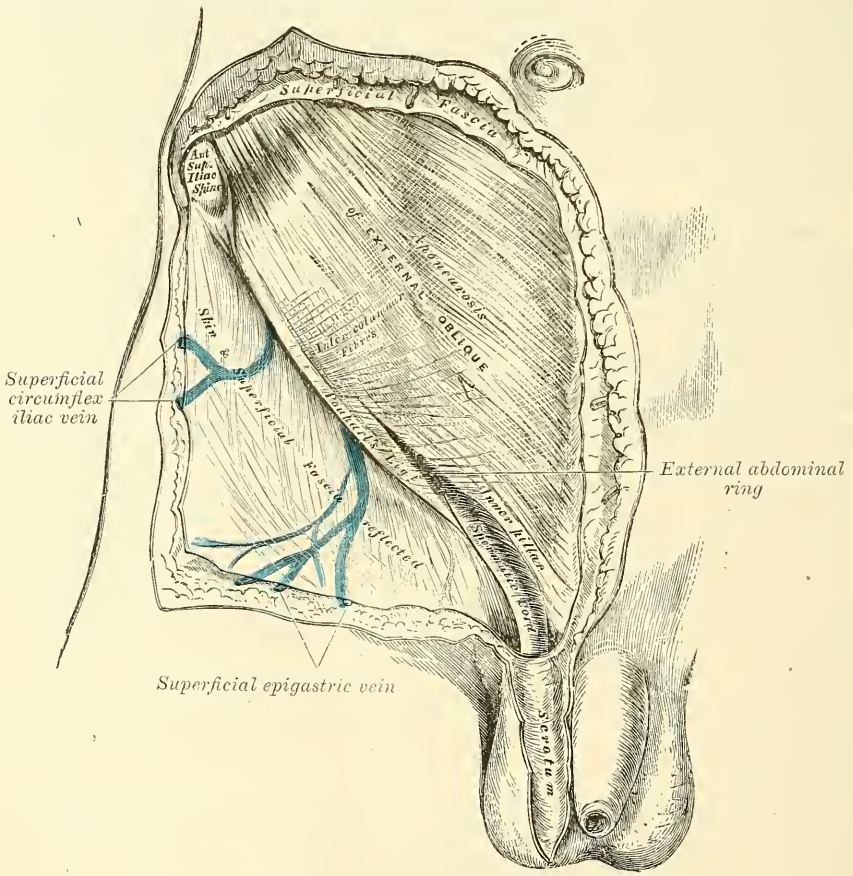
the integument, anastomosing with the deep circumflex iliac and with the gluteal and external circumflex arteries.

The *superficial external pudic* (*superior*) *artery* arises from the inner side of the femoral artery, close to the preceding vessels, and, after passing through the saphenous opening, courses inwards, across the spermatic cord, to be distributed to the integument on the lower part of the abdomen, the penis and scrotum in the male, and the labium in the female, anastomosing with branches of the internal pudic.

The superficial veins.—The veins accompanying these superficial vessels are usually much larger than the arteries: they terminate in the internal saphenous vein.

The *superficial inguinal lymphatic glands* are placed immediately beneath the integument, are of large size, and vary from eight to ten in number. They are

FIG. 689.—Inguinal hernia. Superficial dissection.



divisible into two groups: an upper, disposed irregularly along Poupart's ligament, which receive the lymphatic vessels from the integument of the scrotum, penis, parietes of the abdomen, perineal and gluteal regions, and the mucous membrane of the urethra; and an inferior group, which surround the saphenous opening in the fascia lata, a few being sometimes continued along the saphenous vein to a variable extent. This latter group receive the superficial lymphatic vessels from the lower extremity.

The *deep layer of the superficial fascia* (*fascia of Scarpa*) is thinner and more membranous in character than the superficial layer. In the middle line it is intimately adherent to the linea alba; above, it is continuous with the superficial

fascia over the rest of the trunk; below, it blends with the fascia lata of the thigh, a little below Poupart's ligament; below and internally, in the male, it is continued over the penis and over the outer surface of the cord to the scrotum, where it helps to form the dartos. From the scrotum it may be traced backwards to be continuous with the deep layer of the superficial fascia of the perinæum. In the female it is continuous with the labia majora.

The scrotum is a cutaneous pouch, which contains the testes and part of the spermatic cords, and into which an inguinal hernia frequently descends (see page 1089).

The aponeurosis of the external oblique muscle.—This is a thin, but strong membranous aponeurosis, the fibres of which are directed obliquely downwards and inwards. That portion of the aponeurosis which extends between the anterior superior spine of the ilium and the spine of the os pubis is a broad band, folded inwards and continuous below with the fascia lata; it is called *Poupart's ligament.* The portion which is reflected from Poupart's ligament at the spine of the os pubis, along the pectineal line, is called *Gimbernat's ligament.* From the point of attachment of the latter to the pectineal line, a few fibres pass upwards and inwards, behind the inner pillar of the ring to the linea alba. They diverge as they ascend, and form a thin, triangular, fibrous band, which is called the *triangular ligament of the abdomen.* In the aponeurosis of the External oblique, immediately above the crest of the os pubis, is a triangular opening, the *external* or *superficial abdominal ring,* formed by the separation of the fibres of the aponeurosis in this situation.

The external or superficial abdominal ring.—Just above and to the outer side of the crest of the os pubis, an interval is seen in the aponeurosis of the External oblique, called the *external abdominal ring.* This aperture is oblique in direction, somewhat triangular in form, and corresponds with the course of the fibres of the aponeurosis. It usually measures from base to apex about an inch, and transversely about half an inch. It is bounded below by the crest of the os pubis; above by a series of curved fibres, the *intercolumnar,* which pass across the upper angle of the ring, so as to increase its strength; and on either side, by the margins of the opening in the aponeurosis, which are called the *columns* or *pillars of the ring.*

The *external pillar,* which, at the same time, is *inferior* from the obliquity of its direction, is the stronger; it is formed by that portion of Poupart's ligament which is inserted into the spine of the os pubis; it is curved, so as to form a kind of groove, upon which the spermatic cord rests.

The *internal* or *superior pillar* is a broad, thin, flat band, which is attached to the front of the body of the os pubis, interlacing with its fellow of the opposite side, in front of the symphysis pubis, that of the right side being superficial.

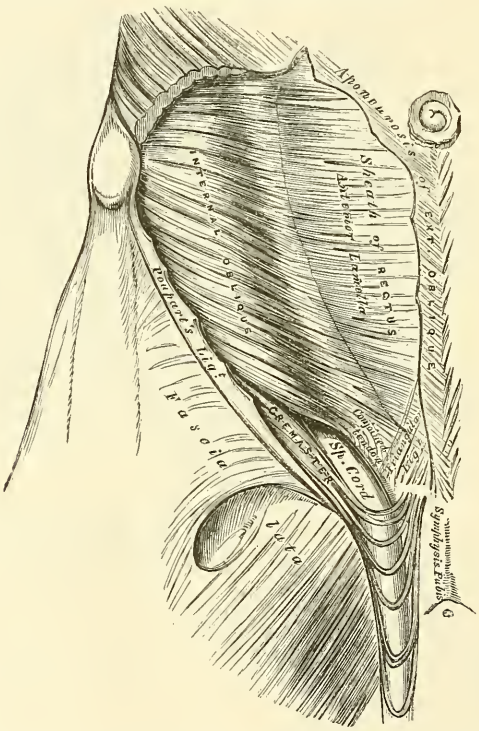
The external abdominal ring gives passage to the spermatic cord in the male, and round ligament in the female; it is much larger in men than in women, on account of the large size of the spermatic cord, and hence the great frequency of inguinal hernia in men.

The *intercolumnar fibres* are a series of curved tendinous fibres, which arch across the lower part of the aponeurosis of the External oblique. They have received their name from stretching across between the two pillars of the external ring; they increase the strength of the lower part of the aponeurosis, and prevent the divergence of the pillars from one another. They are thickest below, where they are connected to the outer third of Poupart's ligament; and are inserted into the linea alba, describing a curve, with the convexity downwards. They are much thicker and stronger at the outer angle of the external ring than internally, and are more strongly developed in the male than in the female. These intercolumnar fibres, as they pass across the external abdominal ring, are themselves connected together by delicate fibrous tissue, thus forming a fascia which, as it is attached to the pillars of the ring, covers it in, and is called the *intercolumnar fascia.* This intercolumnar fascia is continued downwards as a

tubular prolongation around the outer surface of the cord and testis, and encloses them in a distinct sheath; hence it is also called the *external spermatic fascia*. The sac of an inguinal hernia, in passing through the external abdominal ring, receives an investment from the intercolumnar fascia.

If the finger is introduced a short distance into the external ring, and then if the limb is extended and rotated outwards, the aponeurosis of the External oblique, together with the iliac portion of the fascia lata, will be felt to become tense, and the external ring much contracted; if the limb is, on the contrary, flexed upon the pelvis and rotated inwards, this aponeurosis will become lax, and the external ring sufficiently enlarged to admit the finger with comparative ease; hence the patient should always be put in the latter position when the taxis is applied for the reduction of an inguinal hernia, in order that the abdominal walls may be relaxed as much as possible.

Fig. 690.—Inguinal hernia, showing the Internal oblique, Cremaster, and spermatic canal.



The aponeurosis of the External oblique should be removed by dividing it across in the same direction as the external incisions, and reflecting it downwards and outwards; great care is requisite in separating it from the aponeurosis of the muscle beneath. The lower part of the Internal oblique and the Cremaster are then exposed, together with the inguinal canal, which contains the spermatic cord (fig. 690). The mode of insertion of Poupart's and Gimbernat's ligaments into the os pubis should also be examined.

Poupart's ligament, or the crural arch, is the lower border of the aponeurosis of the External oblique muscle, which extends from the anterior superior spine of the ilium to the spine of the os pubis. From this latter point it is reflected outwards to be attached to the pectineal line for about half an inch, forming Gimbernat's ligament. Its general direction is curved downwards towards the thigh, where it is continuous with the fascia lata. Its outer half is rounded and oblique in direction: its inner half gradually widens at its attachment to the os pubis, is more horizontal in direction, and lies beneath the spermatic cord.

Gimbernat's ligament (fig. 698) is that portion of the External oblique muscle

which is reflected downwards and outwards from the spine of the os pubis to be inserted into the pectineal line. It is about half an inch in length, larger in the male than in the female, almost horizontal in direction in the erect posture, and of a triangular form, with the base directed outwards. Its base or outer margin is concave, thin, and sharp, and lies in contact with the crural sheath, forming the inner boundary of the crural ring (see fig. 698). Its apex corresponds to the spine of the os pubis. Its posterior margin is attached to the pectineal line, and is continuous with the pubic portion of the fascia lata. Its anterior margin is continuous with Poupart's ligament.

The **triangular ligament of the abdomen** is a band of tendinous fibres, of a triangular shape, which is attached by its apex to the pectineal line, where it is continuous with Gimbernat's ligament. It passes inwards beneath the spermatic cord, and expands into a somewhat fan-shaped fascia, lying behind the inner pillar of the external abdominal ring, and in front of the conjoined tendon, and interlaces with the ligament of the other side at the linea alba.

The **Internal oblique muscle** has been previously described (page 451). The part which is now exposed is partly muscular and partly tendinous in structure. Those fibres which arise from Poupart's ligament, few in number, and paler in colour than the rest, arch downwards and inwards across the spermatic cord, and, becoming tendinous, are inserted conjointly with those of the Transversalis into the crest of the os pubis and pectineal line, forming what is known as the conjoined tendon of the Internal oblique and Transversalis. This tendon is inserted immediately behind the external abdominal ring, serving to protect what would otherwise be a weak point in the abdominal wall. Sometimes this tendon is insufficient to resist the pressure from within, and is carried forwards in front of the protrusion through the external ring, forming one of the coverings of direct inguinal hernia; or the hernia forces its way through the fibres of the conjoined tendon.

The **Cremaster** is a thin muscular layer, composed of a number of fasciculi which arise from the middle of Poupart's ligament at the inner side of the Internal oblique, being connected with that muscle, and also occasionally with the Transversalis. It passes along the outer side of the spermatic cord, descends with it through the external ring upon the front and sides of the cord, and forms a series of loops, which differ in thickness and length in different subjects. Those at the upper part of the cord are exceedingly short, but they become in succession longer and longer, the longest reaching down as low as the testicle, where a few are inserted into the tunica vaginalis. These loops are united together by areolar tissue, and form a thin covering over the cord and testis, the *fascia cremasterica*. The fibres ascend along the inner side of the cord, and are inserted by a small pointed tendon into the crest of the os pubis, and front of the sheath of the Rectus muscle.

It will be observed that the origin and insertion of the Cremaster is precisely similar to that of the lower fibres of the Internal oblique. This fact affords an easy explanation of the manner in which the testicle and cord are invested by this muscle. At an early period of fœtal life the testis is placed at the lower and back part of the abdominal cavity, but during its descent towards the scrotum, which takes place before birth, it passes beneath the arched border of the Internal oblique. In its passage beneath this muscle some fibres are derived from its lower part, which accompany the testicle and cord into the scrotum.

It occasionally happens that the loops of the Cremaster surround the cord, some lying behind as well as in front. It is probable that, under these circumstances, the testis, in its descent, passes through, instead of beneath, the fibres of the Internal oblique.

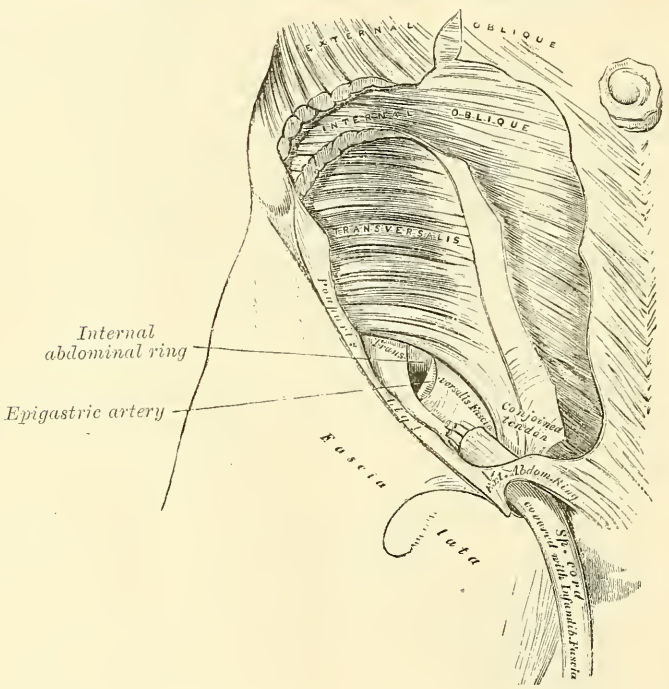
In the descent of an oblique inguinal hernia, which takes the same course as the spermatic cord, the Cremaster muscle forms one of its coverings. This muscle becomes largely developed in cases of hydrocele and large old scrotal herniæ. No such muscle exists in the female, but an analogous structure is

developed in those cases where an oblique inguinal hernia descends beneath the margin of the Internal oblique.

The Internal oblique should be detached from Poupart's ligament, separated from the Transversalis to the same extent as in the previous incisions, and reflected inwards on to the sheath of the Rectus (fig. 691). The circumflex iliac vessels, which lie between these two muscles, form a valuable guide to their separation.

The **Transversalis muscle** has been previously described (page 453). The part which is now exposed is partly muscular and partly tendinous in structure; this portion arises from the outer third of Poupart's ligament, its fibres curve downwards and inwards, and are inserted together with those of the Internal oblique into the lower part of the linea alba, into the crest of the os pubis and pectineal line, forming what is known as the conjoined tendon of the Internal oblique and

Fig. 691.—Inguinal hernia, showing the Transversalis muscle, the transversalis fascia, and the internal abdominal ring.



Transversalis. Between the lower border of this muscle and Poupart's ligament, a space is left in which is seen the fascia transversalis.

The **inguinal** or **spermatic canal** contains the spermatic cord in the male, and the round ligament in the female. It is an oblique canal, about an inch and a half in length, directed downwards and inwards, and placed parallel with, and a little above, Poupart's ligament. It commences, above, at the internal abdominal ring, which is the point where the cord enters the spermatic canal; and terminates, below, at the external ring. It is bounded, *in front*, by the integument and superficial fascia, by the aponeurosis of the External oblique throughout its whole length, and by the Internal oblique for its outer third; *behind*, by the triangular ligament, the conjoined tendon of the Internal oblique and Transversalis, transversalis fascia, and the subperitoneal fat and peritoneum; *above*, by the arched fibres of the Internal oblique and Transversalis; *below*, by the union of the fascia transversalis with Poupart's ligament. That form of protrusion in which the intestine follows the course of the spermatic cord along the spermatic canal is called *oblique inguinal hernia*.

The **fascia transversalis** is a thin aponeurotic membrane, which lies between the inner surface of the Transversalis muscle and the peritoneum. It forms part of the general layer of fascia which lines the interior of the abdominal and pelvic cavities, and is directly continuous with the iliac and pelvic fasciæ.

In the inguinal region, the transversalis fascia is thick and dense in structure, and joined by fibres from the aponeurosis of the Transversalis muscle; but it becomes thin and cellular as it ascends to the Diaphragm. Below, it has the following attachments: external to the femoral vessels it is connected to the posterior margin of Poupart's ligament, and is there continuous with the iliac fascia. Internal to the vessels it is thin, and attached to the os pubis and pectineal line behind the conjoined tendon, with which it is united; and, corresponding to the points where the femoral vessels pass into the thigh, this fascia descends in front of them, forming the anterior wall of the crural sheath. The spermatic cord in the male, and the round ligament in the female, pass through this fascia; the point where they pass through is called the internal or deep abdominal ring. This opening is not visible externally owing to a prolongation of the transversalis fascia on these structures, forming the infundibuliform fascia.

The **internal or deep abdominal ring** is situated in the transversalis fascia, midway between the anterior superior spine of the ilium and the symphysis pubis, and about half an inch above Poupart's ligament. It is of an oval form, the extremities of the oval directed upwards and downwards; it varies in size in different subjects, and is much larger in the male than in the female. It is bounded, above and externally, by the arched fibres of the Transversalis muscle, below and internally by the deep epigastric vessels. It transmits the spermatic cord in the male, and the round ligament in the female. From its circumference a thin, funnel-shaped membrane, the *infundibuliform fascia*, is continued round the cord and testis, enclosing them in a distinct pouch. When the sac of an oblique inguinal hernia passes through the internal or deep abdominal ring, the infundibuliform process of the transversalis fascia forms one of its coverings.

The subperitoneal areolar tissue.—Between the fascia transversalis and the peritoneum is a quantity of loose areolar tissue. In some subjects it is of considerable thickness, and loaded with adipose tissue. Opposite the internal ring it is continued round the surface of the cord, forming a loose sheath for it.

The *deep epigastric artery* arises from the external iliac artery a few lines above Poupart's ligament. It at first descends to reach this ligament, and then ascends obliquely along the inner margin of the internal or deep abdominal ring, lying between the transversalis fascia and the peritoneum, and passing upwards pierces the transversalis fascia and enters the sheath of the Rectus muscle just below the semilunar fold of Douglas. Consequently the deep epigastric artery bears a very important relation to the internal abdominal ring, as it passes obliquely upwards and inwards, from its origin from the external iliac. In this part of its course it lies along the lower and inner margin of the internal ring, and beneath the commencement of the spermatic cord. As it winds round the internal abdominal ring it is crossed by the vas deferens in the male, and by the round ligament in the female.

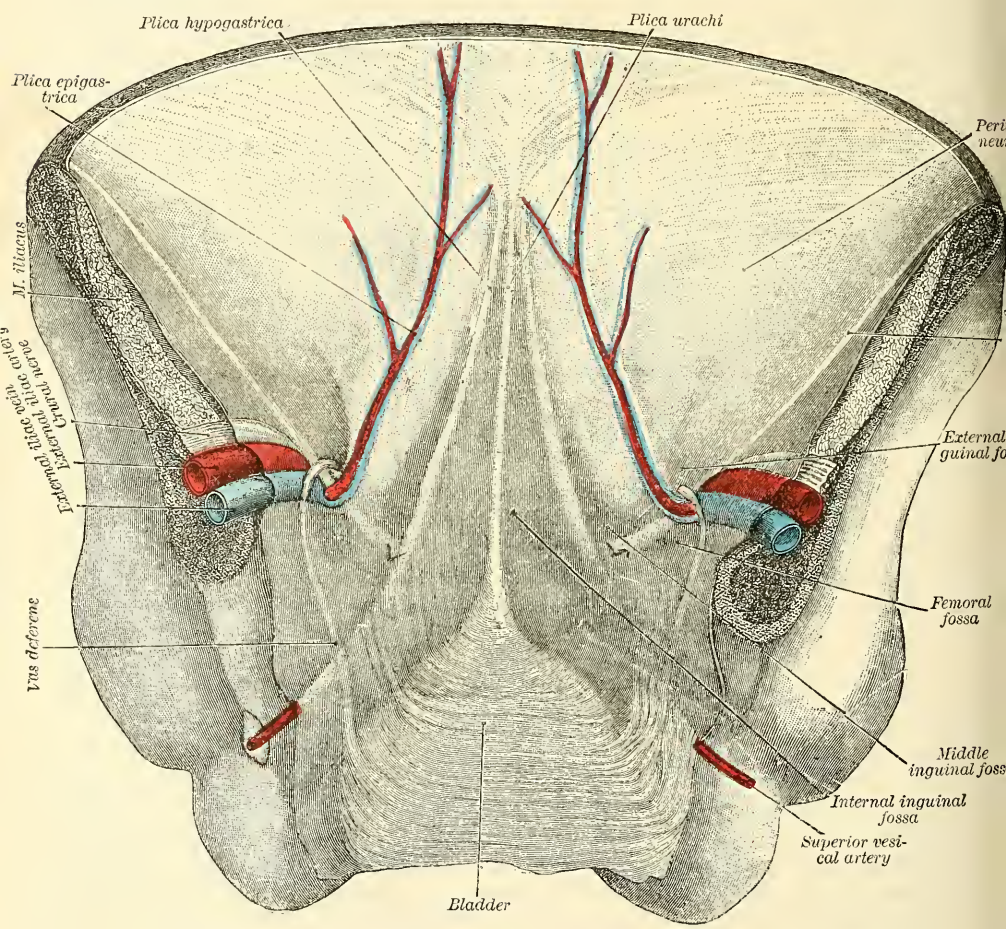
The **peritoneum**, corresponding to the inner surface of the internal ring, presents a well-marked depression, the depth of which varies in different subjects. A thin fibrous band is continued from it along the front of the cord for a variable distance, and becomes ultimately lost. This is the remains of the pouch of peritoneum which, in the fœtus, accompanies the cord and testis into the scrotum; the obliteration of which commences soon after birth. In some cases the fibrous band can only be traced a short distance; but occasionally it may be followed, as a fine cord, as far as the upper end of the tunica vaginalis. Sometimes the tube of peritoneum is only closed at intervals, and presents a sacculated appearance; or a single pouch may extend along the whole length of the cord,

which may be closed above; or the pouch may be directly continuous with the peritoneum by an opening at its upper part.

In the female (in the fœtus) the peritoneum is also prolonged in the form of a tubular process for a short distance into the inguinal canal. This process is called the canal of Nuck. It is generally obliterated in the adult, but sometimes it remains pervious even in advanced life. It is analogous to the peritoneal pouch which accompanies the descent of the testis.

In order to understand the relation of the peritoneum to inguinal hernia, it is necessary to view the anterior abdominal wall from its internal aspect, when it will be seen as shown in fig. 692. Between the upper margin of the front

FIG. 692.—Posterior view of the anterior abdominal wall in its lower half. The peritoneum is in place, and the various cords are shining through. (After Joessel.)



of the pelvis and the umbilicus, the peritoneum, when viewed from behind, will be seen to be raised into five vertical folds, with intervening depressions, by more or less prominent bands which converge to the umbilicus. One of these is situated in the median line, and is caused by the urachus, the remnant of the allantois; it extends from the summit of the bladder to the umbilicus. The fold of peritoneum covering it is known as the *plica urachi*. On either side of this is a prominent band, caused by the obliterated hypogastric artery, which extends from the side of the bladder obliquely upwards and inwards to the umbilicus. This is covered by a fold of peritoneum, which is known as the *plica hypogastrica*. To either side of these three cords is the deep epigastric

artery, which ascends obliquely upwards and inwards from a point midway between the symphysis pubis and the anterior superior spine of the ilium to the semilunar fold of Douglas, beneath which it disappears. It is covered by a fold of peritoneum, which is known as the *plica epigastrica*. Between these raised folds are depressions of the peritoneum, constituting so-called fossæ. The most internal, between the plica urachi and the plica hypogastrica, is known as the *internal inguinal fossa* (*fovea supravesicalis*). The middle one is situated between the plica hypogastrica and the plica epigastrica, and is termed the *middle inguinal fossa* (fovea inguinalis mesialis). The external one is external to the plica epigastrica, and is known as the *external inguinal fossa* (fovea inguinalis lateralis). Occasionally the deep epigastric artery corresponds in position to the obliterated hypogastric artery, and then there is but one fold, and the two external fossæ are merged into one. In the usual condition of the parts the floor of the external inguinal fossa corresponds to the internal abdominal ring, and into this fossa an oblique inguinal hernia descends. To the inner side of the plica epigastrica are the two internal fossæ, and through either of these a direct hernia may descend, as will be explained in the sequel (page 1126). The whole of this space, that is to say, the space between the deep epigastric artery, the margin of the Rectus and Poupart's ligament, is commonly known as *Hesselbach's triangle*. These three depressions or fossæ are situated above the level of Poupart's ligament, and in addition to them is another below the ligament, corresponding to the position of the femoral ring, and into which a femoral hernia descends.

Inguinal Hernia

Inguinal hernia is that form of protrusion which makes its way through the abdomen in the inguinal region.

There are two principal varieties of inguinal hernia—external or oblique, and internal or direct.

External or *oblique inguinal hernia*, the more frequent of the two, takes the same course as the spermatic cord. It is called *external*, from the neck of the sac being on the outer or iliac side of the deep epigastric artery.

Internal or *direct inguinal hernia* does not follow the same course as the cord, but protrudes through the abdominal wall on the inner or pubic side of the deep epigastric artery.

Oblique Inguinal Hernia

In **oblique inguinal hernia** the intestine escapes from the abdominal cavity at the internal ring, pushing before it a pouch of peritoneum, which forms the hernial sac (fig. 694, A). As it enters the inguinal canal it receives an investment from the subserous areolar tissue, and is enclosed in the infundibuliform process of the transversalis fascia. In passing along the inguinal canal it displaces upwards the arched fibres of the Transversalis and Internal oblique muscles, and is surrounded by the fibres of the Cremaster. It then passes along the front of the cord, and escapes from the inguinal canal at the external ring, receiving an investment from the intercolumnar fascia. Lastly, it descends into the scrotum, receiving coverings from the superficial fascia and the integument.

The coverings of this form of hernia, after it has passed through the external ring, are, from without inwards, the integument, superficial fascia, intercolumnar fascia, Cremaster muscle, infundibuliform fascia, subserous areolar tissue, and peritoneum.

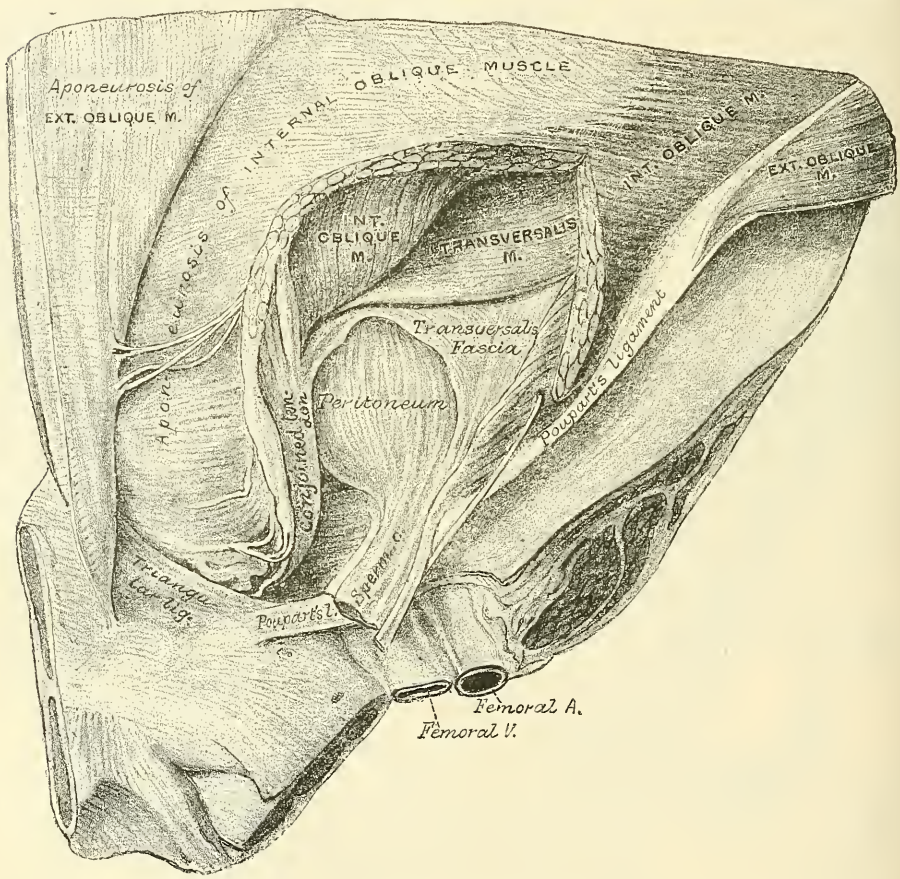
This form of hernia lies in front of the vessels of the spermatic cord, and seldom extends below the testis, on account of the intimate adhesion of the coverings of the cord to the tunica vaginalis.

The *seat of stricture* in oblique inguinal hernia is either at the external ring; in the inguinal canal, caused by the fibres of the Internal oblique or Transversalis;

or at the internal ring; most frequently in the latter situation. If it is situated at the external ring, the division of a few fibres at one point of its circumference is all that is necessary for the replacement of the hernia. If in the inguinal canal, or at the internal ring, it may be necessary to divide the aponeurosis of the External oblique so as to lay open the inguinal canal. In dividing the stricture, the direction of the incision should be upwards.

When the intestine passes along the spermatic canal, and escapes from the external ring into the scrotum, it is called *complete oblique inguinal*, or *scrotal hernia*. If the intestine does not escape from the external ring, but is retained in

Fig. 693.—Oblique inguinal hernia, showing its various coverings. (From a preparation in the Museum of the Royal College of Surgeons.)

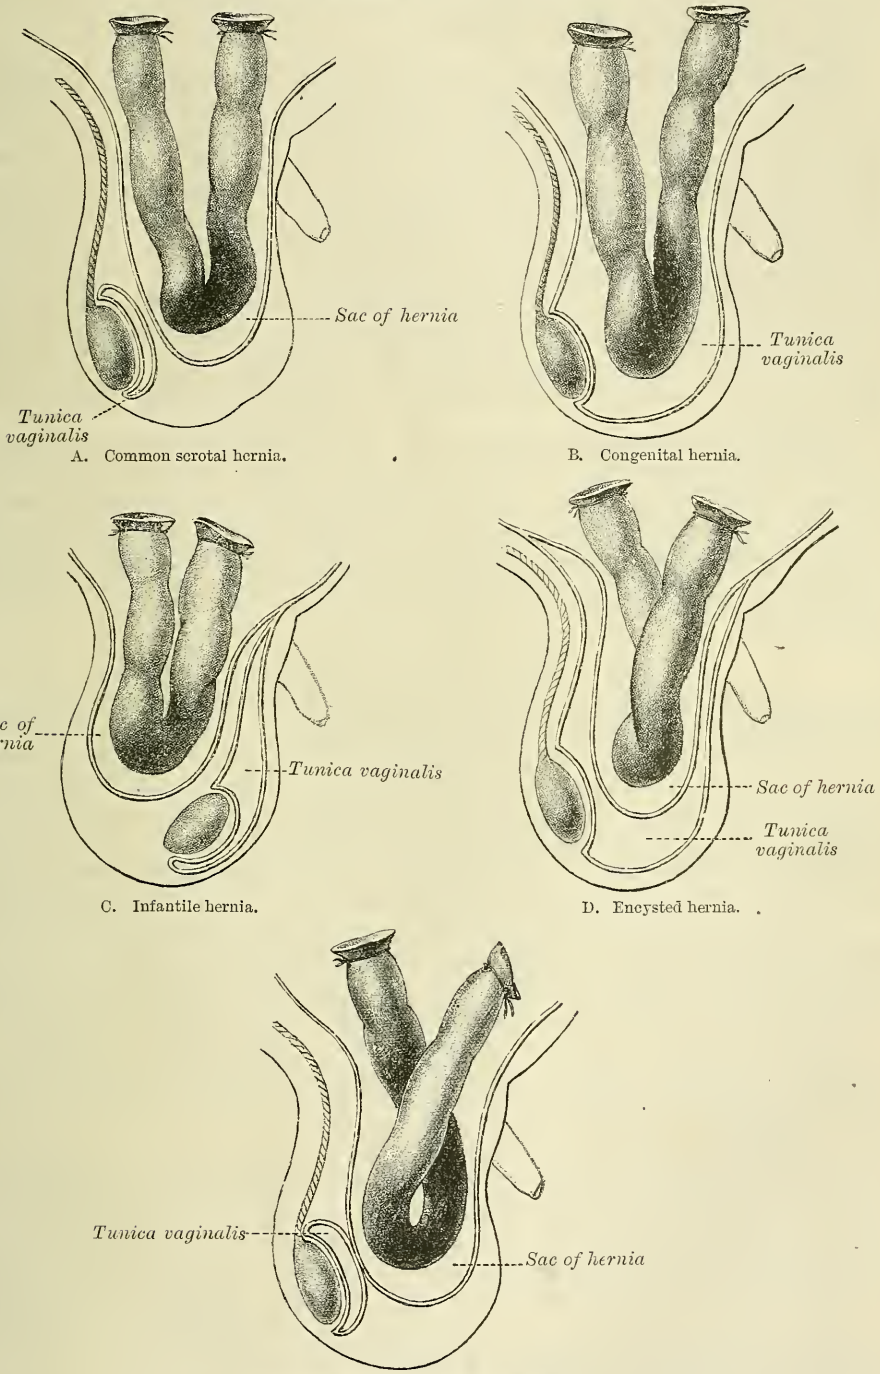


the inguinal canal, it is called *incomplete inguinal hernia*, or *bubonocele*. In each of these cases, the coverings which invest it will depend upon the extent to which it descends in the inguinal canal.

There are some other varieties of oblique inguinal hernia depending upon congenital defects in the processus vaginalis. The testicle in its descent from the abdomen into the scrotum is accompanied by a pouch of peritoneum, which about the period of birth becomes shut off from the general peritoneal cavity by a closure of that portion of the pouch which extends from the internal abdominal ring to near the upper part of the testicle; the lower portion of the pouch remaining persistent as the tunica vaginalis. It would appear that this closure commences at two points, viz. at the internal abdominal ring, and at the top of the epididymis, and gradually extends until, in the normal condition, the whole of the intervening portion is converted into a fibrous cord. From failure in the

completion of this process, variations in the relation of the hernial protrusion to the testicle and tunica vaginalis are produced, which constitute distinct varieties

FIG. 694.—Varieties of oblique inguinal hernia.



A. Common scrotal hernia. B. Congenital hernia.

C. Infantile hernia. D. Encysted hernia.

E. Hernia into the funicular process.

of inguinal hernia, and which have received separate names, and are of surgical importance. These are congenital, infantile, encysted, and hernia of the funicular process.

Congenital hernia (fig. 694, B).—Where the pouch of peritoneum which accompanies the cord and testis in its descent remains patent throughout, and is unclosed at any point, the cavity of the tunica vaginalis communicates directly with the peritoneum. The intestine descends along this pouch into the cavity of the tunica vaginalis, which constitutes the sac of the hernia, and the gut lies in contact with the testicle.

Infantile and encysted hernia.—Where the pouch of peritoneum is occluded at the internal ring only, and remains patent throughout the rest of its extent, two varieties of oblique inguinal hernia may be produced, which have received the names of infantile and encysted hernia. In the *infantile* form (fig. 694, C) the bowel pressing upon the septum and the peritoneum in its immediate neighbourhood causes it to yield and form a sac, which descends behind the tunica vaginalis; so that, in front of the bowel, there are three layers of peritoneum, the two layers of the tunica vaginalis and its own sac. In the *encysted* form (fig. 694, D) pressure in the same position—namely, at the occluded spot in the pouch—causes the septum to yield and form a sac which projects *into* and not *behind* the tunica vaginalis, as in the infantile form, and thus it constitutes a sac within a sac, so that in front of the bowel there are two layers of peritoneum, one layer of the tunica vaginalis and its own sac.

Hernia into the funicular process (fig. 694, E).—Where the pouch of peritoneum is occluded at the lower point only, that is, just above the testicle, the intestine descends into the pouch of peritoneum as far as the testicle, but is prevented from entering the sac of the tunica vaginalis by the septum which has formed between it and the pouch, so that it resembles the congenital form in all respects, except that, instead of enveloping the testicle, that body can be felt below the rupture.

Direct Inguinal Hernia

In **direct inguinal hernia** the protrusion makes its way through some part of the abdominal wall internal to the epigastric artery.

At the lower part of the abdominal wall is a triangular space (*Hesselbach's triangle*), bounded, externally, by the deep epigastric artery; internally, by the margin of the Rectus muscle; below, by Poupart's ligament. The conjoined tendon is stretched across the inner two-thirds of this space, the remaining portion of the space having only the subperitoneal areolar tissue, and the transversalis fascia between the peritoneum and the aponeurosis of the External oblique muscle.

In some cases the hernial protrusion escapes from the abdomen on the outer side of the conjoined tendon, pushing before it the peritoneum, the subserous areolar tissue, and the transversalis fascia. It then enters the inguinal canal, passing along nearly its whole length, and finally emerges from the external ring, receiving an investment from the intercolumnar fascia. The coverings of this form of hernia are precisely similar to those investing the oblique form, with the insignificant difference that the infundibuliform fascia is replaced by a portion derived from the general layer of the fascia transversalis.

In other cases, and this is the more frequent variety, the hernia is either forced through the fibres of the conjoined tendon, or the tendon is gradually distended in front of it, so as to form a complete investment for it. The intestine then enters the lower end of the inguinal canal, escapes at the external ring, lying on the inner side of the cord, and receives additional coverings from the superficial fascia and the integument. This form of hernia has the same coverings as the oblique variety, excepting that the conjoined tendon is substituted for the Cremaster, and the infundibuliform fascia is replaced by a portion derived from the general layer of the fascia transversalis.

The difference between the position of the neck of the sac in these two forms of direct inguinal hernia has been referred, with some probability, to a difference in the relative positions of the obliterated hypogastric artery and the deep epigastric artery. When the course of the obliterated hypogastric artery corre-

sponds pretty nearly with that of the deep epigastric, the projection of these arteries towards the cavity of the abdomen produces two fossæ in the peritoneum. The bottom of the external fossa of the peritoneum corresponds to the position of the internal abdominal ring, and a hernia which distends and pushes out the peritoneum lining this fossa is an oblique hernia. When, on the other hand, the obliterated hypogastric artery lies considerably to the inner side of the deep epigastric artery, corresponding to the outer margin of the conjoined tendon, it divides the triangle of Hesselbach into two parts, so that three depressions will be seen on the inner surface of the lower part of the abdominal wall: viz. an external one, on the outer side of the deep epigastric artery; a middle one, between the deep epigastric and the obliterated hypogastric arteries; and an internal one, on the inner side of the obliterated hypogastric artery (see page 1122). In such a case a hernia may distend and push out the peritoneum forming the bottom of either fossa. When the hernia distends and pushes out the peritoneum forming the bottom of the external fossa, it is an oblique or external inguinal hernia. When the hernia distends and pushes out the peritoneum forming the bottom of either the middle or the internal fossa, it is a direct or internal hernia. The anatomical difference between these two forms of direct or internal inguinal hernia is that, when the hernia protrudes through the middle fossa—that is, the fossa between the deep epigastric and the obliterated hypogastric arteries—it will enter the upper part of the inguinal canal; consequently its coverings will be the same as those of an oblique hernia, with the insignificant difference that the infundibuliform fascia is replaced by a portion derived from the general layer of the fascia transversalis, whereas when the hernia protrudes through the internal fossa it is either forced through the fibres of the conjoined tendon, or the tendon is gradually distended in front of it, so as to form a complete investment for it. The intestine then enters the lower part of the inguinal canal, and escapes from the external abdominal ring lying on the inner side of the cord.

This form of hernia has the same coverings as the oblique variety, excepting that the conjoined tendon is substituted for the Cremaster, and the infundibuliform fascia is replaced by a portion derived from the general layer of the fascia transversalis.

The *seat of stricture* in both varieties of direct hernia is most frequently at the neck of the sac, or at the external ring. In that form of hernia which perforates the conjoined tendon, it not unfrequently occurs at the edges of the fissure through which the gut passes. In dividing the stricture, the incision should in all cases be directed upwards.*

If the hernial protrusion passes into the inguinal canal, but does not escape from the external abdominal ring, it forms what is called *incomplete direct hernia.* This form of hernia is usually of small size, and in corpulent persons very difficult of detection.

Direct inguinal hernia is of much less frequent occurrence than the oblique, their comparative frequency being, according to Cloquet, as one to five. It occurs far more frequently in men than in women, on account of the larger size of the external ring in the former sex. It differs from the oblique in its smaller size and globular form, dependent most probably on the resistance offered to its progress by the transversalis fascia and conjoined tendon. It differs also in its position, being placed over the os pubis, and not in the course of the inguinal canal. The deep epigastric artery runs on the outer or iliac side of the neck of the sac, and the spermatic cord along its external and posterior side, not directly behind it, as in oblique inguinal hernia.

* In all cases of inguinal hernia, whether oblique or direct, it is proper to divide the stricture directly upwards; the reason of this is obvious, for by cutting in this direction the incision is made parallel to the deep epigastric artery—either external to it, in the oblique variety; or internal to it, in the direct form of hernia; and thus all chance of wounding the vessel is avoided. If the incision was made outwards, the artery might be divided if the hernia was direct; and if made inwards it would stand an equal chance of injury if the case was one of oblique inguinal hernia.

SURGICAL ANATOMY OF FEMORAL HERNIA

The dissection of the parts comprised in the anatomy of femoral hernia should be performed, if possible, upon a female subject free from fat. The subject should lie upon its back; a block is first placed under the pelvis, the thigh everted, and the knee slightly bent, and retained in this position. An incision should then be made from the anterior superior spinous process of the ilium along Poupart's ligament to the symphysis pubis; a second incision should be carried transversely across the thigh about six inches beneath the preceding; and these are to be connected together by a vertical one carried along the inner side of the thigh. These several incisions should divide merely the integument; this is to be reflected outwards, when the superficial fascia will be exposed.

The **superficial fascia** forms a continuous layer over the whole of the thigh, consisting of areolar tissue, containing in its meshes much fat, and capable of being separated into two or more layers, between which are found the superficial vessels and nerves. It varies in thickness in different parts of the limb. In the groin it is thick, and the two layers are separated from one another by the superficial inguinal lymphatic glands, the internal saphenous vein, and several smaller vessels. One of these layers, the superficial, is continuous with the superficial fascia of the abdomen.

The superficial layer should be detached by dividing it across in the same direction as the external incisions; its removal will be facilitated by commencing at the lower and inner angle of the space, detaching it at first from the front of the internal saphenous vein, and dissecting it off from the anterior surface of that vessel and its tributaries; it should then be reflected outwards, in the same manner as the integument. The cutaneous vessels and nerves, and superficial inguinal glands, are then exposed, lying upon the deep layer of the superficial fascia. These are the internal saphenous vein, and the superficial epigastric, superficial circumflex iliac, and superficial external pudic vessels, as well as numerous lymphatics ascending with the saphenous vein to the inguinal glands.

The *internal* or *long saphenous vein* ascends along the inner side of the thigh, and, passing through the saphenous opening in the fascia lata, terminates in the femoral vein about an inch and a half below Poupart's ligament. This vein receives, at the saphenous opening, the superficial epigastric, the superficial circumflex iliac, and the superficial external pudic veins.

The *superficial external pudic artery* (superior) arises from the inner side of the femoral artery, and, after passing through the saphenous opening, courses inwards, across the spermatic cord, to be distributed to the integument on the lower part of the abdomen, the penis and scrotum in the male, and the labium in the female, anastomosing with branches of the internal pudic.

The *superficial epigastric artery* arises from the femoral, about half an inch below Poupart's ligament, and, passing through the saphenous opening in the fascia lata, ascends on to the abdomen, in the superficial fascia covering the External oblique muscle, nearly as high as the umbilicus. It distributes branches to the superficial inguinal lymphatic glands, the superficial fascia, and the integument, anastomosing with branches of the deep epigastric and internal mammary arteries.

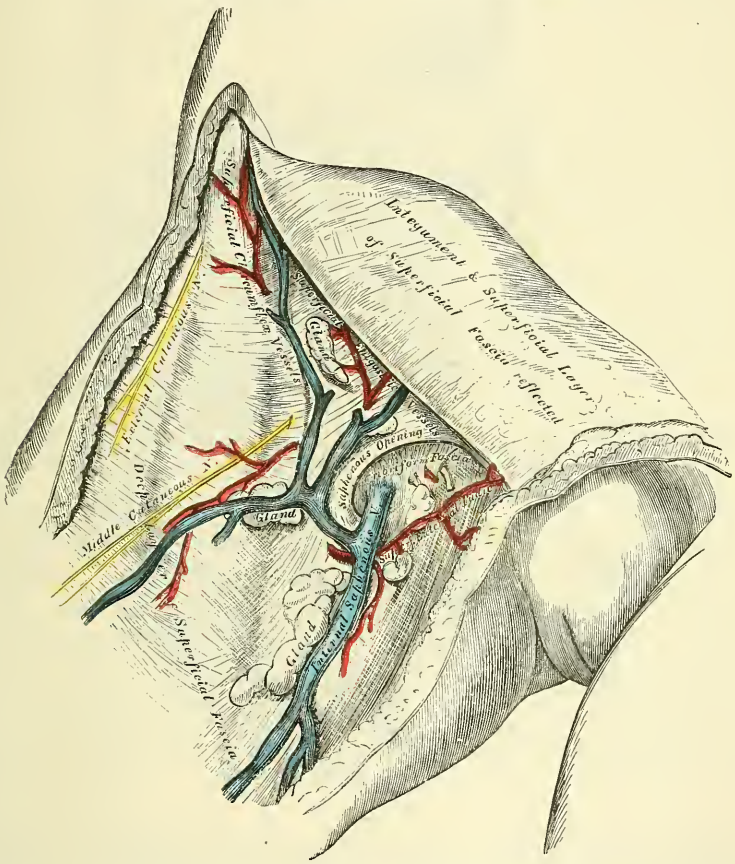
The *superficial circumflex iliac artery*, the smallest of the cutaneous branches, arises close to the preceding, and, piercing the fascia lata, runs outwards, parallel with Poupart's ligament, as far as the crest of the ilium, dividing into branches which supply the superficial inguinal lymphatic glands, the superficial fascia and

the integument of the groin, anastomosing with the deep circumflex iliac, and with the gluteal and external circumflex arteries.

The superficial veins.—The veins accompanying these superficial arteries are usually much larger than the arteries: they terminate in the internal or long saphenous vein at the saphenous opening.

The *superficial inguinal lymphatic glands,* placed immediately beneath the integument, are of large size, and vary from eight to ten in number. They are divisible into two groups: an upper, disposed irregularly along Poupart's ligament, which receive the lymphatic vessels from the integument of the scrotum, penis, parietes of the abdomen, perineal and gluteal regions, and the mucous membrane of the urethra; and an inferior group, which surround the saphenous opening in

Fig. 695.—Femoral hernia. Superficial dissection.



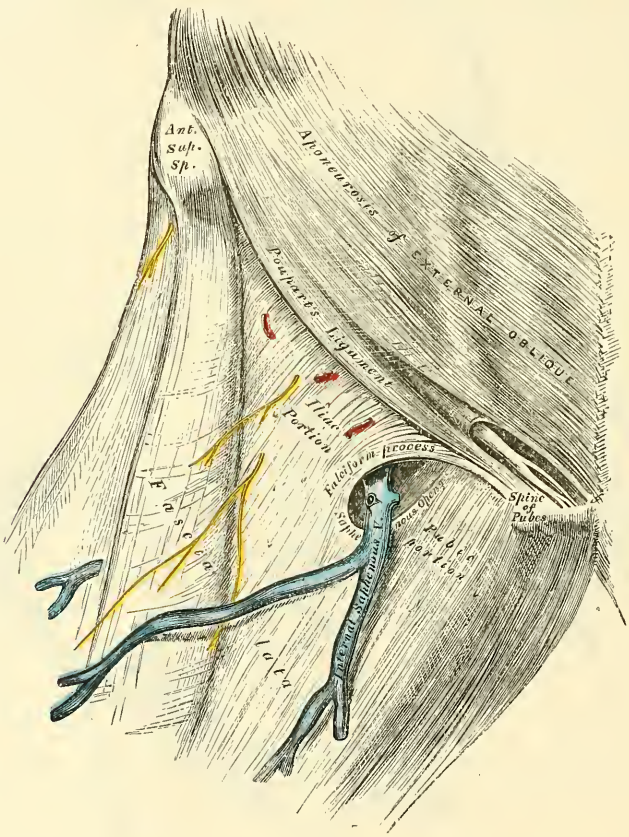
the fascia lata, a few being sometimes continued along the saphenous vein to a variable extent. This latter group receive the superficial lymphatic vessels from the lower extremity.

The *ilio-inguinal nerve* arises from the first lumbar nerve. It escapes at the external abdominal ring, and is distributed to the integument of the upper and inner part of the thigh: to the scrotum in the male, and to the labium in the female. The size of this nerve is in inverse proportion to that of the ilio-hypogastric. Occasionally it is very small, and ends by joining the ilio-hypogastric: in such cases a branch of the ilio-hypogastric takes the place of the ilio-inguinal, or the latter nerve may be altogether absent. The *crural branch of the genito-crural nerve* passes along the inner margin of the Psoas muscle, beneath Poupart's ligament, into the thigh, entering the sheath of the femoral vessels, and lying superficial and a little external to the femoral artery. It pierces the anterior

layer of the sheath of the vessels, and, becoming superficial by passing through the fascia lata, it supplies the skin of the anterior aspect of the thigh as far as midway between the pelvis and knee. On the front of the thigh it communicates with the outer branch of the middle cutaneous nerve, derived from the anterior crural.

The *deep layer of the superficial fascia* is a very thin fibrous layer, best marked on the inner side of the long saphenous vein and below Poupart's ligament. It is placed beneath the subcutaneous vessels and nerves, and upon the surface of the fascia lata, to which it is intimately adherent at the lower margin of Poupart's ligament. It covers the saphenous opening in the fascia lata, is closely united to its circumference, and is connected to the sheath of the femoral vessels corre-

Fig. 696.—Femoral hernia, showing fascia lata and saphenous opening.



sponding to its under surface. The portion of fascia covering this aperture is perforated by the internal saphenous vein, and by numerous blood and lymphatic vessels; hence it has been termed the *cribriform fascia*, the openings for these vessels having been likened to the holes in a sieve. The cribriform fascia adheres closely both to the superficial fascia and to the fascia lata, so that it is described by some anatomists as a part of the fascia lata, but it is usually considered (as in this work) as belonging to the superficial fascia. It is not till the cribriform fascia has been cleared away that the saphenous opening is seen, so that this opening does not in ordinary cases exist naturally, but is the result of dissection. A femoral hernia, in passing through the saphenous opening, receives the cribriform fascia as one of its coverings.

The deep layer of superficial fascia, together with the cribriform fascia, having been removed, the fascia lata is exposed.

The **fascia lata** has been already described with the muscles of the front of the thigh (page 510). At the upper and inner part of the thigh, a little below

Poupart's ligament, a large oval-shaped aperture is observed after the superficial fascia has been cleared away; it transmits the internal saphenous vein and other smaller vessels, and is called the *saphenous opening*. In order the more correctly to consider the mode of formation of this aperture, the fascia lata in this part of the thigh is described as consisting of two portions, an iliac portion and a pubic portion.

The *iliac portion* is all that part of the fascia lata on the outer side of the saphenous opening. It is attached externally to the crest of the ilium and its anterior superior spine; to the whole length of Poupart's ligament as far internally as the spine of the os pubis; and to the pectineal line in conjunction with Gimbernat's ligament. From the spine of the os pubis it is reflected downwards and outwards, forming an arched margin, the outer boundary, or falciform process or superior cornu of the saphenous opening. This margin overlies and is adherent to the anterior layer of the sheath of the femoral vessels; to its edge is attached the cribriform fascia, and, below, it is continuous with the pubic portion of the fascia lata.

The *pubic portion of the fascia lata* is situated at the inner side of the saphenous opening; at the lower margin of this aperture it is continuous with the iliac portion; traced upwards, it covers the surface of the Pectineus, Adductor longus, and Gracilis muscles; and, passing behind the sheath of the femoral vessels, to which it is closely united, is continuous with the sheath of the Psoas and Iliacus muscles, and is attached above to the ilio-pectineal line, where it becomes continuous with the fascia covering the Iliacus muscle. From this description it may be observed that the iliac portion of the fascia lata passes in front of the femoral vessels and the pubic portion behind them, so that an apparent aperture consequently exists between the two, through which the internal saphenous joins the femoral vein.

The **saphenous opening** is an oval-shaped aperture, measuring about an inch and a half in length, and half an inch in width. It is situated at the upper and inner part of the front of the thigh, below Poupart's ligament, and is directed obliquely downwards and outwards.

Its *outer margin* is of a semilunar form, thin, strong, sharply defined, and lies on a plane considerably anterior to the inner margin. If this edge is traced upwards, it will be seen to form a curved elongated process, the *falciform process*, or *superior cornu*, which ascends in front of the femoral vessels, and, curving inwards, is attached to Poupart's ligament and to the spine of the os pubis and pectineal line, where it is continuous with the pubic portion. If traced downwards, it is found continuous with another curved margin, the concavity of which is directed upwards and inwards: this is the inferior cornu of the saphenous opening, and is blended with the pubic portion of the fascia lata covering the Pectineus muscle.

The *inner boundary of the opening* is on a plane posterior to the outer margin and behind the level of the femoral vessels; it is much less prominent and defined than the outer, from being stretched over the subjacent Pectineus muscle. It is through the saphenous opening that a femoral hernia passes after descending along the crural canal.

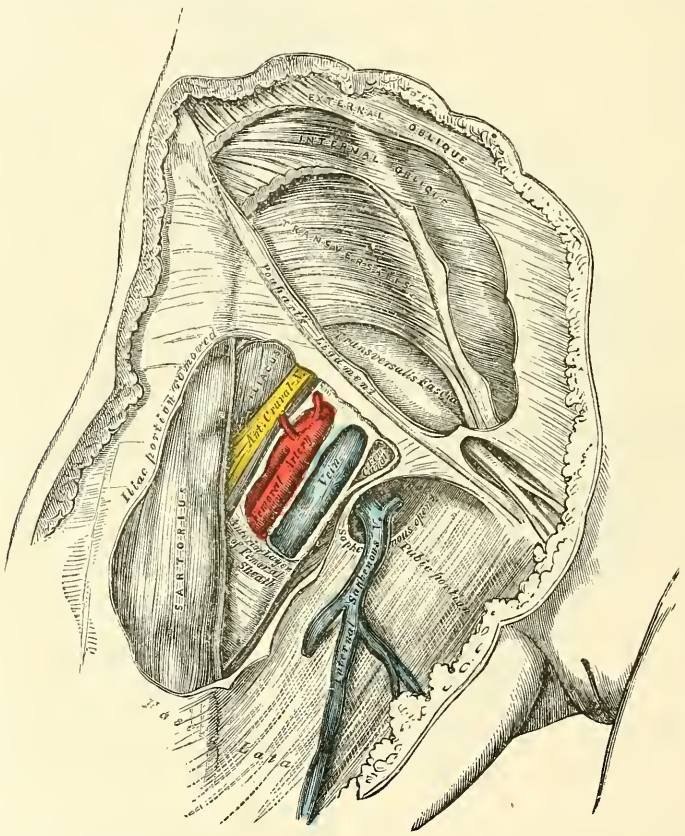
If the finger is introduced into the saphenous opening while the limb is moved in different directions, the aperture will be found to be greatly constricted on extending the limb or rotating it outwards, and to be relaxed on flexing the limb and inverting it: hence the necessity for placing the limb in the latter position in employing the taxis for the reduction of a femoral hernia.

The iliac portion of the fascia lata, but not its falciform process, should now be removed by detaching it from the lower margin of Poupart's ligament, carefully dissecting it from the subjacent structures, and turning it inwards, when the sheath of the femoral vessel is exposed descending beneath Poupart's ligament (fig. 697).

Poupart's ligament, or the **crural arch**, is the lower border of the aponeurosis of the External oblique muscle, which extends from the anterior superior spine

of the ilium to the spine of the os pubis. From this latter point it is reflected outwards, to be attached to the pectineal line for about half an inch, forming Gimbernat's ligament. Its general direction is curved downwards towards the thigh, where it is continuous with the fascia lata. Its outer half is rounded and oblique in direction. Its inner half gradually widens at its attachment to the os pubis, is more horizontal in direction, and lies beneath the spermatic cord. Nearly the whole of the space included between the crural arch and innominate bone is filled in by the parts which descend from the abdomen into the thigh (fig. 698). The outer half of the space is occupied by the Iliacus and Psoas muscles, together with the external cutaneous and anterior crural nerves. The pubic half

Fig. 697.—Femoral hernia. Iliac portion of fascia lata removed, and sheath of femoral vessels and femoral canal exposed.

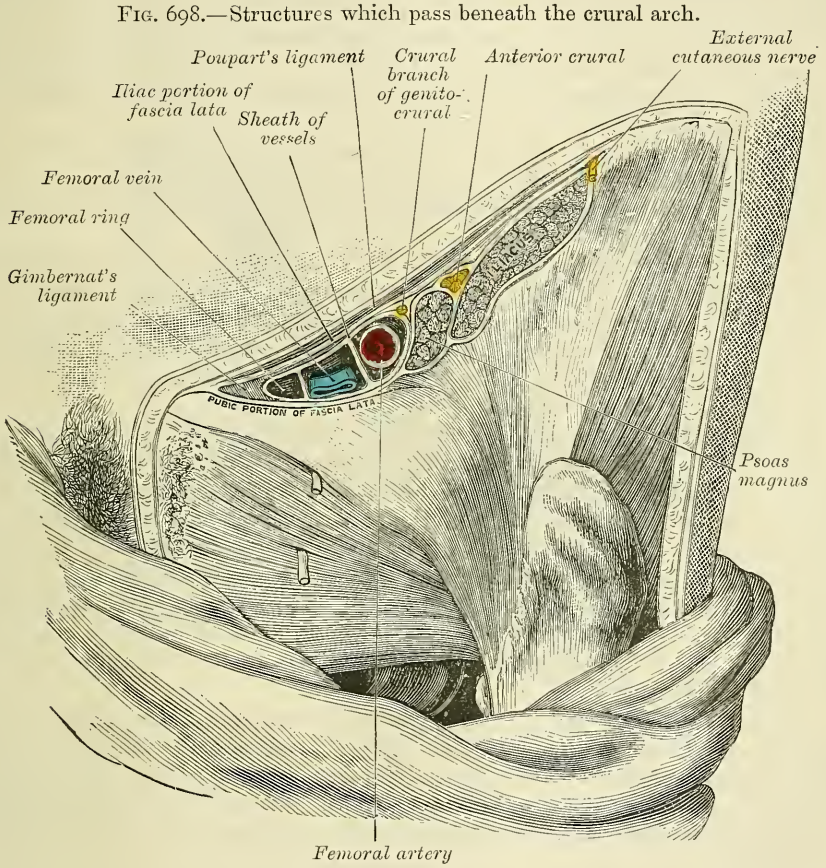


of the space is occupied by the femoral vessels included in their sheath; a small oval-shaped interval existing between the femoral vein and the inner wall of the sheath, which is occupied merely by a little loose areolar tissue, a few lymphatic vessels, and occasionally by a small lymphatic gland: this is the crural ring, through which the gut descends in femoral hernia.

Gimbernat's ligament (figs. 698, 699) is that part of the aponeurosis of the External oblique muscle which is reflected downwards and outwards, from the spine of the os pubis, to be inserted into the pectineal line. It is about half an inch in length, larger in the male than in the female, almost horizontal in direction in the erect posture, and of a triangular form, with the base directed outwards. Its *base*, or outer margin, is concave, thin, and sharp, and lies in contact with the crural sheath. Its *apex* corresponds to the spine of the os pubis. Its *posterior margin* is attached to the pectineal line, and is continuous with the pubic portion of the fascia lata. Its *anterior margin* is continuous with Poupart's ligament.

Crural sheath.—The femoral or crural sheath is a continuation downwards of the fasciæ that line the abdomen, the transversalis fascia passing down in front of the femoral vessels, and the iliac fascia descending behind them; these fasciæ are directly continuous on the iliac side of the femoral artery, but a small space exists between the femoral vein and the point where they are continuous on the pubic side of that vessel, which constitutes the femoral or crural canal. The femoral sheath is closely adherent to the contained vessels about an inch below the saphenous opening, being blended with the areolar sheath of the vessels, but opposite Poupart's ligament it is much larger than is required to contain them; hence the funnel-shaped form which it presents. The outer

Fig. 698.—Structures which pass beneath the crural arch.



border of the sheath is perforated by the genito-crural nerve. Its inner border is pierced by the internal saphenous vein and numerous lymphatic vessels. In front, it is covered by the iliac portion of the fascia lata; and behind it is the pubic portion of the same fascia.

If the anterior wall of the sheath is removed, the femoral artery and vein are seen lying side by side, a thin septum separating the two vessels, while another septum may be seen lying just internal to the vein, and cutting off a small space between the vein and the inner wall of the sheath. The septa are stretched between the anterior and posterior walls of the sheath, so that each vessel is enclosed in a separate compartment. The interval left between the vein and the inner wall of the sheath is not filled up by any structure, excepting a little loose areolar tissue, a few lymphatic vessels, and occasionally by a small lymphatic gland; this is the femoral or crural canal, through which the intestine descends in femoral hernia.

Deep crural arch.—Passing across the front of the crural sheath on the abdominal side of Poupart's ligament, and closely connected with it, is a thickened band of fibres, called the *deep crural arch*. It is apparently a thickening of the fascia transversalis, joining externally to the centre of Poupart's ligament, and arching across the front of the crural sheath, to be inserted by a broad attachment into the pectineal line, behind the conjoined tendon. In some subjects this structure is not very prominently marked, and not unfrequently it is altogether wanting.

The **crural canal** is the narrow interval between the femoral vein and the inner wall of the crural sheath. It exists as a distinct canal only when the sheath has been separated from the vein by dissection, or by the pressure of a hernia or tumour. Its length is from a quarter to half an inch, and it extends from Gimbernat's ligament to the upper part of the saphenous opening.

Its *anterior wall* is very narrow, and formed by a continuation downwards of the fascia transversalis, under Poupart's ligament, covered by the falciform process of the fascia lata.

Its *posterior wall* is formed by a continuation downwards of the iliac fascia covering the pubic portion of the fascia lata.

Its *outer wall* is formed by the fibrous septum separating it from the inner side of the femoral vein.

Its *inner wall* is formed by the junction of the processes of the transversalis and iliac fasciæ, which form the inner side of the femoral sheath, and lies in contact, at its commencement, with the outer edge of Gimbernat's ligament.

This canal has two orifices—an upper one, the *femoral* or *crural ring*, closed by the septum crurale; and a lower one, the *saphenous opening*, closed by the cribriform fascia.

The **femoral** or **crural ring** (fig. 699) is the upper opening of the femoral canal, and leads into the cavity of the abdomen. It is bounded, in front, by Poupart's ligament and the deep crural arch; behind, by the os pubis, covered by the Pectineus muscle, and the pubic portion of the fascia lata; internally, by the base of Gimbernat's ligament, the conjoined tendon, the transversalis fascia, and the deep crural arch; externally, by the fibrous septum lying on the inner side of the femoral vein. The femoral ring is of an oval form; its long diameter, directed transversely, measures about half an inch, and is larger in the female than in the male, which is one of the reasons of the greater frequency of femoral hernia in the former sex.

Position of parts around the ring.—The spermatic cord in the male, and round ligament in the female, lie immediately above the anterior margin of the femoral ring, and may be divided in an operation for femoral hernia if the incision for the relief of the stricture is not of limited extent. In the female this is of little importance, but in the male the spermatic artery and vas deferens may be divided.

The *femoral vein* lies on the outer side of the ring.

The *deep epigastric artery*, in its passage upwards and inwards from the external iliac artery, passes across the upper and outer angle of the crural ring, and is consequently in danger of being wounded if the stricture is divided in a direction upwards and outwards.

The *communicating branch* between the deep epigastric and obturator lies in front of the ring.

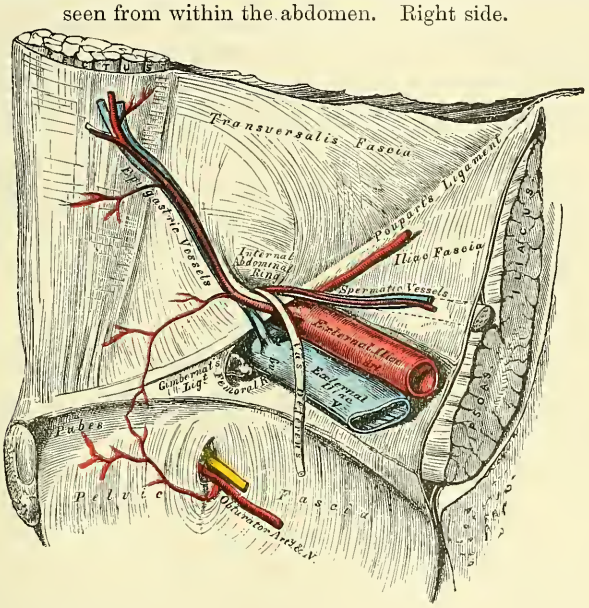
The circumference of the ring is thus seen to be bounded by vessels in every part, excepting internally and behind. It is in the former position that the stricture is divided in cases of strangulated femoral hernia.

The *obturator artery*, when it arises by a common trunk with the deep epigastric, which occurs once in every three subjects and a half, bears a very important relation to the crural ring. In some cases it descends on the inner side of the external iliac vein to the obturator foramen, and will consequently lie on the outer side of the crural ring, where there is no danger of its being wounded in the operation for dividing the stricture in femoral hernia (see fig. 414, page

636, fig. A). Occasionally, however, the obturator artery curves along the free margin of Gimbernat's ligament in its passage to the obturator foramen; it would, consequently, skirt along the greater part of the circumference of the crural ring, and could hardly avoid being wounded in the operation (see fig. 414, page 636, fig. B).

Septum crurale.—The femoral ring is closed by a layer of condensed areolar tissue, called, by J. Cloquet, the *septum crurale*. This serves as a barrier to the protrusion of a hernia through this part. Its upper surface is slightly concave, and supports a small lymphatic gland, by which it is separated from the subserous areolar tissue and peritoneum. Its under surface is turned towards the femoral canal. The septum crurale is perforated by numerous apertures for the passage of lymphatic vessels, connecting the deep inguinal lymphatic glands with those surrounding the external iliac artery.

Fig. 699.—Hernia. The relations of the femoral and internal abdominal rings seen from within the abdomen. Right side.



The size of the femoral canal, the degree of tension of its orifices, and, consequently, the degree of constriction of a hernia, vary according to the position of the limb. If the leg and thigh are extended, abducted, or everted, the femoral canal and its orifices are rendered tense, from the traction on these parts by Poupart's ligament and the fascia lata, as may be ascertained by passing the finger along the canal. If, on the contrary, the thigh is flexed upon the pelvis, and at the same time adducted and rotated inwards, the femoral canal and its orifices become considerably relaxed; for this reason the limb should always be placed in the latter position when the application of the taxis is made in attempting the reduction of a femoral hernia.

The *subperitoneal areolar tissue* is continuous with the subserous areolar tissue of surrounding parts. It is usually thickest and most fibrous where the iliac vessels leave the abdominal cavity. It covers over the small interval (crural ring) on the inner side of the femoral vein. In some subjects it contains a considerable amount of adipose tissue. In such cases, where it is protruded forwards in front of the sac of a femoral hernia, it may be mistaken for a portion of omentum. The peritoneum lining the portion of the abdominal wall between Poupart's ligament and the brim of the pelvis is similar to that lining any other portion of the abdominal wall, being very thin. It has here no natural aperture for the escape of intestine.

Descent of the hernia.—From the preceding description it follows that the femoral ring must be a weak point in the abdominal wall: hence it is that, when violent or long-continued pressure is made upon the abdominal viscera, a portion of intestine may be forced into it, constituting a femoral hernia; and the changes in the tissues of the abdomen which are produced by pregnancy, together with the larger size of this aperture in the female, serve to explain the frequency of this form of hernia in women.

When a portion of the intestine is forced through the femoral ring, it carries before it a pouch of peritoneum, which forms what is called the *hernial sac*; it receives an investment from the subserous areolar tissue, and from the septum crurale, and descends vertically along the crural canal in the inner compartment of the sheath of the femoral vessels as far as the saphenous opening; at this point it changes its course, being prevented from extending farther down the sheath, on account of the narrowing of the sheath and its close contact with the vessels, and also from the close attachment of the superficial fascia and crural sheath to the lower part of the circumference of the saphenous opening; the tumour is, consequently, directed forwards, pushing before it the cribriform fascia, and then curves upwards on to the falciform process of the fascia lata and lower part of the tendon of the External oblique, being covered by the superficial fascia and integument. While the hernia is contained in the femoral canal, it is usually of small size, owing to the resisting nature of the surrounding parts; but when it has escaped from the saphenous opening into the loose areolar tissue of the groin, it becomes considerably enlarged. The direction taken by a femoral hernia in its descent is at first downwards, then forwards and upwards; this should be borne in mind, as in the application of the taxis for the reduction of a femoral hernia pressure should be directed in the reverse order.

Coverings of the hernia.—The coverings of a femoral hernia, from within outwards, are: peritoneum, subserous areolar tissue, the septum crurale, crural sheath, cribriform fascia, superficial fascia, and integument.*

Varieties of femoral hernia.—If the intestine descends along the femoral canal only as far as the saphenous opening, and does not escape from this aperture, it is called *incomplete femoral hernia*. The small size of the protrusion in this form of hernia, on account of the firm and resisting nature of the canal in which it is contained, renders it an exceedingly dangerous variety of the disease, from the extreme difficulty of detecting the existence of the swelling, especially in corpulent subjects. The coverings of an incomplete femoral hernia would be, from without inwards: integument, superficial fascia, falciform process of fascia lata, crural sheath, septum crurale, subserous areolar tissue, and peritoneum. When, however, the hernial tumour protrudes through the saphenous opening, and directs itself forwards and upwards, it forms a *complete femoral hernia*. Occasionally the hernial sac descends on the iliac side of the femoral vessels, or in front of these vessels, or even sometimes behind them.

The *seat of stricture of a femoral hernia* varies: it may be in the peritoneum at the neck of the hernial sac; in the greater number of cases it would appear to be at the point of junction of the falciform process of the fascia lata with the lunated edge of Gimbernat's ligament; or at the margin of the saphenous opening in the thigh. The stricture should in every case be divided in a direction upwards and inwards; and the extent necessary in the majority of cases is about two or three lines. By these means, all vessels or other structures of importance, in relation with the neck of the hernial sac, will be avoided.

* Sir Astley Cooper has described an investment for femoral hernia, under the name of 'fascia propria,' lying immediately external to the peritoneal sac, but frequently separated from it by more or less adipose tissue. Surgically, it is important to remember the existence (at any rate, the occasional existence) of this layer, on account of the ease with which an inexperienced operator may mistake the fascia for the peritoneal sac, and the contained fat for omentum. Anatomically, this fascia appears identical with what is called in the text 'subserous areolar tissue,' the areolar tissue being thickened and caused to assume a membranous appearance by the pressure of the hernia.

SURGICAL ANATOMY OF THE ISCHIO-RECTAL REGION AND PERINÆUM

Dissection.—The student should select a well-developed muscular subject, free from fat, and the dissection should be commenced early, in order that the parts may be examined in as recent a state as possible. A staff having been introduced into the bladder, and the subject placed in the position shown in fig. 700, the scrotum should be raised upwards, and retained in that position, and the rectum moderately distended with tow.

The space which is now to be examined corresponds to the inferior aperture or outlet of the pelvis. Its deep boundaries are, in front, the pubic arch and subpubic ligament; behind, the tip of the coccyx; and on each side, the rami of the os pubis and ischium, the tuberosities of the ischium, and great sacro-sciatic ligaments. The space included by these boundaries is somewhat lozenge-shaped, and is limited on the surface of the body by the scrotum in front, by the buttocks behind, and on each side by the inner side of the thighs. A line drawn transversely between the anterior part of the tuberosity of the ischium, on each side, in front of the anus, divides this space into two portions. The anterior portion contains the penis and urethra, and is called the *perinæum*. The posterior portion contains the termination of the rectum, and is called the *ischio-rectal region*.

Ischio-rectal Region

The ischio-rectal region corresponds to the portion of the outlet of the pelvis situated immediately behind the perinæum: it contains the termination of the rectum and a deep fossa, filled with fat, on each side of the intestine, between it and the tuberosity of the ischium: this is called the *ischio-rectal fossa*.

The **ischio-rectal region** presents in the middle line the *aperture of the anus*; around this orifice the integument is thrown into numerous folds, which are obliterated on distension of the intestine. The integument is of a dark colour, continuous with the mucous membrane of the rectum, and provided with numerous follicles, which occasionally inflame and suppurate, and may be mistaken for fistulæ. The veins round the margin of the anus are occasionally much dilated, forming a number of hard pendent masses, of a dark bluish colour, covered partly by mucous membrane and partly by the integument. These tumours constitute the disease called *piles*.

Dissection (fig. 700).—Make an incision through the integument, along the median line, from the base of the scrotum to the anterior extremity of the anus: carry it round the margins of this aperture to its posterior extremity, and continue it backwards to about an inch behind the tip of the coccyx. A transverse incision should now be carried across the base of the scrotum, joining the anterior extremity of the preceding; a second, carried in the same direction, should be made in front of the anus; and a third at the posterior extremity of the first incision. These incisions should be sufficiently extensive to enable the dissector to raise the integument from the inner side of the thighs. The flaps of skin corresponding to the ischio-rectal region should now be removed. In dissecting the integument from this region great care is required, otherwise the Corrugator cutis ani and External sphincter will be removed, as they are intimately adherent to the skin.

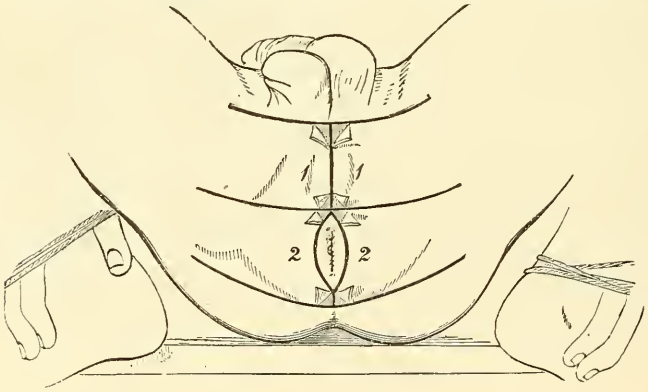
The **superficial fascia** is exposed on the removal of the skin : it is very thick, areolar in texture, and contains much fat in its meshes. In it are found ramifying two or three cutaneous branches of the small sciatic nerve ; these turn round the inferior border of the Gluteus maximus, and are distributed to the integument around the anus.

In this region, and connected with the lower end of the rectum, are four muscles : the Corrugator cutis ani ; the two Sphincters, External and Internal ; and the Levator ani.

These muscles have been already described (see page 459).

The **ischio-rectal fossa** is situated between the end of the rectum and the tuberosity of the ischium on each side. It is triangular in shape ; its base, directed to the surface of the body, is formed by the integument of the ischio-rectal region ; its *apex*, directed upwards, corresponds to the point of division of the obturator fascia, and the thin membrane given off from it, which covers the outer surface of the Levator ani (ischio-rectal or anal fascia). Its dimensions are about an inch in breadth at the base, and about two inches in depth, being deeper behind than in front. It is bounded, *internally*, by the Sphincter ani, Levator ani, and Coccygeus muscles ; *externally*, by the tuberosity of the ischium

Fig. 700.—Dissection of perinæum and ischio-rectal region.



and the obturator fascia, which covers the inner surface of the Obturator internus muscle ; *in front*, it is limited by the line of junction of the superficial and deep perineal fasciæ ; and *behind*, by the margin of the Gluteus maximus, and the great sacro-sciatic ligament. This space is filled with a large mass of adipose tissue, which explains the frequency with which abscesses in the neighbourhood of the rectum burrow to a considerable depth.

If the subject has been injected, on placing the finger on the outer wall of this fossa, the internal pudic artery, with its accompanying veins and nerve, will be felt about an inch and a half above the margin of the ischiatic tuberosity, but approaching nearer the surface as they pass forwards along the inner margin of the pubic arch. These structures are enclosed in a sheath (canal of Alcock) formed by the obturator fascia, the pudic nerve lying below the artery (fig. 415). Crossing the space transversely, about its centre, are the inferior hæmorrhoidal vessels and nerves, branches of the internal pudic ; they are distributed to the integument of the anus, and to the muscles of the lower end of the rectum. These vessels are occasionally of large size, and may give rise to troublesome hæmorrhage when divided in the operation of lithotomy, or of fistula in ano. At the back part of this space may be seen a branch of the fourth sacral nerve ; and at the fore part of the space, the superficial perineal vessels and nerves can be seen for a short distance.

The Perinæum in the Male

The perineal space is of a triangular form; its deep boundaries are limited, laterally, by the rami of the pubic bones and ischia, meeting, in front, at the pubic arch: behind, by an imaginary transverse line, extending between the tuberosities of the ischia. The lateral boundaries are, in the adult, from three inches to three inches and a half in length; and the base from two to three inches and a half in breadth; the average extent of the space being two inches and three-quarters.

The variations in the diameter of this space are of extreme interest in connection with the operation of lithotomy, and the extraction of a stone from the cavity of the bladder. In those cases where the tuberosities of the ischia are near together it would be necessary to make the incisions in the lateral operation of lithotomy less oblique than if the tuberosities were widely separated, and the perineal space, consequently, wider. The perinæum is subdivided by the median raphé into two equal parts. Of these, the left is the one in which the operation of lithotomy is performed.

In the middle line the perinæum is convex, and corresponds to the bulb of the urethra. The skin covering it is of a dark colour, thin, freely movable upon the subjacent parts, and covered with sharp crisp hairs, which should be removed before the dissection of the part is commenced. In front of the anus a prominent line commences, the *raphé*, continuous in front with the raphé of the scrotum.

Upon removing the skin and superficial structures from this region, in the manner shown in fig. 700, a plane of fascia will be exposed, covering in the triangular space and stretching across from one ischio-pubic ramus to the other. This is the *deep layer of the superficial fascia* or *fascia of Colles*. It has already been described (page 461). It is a layer of considerable strength, and encloses and covers a space in which are contained muscles, vessels, and nerves. It is continuous, in front, with the dartos of the scrotum; on each side, it is firmly attached to the margin of the ischio-pubic ramus and to the tuberosity of the ischium; and posteriorly it curves down behind the Transversus perinæi muscles to join the lower margin of the deep perineal fascia.

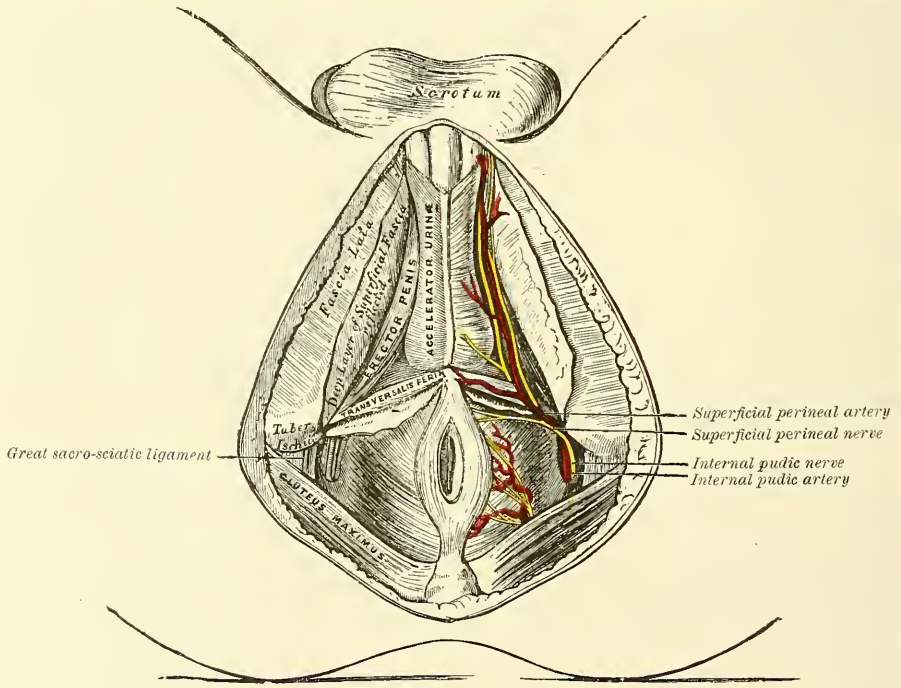
It is between this layer of fascia and the next layer, the superficial layer of the deep perineal fascia, that extravasation of urine most frequently takes place in cases of rupture of the urethra. The superficial layer of the deep perineal fascia (see page 464) is also attached to the ischio-pubic rami, and in front to the subpubic ligament. It is clear, therefore, that when extravasation of fluid takes place between these two layers, it cannot pass backwards, because the two layers are continuous with each other around the Transversus perinæi muscles; it cannot extend laterally, on account of the connection of both these layers to the rami of the os pubis and ischium; it cannot find its way into the pelvis, because the opening into this cavity is closed by the deep perineal fascia, and, therefore, so long as these two layers remain intact, the only direction in which the fluid can make its way is forwards into the areolar tissue of the scrotum and penis, and from thence on to the anterior wall of the abdomen.

When the deep layer of the superficial fascia is removed, a space is exposed, between this fascia and the deep perineal fascia, in which are contained most of the branches of the internal pudic artery, with their accompanying veins; the terminal branches of the internal pudic nerve; some of the muscles connected with the penis and urethra; in the middle line, the Accelerator urinæ; on each side, the Erector penis; and behind, the Transversus perinæi;—the crura of the corpora cavernosa; and the bulb of the corpus spongiosum. Here also is seen the *central tendinous point of the perinæum*. This is a fibrous point in the middle line of the perinæum between the urethra and the rectum, being about half an inch in front of the anus. At this point five muscles converge and are attached: viz. the External sphincter ani, the Acceleratores urinæ, and the two Transversi perinæi muscles; so that by the contraction of these muscles, which extend in opposite directions, it serves as a fixed point of support.

The Accelerator urinæ, the Erector penis, and the Transversus perinæi muscles have been already described (page 462). They form a triangular space, bounded, internally, by the Accelerator urinæ; externally, by the Erector penis;

and behind, by the Transversus perinæi. The floor of this space is formed by the triangular ligament of the urethra (deep perineal fascia); and running from behind forwards in it are the superficial perineal vessels and nerves, and the transverse perineal artery coursing along the posterior boundary of the space, on the Transversus perinæi muscle. The two terminal branches of the internal pudic artery are also to be seen in this space: the dorsal artery of the penis ascending between the crus and the pubic arch, and the artery to the corpus cavernosum entering the crus immediately after the division of the parent trunk. The perineal nerve and dorsal nerve of the penis, the two terminal branches of the pudic nerve, are also contained in this space: the perineal dividing into muscular and cutaneous branches, and the dorsal nerve accompanying the dorsal artery along the ischio-pubic ramus, and with it piercing the suspensory ligament to be distributed to the penis.

Fig. 701.—The superficial muscles and vessels of the perinæum.



The Accelerator urinæ and Erector penis should now be removed, when the deep perineal fascia will be exposed, stretching across the front part of the outlet of the pelvis. The urethra is seen perforating its centre, just behind the bulb; and on each side is the crus penis, connecting the corpus cavernosum with the rami of the ischium and os pubis.

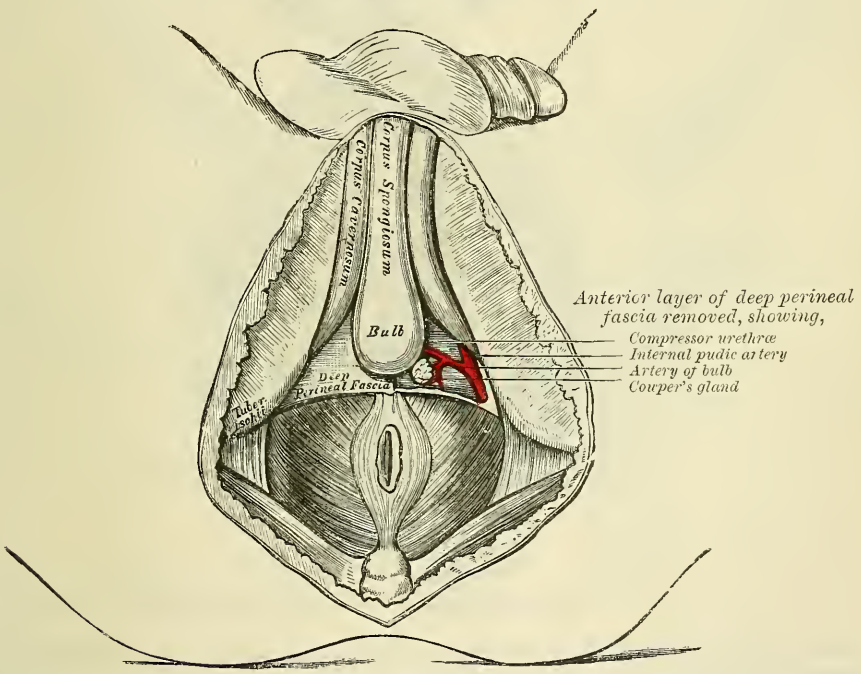
The **deep perineal fascia** (*triangular ligament*), which has already been described (see page 464), consists of two layers, the inferior or superficial layer of which, sometimes called the *anterior layer of the triangular ligament*, is now exposed. It is united to the superior or deep layer behind, but is separated in front by a subfascial space in which are contained certain structures.

The *superficial layer of the deep perineal fascia* consists of a strong fibrous membrane, the fibres of which are disposed transversely, which stretches across from one ischio-pubic ramus to the other, and completely fills in the pubic arch; it is attached in front to the subpubic ligament, except just in the centre, where a small interspace is left for the dorsal vein of the penis. In the erect position of the body it is almost horizontal. It is perforated by the urethra in the middle line, and on each side by the ducts of Cowper's glands. It is pierced also by three branches of the internal pudic artery: viz. the dorsal artery of the penis near

the apex of the ligament; the artery to the corpus cavernosum more posteriorly, close to the lateral margin of the ligament; and the artery to the bulb in front of the opening for Cowper's duct. The dorsal nerve of the penis also passes through the ligament, in company with the artery of the same name. The *crura penis* are exposed, lying superficial to this ligament. They will be seen to be attached by blunt pointed processes to the rami of the os pubis and ischium, in front of the tuberosities, and passing forwards and inwards joining to form the body of the penis. In the middle line is the bulb and corpus spongiosum exposed by the removal of the Accelerator urinæ muscle.

If the superficial layer of the deep perineal fascia is detached on either side, the deep perineal interspace will be exposed and the following parts will be seen, between it and the deep layer of the fascia: the subpubic ligament in front, close to the symphysis pubis; the dorsal vein of the penis; the membranous portion of the urethra and the Compressor urethræ muscle; Cowper's glands and their ducts; the pudic vessels and the dorsal nerve of the penis; the artery and nerve of the bulb, and a plexus of veins.

Fig. 702.—Deep perineal fascia. On the left side the anterior layer has been removed.



The *superior* or *deep layer of the deep perineal fascia* is derived from the obturator fascia, or is continuous with it along the pubic arch. Behind, it joins with the superficial layer of the deep perineal fascia, and is continuous with the anal fascia. Above it is the recto-vesical fascia, separated from it on each side by the anterior fibres of the Levator ani, but in the median line these two layers of fascia are continuous and form a median septum, in consequence of the recto-vesical fascia dipping down to join the deep layer of the deep perineal fascia. Thus on each side of the middle line, beneath this fascia, is a little interspace in which is contained the anterior fibres of the Levator ani (Levator prostatæ). It is bounded, below, by the deep layer of the deep perineal fascia; above, by the recto-vesical fascia, and is separated internally from the space on the other side by the median septum. The deep layer of the deep perineal fascia is pierced by the urethra, and is continued backwards around the posterior part of the membranous portion of the urethra and the outer surface of the prostate gland.

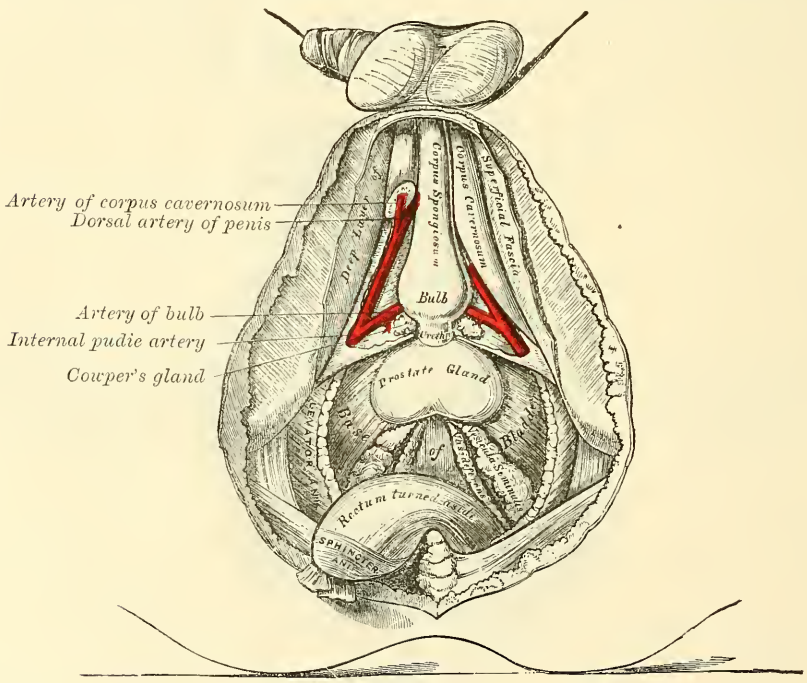
The **Compressor urethræ** has already been described (page 465). In addition to this muscle and immediately beneath it, *circular muscular fibres* surround the membranous portion of the urethra from the bulb in front to the prostate behind, and are continuous with the muscular fibres of the bladder. These fibres are involuntary.

Cowper's glands are situated immediately below the membranous portion of the urethra, close behind the bulb and below the artery of the bulb.

The **pudic vessels** and **dorsal nerve of the penis** are placed along the inner margin of the pudic arch (pages 637 and 847).

The **artery of the bulb** passes transversely inwards, from the internal pudic along the base of the triangular ligament, between the two layers of fascia, accompanied by a branch of the pudic nerve (page 849). If the posterior layer of the deep perineal fascia is removed and the crus penis of one side detached from the bone, the under or perineal surface of the Levator ani is brought fully into

Fig. 703.—A view of the position of the viscera at the outlet of the pelvis.



view. This muscle, with the triangular ligament in front and the Coccygeus and Pyriformis behind, closes the outlet of the pelvis.

The Levator ani and Coccygeus muscles have already been described (page 459).

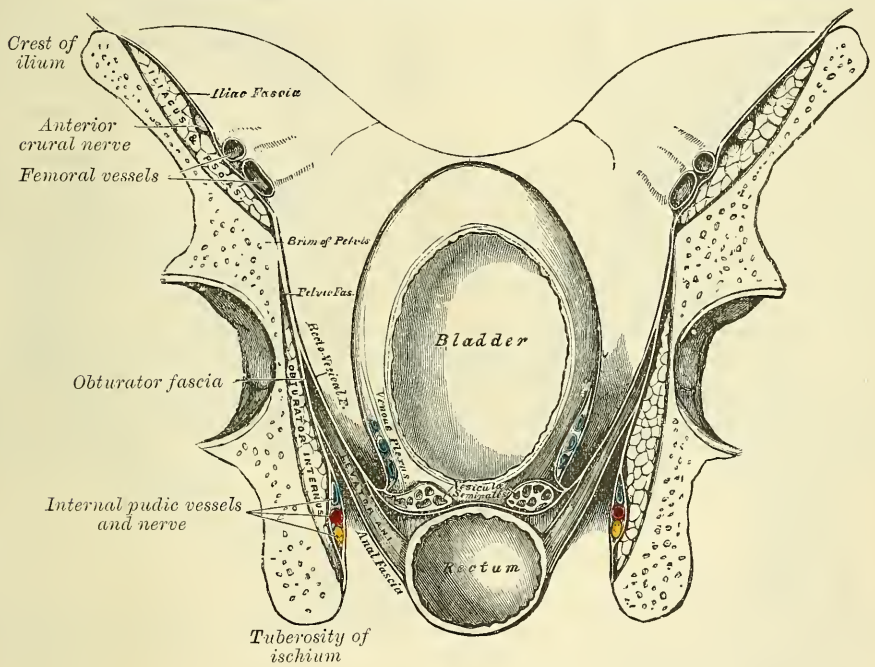
Position of the Viscera at the Outlet of the Pelvis.—Divide the central tendinous point of the perinæum, separate the rectum from its connections by dividing the fibres of the Levator ani, which descend upon the sides of the prostate gland, and draw the gut backwards towards the coccyx, when the under surface of the prostate gland, the neck and base of the bladder, the vesiculæ seminales, and the vasa deferentia will be exposed.

The **prostate gland** is a pale, firm, glandular body which is placed immediately in front of the neck of the bladder, around the commencement of the urethra. It is placed in the pelvic cavity, behind and below the symphysis pubis, posterior to the deep perineal fascia, and rests upon the rectum, through which it may be distinctly felt, especially when enlarged. In shape and size it resembles a chestnut. Its base is directed backwards towards the neck of the bladder. Its apex is directed forwards to the deep perineal fascia, which it touches.

Its under surface is smooth, marked by a slight longitudinal furrow, and rests on the rectum, to which it is connected by areolar tissue. Its upper surface is flattened, marked by a slight longitudinal furrow, and placed about three-quarters of an inch below the pubic symphysis. It measures about an inch and a half in its transverse diameter at the base, an inch in its antero-posterior diameter, and three-quarters of an inch in depth. Hence the greatest extent of incision that can be made in it without dividing its substance completely across, is obliquely backwards and outwards. This is the direction in which the incision is made in the lateral operation of lithotomy.

Behind the prostate is the posterior surface of the neck and base of the bladder: a small triangular portion of the bladder being seen, bounded, in front, by the prostate gland; behind, by the recto-vesical fold of the peritoneum; on each side, by the vesicula seminalis and the vas deferens. It is separated from direct contact with the rectum by the recto-vesical fascia. The relation of this portion of the bladder to the rectum is of extreme interest to the surgeon. In cases of retention

FIG. 704.—A transverse section of the pelvis, showing the pelvic fascia from behind.



of urine this portion of the organ is found projecting into the rectum, between three and four inches from the margin of the anus, and may be easily perforated, without injury to any important parts; this portion of the bladder is, consequently, occasionally selected for the performance of the operation of tapping the bladder.

Surgical Anatomy.—The student should consider the position of the various parts in reference to the lateral operation of lithotomy. This operation is performed on the left side of the perinæum, as it is most convenient for the right hand of the operator. A staff having been introduced into the bladder, the first incision is commenced midway between the anus and the back of the scrotum (i.e. in an ordinary adult perinæum, about an inch and a half in front of the anus), a little on the left side of the raphé, and carried obliquely backwards and outwards to midway between the anus and tuberosity of the ischium. The incision divides the integument and superficial fascia, the inferior hæmorrhoidal vessels and nerves, and the superficial and transverse perineal vessels. If the forefinger of the left hand is thrust upwards and forwards into the wound, pressing at the same time the rectum inwards and backwards, the staff may be felt in the membranous portion of the urethra. The finger is fixed upon the staff, and the structures covering it are divided with the point of the knife, which must be directed along the groove towards

the bladder, the edge of the knife being turned outwards and backwards, dividing in its course the membranous portion of the urethra, and part of the left lobe of the prostate gland, to the extent of about an inch. The knife is then withdrawn, and the forefinger of the left hand passed along the staff into the bladder. The position of the stone having been ascertained, the staff is to be withdrawn, and the forceps is introduced over the finger into the bladder. If the stone is very large, the opposite side of the prostate may be notched before the forceps is introduced: the finger is now withdrawn, and the blades of the forceps opened and made to grasp the stone, which must be extracted by slow and cautious undulating movements.

Parts divided in the operation.—The various structures divided in this operation are as follow:—the integument, superficial fascia, inferior hæmorrhoidal vessels and nerves and probably the superficial perineal vessels and nerves, the posterior fibres of the Accelerator urinæ, the Transversus perinæi muscle and artery, the deep perineal fascia, the anterior fibres of the Levator ani, part of the Compressor urethræ, the membranous and prostatic portions of the urethra, and part of the prostate gland.

Parts to be avoided in the operation.—In making the necessary incisions in the perinæum for the extraction of a calculus, the following parts should be avoided. The primary incision should not be made too near the middle line, for fear of wounding the bulb of the corpus spongiosum or the rectum; nor too far externally, otherwise the pudic artery may be implicated as it ascends along the inner border of the pubic arch. If the incisions are carried too far forwards, the artery of the bulb may be divided; if carried too far backwards, the entire breadth of the prostate and neck of the bladder may be cut through, which allows the urine to become infiltrated behind the pelvic fascia into the loose areolar tissue between the bladder and rectum, instead of escaping externally: diffuse inflammation is consequently set up, and peritonitis, from the close proximity of the recto-vesical peritoneal fold, is the result. If, on the contrary, only the anterior part of the prostate is divided, the urine makes its way externally, and there is less danger of infiltration taking place.

During the operation it is of great importance that the finger should be passed into the bladder *before* the staff is removed; if this is neglected, and if the incision made in the prostate and neck of the bladder is too small, great difficulty may be experienced in introducing the finger afterwards; and in the child, where the connections of the bladder to the surrounding parts are very loose, the force made in the attempt is sufficient to displace the bladder upwards into the abdomen, out of the reach of the operator. Such a proceeding has not unfrequently occurred, producing the most embarrassing results, and total failure of the operation.

It is necessary to bear in mind that the arteries in the perinæum occasionally take an abnormal course. Thus the artery of the bulb, when it arises, as sometimes happens, from the pudic opposite the tuber ischii, is liable to be wounded in the operation for lithotomy, in its passage forwards to the bulb. The accessory pudic may be divided near the posterior border of the prostate gland, if this is completely cut across; and the prostatic veins, especially in people advanced in life, are of large size, and give rise, when divided, to troublesome hæmorrhage.

The Female Perinæum

The **female perinæum** presents certain differences from that of the male, in consequence of the whole of the structures which constitute it being perforated in the middle line by the vulvo-vaginal passage.

The **superficial fascia**, as in the male, consists of two layers: of which the superficial one is continuous with the superficial fascia over the rest of the body; and the deep layer, corresponding to the fascia of Colles in the male, is like it attached to the ischio-pubic ramus, and in front is continued forwards through the labia majora to the inguinal region. It is of less extent than the male, in consequence of being perforated by the aperture of the vulva.

On removing this fascia the muscles of the female perinæum, which have already been described (page 465), are exposed. The Sphincter vaginæ, corresponding to the Accelerator urinæ in the male, consists of an attenuated plane of fibres, forming an orbicular muscle around the orifice of the vagina, instead of being united in a median raphé, as in the male. The Erector clitoridis is proportionately reduced in size, but differs in no other respect; and the Transversus perinæi is similar to the muscle of the same name in the male.

The *deep perineal fascia* is not so strongly marked as in the male. It transmits the urethra, and is wide, separated in the median line by the aperture of the vagina.

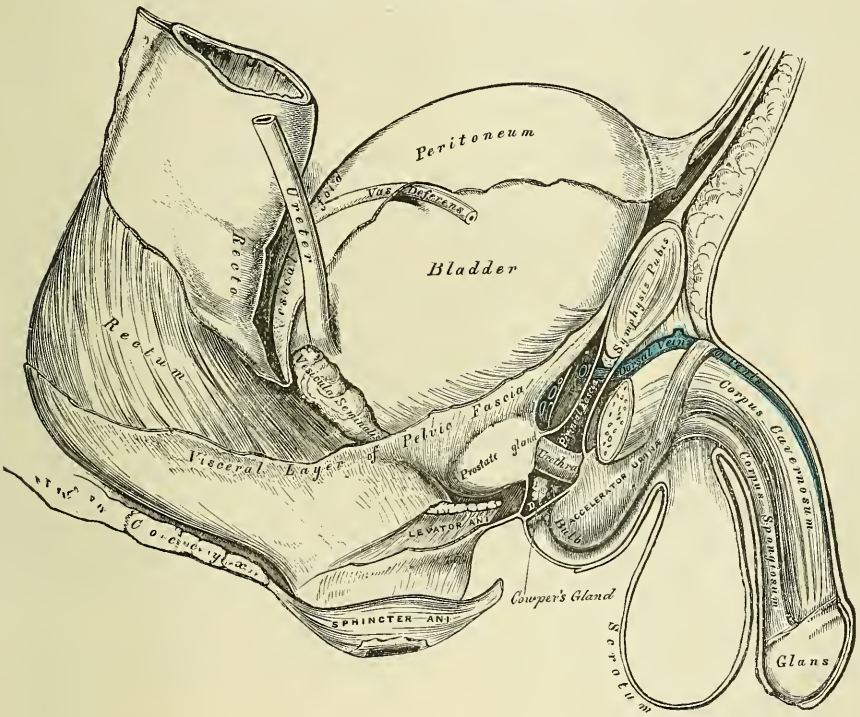
The **Compressor urethræ** (*Transversus perinæi profundus*) is the analogue of the Compressor urethræ in the male. It arises from the ischio-pubic ramus, and, passing inwards, its anterior fibres blend with the muscle of the opposite side in front of the urethra; its middle fibres, the most numerous, are inserted into the side of the vagina, and the posterior fibres join the central point of the perinæum.

The distribution of the internal pudic artery is the same as in the male (see page 639), and the pudic nerve has also a similar arrangement, the dorsal nerve being, however, very small and supplying the clitoris.

The corpus spongiosum is divided into two lateral halves, which are represented by the *bulbi vestibuli* and *partes intermediales* (see page 1101).

The **perineal body** fills up the interval between the lower part of the vagina and the rectum. Its base is covered by the skin lying between the anus and

Fig. 705.—Side view of the pelvic viscera of the male subject, showing the pelvic and perineal fasciæ.



vagina on what is called the 'perinæum.' Its anterior surface lies behind the posterior vaginal wall, and its posterior surface lies in front of the anterior rectal wall and the anus. It measures about an inch and a quarter from before backwards, and laterally extends from one tuberosity of the ischium to the other. In it are situated the muscles belonging to the external organs of generation. Through its centre runs the transverse perineal septum, which is of great strength in women, and forms on either side, behind the posterior commissure, a hard, ill-defined body, consisting of connective tissue, with much yellow elastic tissue and interlacing bundles of involuntary muscular fibres, in which the voluntary muscles of the perinæum are inserted.

Pelvic Fascia

The **pelvic fascia** (fig. 704) is a thin membrane which lines the whole of the cavity of the pelvis, and is continuous with the transversalis and iliac fasciæ. It

is attached to the brim of the pelvis, for a short distance, at the side of the cavity, and to the inner surface of the bone round the attachment of the Obturator internus. At the posterior border of this muscle, it is continued backwards as a very thin membrane in front of the Pyriformis muscle and sacral nerves to the front of the sacrum. In front, it follows the attachment of the Obturator internus to the bone, arches beneath the obturator vessels, completing the orifice of the obturator canal, and at the front of the pelvis is attached to the lower part of the symphysis pubis. At the level of a line extending from the lower part of the symphysis pubis to the spine of the ischium, is a thickened whitish band; this marks the attachment of the Levator ani muscle to the pelvic fascia, and corresponds to its point of division into two layers, the *obturator* and *recto-vesical.*

The **obturator fascia** descends and covers the Obturator internus muscle. It is a direct continuation of the pelvic fascia below the white line above mentioned, and is attached to the pubic arch and to the margin of the great sacro-sciatic ligament. From its attachment to the rami of the os pubis and ischium a process is given off which is continuous with a similar process from the opposite side, so as to close the front part of the outlet of the pelvis, forming the posterior layer of the triangular ligament. This fascia forms a canal for the pudic vessels and nerve in their passage forwards to the perinæum, and gives off a thin membrane which covers the perineal aspect of the Levator ani muscle, called the *ischio-rectal* (*anal*) *fascia.*

The **recto-vesical fascia** (*visceral layer of the pelvic fascia*) descends into the pelvis upon the upper surface of the Levator ani muscle, and invests the prostate, bladder, and rectum. From the inner surface of the symphysis pubis a short rounded band is continued to the upper surface of the prostate and neck of the bladder, forming the pubo-prostatic or anterior true ligaments of the bladder. At the side, this fascia is connected to the side of the prostate, enclosing this gland and the vesico-prostatic plexus of veins, and is continued upwards on the side of the bladder, forming the lateral true ligaments of the organ. Another prolongation invests the vesiculæ seminales, and passes across between the bladder and rectum, being continuous with the same fascia of the opposite side. Another thin prolongation is reflected round the surface of the lower end of the rectum. The Levator ani muscle arises from the point of division of the pelvic fascia; the visceral layer of the fascia descending upon and being intimately adherent to the upper surface of the muscle, while the under surface of the muscle is covered by a thin layer derived from the obturator fascia, called the *ischio-rectal* or *anal fascia.* In the female, the vagina perforates the recto-vesical fascia, and receives a prolongation from it.

Arteries, development of, 104
Arteries, *General Anatomy of*, 52 ; anastomoses of, 546 ; capillary, 54 ; development of, 104 ; distribution of, 546 ; mode of division, 546; mode of origin of branches, 546 ; nerves of, 54 ; sheath of, 53 ; structure of, 52 ; subdivision of, 546 ; systemic, 546; vessels of, 53
Arteries or Artery, accessory pudic, 638 ; acromial thoracic, 603; alar thoracic, 604 ; alveolar, 571 ; anastomotica magna of brachial, 608 ; of femoral, 652 ; angular, 564 ; anterior cerebral, 581 ; anterior choroid, 582 ; anterior ciliary, 581 ; anterior communicating, 581 ; anterior intercostal, 596 ; anterior and internal frontal, 581 ; anterior inferior cerebellar, 593 ; anterior spinal, 592 ; antero-lateral ganglionic, 582 ; antero-median ganglionic, 581 ; aorta, 548 ; abdominal, 620 ; arch of, 550 ; ascending aorta, 549 ; descending aorta, 617 ; thoracic, 617 ; articular, knee, 657 ; ascending cervical, 594 ; pharyngeal, 566 ; auditory, 593, 918 ; auricular anterior, 567 ; posterior, 566 ; axillary, 600 ; azygos of knee, 657
basilar, 593 ; brachial, 604 ; bronchial, 619, 1054 ; buccal, 570 ; of bulb, 639
calcanean, external, 663 ; internal, 663 ; carotid common, 554 ; external, 559 ; internal, 574 ; carpal ulnar, 616 ; carpal radial, 611 ; of cavernous body, 639 ; centralis retinæ, 581 ; cerebellar, 593 ; cerebral, 581, 583, 593 ; ascending cervical, 594 ; superficial, 596 ; princeps, 565 ; profunda, 598 ; choroid anterior, 582 ; posterior, 594; ciliary, 580 ; circle of Willis, 583, 594; circumflex of arm, 604 ; of thigh, 651 ; iliac, deep, 644 ; superficial, 649; cochlear, 918 ; coccygeal, 639 ; colica dextra, 627 ; media, 627 ; sinistra, 627 ; cœliac axis, 622 ; comes nervi ischiadici, 640 ; phrenici, 596 ; common carotid, 554 ; iliac, 631 ; communicating, anterior cerebri, 581 ; posterior cerebri, 593 ; communicating branch of ulnar, 616 ; coronary of heart, 549 ; of lip, 564 ; cremasteric, 643 ; crico-thyroid, 561 ; cystic, 625
deep branch of ulnar, 616 ; cervical, 598 ; palmar branch, 610 ; temporal, 570; deferent, 635 ; dental inferior, 570 ; anterior, 571 ; descending aorta, 617 ; palatine, 571 ; digital plantar, 664 ; digital of ulnar, 616 ; dorsal of penis, 639 ; of scapula, 604 ; dorsalis hallucis, 660 ; indicis, 612 ; linguæ, 561 ; pedis, 659 ; pollicis, 612
epigastric, deep, 643 ; superior, 598 ; superficial, 649 ; ethmoidal, 578 ; external carotid, 559 ; plantar, 663 ; iliac, 642
facial, 562 ; femoral, 644 ; deep, 650 ; frontal, 580
gastric, 623, 625 ; gastro-duodenalis, 624 ; gastro-epiploica dextra, 624 ; gastro-epiploica sinistra, 625 ; gluteal, 641 ; inferior, 640
helicine, 1087 ; hæmorrhoidal inferior, 638 ; middle, 636 ; superior, 627 ; hepatic, 623 ; hyoid branch of lingual, 561 ; of superior thyroid, 560 ; hypogastric in fœtus, 634, 1028
ileo-colic, 626 ; iliac common, 631 ; external, 640 ; internal, 633 ; ilio-lumbar, 640 ; inferior cerebellar, 593 ; dental, 570 ; labial, 564 ; laryngeal, 594 ; mesenteric, 627 ; profunda, 608 ; pyloric, 624 ; thyroid, 594 ; infra-orbital, 571 ; innominate, 553 ; intercostal, 619 ; anterior, 596 ; superior, 598 ; internal, auditory, 918 ; carotid, 574 ; iliac, 633 ;

Arteries or Artery (*continued*)
mammary, 596; maxillary, 568; plantar, 663; interosseous ulnar, 614; of foot, 660; of hand, 613; intestini tenuis, 626
labial inferior, 564; lachrymal, 578; laryngeal superior, 560; inferior, 594; lateral sacral, 641; spinal, 592; lateralis nasi, 564; lingual, 561; long ciliary, 581; thoracic, 604; lumbar, 629
malleolar, 659; mammary internal, 596; masseteric, 570; maxillary internal, 568; median of forearm, 615, of spinal cord, 592; mediastinal, 596; posterior, 619; meningeal anterior, 577, middle, 569, small, 570; from occipital, 565; from pharyngeal, 567, from vertebral, 592; mesenteric inferior, 627; superior, 625; metacarpal, 612; metatarsal, 660; middle cerebral, 581; sacral, 630; musculo-phrenic, 598; mylo-hyoid, 570
nasal, of ophthalmic, 580; of septum inferior, 564, superior, 571; nutrient of humerus, 608; femur, 652; fibula, 663; radius and ulna, 615; tibia, 663
obturator, 636; occipital, 565; œsophageal, 619; ophthalmic, 577; orbital, 571; ovarian, 629
palatine, ascending, 563; descending, 571; of pharyngeal, 566; palmar arch, superficial, 616, deep, 610; palmar interossei, 613; palpebral, 580; pancreatic, 625; pancreatico-duodenalis, 624; inferior, 626; perforating, of hand, 613, of thigh, 652, of foot, 664, of anterior intercostal, 598, plantar, 664; pericardiac, 596, 618; perineal, superficial, 638; transverse, 638; peroneal, 662, anterior, 663; pharyngeal, ascending, 566; phrenic, 629; popliteal, 652; posterior auricular, 566, cerebral, 593; communicating, 582, meningeal, from vertebral, 592; princeps cervicis, 565, pollicis, 612; profunda of arm, inferior, 608, superior, 608, cervicis, 598, femoris, 650; pterygoid, 570, pterygo-palatine, 571; pudic, deep external, 650; superficial external, 649, internal, in male, 637, in female, 641; pulmonary, 547, 1052; pyloric inferior, 624; of hepatic, 624
radial, 609; radialis indicis, 613; ranine, 561; recurrent interosseous, 615, radial, 609; ulnar anterior, 614, posterior, 614; tibial anterior, 659, posterior, 659; renal, 628
sacral lateral, 641; middle, 630; scapular, posterior, 596; sciatic, 639; short ciliary, 580; sigmoid, 627; spermatic, 629, 1090; spheno-palatine, 571; spinal anterior, 592; lateral, 592; posterior, 592; median, 592; splenic, 625; sterno-mastoid, 560, 565; stylo-mastoid, 566; subclavian, 585; sublingual, 561; submaxillary, 564; submental, 564; subscapular, 604; superficial cervical, 596; circumflex iliac, 649; perineal, 638; palmar arch, 616; superficialis volæ, 611, superior cerebellar, 593, epigastric, 598, hæmorrhoidal, 627, intercostal, 598, laryngeal, 560, mesenteric, 625, profunda, 608, thoracic, 603, thyroid,
Arteries or Artery (*continued*)
560; supra-orbital, 578, suprarenal, 628, suprascapular, 595; sural, 655
tarsal, 660; temporal, 567; anterior, 567; deep, 570; middle, 567; posterior, 567; thoracic, acromial, 603, alar, 604, aorta, 617; long, 604; superior, 603; thyroid axis, 594; thyroid inferior, 594; superior, 560; thyroidea ima, 553, 1056; tibial anterior, 657, posterior, 660, recurrent, 659; tonsillar, 563; transverse facial, 567; transversalis colli, 595; tympanic, from internal carotid, 577, from internal maxillary, 569
ulnar, 613; recurrent anterior, 614, posterior, 614; umbilical in fœtus, 634, 1028; uterine, 636
vaginal, 636, vasa aberrantia, of arm, 606; brevia, 625; intestini tenuis, 626; vertebral, 591; vesical inferior, 635; middle, 635; superior, 635; vestibular, 918; Vidian, 571
Arteriolæ rectæ, 1067
Arthrodia, 308
Articular arteries (knee), from popliteal, 657
Articular cartilage, 22
Articular end bulbs, 48; lamella of bone, 305; processes of vertebræ, 121; synovial membranes, 305
Articulations in general, 305; different kinds of, 306
acromio-clavicular, 336; ankle, 373; astragalo-calcanean, 376; astragalo-navicular, 378; atlanto-axial, 315
calcaneo-astragaloid, 376; calcaneo-cuboid, 377; calcaneo-navicular, 378; carpo metacarpal, 354; carpal, 352; classification of, 309; coccygeal, 332; chondro-sternal, 326; costo-transverse, 324; costo-vertebral, 323; of cuboid with external cuneiform, 380; of cuneiform with each other, 379
elbow, 343
femoro-tibial, 363
hip, 357
immovable, 306
knee, 363
metacarpal, 356; metacarpo-phalangeal 356; metatarso-phalangeal, 382; metatarsal, 381; mixed, 307; movable, 307, movements of, 308
naviculo-cuneiform, 379; naviculo-cuboid, 379
occipito-atlantal, 317; occipito-axial, 318
pelvis, 330; pelvis with spine, 329; phalanges, 357; pubic, 333
radio-carpal, 350; radio-ulnar, inferior, 349; middle, 348; superior, 347
sacro-coccygeal, 332; sacro-iliac, 330; sacro-sciatic, 331; sacro-vertebral, 329; scapulo-clavicular, 336; scapulo-humeral, 339; shoulder, 339; sterno-clavicular, 334; of sternum, 328
tarso-metatarsal, 380; tarsal, 376; temporo-maxillary, 320; tibio-fibular, inferior, 372; middle, 372; superior, 371; of tympanic bones, 909
vertebral column, 311
wrist, 350
Aryteno-epiglottideus superior, 1039; inferior, 1039

Aryteno-epiglottidean folds, 1036
Arytenoid cartilages, 1034; glands, 1040
Arytenoid muscle, 1038
Arytenoideus rectus, 1039 (*foot-note*)
Ascending colon, 984; oblique muscle of abdomen, 451
Ascending frontal artery, 582
Ascending palatine artery, 563; pharyngeal artery, 566; surgical anatomy of, 567
Ascending parietal artery, 582
Association fibres of hemispheres of brain, 764
Astragalus, 291; development of, 300
Atlanto-axial articulation, 315
Atlas, 122; development of, 130
Atlo-odontoid joint, 315
Atrabiliary capsules, 1072
Atrium bursæ omentalis, 955
Attic of tympanum, 154
Attollens aurem muscle, 390
Attrahens aurem muscle, 390
Auditory artery, 918; internal, 593; canal, 904; meatus, external, 155; surface form of, 905; internal, 155; nerve, 801, 918; surgical anatomy of, 802; veins, 918; vesicle, 99
Auerbach's plexus, 982
Auricle of ear, 902; cartilage of, 902; ligaments of, 903
Auricle of heart, left, 1022; appendix of, 1023; sinus of, 1023; right, 1018; openings in, 1019; valves in, 1020; sinus of, 1019; septum of, 1018, 1026
Auricular artery, posterior, 566; anterior, 567; fissure, 157, 195; lymphatic glands, 699; nerve of vagus, 806; posterior from facial, 798; veins, anterior, 669; posterior, 670; surface of sacrum, 134
Auricularis anterior muscle, 390; posterior, 390; superior, 390
Auricularis magnus nerve, 818
Auriculo-temporal nerve, 791
Auriculo-ventricular groove of heart, 1018; opening, left, 1024; opening, right, 1021
Axes of the pelvis, 269
Axilla, 598; dissection of, 467; surgical anatomy of, 600
Axillary artery, 600; peculiarities, 602; surgical anatomy of, 602; branches of, 603; surface marking of, 602; lymphatic glands, 702; space, 598; vein, 682; surgical anatomy of, 682
Axis, or second vertebræ, 124; development of, 130
Axis, cerebro-spinal, 712; cœliac, 622; thyroid, 594
Axis-cylinder of nerve-tubes, 42
Azygos artery, articular, 657; of vagina, 636; veins, 685; uvulæ muscle, 421

Bacillary layer of retina, 890
Back, muscles of, first layer, 427; second layer, 430; third layer, 431; fourth layer, 434; fifth layer, 437
Ball-and-socket joint. *See* Enarthrodia
Bartholin, duct of, 938; glands of, 1101
Basal ridge, or cingulum of teeth, 923
Base of brain, 747; of skull, 190; external surface, 193; internal surface, 190; of sacrum, 134
Basement membranes, 19
Basi-hyal of hyoid bone, 209
Basilar artery, 593; groove, 144; membrane of cochlea, 916; process, 143; suture, 188
Basilic vein, 681; median, 681
Basis vertebrarum venæ, 687
Bauhin, valve of, 983
Beak of corpus callosum, 751
Beaunis et Bouchard, table of development of fœtus, from, 117
Bend of elbow, 605
Biceps flexor cruris, 524
Biceps flexor cubiti, 478
Bicipital fascia, 479, 681; groove, 233; tuberosity, 243; ridges, 233
Bicuspid teeth, 924
Biliary ducts, 1001, 1003; structure of, 1003
Bioplasm, 8
Biventer cervicis muscle, 436
Bladder, 1073; development of, 112; ligaments of, 1076; trigone of, 1078; vessels and nerves of, 1079; female, 1101; surface form of, 1079; surgical anatomy of, 1079
Blastema, 8
Blastodermic membrane, 76
Blood, *General Composition of*, 1; corpuscles, 2; crystals, 6; gases of, 6; globules, 2; plaques or platelets, 5
Blood, circulation of, in adult, 1018; in fœtus, 1029
Blood-discs, development of, 102
Blood-vascular system, development of, 101
Blood-vessels of brain, 583
Bochdalek, ganglion of, 788, 790; on musculus triticeo-glossus, 1039 *note*
Body of a tooth, 923; of a vertebra, 121
Bone, *General Anatomy of*, 25; animal constituent of, 29; apophyses of, 120; articular lamella of, 305; canaliculi of, 29; cancellous tissue of, 25; cells, 29; chemical analysis of, 30; compact tissue of, 25; diploë of, 120; development of, 30; earthy constituent of, 30; eminences and depressions of, 120; epiphyses of, 120; growth of, 34; Haversian canals of, 27; systems of, 27; inorganic constituent of, 30; lacunæ of, 28; lamellæ of, 28; lymphatics of, 27; marrow of, 25; medullary canal of, 25, 119; medullary membrane of, 25; microscopic appearances, 27; nerves of, 27; organic constituent of, 29; ossification of, 30; ossific centres, number of, 35; periosteum of, 25; spongy tissue of, 25; vessels of, 26
Bones, forms of, viz. long, short, flat, mixed or irregular, 119; number of, in the body, 119
Bones or Bone, *Descriptive Anatomy of*, 119; astragalus, 291; atlas, 122; axis, 124; calcaneum, 287; carpal, 246; clavicle, 222; coccyx, 136; cranial, 141; cuboid, 293; cuneiform of carpus, 250; of tarsus, 294
ear, 908; ethmoid, 163
facial, 167; femur, 271; fibula, 285; frontal, 148

Bones or Bone (*continued*)
hand, 246; humerus, 231; hyoid, 209
ilium, 259; incus, 909; inferior maxillary, 183; turbinated, 180; innominate, 259; ischium, 262
lachrymal, 174; lesser lachrymal, 175; lingual, 209
magnum, 252; malar, 175; malleus, 908; maxillary, inferior, 183; superior, 169; metacarpal, 253; metatarsal, 297
nasal, 167; navicular, 294
occipital, 141; orbicular, 909
palate, 177; patella, 279; parietal, 145; pelvic, 267; phalanges of foot, 300; of hand, 256; pisiform, 250; pubic, 264
radius, 243; ribs, 214
sacrum, 132; scaphoid, 246; scapula, 225; semilunar, 249; sesamoid, 304; sphenoid, 158; sphenoidal spongy, 159; stapes, 909; sternum, 211; superior maxillary, 169
tarsal, 287; temporal, 151; tibia, 280; trapezium, 251; trapezoid, 251; triquetral, 167; turbinate, superior, 165; middle, 165; inferior, 180; tympanic, 155
ulna, 238; unciform, 252
vertebra prominens, 125; vertebræ, cervical, 121; dorsal, 125; lumbar, 127; vomer, 181
Wormian, 167
Bone, articular lamella of, 305
Bowman, glands of, 877; sarcous elements of, 38
Bowman's capsule, 1063
Brachia of optic lobes, 762
Brachial artery, 604; branches of, 608; peculiarities of, 605; surgical anatomy of, 607; surface marking of, 607; lymphatic glands, 702; plexus, 820; surgical anatomy of, 831; veins, 682
Brachialis anticus muscle, 479
Brachio-cephalic artery. *See* Innominate
Brachio-radialis muscle. *See* Supinator longus
Brain, *General anatomy of*, 44; development of, 93
Brain, 723; base of, 747; convolutions of, 737; dura mater of, 723; interior of, 751; lobes of, 738; membranes of, dissection of, 723; subdivision into parts, 726; upper surface of, 736; weight of, 727
Branchial arches, 93
Breasts, 1112
Bregma, 189
Brim of pelvis, 267
Broad ligaments of uterus, 1105; formation of, 961
Bronchi, right and left, 1042; septum of, 1042; in lung, 1052
Bronchial arteries, 619, 1054; lymphatic glands, 710; septum, 1042; veins, 686, 1054; tubes, *see* Bronchi
Brunner's glands, 979
Bubonocele, 1124
Buccal arteries, 570; cavity, 921; development of, 109; glands, 922; lymphatic glands, 699; nerve of facial, 800; of inferior maxillary, 791; veins, 669
Buccinator muscle, 399
Bulb, artery of, 639; of corpus cavernosum, 1086; of corpus spongiosum, 1087; olfactory, 748, 766, 777
Bulbar portion of spinal accessory nerve, 809
Bulbi vestibuli, 1111
Bulbo-cavernosus muscle, 463
Bulbous portion of urethra, 1081
Bulbs of the fornix, 749
Burdach's column, 720
Burns's space, 406
Bursæ mucosæ, 306; synoviæ, 306
Bursæ of shoulder, 341; of knee, 367
Bursal synovial membranes, 306
Bursa omentalis, 955; pharyngea, 942

Cæcum, 982
Calamus scriptorius, 774
Calcanean arteries, internal, 663; external, 663
Calcaneo-astragaloid ligaments, 376
Calcaneo-cuboid ligaments, 377
Calcaneo-navicular ligaments, 378
Calcaneum, 287
Calcar femorale, 276; avis, 753
Calcarine fissure, 743
Calices of kidney, 1069
Calloso-marginal fissure, 742
Camper's ligament. *See* Triangular ligament of Urethra
Canals or Canal, accessory palatine, 179; alimentary, 921; anterior dental, 170; palatine, 172; for Arnold's nerve, 157; auditory, 904; carotid, 155, 156; central of modiolus, 913; for chorda tympani, 153, 906; of cochlea, 916; crural, 1134; dental posterior, 171; ethmoidal, 150; Haversian, of bone, 27; of Huguier, 153; incisive, 193; inferior dental, 184; infra-orbital, 170; inguinal, 1120; for Jacobson's (tympanic) nerve, 156; lachrymal, 899; naso-palatine, 181; of Nuck, 1097, 1112; of Petit, 894; palatine posterior, 170; anterior, 172; pterygo-palatine, 160; sacral, 135; of Schlemm, 882; spermatic, 1120; of spinal cord, 717; spiral of cochlea, 913; of Stilling, 893; of modiolus, 913; semicircular, 912; for tensor tympani, 157, 907; temporo-malar, 175; vertebral, 139; Vidian, 161; of Wirsung, 1006
Canaliculi of bone, 29
Canalis centralis modioli, 913; membranacea, 916; reuniens, 915; spiralis modioli, 913
Cancellous tissue of bone, 25
Canine eminence, 170; fossa, 169; teeth, 924
Canthi of eyelids, 896
Capillaries, 54; structure of, 54
Capitellum of humerus, 235
Capsular ligament of hip, 357; of knee, 365; of shoulder, 339; of thumb, 354; of vertebræ, 313
Capsule, external, of brain, 754; internal, of brain, 754; of Glisson, 998; of lens, 893; in fœtus, 99; of kidney, 1061; of Tenon, 879
Capsules, suprarenal, 1071
Caput cornu of cord, 716, 720; gallinaginis, 1080

Cardiac lymphatics, 710; muscular tissue, 40; nerves, 858; from pneumogastric, 808; plexus of nerves, deep, 861; superficial, 862, veins, 695
Cardinal veins, fœtal, 107
Carotid artery, common, 554; branches of (occasional), 557; peculiarities of, 557; surgical anatomy of, 557; surface marking of, 557; external, 559; branches of, 560; surgical anatomy of, 559; surface marking of, 559; internal, 574; branches of, 577; peculiarities of, 576; surgical anatomy, 577; tubercle, 122
Carotid branch of Vidian, 788
Carotid canal, 155, 156; ganglion, 856; groove, 159; plexus, 856; triangle, inferior, 572; triangle, superior, 572
Carpal arch, anterior, 611; posterior, 612
Carpal arteries, from radial, 611; from ulnar, 616; ligaments, 352
Carpo-metacarpal articulations, 354
Carpus, 246; development of, 258; articulations of, 352; surface form of, 257; surgical anatomy of, 258
Cartilage, *General Anatomy of*, 21; cellular, 21; costal, 23; articular, 22; fibrous, 23; hyaline, 21; intercellular substance of, 22; reticular, 24; temporary, 23
arytenoid, 1034; of auricle, 902
of bronchi, 1052
costal, 23, 218; cricoid, 1033; cuneiform, 1034; of ear, 902, 904; ensiform, 213; of epiglottis, 1034
of Jacobson, 876
of larynx, 1032
of the nose, 874
of the pinna, 902
of Santorini, 1034; semilunar of knee, 366; of septum of nose, 874
tarsal, 897; thyroid, 1032; of trachea, 1042; of Wrisberg, 1034
xiphoid, 213
Cartilage, articular, 22; cellular, 21; costal, 23; hyaline, 21; permanent, 21; temporary, 23; white fibro-, 23; yellow elastic, 24
Cartilage cells, 22; lacunæ, 22
Cartilagines minores, 874
Cartilago triticea, 1035
Caruncula lachrymalis, 899
Carunculæ myrtiformes, 1101
Cauda equina, 844
Cava inferior, 691; peculiarities, 692; superior, 684
Cavernous body, artery of, 639; groove, 159; nerves of penis, 865; plexus, 858; sinus, 676; nerves in, 795; surgical anatomy of, 677
Cavity, cotyloid, 265; glenoid, 228; of pelvis, 268; sigmoid, greater, 238; lesser, 240; of the great omentum, 962
Cell, definition of, 7; division of, direct, 11; division of, indirect, 10; nucleus of, 8; reproduction of, 10; structure of, 8
Cell wall, 11
Cells of bone, 29; ethmoidal, 164; fat, 20; goblet or chalice, 14; mastoid, 154; prickle, 14
Cellular tissue, lymphoid, 19; mucoid, 18; retiform, 19
Cement of teeth, 928; formation of, 932
Central canal of cord, 717; lobe of cerebrum, 742; ganglionic vessels of brain, 584; tendon of diaphragm, 444
Central ganglionic system of arteries, 584
Centres of ossification, 35
Centrifugal nerve fibres, 47
Centripetal nerve fibres, 47
Centrum ovale majus, 751; minus, 751
Centrum of vertebræ, 121
Cephalic vein, 681; median, 681
Cerato-hyal of hyoid bone, 210
Cerebellar arteries, anterior, inferior, 593; superior, 593; column, 719; veins, 674
Cerebelli incisura, anterior, 769; posterior, 768
Cerebellum, 768; corpus dentatum of, 771, 774; hemispheres of, 768; laminæ of, 772; lobes of, 769; median lobe of, 769; peduncles of, 772; structure of, 771; under surface of, 770; upper surface of, 769; the valley of, 770; ventricle of, 774; weight of, 768
Cerebral arteries, 583; anterior, 581; middle, 581; posterior, 593; convolutions, 737; lymphatics, 701; topography, 744; veins, 674; ventricles, 752, 757, 759, 774
Cerebro-spinal Axis, 712; fluid, 726; nerves, 45
Cerebro-spinal system, 40
Cerebrum, 726, 735; base of, 747; commissures of, 760; commissural fibres of, 764; convolutions of, 737; crura of, 750; fibres of, 763; fissures of, 738; general arrangement of its parts, 750; grey matter of, 44, 765; hemispheres of, 735; interior of, 751; labia of, 751; lobes of, 747; peduncles of, 751; structure of, 763; sulci, 736; under surface, 747; upper surface, 736; ventricles of, 752, 757, 759, 774
Ceruminous glands, 905
Cervical artery, ascending, 594; superficial, 596; princeps, 565; profunda, 598
Cervical fascia, 405
Cervical ganglion inferior, 859; middle, 859; superior, 856
Cervical lymphatic glands, deep, 702; superficial, 701; surgical anatomy of, 702
Cervical nerves, 814; anterior divisions of, 816; posterior divisions of, 814; roots of, 814
Cervical plexus, 818; deep branches of, 819; posterior, 816; superficial branches of, 818
Cervical rib, 125
Cervical veins, deep, 672
Cervical vertebræ, 121; surgical anatomy of, 319
Cervicalis ascendens muscle, 435
Cervico-facial nerve, 800
Cervix cornu of cord, 720; uteri, 1104
Chalice cells, 13
Chambers of the eye, 892
Chassaignac's tubercle, 122
Check ligaments, 319
Cheek, muscles of, 396
Cheeks, structure of, 922
Chest, muscles of front of, 468; side, 472;

surface form of, 219; surgical anatomy of, 220
Chiasma, or optic commissure, 778
Cholesterine, 3
Chondro-glossus muscle, 414; sternal ligaments, 326; xiphoid ligament, 328
Chorda dorsalis, 80, 88
Chorda tympani nerve, 798, 911
Chordæ tendineæ, of right ventricle, 1021; of left, 1024; vocales, 1037; Willisii, 675
Chorion, 85
Choroid arteries, anterior, 582; posterior 594; coat of eye, 883; plexus of lateral ventricle, 755; of fourth ventricle, 776; of third ventricle, 759; veins of brain, 674
Choroidal fissure 98
Chromatin, 8
Chromocytes, 2
Chyle, 7
Chyli receptaculum, 698
Cilia, or eyelashes, 897
Ciliary arteries, 580, 886; ganglion, 784; muscle, 887; nerves, long, 784; short, 786; processes of eye, 884
Ciliaris muscle, 390; ciliated epithelium, 13; cingulum, 923
Circle of Willis, 583, 594
Circular sinus, 677
Circulation of blood in adult, 1018; in fœtus, 1029
Circulus tonsillaris, 790
Circumduction, 310
Circumferential fibro-cartilage, 24
Circumflex artery of arm, anterior, 604; posterior, 604; of thigh, external, 651; internal, 651; iliac artery, 644; superficial, 649; iliac vein, 690; superficial, 688; nerve, 823; surgical anatomy of, 831
Circumflexus palati muscle, 421
Circumvallate papillæ of tongue, 869
Cisterna magna, 725; pontis, 725
Cistern of Pecquet, 698
Clarke's vesicular column, 721
Claustral formation of cortex, 766
Claustrum, 754, 766
Clava of funiculus gracilis, 730
Clavicle, 222; development of, 224; fracture of, 503; peculiarities in sexes, 224; surface form of, 224; surgical anatomy of, 224
Cleft palate, 422
Clinoid processes, anterior, 161; middle, 158; posterior, 158
Clitoris, 1100; frænum of, 1100; lymphatics of, 707; muscles of, 466, 1101; prepuce of, 1100
Clivus, 159; of cerebellum, 770
Cloaca, 111, 115
Coccygeal artery, 639; gland, 630; nerve, 844
Coccygeus muscle, 460
Coccyx, 136; development of, 137
Cochlea, 913; aqueduct of, 156; arteries of, 918; central axis of, 913; cupola of, 913; infundibulum of, 913; lamina spiralis of, 914; nerves of, 919; scalæ of, 916; spiral canal of, 913; veins of, 918
Cochlear artery, 918; nerve, 802, 919
Cochleariform process, 157, 907
Cœliac axis, 622; plexus, 864
Cohnheim, areas of, 38
Colica dextra artery, 627; media, 627; sinistra, 627
Collateral circulation. *See* Surgical Anatomy of each artery; collateral intercostal artery, 620; fibres of cerebrum, 764; fissure, 743
Collecting tubes of kidney, 1064
Colles, fascia of, 461
Colliculus nervi optici, 887
Colon, 984
Colostrum corpuscles, 1113
Columella cochleæ, 913
Columns of abdominal ring, 1117; of spinal cord, 716; of vagina, 1103
Columnæ carneæ of left ventricle, 1024; of right ventricle, 1022; papillares, 1022, 1024
Columna nasi, 874
Columnar epithelium, 13
Comes nervi ischiadici artery, 640; phrenici artery, 596
Commissura brevis of cerebellum, 770
Commissural fibres of brain, 764
Commissure of Gudden, 778
Commissure, optic, 778
Commissures of brain, anterior, 760; middle or soft, 760; posterior, 760; of spinal cord, grey, 717; white, 716
Common ligaments of vertebræ, 311
Communicans hypoglossi nerve, 819; peronei, 852; poplitei, 850
Communicating artery of brain, anterior, 581; posterior, 582; from dorsalis pedis, 660; from ulnar, 616
Compact tissue of bone, 25, 119
Complexus muscle, 436
Compressor narium minor, 396; nasi, 396; sacculi laryngis, 1039; urethræ, 465; in female, 467
Conarium, 762
Concentric corpuscles of thymus, 1058
Conception, where effected, 74
Concha, 902
Conducting tracts of cord, 718
Conductor sonorus, 776
Condyles of bones. *See* Bones
Condyloid articulations, 308; foramina, 143; fossæ, 143; process, 185; ridge, external, 235; internal, 235; veins, posterior, 672, 676
Cone-granules of retina, 890; cones of retina, 890
Congenital fissures in cranium, 167; hernia, 1126
Conglobate glands, 58, 697
Coni vasculosi, 1094
Conjoined tendon of internal oblique and transversalis, 452, 1119
Conjunctiva, 898
Connecting fibro-cartilages, 24
Connective tissue, 15; development of, 18; vessels of, 18; lymphatics of, 18; nerves of, 18; adenoid, 18; elastic, 16; fibrous, 15; lymphoid, 19; mucoid, or gelatinous, 18; retiform, 19; yellow, 16
Conoid ligament, 337; tubercle, 222
Constrictor inferior muscle, 418; medius, 418; superior, 419; isthmi faucium, 421; urethræ, in male, 465; in female, 467
Contractile fibre cells, 39

Conus arteriosus, 1020
Convolution of corpus callosum, 744
Convolutions of cerebrum, structure of, 737; topography of, 744
Convolutions, angular, 740; of corpus callosum, 744; cuneate, 744; frontal, 738; marginal, 744; occipital, 741; occipito-temporal, 744; orbital, 738; parietal, 739; precuneus, 744; quadrate, 744; supramarginal, 740; temporo-sphenoidal, 741; uncinate, 744
Coraco-acromial ligament, 338; coraco-brachialis muscle, 478; coraco-clavicular ligament, 335; coraco-humeral ligament, 314
Coracoid ligament, 339; process, 229; process, fracture of, 503
Cord, spermatic, 1090; spinal, 714; umbilical, 88
Cordiform tendon of diaphragm, 444
Corium of mucous membrane, 69; of skin, 63; of tongue, 868
Cornea, 880
Corneal corpuscles, 881; spaces, 881
Cornicula laryngis, 1034
Cornu Ammonis, 756, 766; formation of, 766
Cornua of the coccyx, 136; of hyoid bone, 210; of the sacrum, 133; of thyroid cartilage, 1033
Corona glandis, 1086; radiata, 45, 764
Coronal suture, 188
Coronary artery of stomach, 623
Coronary arteries of lip, 564; arteries of heart, 549; peculiarities, 550; ligament of liver, 995; ligaments of knee, 366; plexus, anterior, 862; posterior, 862; sinus, 695; opening of, 1020; valve, 696, 1020
Coronoid depression, 235; process of jaw, 185; of ulna, 238
Corpora albicantia, 749; Arantii, 1022, 1024; mammillaria, 749; cavernosa penis, 1086; crura of, 1086; cavernosa clitoridis, 1101; geniculata, 759, 763; quadrigemina, 762; striata, 753; veins of, 674
Corpus callosum, 751, 764; convolution of, 744; genu of, 751; peduncles of, 751; ventricle of, 751; dentatum of cerebellum, 774; of olivary body, 733; fimbriatum, 758; Highmorianum, 1093; spongiosum, 1087
Corpus cavernosum, artery of, 639; dentatum, 771, 774
Corpuscles, blood, 2; coloured, 2; white, 3
Corpuscles, development of, 102; of Herbst, 49; Malpighian, of kidney, 1063; of Purkinje, 773; of spleen, 1011; tactile, 49; of Vater, 48
Corrugator cutis ani, 459; supercilii muscle, 391
Cortex of cerebrum, 765; of cerebellum, 772
Corti, membrane of, 916; organ of, 916; rods of, 916
Cortical arteries of brain, 584
Cortical columns, 1062; cortical arches, 1062
Cortical substance of brain, 765; of kidney, 1062; of suprarenal capsules, 1072; of teeth, 928
Costal cartilages, 23, 218; connection with ribs, 328; process, 122, 129
Costo-central articulation, 323
Costo-chondral articulation, 328; costo-clavicular ligament, 335; costo-coracoid fascia, 470; costo-coracoid ligament, 470; costo-transverse articulations, 324; costo-vertebral articulations, 323; costo-vertebral ligaments, 323; chondro-xiphoid ligaments, 328
Costo-transverse articulation, 323
Cotunnius, nerve of, 790
Cotyloid cavity, 265; ligament, 359; notch, 265
Coverings of direct inguinal hernia, 1127; of femoral hernia, 1136; of oblique, 1123; of testis, 1092
Cowper's glands, 1085, 1142
Cranial bones, 141; articulations of, 186
Cranial fossæ, 190
Cranial Nerves, 776; eighth pair, 801; eleventh, 809; fifth, 782; first, 777; fourth, 781; ninth, 802; second, 778; seventh, 796; sixth, 795; tenth, 803; third, 779; twelfth, 809
Cranial nerves, development of, 97
Cranial sutures, 186
Cranium, 141; development of, 90, 166; congenital fissures in, 167; lymphatics of, 701
Cremaster muscle, 452; formation of, 1119
Cremasteric artery, 643; fascia, 452
Crescents of Gianuzzi, 938
Crest, frontal, 149; of ilium, 262; lachrymal, 174; nasal, 168; occipital, 141; internal, 143; turbinated, of palate, 178; of superior maxillary, 172; of os pubis, 264; of spine of scapula, 227; of tibia, 282
Cribriform fascia, 510, 1130; plate of ethmoid, 164
Crico-arytenoideus lateralis muscle, 1038; posticus muscle, 1038
Crico-thyroid artery, 561; membrane, 1035; muscle, 1038
Cricoid cartilage, 1033
Crista falciformis, 155; galli, 164, 191; pubis, 264; vestibuli, 912
Crochet of uncinate gyrus, 744
Cross pyramidal tract, 719, 729
Crown of a tooth, 923
Crucial anastomosis, 640, 651; ligaments of knee, 365
Cruciform ligament, 316
Crura cerebri, 750; of corpora cavernosa, 1086; of clitoris, 1101; of diaphragm, 444; of fornix, 757
Crural arch, 450, 1131; deep, 457, 1134; canal, 1134; nerve, anterior, 841; surgical anatomy of, 853; ring, 1134; sheath, 1133; septum, 1135
Crureus muscle, 514
Crus penis, 1085
Crusta petrosa of teeth, 928; of crus cerebri, 750, 763
Crypts of Lieberkühn, 979
Crystalline lens, 893
Crystals, blood, 6
Cuboid bone, 293
Culmen of cerebellum, 770
Cuneate lobe, 744; funiculus, 731
Cuneiform bone, hand, 250; foot, external, 296; internal, 294; middle, 295; cartilages, 1034

Cupola of cochlea, 913
Curvatures of the spine, 138
Cuspidate teeth, 924
Cutaneous branches of anterior tibial nerve, 852; of cervical plexus, 818; of circumflex, 823; of dorsal nerve of penis, 849; of dorsal nerves, 832; of external popliteal, 851; internal, 850; of inferior hæmorrhoidal nerve, 847; of ilio-hypogastric, 838; of ilio-inguinal, 839; of intercostal nerves, 834; of lesser sciatic nerve, 847; of lumbar nerves, 836; of median, 827; of musculo-spiral, 830; of ulnar nerve, 828; of arm, musculo-cutaneous, 826; internal, 826; lesser internal, 826; of buttock and thigh, 847; of inguinal region, 1129; of ischio-rectal region, 1138; from obturator, 841; of thigh, external, 839; internal, 842; middle, 842; of patella, 843; of perineal nerve, 849; of plantar nerve, 851; of posterior tibial, 850; of radial, 831; of sacral nerves, 844; of ulnar, 828
Cuticle of skin, 61
Cuticula dentis, 931
Cutis vera, 63
Cuvier, ducts of, 106
Cylindrical epithelium, 13
Cystic artery, 625; duct, 1002; valve of, 1003; plexus of nerves, 864; veins, 695

Dartos, 1089
Decidua, 86; serotina, 87; reflexa, 86; vera, 86
Deciduous teeth, 923
Decussation of optic nerves, 778; of pyramids, 729
Deep crural arch, 457, 1134; palmar arch, 610; perineal fascia, 464, 1140
Deferent artery, 635
Deglutition, actions of, 422
Deltoid aponeurosis, 473; muscle, 473; tubercle, 222
Demilunes of Heidenhain, 938
Demours, membrane of, 881
Dens sapientiæ, 925
Dental artery, inferior, 570; posterior, 571; canal, anterior, 170; inferior, 184; posterior, 170; furrow, 929; germ, 929; lamina, 929; nerves, anterior, 788; inferior, 792; middle, 788; posterior, 787; pulp, 932; sacs, 930; tubuli, 927; vein, inferior, 670
Dentate fissure, 744
Dentinal sac, 930; sheath, 927; tubuli, 927
Dentine, 927; formation of, 931
Depressions for Pacchionian bodies, 147, 149
Depressor alæ nasi, 396; anguli oris, 398; epiglottidis, 1039; labii inferioris, 397
Derma, or true skin, 63
Dermic coat of hair follicle, 65
Descemet, membrane of, 881
Descendens hypoglossi nerve, 811
Descending aorta, 617; colon, 984; oblique muscle of abdomen, 448
Descent of testicle, 1097
Development of atlas, 130; axis, 130; alimentary canal and its appendages, 108; arteries, 104
bone, 30
Development (*continued*)
carpus, 258; clavicle, 224; coccyx 137; cranium, 90, 166
ear, 99; ethmoid, 166; eye, 97
face, 90; femur, 277; fibula, 286; foot, 301; frontal bone, 151
genital organs, 112
hand, 258; heart, 103; humerus, 235; hyoid bone, 210
inferior turbinated bone, 181
lachrymal bone, 175; lens, 98; lower jaw, 185; lumbar vertebræ, 131
malar bone, 176; mammæ, 100; metacarpus, 258; metatarsus, 300; muscles, 101
nasal bone, 169; nervous centres, 93; nose, 100
occipital bone, 145; os innominatum, 265
palate, 92; palate bone, 181; parietal bone, 147; patella, 280; permanent teeth, 932; phalanges of hand, 259; of foot, 300
radius, 244; ribs, 218
sacrum, 135; scapula, 230; seventh cervical, 131; skin, 100; sphenoid, 162; spine, 88; sternum, 213; superior maxillary bone, 173
tarsus, 300; temporary teeth, 929; temporal bone, 157; tibia, 284
ulna, 242
veins, 105; vertebræ, 129; vomer, 182
Wormian, 167
Development of organs, chronological table of, 117
Diameters of pelvis, 269
Diaphragm, 443; development of, 110; lymphatics of, 710
Diaphysis, 35
Diarthrosis, 307
Digastric muscle, 411; fossa, 154; lobe of cerebellum, 770; nerve, from facial, 798
Digestion, organs of, 921
Digital arteries from ulnar, 616; plantar, 564; cavity of lateral ventricle, 752; fossa, 273; nerves from median, 828; from radial, 831; from ulnar, 829; of foot, 850
Dilatator naris anterior, 396; posterior, 396
Diploë, 120; veins of, 673
Direct inguinal hernia, 1126; course of, 1126; coverings of, 1127; pyramidal tract, 718
Disc, intermediate, 37; lateral, 37; median of Hensen, 38; transverse, 37
Discs, blood, 2; development of, 102
Discus proligerus, 73, 1111
Dissection of abdominal muscles, 447; arm, 473; auricular region, 389; axilla, 467
back, 427
epicranial region, 387; eye, 882
femoral hernia, 1128; face, 390; foot, 535; forearm, 481
gluteal region, 518
hand, 492; heart, left auricle, 1022; left ventricle, 1024; right auricle, 1018; right ventricle, 1021; hernia, femoral, 1128; inguinal, 1115
iliac region, 507
inferior maxillary region, 397; infra-hyoid region, 409; inguinal hernia, 1115; ischio-rectal region, 1137

Dissection of intermaxillary region, 398
leg, 526; lingual region, 413
neck, 404
orbit, 392
palatal region, 420; palm of hand, 492; palpebral region, 390; pancreas, 1005; pectoral region, 467; perinæum, 1137; pharynx, 418; pterygoid muscles, 401
radial region, 486
scalp, 387
sole of foot, 537; spinal cord and membranes, 712; supra-hyoid region, 411
temporal muscle, 400; thigh, front of, 510; back of, 524; inner side of, 515
Diverticulum, Meckel's, 976
Division of cells, 10; direct, 11; indirect, 10
Dorsal artery of penis, 639
Dorsal nerves, 832; posterior divisions of, 832; anterior divisions of, 834; roots of, 832; peculiar, 835
Dorsal nerve of penis, 849
Dorsal vein of penis, 691
Dorsal vertebræ, 125; peculiar, 127
Dorsales pollicis arteries, 612
Dorsalis hallucis artery, 660; indicis, 612; linguæ, 561; pedis, 659; branches of, 660; peculiarities of, 660; surgical anatomy of, 660; surface marking of, 660; scapulæ, 604
Dorsi-lumbar nerve, 837
Dorsi-spinal veins, 686
Dorsum of scapula, 225; ephippii or sellæ, 158
Douglas, pouch of, 961, 1104; semilunar fold of, 455
Ducts or Duct, of Bartholin, 938; biliary, 1001; of Cowper's glands, 1081; of Cuvier, 106; cystic, 1002; ejaculatory, 1096; of Gartner, 114; galactophorous, 1113; hepatic, 1001, 1002; of kidney, 1069; lactiferous, 1113; of liver, 1001; lymphatic, right, 699; nasal, 900; of pancreas, 1006; parotid, 936; Rivini, 937; seminal, 1094; Stenson's, 936; thoracic, 698; Wharton's, 937
Ductless glands: spleen, 1008; suprarenal capsule, 1071; thyroid, 1055; thymus, 1057
Ductus arteriosus, 548, 1028; how obliterated in fœtus, 1031; communis choledochus, 1003; endo-lymphaticus, 912; pancreaticus accessorius, 1006; Rivini, 937; santorini, 1006; venosus, 106, 1030; how obliterated, 1031
Duodenal glands, 979; loop, 951; mesentery, 952
Duodenum, 973; vessels and nerves of, 975
Dura mater of brain, 723; arteries of, 723; nerves of, 724; processes of, 724; veins of, 723; of cord, 712; peculiarities of, 712
Dyaster or daughter star, 10

Ear, 901; arteries of, 903, 910, 918; auditory canal, 904; cochlea, 913; internal, or labyrinth, 911; membranous labyrinth, 914; muscles of auricle, 903; of tympanum, 910; ossicula of, 908; pinna or auricle of, 902; semicircular canals, 912; surgical anatomy of, 919; surface form of, 905; tympanum, 905; vestibule, 911
Ear, development of, 99
Earthy constituents of bone, 30
Ectoderm, 79
Efferent nerves, 47
Egg-tubes, 113
Eighth nerve, 801; surgical anatomy of, 802
Ejaculator seminis muscle, 463
Ejaculatory ducts, 1096
Elastic lamina of cornea, 882; cartilage, 24
Elbow, bend of, 605; joint, 343; anastomoses around, 608; surface form of, 346; surgical anatomy of, 346; vessels and nerves of, 345
Eleventh nerve, 809; surgical anatomy of, 809
Embryo, first rudiments of, 79; development of, 88
Eminence of aqueductus Fallopii, 907; canine, 170; frontal, 148; ilio-pectineal, 262; nasal, 149; parietal, 146
Eminences and depressions of bones, 120
Eminentia articularis, 152; collateralis, 756; teres, 776
Emissary veins, 678
Enamel cells, 930; droplet, 931; epithelium, 930; of teeth, 928; formation of, 930; organ, 930; rods, 928
Enarthrosis, 308
End-bulbs of Krause, 47
End-plates, motorial, of Kühne, 50
Endocardium, 1025
Endolymph, 914
Endomysium, 36
Endoneurium, 45
Endothelium, 12
Ensiform appendix, 213
Entoderm, 79
Eosinophile cells, 4
Eparterial division of bronchus, 1042
Epencephalon, 94
Ependyma, 752
Epiblast, 76, 79
Epicondyles, 234
Epidermic coat of hair follicle, 65
Epidermis, structure of, 62; development of, 100
Epididymis, 1094; development of, 114
Epigastric artery, deep, 643; peculiarities, 644; relation to femoral ring, 1134; with internal ring, 1121; superficial, 649; superior, 598; plexus, 862; region, 947; vein, 690; superficial, 688
Epiglottic glands, 1040
Epiglottis, 1034
Epimysium, 36
Epineurium, 45
Epiphysial cartilage, 30, 34
Epiphysis, 35, 120
Epiphysis cerebri, 761
Epithelium, 12; ciliated, 13; columnar, 13; cylindrical, 13; pavement, 12; spheroidal or glandular, 13; stratified, 14; transitional, 15. *See* Various Organs
Epoophoron, 111, 114
Erectile tissue, its structure, 1087; of penis, 1087; of clitoris, 1101

Erector clitoridis, 466, 1101; penis, 464; spinæ, 434
Eruption of the teeth, 933
Erythroblasts, 2
Ethmo-sphenoidal suture, 191
Ethmoid bone, 163; articulations of, 166; cribriform plate of, 164; development of, 166; lateral masses of, 164; perpendicular plate of, 164; os planum of, 165; unciform process of, 165
Ethmoidal artery, 578; canal anterior, 150; posterior, 150; cells, 164; notch, 149; process of inferior turbinated, 181; spine, 158
Ethmo-frontal suture, 191
Eustachian tube, 157, 908; surgical anatomy of, 920; valve, 1020; in fœtal heart, 1028
Expiration, muscles of, 447
Extensor coccygis, 438; brevis digitorum muscle, 536; carpi radialis brevior, 487; longior, 487; carpi ulnaris, 489; communis digitorum (hand), 488; indicis, 491; longus digitorum (foot), 527; minimi digiti, 488; ossis metacarpi pollicis, 489; brevis pollicis, 491; proprius hallucis, 527; longus pollicis, 491
Extensor primi internodii pollicis. *See* Extensor longus pollicis
Extensor secundi internodii pollicis. *See* Extensor brevis pollicis
External abdominal ring, 449, 1117; annular ligament, 535; capsule, 754; inguinal hernia, 1123; orbital foramina, 161; pterygoid plate, 162; spermatic fascia, 450, 1118; sphincter ani, 459
External and inferior frontal artery, 582
Extrinsic muscles of tongue, 415
Eye, 879; appendages of, 896; chambers of, 892; ciliary muscle, 887; processes of, 884; humours of, 892; aqueous, 892; crystalline lens, 893; vitreous, 892; membrana pupillaris, 887; choroid, 883; conjunctiva, 898; cornea, 880; hyaloid membrane, 892; iris, 885; Jacob's, 890; retina, 887; sclerotic, 880; pupil of, 885; tunics of, 880; uvea of, 885; vessels of globe of, 894; elastic lamina of cornea, 882; surgical anatomy of, 895
Eye, development of, 97
Eyeball, muscles of, 392; nerves of, 895; vessels of, 894
Eyebrows, 896
Eyelashes, 897
Eyelids, 896; cartilages or plates of, 897; development of, 99; Meibomian glands of, 897; muscles of, 390; tarsal ligament of, 897
Eye-teeth, 924

Face, arteries of, 562; bones of, 141, 167; development of, 90; muscles of, 386; lymphatics of, 699; nerves of, 796; veins of, 668
Facial artery, 562; surgical anatomy of, 565; peculiarities of, 564; transverse, 567; bones, 167; nerve, 796; surgical anatomy of, 801; vein, 669; surgical anatomy of, 669
Falciform process of fascia lata, 512; ligament of liver, 995; ligament of sacro-sciatic articulation, 332
Fallopian tubes, 1108; development of, 111; fimbriated extremity of, 1108; lymphatics of, 708; nerves of, 1112; structure of, 1108; vessels of, 1112
False ligaments of bladder, 1077; pelvis, 267; ribs, 215
Falx cerebelli, 724; cerebri, 724
Fangs of teeth, 923
Fasciæ, general description of, 385
Fascia, anal, 1146; of arm, 473; of cranial region, 388
cervical, deep, 405; superficial, 404; of Colles, 461; costo-coracoid, 470; cremasteric, 452; cribriform, 1130
deep, 386; dentata, 756; dorsal of foot, 536
fibro-areolar, its structure, 385; plantar, of foot, 535; of forearm, 481
of hand, 492
iliac, 507; infundibuliform, 1121; intercolumnar, 450, 1117; intercostal, 441; intermuscular, of arm, 478; of foot, 536; ischio-rectal, 1146
lata, 510, 1130; falciform process of, 1131; iliac portion, 512, 1131; pubic portion, 512, 1131; of leg, 526; deep transverse, 530; lumborum, 432
of mamma, 468; masseteric, 400
of neck, 403
obturator, 1146
palmar, 494; parotid, 400, 406; pelvic, 1145; perineal, deep, 1140; superficial, 1139; pharyngeal, 406; plantar, 535; prevertebral, 406; propria of spermatic cord, 1090; of femoral hernia, 1128
recto-vesical, 1146
of Scarpa, 448; spermatic, 450, 1118; superficial, 386; of inguinal region, 1115; of ischio-rectal region, 1138; of thigh, 509
temporal, 400; of thigh, deep, 510; superficial, 510; of thorax, 441, 468; transversalis, 1121; triangular, 451
visceral layer of pelvic, 1146
Fasciculi teretes. *See* Eminentia teres
Fasciculus, of Türck, 718; unciformis, 748
Fat, 20; fat cells, 20
Fauces, isthmus of, 934
Fecundation of ovum, 74
Female Organs of Generation: bulbi vestibuli, 1101; carunculæ myrtiformes, 1101; clitoris, 1100; development of, 113, 116; fossa navicularis, 1100; glands of Bartholin, 1101; hymen, 1101; labia majora, 1099; minora, 1100; nymphæ, 1100; uterus, 1103; vagina, 1102; vestibule, 1101
Femoral artery, 644; branches of, 649; common, 646; deep, 650; superficial, 646; peculiarities of, 647; surgical anatomy of, 647; surface marking of, 647; or crural canal, 1134; variation in size of, according to position of limb, 1135; hernia, complete, 1136; coverings of, 1136; descent of, 1136; dissection of, 1128; incomplete, 1136; seat of stricture, 1136; surgical anatomy of, 1128
region, muscles of anterior, 509; internal,

Femoral (*continued*)
515; posterior, 524; ring, 1134; position of surrounding parts, 1134
sheath, 1133; spur, 276
vein, 689; relation of femoral ring, 1134
Femur, 271; articulations of, 277; attachment of muscles to, 278; development of, 277; fracture of, above condyles, 544; below trochanters, 544; head of, 272; neck of, 272; trochanters of, 273; condyles of, 276; structure of, 276; neck, fracture of, 543; surface form of, 278; surgical anatomy of, 278
Fenestra ovalis, 907; rotunda, 907, 913
Fenestrated membrane of Henle, 17, 52
Ferrein, pyramids of, 1064
Fertilisation of ovum, 74
Fibre-cells, contractile, 39
Fibres of muscle, 36; of Müller, 890; of nerves, 39, 50; of Remak, 43
Fibrin, 1, 5
Fibrinogen, 1, 5
Fibrin ferment, 1
Fibro-cartilage, 23; interarticular, 23; connecting, circumferential, and stratiform, 24; yellow, 24
Fibro-cartilages, acromio-clavicular, 337; intercoccygean, 333; intervertebral, 312; of knee, 366; of lower jaw, 321; pubic, 333; radio-ulnar, 349; sacro-coccygean, 333; sterno-clavicular, 335
Fibrous cartilage, 23; connective tissue, 15; nervous matter, 41; rings of heart, 1025; tissue white, 15; yellow, 16
Fibro-serous membranes, 68
Fibula, 285: articulations of, 286; attachment of muscles to, 287; development of, 286; fracture of, with dislocation of the foot, 545; surface form of, 287
Fibular region, muscles of, 533
Fifth nerve, 782; surface marking of, 794; surgical anatomy of, 794; ventricle of brain, 757
Filiform papillæ of tongue, 869
Fillet of the gyrus fornicatus, 764; fillet, inferior or lateral, 762; superior or mesial, 763
Filum terminale of cord, 714
Fimbriæ of Fallopian tube, 1108
First nerve, 777; surgical anatomy of, 778
Fissure, auricular, 157; horizontal of cerebellum, 796; of ductus venosus, 996; for gall-bladder, 996; Glaserian, 152, 906; of liver, 996; longitudinal of liver, 996; longitudinal of cerebrum, 735, 748; of lung, 1049; of medulla oblongata, 728; portal, 996; pterygo-maxillary, 198; spheno-maxillary, 198; sphenoidal, 161; of spinal cord, 715; Sylvian, 738, 748; transverse, of liver, 996; of cerebrum, 756; umbilical, 996; for vena cava, 996
Fissures, congenital, in cranium, 167
calcarine, 743; collateral, 743; calloso-marginal, 742; dentate, 744
intra-parietal, 739
parallel, 741; parieto-occipital, 738, 743
precentral, 738
Rolando, 738
Sylvius, 738, 745
Flat bones, 119
Flexor accessorius muscle, 538; brevis digitorum, 537; brevis minimi digiti, (hand) 499; (foot), 540; brevis pollicis, 496; brevis hallucis, 539; carpi radialis, 482; ulnaris, 482; digitorum sublimis, 483; digitorum profundus, 484; longus digitorum, 532; longus pollicis, 485; longus hallucis, 531; ossis metacarpi pollicis, 495
Floating ribs, 215
Flocculus, 770
Flood's ligaments, 340
Fluids of the body, 1
Fœtus, circulation in, 1029; Eustachian valve in, 1028; foramen ovale in, 103, 1028; liver of, distribution of its vessels, 1029; ovaries in, 113; vascular system in, peculiarities, 1028
Fold of Douglas, 452, 455
Folds, aryteno-epiglottidean, 1036; genital, 116; recto-uterine, 1104; recto-vesical, 1077; vesico-uterine, 1104
Folium cacuminis, 770
Follicle of hair, 65; of intestine, 979
Follicles, sebaceous, 66
Fontana, spaces of, 882
Fontanelles, 144, 166
Foot, arteries of, 659, 663; bones of, 287; development of, 300; dorsum, muscles of, 536; fascia of, 536; ligaments of, 376; sole of, muscles of, 536; fascia of, 535; nerves of, 850; surface form of, 302; surgical anatomy, 302; veins of, 689
Foramen cæcum of frontal bone, 149, 191; of medulla oblongata, 728; of tongue, 868; carotid, 156; condyloid, 143, 144; dental inferior, 184; ethmoidal, 191; incisive, 193; jugular, 193; infra-orbital, 170; intervertebral, 139; lacerum anterius, 161, 192; medium, 192; posterius, 193; of Majendie, 725, 775; magnum, 142; mastoid, 153; mental, 183; of Monro, 755, 761; obturator, 265; optic, 161, 192; ovale of heart, 103, 1028; of sphenoid, 160, 192; palatine anterior, 172, 193; posterior, 178, 193; parietal, 146; pterygo-palatine, 160; quadratum of diaphragm, 445; rotundum, 160, 192; sacro-sciatic, 263, 332; of Scarpa, 173, 193; of Sömmerring, 887; spheno-palatine, 180, 199; spinosum, 160, 192; of Stenson, 173, 193; sternal, 211; stylo-mastoid, 157; supra-orbital, 149; thyroid, 265; Vesalii, 160, 192; of Winslow, 958
Foramina, sacral, 132, 133; of diaphragm, 445; external orbital, 161; of Key and Retzius, 726, 775; malar, 175; olfactory, 164; Thebesii, 696, 1020
Forearm, arteries of, 609; bones of, 237; fascia of, 481; lymphatics of, 703; muscles of, 481; nerves of, 827; veins of, 680
Fore-gut, development of, 108
Form of bones, 119
Formatio reticularis of medulla, 733
Formation of the cornu Ammonis, 766
Fornix, 757; bulbs of, 749; conjunctivæ, 898; crura of, 757
Fossa acetabuli, 265; of antihelix, 902; canine, 169; condyloid, 143; cochlearis, 912; cystis felleæ, 996; digastric, 154;

digital, 273; glenoid, 228; of helix, 902; iliac, 262; infra- and supra-spinous, 225; incisive, 169, 183; innominata, 902; ischio-rectal, 1137; jugular, 156; lachrymal, 150; myrtiform, 169; navicularis of urethra, 1081; of vulva, 1100; occipital, 143; olfactory of fœtus, 100; ovalis, 1020; palatine anterior, 172; pituitary, 158; pterygoid of sphenoid, 162; of lower jaw, 185; scaphoid, 162; scaphoidea, 902; sigmoidea, 154; spheno-maxillary, 198; of skull, anterior, 190; middle, 191; posterior, 192; subscapular, 225; sublingual, 184; submaxillary, 184; temporal, 197; triangularis, 902; trochanteric, 273; vesicalis, 994; zygomatic, 197
Fossa inguinalis lateralis, 1123; mesialis, 1123; supra vesicalis, 1123
Fossæ, nasal, 201, 875; of skull, 190
Fourchette, 1100
Fourth nerve, 781; surgical anatomy of, 781; ventricle, 774
Fovea inferior of fourth ventricle, 776; centralis retinæ, 887; hemispherica, 912; superior of fourth ventricle, 776; semielliptica, 912
Fracture of acromion process, 503
centre of clavicle, 503; acromial end of, 503; coracoid process, 503; coronoid process of ulna, 246
femur above condyles, 544; below trochanters, 544; fibula, with dislocation of tibia, 545
humerus, anatomical neck, 237; shaft of, 504; non-union of, 237; surgical neck, 504
neck of femur, 543
olecranon process, 505
patella, 545
Pott's, 545
radius, 505; lower end of, 506; neck of, 505; shaft of, 505, and ulna, 506
tibia, shaft of, 545
ulna, shaft of, 505
Fræna of ileo-cæcal valve, 984
Frænulum of Vieussens' valve, 772
Frænum clitoridis, 1100; labii superioris et inferioris, 922; linguæ, 867; præputii, 1086
Frontal artery, 580; bone, 148; articulations of, 151; attachment of muscles to, 151; development of, 151; structure of, 151; crest, 149; eminence, 148; lobe, 738; nerve, 783; process of malar, 175; sinuses, 149; suture, 148, 151; vein, 668
Frontalis muscle, 389
Fronto-nasal process, 92
Fronto-sphenoidal suture, 188
Fundus of uterus, 1103
Fungiform papillæ of tongue, 869
Funiculi of nerve, 45
Funiculus cuneatus, 729; gracilis, 730; of Rolando, 729; teres, 776
Furrow, auriculo-ventricular, 1018; genital, 116; interventricular, 1018
Furrowed band of cerebellum, 770

Galactophorous ducts, 1113
Galen, veins of, 695, 759
Gall-bladder, 1002; development of, 110; fissure for, 996; structure of, 1002; valve of, 1002; surface form, 1003
Ganglion or Ganglia, *General Anatomy of*, 50; of Andersch, 802; Arnold's, 793; of Bochdalek, 788, 790
cardiac, 862; carotid, 856; cephalic, 784; cervical, inferior, 859; middle, 859; superior, 856; ciliary, 784; on circumflex nerve, 823
diaphragmatic, 864
on facial nerve, 797; of fifth nerve, 784
Gasserian, 782; of glosso-pharyngeal, 805; geniculate, 797
impar, 854, 861; inferius, 805; intercarotid, 859; on posterior interosseous nerve, 831
jugular, 805
lenticular, 784; lingual, 859; lumbar, 860
Meckel's, 788; mesenteric, 865
ophthalmic, 784; otic, 793
petrous, 803; pharyngeal, 859; of pneumogastric, 806; of portio dura, 797; of Ribes, 858; of root of vagus, 805
sacral, 861; semilunar, of abdomen, 862; of fifth nerve, 784; spheno-palatine, 788; of spinal nerves, 813; spirale, 919; submaxillary, 794; suprarenal, 864; of sympathetic nerve, 854
temporal, 859; thoracic, 860; thyroid, 859; of trunk of vagus, 805
of Valentin, 788
of Wrisberg, 862
Ganglion of the cerebellum, 774
Ganglion corpuscles, 51
Ganglionic branch of nasal nerve, 784
Ganglionic nerves, 45
Gartner, duct of, 114
Gases of the blood, 6
Gasserian ganglion, 782; depression for, 155
Gastric arteries (vasa brevia), 625; artery, 623; follicles, 970; impression of liver, 994; nerves from vagus, 808; plexus, 864; vein, 694
Gastrocnemius muscle, 528
Gastro-colic, omentum, 965
Gastro-duodenal artery, 624; plexus, 864
Gastro-epiploica dextra artery, 624; sinistra, 625
Gastro-epiploic plexus, 864; veins, 693
Gastro-hepatic omentum, 964
Gastro-phrenic ligament, 968
Gastro-splenic omentum, 965
Gelatinous connective tissue, 18
Gemellus inferior muscle, 522; superior, 522
Generative Organs, development of, 112; female, 1099; male, 1083
Genial tubercles, 183
Geniculate bodies, 759, 763; ganglion, 797
Genio-hyo-glossus muscle, 413
Genio-hyoid muscle, 412
Genital cord, 111; corpuscles, 48; folds, 116; furrow, 116; ridge, 112; tubercle, 116
Genito-crural nerve, 839
Genu of corpus callosum, 751
Gerlach's nerve network, 721
Germinal area, 76; disc, 76; epithelium, 112; matter, 8; vesicle, 73; spot, 73
Giant cells, 26
Gianuzzi, crescents of, 938
Gimbernat's ligament, 450, 1132

Gingival branches of dental nerves, 787
Ginglymus, 308
Giraldès, organ of, 114
Girdle, shoulder, 221 ; pelvic, 221
Glabella of frontal bone, 149, 199
Gladiolus, 211
Glands, development of, 100
Glands, simple secreting, 71 ; tubular, 71 ; convoluted tubular, 71 ; racemose or saccular, 71 ; compound tubular, 71
Glands, Ductless, 1008; spleen, 1008; suprarenal, 1071 ; thymus, 1057 ; thyroid, 1055
Glands, Lymphatic, 58
Gland or Glands, Secreting, 70; accessory of parotid, 936 ; arytenoid, 1040
of Bartholin, 1101 ; of biliary ducts, 1003; Brunner's, 979; buccal, 922
ceruminous, 905 ; coccygeal, 630; Cowper's, 1085, 1142
duodenal, 979
epiglottic, 1040
gastric, 970
of Havers, 306
labial, 922; lachrymal, 899; of larynx, 1040 ; lingual, 870; of Littré, 1081 ; of Luschka, 630
mammary, 1112; Meibomian, 897 ; molar, 922 ; mucilaginous of Havers, 306
odoriferæ, 1086
œsophageal, 944
of Pacchioni, 675, 724; palatal, 934, 939; parotid, 935; Peyer's, 980; pharyngeal, 942 ; pineal, 761 ; pituitary, 749 ; prostate, 1083
salivary, 935; sebaceous, 66 ; solitary, 979; sublingual, 937; submaxillary, 937 ; sudoriferous, 66; suprarenal, 1071
thymus, 1057; thyroid, 1055 ; tracheal, 1043 ; of Tyson, 1086
uterine, 1106
of vulva, 1101
Glandulæ odoriferæ, 1086 ; Pacchioni, 675, 723, 724
Glandular epithelium, 13
Glans penis, 1085 ; clitoridis, 1101
Glasserian fissure, 152, 906
Gleno-humeral ligament, 340
Glenoid cavity, 228; fossa, 152 ; ligament of shoulder, 340 ; of Cruveilhier, 356, 382 ; of phalanges, 356
Gliding movement, 310
Glisson's capsule, 965, 998
Globules, blood, 2 ; development of, 102
Globus major of epididymis, 1004 ; minor, 1004
Glosso-epiglottic ligaments, 867, 1035
Glosso-pharyngeal nerve, 802
Glottis, rima of, 1036
Gluteal aponeurosis, 519
Gluteal artery, 641 ; inferior, 640; lymphatic glands, 704; nerve, inferior, 847 ; superior, 846 ; region, lymphatics of, 706 ; muscles of, 518; ridge, 274; veins, 690
Gluteus maximus muscle, 518 ; medius, 519 ; minimus, 520
Goblet cells, 13
Golgi, organs of, 50
Goll's tract, 720
Gomphosis, 307
Graafian vesicles, 1110; membrana granulosa of, 1111 ; ovicapsule of, 1111 ; structure of, 1110
Gracilis muscle, 515
Granular formation of cortex, 766 ; cells, 18 ; layer of dentine, 928
Great omentum, 965 ; sciatic nerve, 849 ; surgical anatomy of, 853
Greater wings of sphenoid, 160
Grey matter of cerebellum, 772 ; of cerebrum, 765 ; of medulla oblongata, 733 ; of spinal cord, 720
Grey nervous substance, 41
Groin, 1128 ; cutaneous vessels and nerves of, 1128 ; superficial fascia of, 1128 ; surgical anatomy of, 1128
Groove, auriculo-ventricular, 1018; bicipital, 233 ; cavernous, 159 ; infra-orbital, 170 ; lachrymal, 172 ; mylo-hyoid, 184 ; nasal, 168 ; occipital, 154 ; optic, 158 ; subclavian, 218
Grooves in the radius, 244 ; interventricular, 1018
Growth of bone, 34
Gubernaculum dentis, 932 ; testis, 1097
Gulf of internal jugular vein, 671
Gums, 922
Gustatory nerve, 792
Gyri, or convolutions of brain, 736
Gyri, annectant, 740, 741 ; operti, 742
Gyrus fornicatus, 744
Gyrus, or lingual lobule, 744

Hæmatoidin crystals, 6
Hæmin crystals, 6
Hæmoglobin, 3 ; crystals, 6
Hæmorrhoidal artery, inferior, 638; middle, 636 ; superior, 627 ; nerve, inferior, 847 ; plexus of nerves, 865 ; venous plexus, 690; surgical anatomy of, 690
Hair cells, of internal ear, 917
Hairs, 64 ; structure of, 65 ; root-sheath, 65 ; follicles, 65 ; shaft, 66
Ham, region of the, 652
Hamstring tendons, surgical anatomy of, 525
Hamular process of sphenoid, 162 ; of humerus, 234 *note* ; of lachrymal, 175
Hand, arteries of, 610; bones of, 246; fascia of, 492 ; ligaments of, 352 ; muscles of, 492 ; nerves of, from median, 827 ; from radial, 831 ; from ulnar, 829 ; surface form of, 257, 502 ; veins of, 680
Hard palate, 934
Harmonia, 307
Hasner, valve of, 900
Havers, glands of, 306
Haversian canals of bone, 27 ; systems of bone, 27
Head, lymphatics of, 699 ; muscles of, 387 ; veins of, 667 ; of scapula, 228 ; of ulna, 242
Head, kidney, 111
Heart, 1017 ; development of, 103
annular fibres of auricles, 1026 ; arteries of, 549, 1027
circular fibres of, 1026 ; component parts of, 1018
endocardium, 1025
fibres of the auricles, 1026 ; of the ventricles, 1026 ; fibrous rings of, 1025 ; fœtal relics in, 1019
infundibulum of, 1020

Heart (*continued*)
left auricle, 1022 ; ventricle, 1024 ; looped fibres of auricles, 1026 ; lymphatics of, 710, 1027
muscular fibres of, 1026 ; structure of, 40
nerves of, 808, 861, 1027
position of, 1018
right auricle, 1018 ; ventricle, 1020
septum, ventriculorum, 1024 ; size and weight, 1018 ; spiral fibres of, 1026 ; structure of, 1025 ; subdivision into cavities, 1018 ; surface marking of, 1027 ; veins of, 1027 ; vortex of, 1026
Heidenhain, demilunes of, 938
Helicine arteries, 1087
Helicis, major muscle, 903 ; minor, 903
Helicotrema of cochlea, 913
Helix, 902 ; fossa of, 902 ; muscles of, 903 ; process of, 902
Henle, looped tubes of, 1064
Henle's layer of hair follicle, 65
Hepatic artery, 623, 1000 ; cells, 999 ; duct, 1002 ; plexus, 864 ; veins, 693, 998, 1000
Herbst, corpuscles of, 49
Hernia, congenital, 1126 ; direct inguinal, 1126 ; femoral, coverings of, 1136 ; descent, of, 1136 ; dissection of, 1128 ; encysted, 1126 ; of funicular process, 1126 ; infantile, 1126 ; inguinal, 1115 ; dissection of, 1115 ; oblique inguinal, 1123 ; scrotal, 1124
Hesselbach's triangle, 1123, 1126
Hiatus Fallopii, 155
Highmore, antrum of, 171
Hilton's muscle, 1039
Hilum of kidney, 1061 ; of spleen, 1008
Hind-gut, development of, 109 ; hind-kidney, 111
Hinge-joint, 308
Hip-joint, 357 ; muscles of, 518 ; in relation with, 360 ; surface form of, 361 ; surgical anatomy of, 361
Hippocampus major, 756 ; minor, 753
Horizontal plate of ethmoid, 164 ; of palate, 177
Horner's muscle, 392
Houston's valves of rectum, 989
Howship's lacunæ, 26
Huguier, canal of, 153, 906
Humerus, 231 ; anatomical neck, fracture of, 237 ; articulations of, 236 ; attachment of muscles to, 236 ; development of, 235 ; head of, 231 ; neck of, 231 ; nutrient artery of, 608 ; shaft, fracture of, 504 ; surgical neck, fracture of, 504 ; tuberosities of, greater, 231 ; lesser, 232 ; surface form of, 236 ; surgical anatomy, 237
Humours of the eye, 892
Hunter's canal, 645
Huxley's layer of hair follicle, 65
Hyaline cartilage, 21 ; cell, 4
Hyaloid membrane of eye, 892
Hydatid of Morgagni, 114
Hymen, 1101
Hyo-epiglottic ligament, 1034
Hyo-glossal membrane, 867, 871
Hyo-glossus muscle, 413
Hyoid arch (fœtal), 93 ; artery of superior thyroid, 560 ; bone, 209 ; attachment of muscles to, 210 ; cornua of, 210 ; development of, 210 ; branch of lingual artery, 561 ; region, muscles of, infra, 409 ; supra, 411
Hyparterial branch of bronchus, 1042
Hypoblast, 76, 79
Hypochondriac regions, 947
Hypogastric arteries in fœtus, 104, 634, 1028 ; how obliterated, 1031 ; plexus, 865 ; inferior, 865 ; region, 948
Hypoglossal nerve, 809 ; surgical anatomy, of, 812
Hypophysis cerebri, 749 ; of pituitary body, 95

Ileo-cæcal fossa, 983 ; valve, 983
Ileo-colic artery, 626 ; fossa, 983
Ileum, 975
Iliac arteries, common, 631 ; peculiarities, 631 ; surgical anatomy of, 632 ; surface marking of, 632 ; external, 642 ; surgical anatomy of, 642 ; surface marking of, 642 ; internal, 633 ; peculiarity in the fœtus, 634 ; at birth, 634 ; surgical anatomy of, 634 ; fascia, 507 ; portion of fascia lata, 512 ; fossa, 262 ; furrow, 270 ; lymphatic glands, 706 ; region, muscles of, 507 ; veins, common, 691 ; peculiarities of, 691 ; external, 690 ; internal, 690
Iliacus muscle, 508
Ilio-costalis muscle, 435
Ilio-femoral ligament, 358
Ilio-hypogastric nerve, 838
Ilio-inguinal nerve, 839
Ilio-lumbar artery, 640 ; ligament, 330 ; vein, 691
Ilio-pectineal eminence, 264
Ilio-tibial band, 511, 512
Ilio-trochanteric ligament, 358
Ilium, 259 ; crest of, 262 ; dorsum of, 260 ; spines of, 262 ; venter of, 262
Impressio colica, 994 ; duodenalis, 994 ; renalis, 994
Incisive foramina, 193 ; fossa, 169, 183
Incisor teeth, 923
Incisura intertragica, 902 ; cerebelli posterior or marsupialis, 769 ; anterior or semilunaris, 769 ; Rivini, 906, 909 ; Santorini, 904
Incremental lines of dentine, 928
Incus, 909 ; development of, 99 ; ligament of, 909 ; suspensory, 910
Infantile hernia, 1126
Inferior dental artery, 570 ; dental canal, 184 ; maxillary bone, 183 ; changes produced by age in, 186 ; meatus of nose, 204 ; occipital fossa, 143 ; profunda artery, 608 ; turbinated bones, 180 ; articulations of, 181 ; development of, 181 ; ethmoidal process of, 181 ; lachrymal process of, 181 ; maxillary process of, 181 ; vena cava, 691
Inferior posterior lobe of cerebellum, 770
Infracostal muscles, 442
Infraglenoid tubercle, 228
Inframaxillary nerves from facial, 800
Infra-orbital artery, 571 ; canal, 170 ; foramen, 170 ; groove, 170 ; plexus of nerves, 786 ; branches of facial, 799
Infraspinatus muscle, 476
Infraspinous fascia, 475 ; fossa, 225

Infra-sternal depression, 219
Infratrochlear nerve, 784
Infundibula of kidney, 1069
Infundibuliform fascia, 457, 1121
Infundibulum of brain, 749; of ethmoid, 166; of cochlea, 913; of heart, 1020
Ingrassias, processes of, 161
Inguinal canal, 1120; glands, deep, 704; superficial, 704, 1116; hernia, 1115; region, 948; dissection of, 1115
Inlet of pelvis, 268
Innominate artery, 553; peculiarities of, 553; surgical anatomy of, 554; bone, 259; articulations of, 266; attachment of muscles to, 266; development of, 265; veins, 683; peculiarities of, 684
Inorganic constituents of bone, 30
Insertion of muscles, 385
Inspiration, muscles of, 446
Interarticular fibro-cartilage, 23; of acromio-clavicular joint, 337; of jaw, 321; of knee, 366; of radio-ulnar joint, 349; of sterno-clavicular joint, 335; ligament of ribs, 324
Intercarotid ganglion, 859
Intercellular substance of cartilage, 22; biliary passages, 1001
Interchondral ligaments, 328
Interclavicular ligament, 335
Intercolumnar fascia, 450, 1117; fibres, 450
Intercondyloid notch, 275
Intercostal arteries, 619; anterior, 596; superior, 598; fasciæ, 441; lymphatics, 710; lymphatic glands, 709; muscles, 441; nerves, 834; spaces, 215; veins, superior, 684
Intercosto-humeral nerves, 827, 835
Interglobular spaces, 928
Interlobular arteries of kidney, 1066
Interlobular biliary plexus, 1001
Intermaxillary suture, 199
Intermediate cell mass, 111
Intermediate disc of muscular fibre, 37
Intermembranous ossification, 34
Internal abdominal ring, 1121; annular ligament, 535; capsule, 754; carotid artery, 574; cutaneous nerve, 826; inguinal hernia, 1123; mammary artery, 596; maxillary artery, 568; branches of, 569; mammary vein, 684; oblique muscle, 451; occipital crest, 143; pterygoid plate, 162; sphincter, 459
Internasal suture, 199
Internodia, or phalanges, 256
Internodal segment of nerves, 43
Interossei muscles, dorsal of hand, 499; of foot, 541; palmar, 500; plantar, 541
Interosseous artery of forearm, 614; recurrent, 615; of foot, 660
Interosseous fibro-cartilages, 307
Interosseous membrane of forearm, 348; of leg, 372
Interosseous nerve, anterior, 827; posterior, 831
Interosseous veins of forearm, 682
Interpeduncular space of brain, 749
Interspinales muscles, 438
Interspinous ligaments, 314
Intertransversales muscles, 438; laterales, 438; mediales, 438
Intertransverse ligaments, 314
Intertrochanteric line, anterior, 273; posterior, 274
Intertubular stroma of kidney, 1068
Intervertebral notches, 121; foramen, 139; substance, 312
Intestine, development of, 108; lymphatics of, 709; large, coats of, 988; small, 973; coats of, 976; surface marking, 990; surgical anatomy of, 990
Intracartilaginous ossification, 30
Intralobular veins, 1000
Intramembranous ossification, 34
Intraparietal fissure, 739
Intrinsic muscles of tongue, 415
Intumescentia ganglioformis, 797
Investing mass of Rathke, 91
Involuntary muscle, 39
Iris, 885
Irregular bones, 120
Ischiatic lymphatic glands, 704
Ischio-capsular ligament, 358
Ischio-rectal fascia, 1146; fossa, 1137; position of vessels and nerves in, 1137; region, surgical anatomy of, 1137
Ischium, 262; body of, 262; ramus of, 263; spine of, 263; tuberosity of, 263
Island of Reil, 742
Isthmus of the fauces, 934; of thyroid gland, 1055
Iter a tertio ad quartum ventriculum, 761; chordæ anterius, 798; posterius, 798
Ivory of tooth, 927

Jacob's membrane, 890
Jacobson's nerve, 803, 911; canal for, 156; organ of, 876; cartilage of, 876
Jaw, lower, 183; condyle of, 185; changes produced in, by age, 186; development of, 185; articulations of, 186; ligaments of, 320; attachment of muscles to, 186; oblique line of, 184; pterygoid fossa of, 185; rami of, 184; sigmoid notch of, 185; symphysis of, 183; upper, *see* Maxillary Bone
Jejunum, 975
Jelly of Wharton, 88
Joint. *See* Articulations
Jugular foramen, 193; fossa, 156, 195; ganglion, 803; process, 143; vein, anterior, 671; external, 670; surgical anatomy of, 671; posterior external, 671; internal, 671; surgical anatomy of, 672; sinus or gulf of, 671; surface, 157

Karyokinesis, 10
Karyomitosis, 10
Kerkring, valves of, 976
Kidney, 1060; calices of, 1062; cortical substance of, 1062; development of, 110; ducts of, 1069; hilum of, 1061; infundibula of, 1062; lymphatics of, 708, 1068; Malpighian bodies of, 1063; mammillæ of, 1062; medullary substance, 1062; nerves of, 1068; papillæ of, 1062; pelvis of, 1062; pyramids of Ferrein, 1064; renal artery, 628, 1066; sinus of, 1061; surface marking of, 1068; surgical anatomy of, 1069; tubuli uriniferi, 1063; veins of, 693, 1067; weight and dimensions of, 1060

Knee-joint, 363; surface form of, 370; surgical anatomy of, 370
Krause's membrane, 37; end bulbs of, 47
Kuhne, his views on the terminations of motor nerves, 50
Küschner, on structure of heart's valves, 1021

Labia cerebri, 751; pudendi majora, 1099; minora, 1100; lymphatics of, 707
Labial artery, 564; glands, 922; veins, superior, 669; inferior, 669
Labio-dental strand, 929
Labium tympanicum, 916; vestibulare, 916
Labyrinth, 914; arteries of, 918; fibro-serous membrane of, 918
Lachrymal apparatus, 899; artery, 578; bone, 174; articulations of, 175; attachment of muscles to, 175; development of, 175; canals, 899; caruncula, 899; crest, 174; fossa, 150; gland, 899; groove, 172; nerve, 783; notch, 170; papilla, 899; process of inferior turbinated bone, 181; puncta, 899; sac, 900; tubercle, 172
Lacteals, 697, 709, 978
Lactiferous ducts, 1113
Lacuna magna, 1081
Lacunæ of bone, 28; Howship's, 26
Lacus lachrymalis, 896, 899
Lambda, 189
Lambdoid suture, 188
Lamella, horizontal, of ethmoid, 164; perpendicular of ethmoid, 164
of bone, articular, 305
Lamellæ of bone, 28
Lamina cinerea, 748; cribrosa, 155; cribrosa of sclerotic, 880; fusca, 880; spiralis ossea of cochlea, 913; suprachoroidea, 883; vitrea, 884
Lamina of cornea, elastic, 882; of the vertebræ, 121; cerebellum, 768
Laminæ dorsales, 80, 88
Laminated tubercle of cerebellum, 771
Lancisi, nerves of, 751
Lanugo (fœtal hairs), 100
Large intestine, 982; areolar coat, 989; cæcum, 982; colon, 984; ileo-cæcal valve, 983; mucous coat, 989; muscular coat, 988; rectum, 987; serous coat, 988
Laryngeal artery, inferior, 594; superior, 560; nerve, external, 807; internal, 807; recurrent, 807, superior, 807, from sympathetic, 858: pouch, 1037; veins, 671; nerves, surgical anatomy of, 808
Laryngo-tracheotomy, 1044
Laryngotomy, 1045
Larynx, 1032; actions of muscles of, 1039; arteries of, 1040; cartilages of, 1032; cavity of, 1036; glands of, 1040; interior of, 1036; ligaments of, 1035; lymphatics of, 1040; mucous membrane of, 1040; muscles of, 1038; nerves of, 1040; rima glottidis, 1036; superior aperture of, 1036; surface form of, 1044; surgical anatomy of, 1044; veins of, 1040; ventricle of, 1037; vocal cords of, false, 1037; true, 1037
Lateral disc of muscular fibre, 37; ligaments of liver, 995; masses of ethmoid, 164; patellar ligaments, 364; recess of fourth ventricle, 774; region of skull, 196; sinus of brain, 676; horn of spinal cord, 721; tract of medulla oblongata, 729, 731
Lateralis nasi artery, 564
Latissimus dorsi muscle, 429
Lecithin, 3
Leg, arteries of, 652
bones of, 279
fascia of, 525; deep transverse, 530
ligaments of, 371
lymphatics of, 704
muscles of, 525; back of, 528; front of, 525
nerves of, 850
veins of, 687
Lens, 893; changes produced in, by age, 894; development of, 98; suspensory ligament of, 894
Lenticular ganglion, 784; glands of stomach, 971
Lesser lachrymal bone, 175; omentum, 964; sciatic nerve, 847; wings of sphenoid, 160
Levator anguli oris, 397; anguli scapulæ, 430; ani, 459; glandulæ thyroideæ, 1056; labii inferioris, 397; labii superioris alæque nasi, 396; labii superioris, 396; menti, 397; palati, 420, palpebræ, 392; prostatæ, 460
Leucocytes, 3; development of, 99
Levatores costarum, 443
Lieberkühn, crypts of, 979
Lieno-renal ligament, 1008
Ligament, structure of, 305; acromio-clavicular, superior, 336; inferior, 336; alar of knee, 367; of ankle, anterior, 373; lateral, 373; annular of radius, 348; of wrist, anterior, 351; posterior, 351; of ankle, 534; external, 535; internal, 535, of stapes, 909; anterior of knee, 363; arcuate, 444; arytenoepiglottic, 1034; astragalo-navicular, 378; atlanto-axial, anterior, 315; posterior, 316
of bladder, false, 1077; true, 1076
broad, of liver, 995
calcaneo-astragaloid, external, 376; posterior, 377; interosseous, 377; calcaneo-cuboid, internal, 377; long, 377; short, 377; superior, 377; calcaneo-navicular, inferior, 378; superior, 378; capsular (*see* Individual Joints); carpo-metacarpal, dorsal, 355; interosseous, 355; palmar, 355; of carpus, 352; central of spinal cord, 714; check, 319; common vertebral anterior, 311; posterior, 312; conoid, 337; coraco-acromial, 338; coraco-clavicular, 337; coraco-humeral, 340; coracoid, 339; coronary of liver, 995; costo-clavicular, 335; chondro-sternal, anterior, 326; posterior, 327; costo-transverse, 325; costo-vertebral, or stellate, 323; cotyloid, 359; crico-arytenoid, 1036; crico-thyroid, 1035; crucial of knee, 365; cruciform, 316
deltoid, 373; dorsal (*see* Individual Joints) of elbow, 343; anterior, 343; external lateral, 345; internal lateral, 344; posterior, 344
falciform of liver, 995; of pelvis, 332
gastro-phrenic, 968; Gimbernat's, 450; 1118, 1132; glenoid, 340; glosso-epiglottidean, 867, 1035

Ligament (*continued*)
of Hesselbach, 455
of hip, 357; hyo-epiglottic, 1034
ilio-femoral, 358, ilio-lumbar, 330; ilio-trochanteric, 358; of incus, 909; interarticular of ribs, 324; interclavicular, 335; interchondral, 328; interosseous (*see* Individual Joints); interspinous, 314; intertransverse, 314; intervertebral, 312; ischio-capsular, 358
of jaw, 320
of knee, 363
of larynx, 1035; lateral (*see* Individual Joints); longitudinal of liver, 995; long plantar, 377; lumbo-iliac, 330; lumbo-sacral, 330
metacarpal, 356; metacarpo-phalangeal, 356; metatarsal, 381; metatarso-phalangeal, 382; mucosum of knee, 367; of malleus, 909
nuchæ, 429
oblique, 348; oblique sacro-iliac, 331; obturator, 521; occipito-atlantal, anterior, 317; lateral, 318; posterior, 318; occipito-axial, 318; odontoid, 319; orbicular, 348; of ossicula, 909; of ovary, 1112
palpebral or tarsal, 897; of patella, 363; of pelvis, 330; of the phalanges, hand, 357; foot, 383; phreno-colic, 966; of the pinna, 903; plantar, 377; posterior of knee, or posticum Winslowii, 364; Poupart's, 450, 1118, 1131; pterygo-maxillary, 399; pubic, anterior, 333; posterior, 333; superior, 333; subpubic, 333; pubo-femoral, 358; pubo-prostatic, 1077
radio-carpal, 350; radio-ulnar joint, inferior, 349; middle, 348; superior, 347; recto-uterine, 1104; rhomboid, 335; round, of uterus, 1112; of liver, 996; of radius and ulna, 347; of hip, 357
sacro-coccygeal, anterior, 332; posterior, 332; sacro-iliac, anterior, 331; oblique, 331; posterior, 331; sacro-sciatic, greater, 331; lesser, 332; sacro-uterine, 1105; sacro-vertebral, 329; of scapula, 338; scapulo-clavicular, 336; of shoulder, 339; spring, 378; stellate, 323; sterno-clavicular, anterior, 334; posterior, 335; of sternum, 328; stylo-maxillary, 321; subpubic, 333; supra-spinatus, 314; suspensory of incus, 910; of lens, 894; of liver, 995; of malleus, 909; of mamma, 468; of penis, 1085; of spleen, 1008; sutural, 307
tarsal of eyelids, 391, 897
tarso-metatarsal, 380; of tarsus, 376; teres of hip, 359; thyro-arytenoid, inferior, 1037; superior, 1037; of thumb, 354; tibio-tarsal, 373; thyro-epiglottic, 1034; thyro-hyoid, 1035; tibio-fibula, 371; transverse of atlas, 316; of hip, 360; of knee, 366; of scapula, 339; transverse humeral, 340; trapezoid, 337; triangular of urethra, 1140; of tympanic bones, 909
of uterus, 1104
of vertebræ, 311; vesico-uterine, 1104
Ligament (*continued*)
of Winslow, 364; of wrist, anterior, 351; lateral external, 351; lateral internal, 351; posterior, 351
of Zinn, 393
Ligamenta alaria, 367; subflava, 313; suspensoria of mamma, 468
Ligamentous action of muscles, 310
Ligamentum arcuatum externum, 444; internum, 444; denticulatum, 714; latum pulmonis, 1046; mucosum, 367; nuchæ, 429; oculi, 879; patellæ, 363; pectinatum iridis, 882, 885; posticum Winslowii, 364; spirale, 916; suspensorium, 319; teres, 359
Ligature of arteries. *See each* Artery.
Ligula, 775
Limbs, development of, 100
Limbus laminæ spiralis, 916; luteus, 887
Linea alba, 456; aspera, 274; ilio-pectinea, 264; quadrata, 274; splendens, 714; suprema, 142
Lineæ semilunares, 456; transverse of abdomen, 456
Lines of Schreger, 928
Lingual artery, 561; surgical anatomy of, 562; bone, 209; ganglion, 859; lobule, 744; nerve, 792; strand, 929; veins, 672
Lingualis muscle, inferior, 417; superior, 416; transverse, 416; vertical, 416
Lingula, 770, 772; of inferior maxilla, 184; of sphenoid, 159
Lips, 921; arteries of, 564
Liquor, amnii, 85; Cotunnii, 918; Scarpæ, 915; sanguinis, 5
Lithotomy, parts concerned in operation of, 1143; avoided in operation, 1144; divided, 1144
Littré, glands of, 1081
Liver, 993; changes of position in, 1003; development of, 110; distribution of vessels to, in fœtus, 1029; ducts of, 1001; fibrous coat of, 998; fissures of, 996; hepatic artery, 623, 1000; hepatic cells, 999; hepatic duct, 1002; hepatic veins, 693, 1,000; ligaments of, 995; lateral, 995; coronary, 995; round, 996; longitudinal, 995; lobes of, 997; lobules of, 998; lymphatics of, 708; nerves of, 864; portal vein, 695; situation, size, and weight, 993; structure of, 998; its surfaces and borders, 993; surface marking of, 1003; vessels of, 999; surgical anatomy, 1004
Liver ridge, 952
Lobe, central, 742; cuneate, 744; frontal, 738; marginal, 744; occipital, 741; orbital, 738; parietal, 739; quadrate, 744; temporo-sphenoidal, 741; uncinate, 744
Lobes of cerebrum, 737; of cerebellum, 768; of liver, 997; of lung, 1049; of nose, 874; of prostate, 1084; of testis, 1093; of thyroid, 1055; of thymus, 1057; of kidney, 1061
Lobule of the ear, 902
Lobules of liver, 998; of lung, 1051; of kidney, 1061
Lobuli testes, 1093
Lobus centralis, 770; Spigelii, 997
Lobus caudatus, 997; clivi, 770; culminis, 770; quadratus, 997

Locus cæruleus, 776; niger, 750
Long bones, 119
Long saphenous nerve, 842
Longissimus dorsi muscle, 435
Longitudinal fissure, of brain, 735, 748; of liver, 996; ligament of liver, 995; sinus of brain, superior, 675; inferior, 676
Longus colli muscle, 424
Looped tubes of Henle, 1064
Lower extremity, arteries of, 644; bones of, 259; fascia of, 506; lymphatics of, 704; ligaments of, 357; muscles of, 506; nerves of, 837; veins of, 687; surface form of muscles of, 542
Lower, tubercle of, 1020
Lumbar arteries, 629; fascia, 432; ganglia, 860; glands, 707; nerves, 836; anterior divisions of, 837; posterior divisions of, 836; roots of, 836; plexus of nerves, 837; surgical anatomy of, 852; regions, 948; vein, ascending, 692; veins, 692; vertebræ, 127; development of, 131
Lumbo-iliac ligament, 330
Lumbo-sacral ligament, 330; nerve, 837;
Lumbricales muscles, hand, 499; foot, 539
Lungs, 1049; air-cells of, 1052; bronchial, arteries, 1054; veins, 1054; development, 110; capillaries of, 1052; in fœtus, 1031; lobes and fissures of, 1049; lobules of, 1051; lymphatics of, 710, 1054; nerves of, 1054; pulmonary artery, 1052; veins, 1052; root of, 1050; structure of, 1051; surface marking of, 1054; surgical anatomy of, 1055; weight, colour, etc., 1049
Lunula of lip, 92
Lunulæ of nails, 64
Luschka's gland, 630
Lymph, 6
Lymph path or sinus, 60
Lymphatic duct, right, 699
Lymphatic Glands, *General Anatomy of*, 58
Descriptive Anatomy:
anterior mediastinal, 710; auricular posterior, 699; axillary, 702
brachial, 702; bronchial, 710; buccal, 699
cervical, deep, 702; superficial, 701
in front of elbow, 702
gluteal, 704
of head, 699
iliac, external, 706; internal, 707; inguinal, deep, 704; superficial, 704; intercostal, 709; internal mammary, 709; ischiatic, 704
of large intestine, 709; of lower extremity, 704; lumbar, 707
of neck, 701
occipital, 699
parotid, 699; of pelvis, 706; popliteal, 704
radial, 702
sacral, 707; of small intestines, 709; of spleen, 709; of stomach, 709; submaxillary, 701
of thorax, 709; tibial anterior, 704
ulnar, 702; of upper extremity, 702
zygomatic, 699
Lymphatics, *General Anatomy of*, 57; origin of, 58; plexus of, 58; subdivision into deep and superficial, 697; terminations of, 58; valves of, 57
Descriptive Anatomy:
abdomen, 707; arm, 703
bladder, 708; cone, 27; broad ligaments, 708; cardiac, 710; cerebral, 701; cervical, superficial, and deep, 702; chest, 710; of clitoris, 707; of cranium, 701;
diaphragm, 710
face, superficial, 700; deep, 700; Fallopian tubes, 708
gluteal region, 707
head, superficial, 699; heart, 710
intercostal, 710; internal mammary, 710; intestines, 709
kidneys, 708
labia, 707; lacteals, 709; large intestine, 709; leg, 705; liver, 708; lower extremity, 705; lung, 710; lymphatic duct, 699
meningeal, 701; mouth, 700
neck, 699; nose, 700; nymphæ, 707
œsophagus, 711; ovaries, 708
pancreas, 709; pelvis, 707; penis, 707; perinæum, 707; pharynx, 702; pia mater, 701; prostate, 708
rectum, 708
scrotum, 707; small intestine, 709; spleen, 709; stomach, 709
testicle, 708; thoracic duct, 698; thorax, 709; thymic, 711; thyroid, 711
upper extremity, 702; superficial, 703; deep, 704; uterus, 708
vagina, 708
Lymphocyte, 4
Lymphoid connective tissue, 19; of tongue, 871; of tonsil, 935
Lyra of fornix, 758

Macula cribrosa, 912; germinativa, 73; lutea, 887
Magnum of carpus, 252
Majendie, foramen of, 713
Malar bone, 175; articulations of, 177; attachment of muscles to, 177; development of, 176; foramina, 175; frontal process of, 175; maxillary process of, 176; orbital process of, 175; zygomatic process of, 176; canals, 175; nerves, from facial, 799; process of superior maxillary, 172
Male urethra, 1080
Malleolar arteries, external and internal, 659
Malleolus, external, 286; internal, 283
Malleus, 908; development of, 99; suspensory ligament of, 909
Malpighi, pyramids of, 1062
Malpighian bodies of kidney, 1063; tufts, 1063; capsules, 1063; bodies of spleen, 1011
Mamma, areola of, 1112; lobules of, 1113; nerves of, 1114; nipple or mammilla of, 1112; vessels of, 1114
Mammæ, development of, 100
Mammary artery, internal, 596; glands, 1112; lymphatic glands, 710; veins, internal, 684
Mammilla of breast, 1112; of kidney, 1062
Mammillary processes, 129

Mandibular arch, 93 ; nerve, 800
Manubrium of sternum, 211 ; of malleus, 908
Marginal lobe, 744
Marrow of bone, 25
Marshall, vestigial fold of, 684
Masseter muscle, 400
Masseteric arteries, 570 ; fascia, 400 ; nerve, 791 ; veins, 669
Masto-occipital suture, 188
Masto-parietal suture, 188
Mastoid antrum, 154 ; opening of, 907 ; cells, 154 ; foramen, 153 ; portion of temporal bone, 153, 197 ; process, 154 ; vein, 670
Matrix of nail, 64
Maxillary arch, fœtal, 92 ; artery, internal, 568 ; bone, inferior, 183 ; superior, 169 ; development of, 173 ; nerve, inferior, 790 ; superior, 786 ; process of inferior turbinated, 181 ; malar bone, 176 ; processes (fœtal), 92 ; sinus, 171 ; tuberosity, 170 ; vein, internal, 670
Meatus auditorius externus, 155, 904 ; internus, 155 ; of nose, inferior, 204, 876 ; middle, 203, 876 ; superior, 203, 876 ; urinarius, male, 1081 ; female, 1101
Meatuses of the nose, 203, 876
Meckel's cartilage, 93 ; diverticulum, 976 ; ganglion, 788
Median artery of forearm, 615 ; of spinal cord, 592 ; nerve, 827 ; surgical anatomy of, 831 ; vein, 681
Median disc of Hensen, 38
Mediastinal arteries, from internal mammary, 596 ; posterior, from aorta, 619 ; lymphatic glands, 710
Mediastinum, anterior, 1049 ; middle, 1049 ; posterior, 1049 ; superior, 1048 ; testis, 1093
Medio-tarsal joint, 375, 379
Medulla Oblongata, 728 ; pyramids of, 728 ; arcuate fibres of, 730 ; back of, 730 ; fissures of, 728 ; formatio reticularis of, 733 ; funiculus cuneatus of, 729, 731 ; funiculus of Rolando of, 729 ; funiculus gracilis of, 731 ; grey matter of, 733 ; lateral column, 729 ; tract, 731 ; olivary body of, 729 ; pyramids of, 728 ; restiform bodies of, 729 ; raphé of, 732 ; structure of, 730
Medulla spinalis, 714
Medullary artery of bone, 26 ; canal of bone, 25, 119 ; membrane of bone, 25 ; plates, 80 ; sheath of nerve fibres, 43 ; spaces of bone, 32 ; portion of kidney, 1062 ; of suprarenal capsules, 1072 ; velum inferior of cerebellum, 771, 775 ; velum superior, 772, 775
Medullary canal of bone, formation of, 34
Medullary canal of spine, development of, 80, 93
Medullated nerve fibres, 42
Medulli-spinal veins, 687
Meibomian glands, 897
Meissner's plexus, 982
Membrana basilaris, 916 ; granulosa of Graafian vesicle, 1111 ; limitans of retina, 888, 890 ; nictitans, 899 ; pupilaris, 887 ; sacciformis, 349, 355 ; tectoria, 916 ; tympani, 908 ; tympani secundaria, 907, 913
Membrane of aqueous chamber, 882 ; arachnoid, spinal, 713 ; cerebral, 725 ; choroid, 883 ; of Corti, 916 ; costo-coracoid, 470 ; crico-thyroid, 1035 ; of Descemet, 881 ; fenestrated, 52 ; hyaloid, 892 ; Jacob's, 890 ; of Kölliker, 917 ; limiting, 888, 890 ; pituitary, 875 ; pupillary, 887 ; of Reissner, 916 ; thyro-hyoid, 1035 ; Schneiderian, 875
Membranes of Spinal Cord, 712 ; of brain, 723 ; of fœtus, 84
Membranous labyrinth, 914 ; portion of urethra, 1081 ; semicircular canals, 915
Meningeal artery, from ascending pharyngeal, 567 ; anterior, from internal carotid, 577 ; middle, from internal maxillary, 569 ; from occipital, 565 ; posterior, from vertebral, 592 ; small, from internal maxillary, 570 ; lymphatics, 701 ; veins, 670, 723
Meninges. *See* Membranes
Menisci, 23
Mental foramen, 183, 199 ; process, 183, 199 ; tubercles, 183
Mesencephalon, 94
Mesenteric artery, inferior, 627 ; superior, 625 ; glands, 708 ; plexus of nerves, inferior, 865 ; superior, 864 ; vein, inferior, 693 ; superior, 693
Mesenteries, 965
Mesoblast, 76, 79
Mesoblastic somites, 81
Meso-cæcum, 965
Meso-cardium, anterius, 952 ; posterius, 952
Meso-colon, ascending, 965 ; descending, 965 ; transverse, 966
Mesoderm, 79
Mesogastrium, 951, 954
Mesonephros, 111
Mesorchium, 113
Meso-rectum, 966
Meso-sternum, 211
Mesovarium, 113
Metacarpal artery, 612 ; articulations, 356
Metacarpo-phalangeal articulations, 356
Metacarpus, 253 ; common characters of, 253 ; development of, 259 ; peculiar bones of, 254
Metanephros, 111
Metatarsal artery, 660
Metatarsal articulations, 381 ; bones, 297
Metatarso-phalangeal articulations, 382
Metatarsus, 297 ; development of, 300
Metasternum, 213
Metencephalon, 94
Middle and internal frontal artery, 581
Middle clinoid processes, 158 ; ear, or tympanum, 905 ; fossa of skull, 191 ; meatus of nasal fossæ, 203, 876 ; odontoid ligament, 319
Mid-carpal joint, 353
Mid-frontal process (fœtal), 92
Mid-gut, development of, 109
Mid-kidney, 111
Milk teeth, 926
Mitral valve, 1024
Mixed bones, 120
Modiolus of cochlea, 913
Mohl, glands of, 897
Molar glands, 922 ; teeth, 925
Monaster or mother star, 10

Mons Veneris, 1099
Morgagni, hydatid of, 114; sinus of, 419
Motor nerves, 49
Motor oculi nerve, 779; surgical anatomy of, 781
Motorial end plates, 50
Mouth, 921; mucous membrane of, 921; muscles of, 398; surface form of, 940
Movement admitted in joints, 308
Mucilaginous glands, 306
Mucoid cellular tissue, 18
Mucous glands of tongue, 870; membrane, 69
Müller, duct of, 111; fibres of, 890
Multicuspidati teeth, 925
Multifidus spinæ muscle, 437
Munro, foramen of, 761
Muscle, *General Anatomy of*, 35; of animal life, 35; arrangement of fibres of, 36; bipenniform, 384; blood-vessels of, 39; chemical composition of, 40; derivation of names, 385; development of, 101; fasciculi of, 36; fibrils of, 37; fibres of, 36; form of, 384; fusiform, 384; insertion of, 385; involuntary, 39; lymphatics of, 39; meaning of the terms 'origin' and 'insertion,' 385; mode of connection of, with bone, cartilage, skin, etc., 385; nerves of, 39, 49; of organic life, 39; origin of, 385; penniform, 384; quadrilateral, 384; rhomboidal, 384; sarcous elements of, 38; sheath of, 36; size of, 385; striped, 36; structure of, 36; tendons of, 385; triangular, 384; unstriped, 39, voluntary, 36
Muscle-plates, 101
Muscles or Muscle, *Descriptive Anatomy*:
of abdomen, 447; abductor minimi digiti, (hand) 498; (foot) 538; indicis, 500; pollicis, 495; hallucis, 537; accelerator urinæ, 463; accessorii orbicularis oris, 398; accessorius pedis, 538; accessorius ad ilio-costalem, 435; adductor brevis, 517, longus, 516, magnus, 517; obliquus pollicis, 496; transversus pollicis, 497; obliquus hallucis, 539; transversus hallucis, 540; anconeus, 489; antitragicus, 903; aryteno-epiglottideus, inferior, 1039; superior, 1039; arytenoideus, 1038; arytenoideus rectus (*footnote*), 1039; attollens aurem, 390; attrahens aurem, 390; azygos uvulæ, 421
biceps (arm), 478; (thigh), 524; biventer cervicis, 436; brachialis anticus, 479; buccinator, 399
cervicalis ascendens, 435; chondro-glossus, 414; ciliary of eye, 887; circumflexus palati, 421; coccygeus, 460; complexus, 436; compressor narium minor, 396; nasi, 396; sacculi laryngis, 1039; urethræ, 465; in female, 467; constrictor isthmi faucium, 415; pharyngis inferior, 418; medius, 418; superior, 419; coraco-brachialis, 478; corrugator supercilii, 391; cutis ani, 459; of cranial region, 387; cremaster, 452; crico-arytenoideus lateralis, 1038; posticus, 1038; crico-thyroid, 1038; crureus, 514
deltoid, 473; depressor anguli oris, 398;
Muscles or Muscle (*continued*)
depressor alæ nasi, 396; epiglottidis, 1039; labii inferioris, 397; diaphragm, 443; digastric, 411; dilatator naris, anterior, 396; posterior, 396
of external ear, 389; erector clitoridis, 466; penis, 464; spinæ, 434; external sphincter, 459; extensor brevis digitorum, 536; carpi radialis brevior, 487; longior. 487; ulnaris, 489; coccygis, 438; digitorum communis, 488; indicis, 491; longus digitorum, 527; minimi digiti, 488; ossis metacarpi pollicis, 489; brevis pollicis, 491; proprius hallucis, 527; longus pollicis, 491
of face, 386; femoral region, anterior, 509; internal, 515; posterior, 524; fibula region, 533; flexor accessorius, 538; brevis minimi digiti, of hand, 499; of foot, 540; hallucis, 539; digitorum, 537; pollicis, 496; carpi radialis, 482; ulnaris, 482; digitorum sublimis, 483; longus digitorum, 532; pollicis, 485; hallucis, 531; ossis metacarpi pollicis, 495; profundus digitorum, 484
gastrocnemius, 528; gemellus superior, 522; inferior, 522; genio-hyo-glossus, 413; genio-hyoid, 412; gluteus maximus, 518; medius, 519; minimus, 520; gracilis, 515
of hand, 492; of head and face, 386; helicis, major, 903; minor, 903; Hilton's, 1039; Horner's, 392; hyo-glossus, 413
iliac region, 507; iliacus, 508; ilio-costalis, 435; infracostal, 442; infraspinatus, 476; intercostal, 441; internal sphincter, 459; interossei of foot, 540; of hand, 499; interspinales, 438; intertransversales, 438
labial, 396; of larynx, 1038; latissimus dorsi, 429; of leg, 525; levator anguli oris, 397; ani, 459; anguli scapulæ, 430; glandulæ thyroideæ, 1056; labii inferioris, 397; labii superioris alæque nasi, 396; labii superioris, 396; menti, 397; palati, 420; palpebræ, 392; prostatæ, 460; levatores costarum, 443; lingualis, 410; longissimus dorsi, 435; longus colli, 424; lumbricales (hand), 499; (foot), 539
masseter, 400; multifidus spinæ, 437; musculus accessorius ad ilio-costalem, 435; mylo-hyoid, 412
naso-labialis, 398; of neck, 403
obliquus auris, 903; abdominis externus, 448; internus, 451; capitis superior, 439; inferior, 439; oculi, inferior, 394; superior, 393; obturator externus, 522; internus, 521; occipito-frontalis, 388; omo-hyoid, 410; opponens minimi digiti, 499; pollicis, 495; orbicularis oris, 398; palpebrarum, 390
of palate, 420; palato-glossus, 421; palato-pharyngeus, 421; palmaris brevis, 497; longus, 482; pectineus, 516; pectoralis major, 468; minor, 470; of perinæum, male, 461; female, 465; peroneus brevis, 533; longus, 533; tertius 528; of pharynx, 418; plantaris, 530;

Muscles or Muscle (*continued*)
platysma myoides, 404; popliteus, 531; pronator quadratus, 485; radii teres, 482; psoas magnus, 508; parvus, 508; pterygoid, internal, 402; external, 401; pyramidalis abdominis, 455; nasi, 395; pyriformis, 520
quadratus femoris, 522; lumborum, 458; menti, 397; quadriceps extensor cruris, 513
rectus abdominis, 453; capitis anticus major, 423; minor, 423; posticus major, 438; minor, 438; femoris, 513; oculi, externus, superior, inferior, and internus, 393; lateralis, 424; retrahens aurem, 390; rhomboideus major, 431; minor, 430; risorius, 399; rotatores spinæ, 437
sacro-lumbalis, 435; salpingo-pharyngeus, 421; sartorius, 512; scalenus anticus, 424; medius, 424; posticus, 425; semimembranosus, 525; serratus posticus, superior, 431; inferior, 432; semi-spinalis dorsi, 437; colli, 437; semi-tendinosus, 524; serratus magnus, 472; sole of foot, 536; first layer, 537; second layer, 538; third layer, 539; fourth layer, 540; soleus, 529; sphincter, external, 459; internal, 459; vaginæ, 465; spinalis dorsi, 436; colli, 436; splenius, 432; capitis, 434; colli, 434; stapedius, 910; sterno-cleido-mastoid, 407; sterno-hyoid, 409; sterno-thyroid, 409; stylo-glossus, 414; stylo-hyoid, 412; stylo-pharyngeus, 419; subanconeus, 489; subclavius, 471; subcrureus, 515; subscapularis, 474; supinator brevis, 489; longus, 486; supraspinales, 438; supraspinatus, 475
temporal, 400; tensor palati, 421; tarsi, 392; tympani, 910; vaginæ femoris, 512; teres major, 477; minor, 476; thyro-arytenoideus, 1039; thyro-epiglottideus, 1039; thyro-hyoid, 410; tibialis anticus, 527; posticus, 532; of tongue, 413; trachelo-mastoid, 435; tragicus, 903; transversalis abdominis, 453; colli, 435; transversus auriculæ, 903; perinæi, 462; (female) 465; profundus, 1145; trapezius, 427; triangularis sterni, 442; triceps extensor cubiti, 480; extensor cruris, 514; femoralis, 514; of tympanum, 910; of ureters, 1078
vastus externus, 514; internus and crureus, 514
zygomaticus major, 397, minor, 397
Muscles of inspiration and expiration, 446; of expression, 403; of pelvic outlet, 459
Muscular columns, 38
Muscular fibres of heart, 40
Muscularis mucosæ, 70
Musculi papillares, left ventricle, 1024; right, 1022; pectinati in left auricle, 1023, in right, 1020
Musculo-cutaneous nerve of arm, 823, from peroneal, 852
Musculo-spiral groove, 233; nerve, 830; surgical anatomy of, 832
Musculo-phrenic artery, 598
Musculus accessorius ad ilio-costalem, 435, incisivus inferior, 399; superior, 398; suspensorius duodeni, 975
Myelo-plaques, 26
Mylo-hyoid artery, 570; groove, 184; muscle, 412; nerve, 792; ridge, 184
Myrtiform fossa, 169

Nails, 64
Nares, anterior, 204, 875; posterior, 204, 875, 941; septum of, 203, 875
Nasal angle, 168; artery, of internal maxillary, 571; transverse, 580; of ophthalmic, 580; of septum, 564, 571; bones, 167; development of, 169; articulations of, 169; cartilages, 874; crest, 168; duct, 900; eminence, 149; fossæ, 201, 875; arteries of, 877; mucous membrane of, 875; nerves of, 878; surgical anatomy of, 878; veins of, 877; groove, 168; nerve, 784; nerves from Meckel's ganglion, 790; notch, 149; process, 172; spine, 149; anterior, 173, 199; posterior, 178; venous arch, 668
Nasion, 199
Nasi, dorsalis, artery, 580
Nasmyth's membrane, 931
Naso-labialis muscle, 398
Naso-maxillary suture, 199
Naso-palatine nerve, 790
Nates of brain, 762
Navicular bone, 294; articulations of, 294; attachment of muscles to, 294; tuberosity of, 294
Neck, glands of, 701; lymphatics of, 702; muscles of, 403; triangle of, anterior, 572, posterior, 573; veins of, 670
Nélaton's line, 278
Nerve-corpuscles, 41
Nerve-epithelium cells, 49
Nerves, *General Anatomy of*, 45; cerebro-spinal, 45; development of, 96; endoneurium of, 45; epineurium of, 45; funiculi of, 45; origin of, 47; perineurium of, 45; plexus of, 46; sheath of, 45; termination of, 47; vessels of, 46; spinal roots of, 812; sympathetic, 46
Nerves or Nerve, *Descriptive Anatomy of*: abducens, 795; accessory obturator, 841; anterior crural, 841; auditory, 801; auricular, posterior, 798; of vagus, 806; auricularis magnus, 818; of auriculo-temporal, 791; of second cervical, 816; of small occipital, 818
of brachial plexus, 820; buccal, 791; of facial, 800
cardiac, middle, 859; inferior, 859; superior, 858; plexus, deep, 861; superficial, 862; of pneumogastric, 808; cavernous, of penis, 865; cervical anterior, 816; posterior, 814; superficial, 818; cervico-facial, 800; chorda tympani, 798, 911; ciliary, long, 784; short, 786; circumflex, 823; coccygeal, 844; cochlear, 802; communicans hypoglossi, 819; peronei, 852; of Cotunnius, 790; cranial, 778; crural anterior, 841; cutaneous (*see that heading*)
deep palmar, 829; deep temporal, 791; dental anterior, 792; anterior superior, 788; middle superior, 788; posterior

Nerves or Nerve (*continued*)
superior, 787; inferior, 792; descendens hypoglossi, 811; digastric from facial, 798; digital (foot), 850, 852; dorsal (hand), 831; dorsal of penis, 849; dorsal spinal, 832; peculiar, 835; dorsi-lumbar, 835; of dura mater, 724
eighth pair, 801; eleventh pair, 809; of eyeball, 778
facial, 796; fifth, 782; fourth, 781; frontal, 783
ganglionic branch of nasal, 784; gastric branches of vagus, 808; genito-crural, 839; glosso-pharyngeal, 802; gluteal, inferior, 847; superior, 846; great petrosal, 788; great splanchnic, 860; gustatory, 792
hæmorrhoidal, inferior, 847; of heart (*see* Cardiac); hepatic, 864; hypoglossal, 809
ilio-hypogastric, 838; ilio-inguinal, 839; incisive, 793; inferior maxillary, 790; inframaxillary of facial, 800; infra-orbital of facial, 799; infratrochlear, 784; intercostal, 834; intercosto-humeral, 835; interosseous, anterior, 827, posterior, 831; ischiadic, great, 849; small, 847
Jacobson's, 803
of labyrinth, 918; labial, 788; lachrymal, 783; of Lancisi, 751; large cavernous, 865; laryngeal, external, 807; internal, 807; recurrent, 807; superior, 807; lesser splanchnic, 860; lingual of fifth, 792; of glosso-pharyngeal, 803; long ciliary, 784; long thoracic, 822; long saphenous, 842; lumbar, 836; lumbo-sacral, 837
malar branch of orbital nerve, 787; of facial, 799; masseteric, 791; maxillary inferior, 790; superior, 786; median, 827; mental, 793; middle cardiac, 859; motor of eye, common, 779; external, 795; musculo-cutaneous of arm, 823; leg, 852; musculo-spiral, 830; mylo-hyoid, 792
nasal, ophthalmic, 784; from Meckel's ganglion, 790; from Vidian, 789; naso-palatine, 790; ninth, 802
obturator, 839; œsophageal, 808; occipital, great, 815; small, 818; of third cervical, 816; of facial, 798; olfactory, 777; ophthalmic, 782; optic, 778; orbital nerves, their relation, 795; in cavernous sinus, 795; in orbit, 796; in sphenoidal fissure, 796; orbital of superior maxillary, 786
palatine, anterior or large, 789; external, 790; posterior or small, 790; palmar, cutaneous, of median, 827; ulnar, 829; palpebral, 788; par vagum, 803; pathetic, 781; perforans Casserii, 823; perineal, 849; superficial, 849; peroneal, 851; petrosal, superficial, external or large, 788; deep, large, 789; deep, small, 711; small, superficial, 711; pharyngeal of pneumogastric, 807; of glosso-pharyngeal, 803; of sympathetic, 858; of Meckel's ganglion, 790; of external laryngeal, 807; phrenic, 819; plantar, cutaneous, 850; external, 851;
Nerves or Nerve (*continued*)
internal, 850; pneumogastric, 803; popliteal external, 851; internal, 849; portio dura, 796; portio inter duram et mollem, 797; portio mollis, 801; posterior auricular, 798; pterygoid, 791; pterygo-palatine, 790; pudendal, inferior, 847; pudic, 847; pulmonary, from vagus, 808
radial, 830; recurrent laryngeal, 807; recurrent to tentorium, 783; renal splanchnic, 860; respiratory, external, 822; internal, 819
sacral, 843; plexus, 845; saphenous long or internal, 842; short or external, 850; sciatic, great, 849; small, 847; short ciliary, 786; sixth, 795; small cavernous, 865; spinal, 812; spinal accessory, 809; splanchnic, great, 860; small, 860; smallest, 860; stylo-hyoid of facial, 798; subclavian, 822; suboccipital, 816; posterior branch of, 814; subscapular, 823; superficialis colli, 818; superior cardiac, 858; maxillary, 786; supra-acromial, 819; supraclavicular, 819; supra-orbital, 784; suprascapular, 822; suprasternal, 819; supratrochlear, 783; supramaxillary of facial, 800; sympathetic, 854
temporal, deep, 791; of facial, 799; of auriculo-temporal, 791; temporo-facial, 799; temporo-malar, 786; tenth, 803; third, or motor-oculi, 779; thoracic posterior, 822; anterior, 823; thyro-hyoid, 812; tibial, anterior, 852; posterior, 850; of tongue, 872; tonsillar, 803; trifacial or trigeminus, 782; trochlear, 781; twelfth, 809; tympanic, of glosso-pharyngeal, 803, 911; of facial, 798
ulnar, 828; uterine, 866
vaginal, 865; vagus, 803; vestibular, 802, 918; Vidian, 789
of Wrisberg, 826
Nervi-nervorum, 46
Nervous substance, chemical analysis, 44; grey, 41; white, 41; vesicular, 41; layer, of retina, 888
Nervous System, *General Anatomy of*, 40; fibrous nervous matter, 41; ganglia, 50; grey or cineritious substance, 41; sympathetic, 46; chemical composition of, 44; gelatinous fibres, 41, 43; vesicular nervous matter, 41; white or medullary substance, 41
Nervus cardiacus magnus, 859; minor, 859; petrosus profundus, 789; superficialis cordis, 858
Neumann, dentinal sheath of, 927
Neural arch, 120; crest, 96; canal, 80
Neurilemma, 42; (*footnote*), 42; of cord, 714
Neuroblasts, 97
Neuroglia, 41; of cord, 718
Nidus hirundinis of cerebellum, 771
Ninth nerve, 802
Nipple, 1112
Nodes of Ranvier, 43
Nodule of cerebellum, 770
Non-medullated nerve-fibres, 43
Nose, 873; arteries of, 877; bones of, 167;

cartilages of, 877; cartilage of septum of, 875; development of, 100; fossæ of, 201, 875; mucous membrane of, 875; muscles of, 395; nerves of, 878; surgical anatomy of, 878; veins of, 877
Notch, cotyloid, 265; ethmoidal, 149, 164; intercondyloid, 275; nasal, 149; sacro-sciatic, greater, 263; lesser, 263; sigmoid, 185; spheno-palatine, 180; supra-orbital, 149; suprascapular, 228
Notochord, 80, 88
Nuck, canal of, 1097, 1112
Nuclear membrane, 8
Nucleated sheath of Schwann, 42
Nuclei pontis, 735
Nucleus amygdalæ, 755; caudatus, 754; lenticularis, 754
Nucleus of a cell, 8
Nucleus emboliformis, 774; fastigii, 774; globosus, 774
Nutrient artery of bone, 26
Nymphæ, 1100; lymphatics of, 707

Obelion, 189
Oblique inguinal hernia, 1123; coverings of, 1123; ligament, 348; line of the clavicle, 222; of the fibula, 285; of lower jaw, 183; of radius, 243; ridge of ulna, 240
Obliquus auris muscle, 903; externus abdominis, 448; internus, 451; inferior captis, 439; superior, 439; inferior oculi, 394; superior, 393
Obturator artery, 636; peculiarities of, 637; relation of, to femoral ring, 1134; externus muscle, 522; internus, 521; fascia, 1146; foramen, 265; ligament, or membrane, 521; nerve, 839; surgical anatomy of, 853; accessory, 841; veins, 690
Occipital artery, 565; bone, 141; articulations of, 145; attachment of muscles to, 145; development of, 145; crests, 141, 143; protuberances, 141, 143; fossæ, 143; lobe, 741; lymphatic glands, 699; groove, 154; sinus, 676; triangle, 574; vein, 670
Occipitalis major nerve, 815; minor, 818
Occipitalis muscle, 389
Occipito-atlantal articulation, 317; occipito-axial articulation, 318; occipito-frontalis muscle, 388
Occiput, arteries of, 565
Ocular cleft, 98; cup, 97; vesicle, primitive, 97; secondary, 98
Odontoblasts, 926, 931
Odontoid ligaments, 319; tubercle for, 143; process of axis, 124
Œsophageal arteries, 619; branches of vagus nerve, 808; glands, 944; opening of in diaphragm, 445; plexus, 808
Œsophagus, 942; lymphatics of, 711; structure of, 943; surgical anatomy of, 944
Olecranon process, 238; fossa, 235; fracture of, 505
Olfactory bulb, 748, 777; cells, 877; foramina, 164; fossæ (fœtal), 100; nerve, 777; surgical anatomy of, 778; sulcus, 777
Olivary bodies of medulla oblongata, 729, 731; nuclei, accessory, 733; nucleus, superior, 735; peduncle, 731; process, 158
Omenta, 964
Omental tuberosity of liver, 994
Omentum, gastro-colic, 965; gastro-hepatic, 964; gastro-splenic, 965; great, 965; lesser, 964
Omo-hyoid muscle, 410
Omphalo-mesenteric arteries, fœtal, 102; duct, 82; veins, 103; vessels, 82
Opening of aorta in left ventricle, 1024; aortic in diaphragm, 445; caval in diaphragm, 445; of coronary sinus, 1020; of inferior cava, 1019; left auriculo-ventricular, 1024; œsophageal in diaphragm, 445; of pulmonary artery, 1021; veins, 1023; right auriculo-ventricular, 1021; saphenous, 512, 1131; of superior cava, 1019
Operations:—
amputations of foot, 303; of penis, 1088
arteries, ligature of, abdominal aorta, 622; axillary, 603; brachial, 607; carotid, common, 557; external, 559; internal, 577; femoral, 647; iliac, common, 632; external, 642; internal, 632; innominate, 554; lingual, 562; popliteal, 655; radial, 611; subclavian, 589; thyroid, inferior, 595; tibial, anterior, 658; posterior, 661; ulnar, 614
catheterism of Eustachian tube, 942; cholecystotomy, 1004; for cleft palate, 422; colotomy, 993
division of nerves, facial, 801; infra-orbital, 795; lingual, 795; sciatic, great, 853; spinal accessory, 809; supra-orbital, 794
excision of, ankle, 376; elbow, 347; hip, 363; knee, 371; of shoulder, 343; extirpation of thyroid, 1057; of spleen, 1013
gastrostomy, 972; gastrotomy, 972
hamstring tendons, division of, 525
laryngotomy, 1045; lithotomy, 1143
nephrotomy and nephrectomy, 1069
œsophagotomy, 944
paracentesis of pericardium, 1017; prostatectomy, 1085; puncture of the bladder, 1080
removal of the clavicle, 225; lower jaw, 209; upper jaw, 208; tongue, 417, 873; scapula, 231; testis, 1095
for strabismus, 395
tapping chest, 221; for torticollis, 409; tracheotomy, 1045
venesection, 681
Operculum of the insula, 748
Ophthalmic artery, 577; ganglion, 784; nerve, 782; vein, 677; inferior, 677
Opponens minimi digiti muscle, in hand, 499; in foot, 540; pollicis muscle, 495
Optic commissure, 778; foramen, 161, 191; groove, 161, 191; lobes, 762; nerve, 778; inter-retinal fibres of, 778; intercerebral fibres of, 778; surgical anatomy of, 779; recess, 759; thalamus, 759; tract, 778
Ora serrata, 887
Oral cavity, 921
Orbicular bone, 909; ligament, 348

Orbicularis ciliaris, 390; latus, 390; oris muscle, 398; palpebrarum, 390
Orbit, 199; arteries of, 577; muscles of, 392; relation of nerves in, 796
Orbital artery, 571; fascia, 395; foramina, 161; lobe, 738; nerve, 786; process of malar, 175; of palate, 179; sulcus, 738
Organs of Golgi, 50; of Giraldès, 114; of Jacobson, 876; of Rosenmüller, 114
Organic constituent of bone, 30
Orifice, œsophageal of stomach, 967; pyloric of stomach, 967
Origin of muscles, 385
Os calcis, 287; development of, 300; hyoides, 209; innominatum, 259; development of, 265; magnum of carpus, 252; orbiculare, 909; planum, 165; unguis, 174
Os uteri, 1104
Ossa triquetra, 167
Ossicula auditus, 908; ligaments of, 909
Ossification, period of, 35; of bone, 30; of spine, progress in, 131; defects in, 140; intracartilaginous, 30; intramembranous, 34; subperiosteal, 34
Osteoblasts, 25, 31
Osteoclasts, 26, 33
Osteo-dentine, 928
Osteology, 119
Ostium abdominale of Fallopian tube, 1108; internum or uterinum, 1106
Otic ganglion, 793; vesicle, 99
Otoliths, 915
Outlet of pelvis, 268
Ovarian arteries, 629; plexus of nerves, 864; veins, 692
Ovary, 1109; development of, 113; Graafian vesicles of, 1110; ligament of, 1112; lymphatics of, 708; nerves of, 1112; ovicapsule of, 1111; shape, position, and dimensions, 1109; stroma of, 1110; tunica albuginea of, 1110; vessels of, 1112
Ovicapsule of Graafian vesicle, 1111
Oviducts, 1108
Ovisacs of ovary, 1110
Ovula of Naboth, 1107
Ovum, 7, 72; early changes in, 74; discharge of, 1111; discus proligerus of, 73; fertilisation of, 74; germinal spot of, 73; germinal vesicle of, 73; vitelline membrane of, 73; yolk of, 73; zona pellucida of, 73
Oxyntic cells, 971
Oxyntic glands, cardiac, 970; pyloric, 970

Pacchionian depressions, 147; glands, 675, 723, 724
Pacinian corpuscles, 48
Pad of corpus callosum, 751
Palatal glands, 934
Palate, arches of, 934; development of, 92; hard, 934; soft, 934; bone, 177; articulations of, 180; attachment of muscles to, 180; development of, 180; turbinated crest of, 178; vertical plate of, 178; horizontal plate of, 177; orbital process of, 179; sphenoidal process of, 179; muscles of, 935; process of superior maxillary, 172
Palatine aponeurosis, 421; artery, ascending, 563; descending or posterior, 571; canal, anterior, 172; posterior, 170, 178; accessory, 179; fossa, anterior, 172; nerves, 790; process of superior maxillary, 172; veins, inferior, 669
Palato-glossus muscle, 415, 421; pharyngeus, 421
Palmar arch, deep, 610; superficial, 616; surface marking of, 617; cutaneous nerve, 827, 828; fascia, 494; interossei arteries, 613; nerve, deep, of ulnar, 929; superficial, 829; veins, 680
Palmaris brevis muscle, 497; longus muscle, 482
Palpebræ, 896
Palpebral arteries, 580; external, 578; cartilages or plates, 897; fissures, 896; fissure, surface form of, 900; folds of conjunctiva, 898; ligaments, 897; muscles, 390; veins, inferior, 669; superior, 669
Pampiniform plexus of veins, 692, 1091, 1112
Pancreas, 1005; development of, 110; structure of, 1006; lymphatics of, 709; vessels and nerves of, 1007; surface marking of, 1007; surgical anatomy, 1007
Pancreatic arteries, 625; duct, 1006; plexus of nerves, 864; veins, 693
Pancreatica magna artery, 625
Pancreatico-duodenal artery, 624; inferior, 626; vein, 693; plexus of nerves, 864
Papilla lachrymalis, 899; spiralis, 916
Papillæ of tooth, 930; conicæ vel filiformes, 869; fungiformes (mediæ), 869; of kidney, 1062; maximæ (circumvallate), 869; of skin, 63; of tongue, 868
Papillary layer of skin, 63
Par vagum, 803
Paraglobulin, 1, 5
Parallel fissure, 741; striæ of Retzius, 928
Paramastoid process, 143
Parietal bones, 145; articulations of, 148; attachment of muscles to, 148; development of, 147; eminence, 146; foramen, 146; cells of gastric glands, 971; lobe, 739; veins, 106
Parieto-occipital fissure, 738, 743
Parieto-sphenoid artery, 582
Parotid duct, 936; fascia, 400, 406; gland, 935; accessory portion of, 936; nerves of, 937; vessels of, 937; lymphatic glands, 699; veins, 669
Parovarium, 111, 114, 1111
Patella, 279; articulations of, 280; attachment of muscles to, 280; development, of, 280; fracture of, 545; surface form of, 280; surgical anatomy of, 280
Pecquet, reservoir of, 698
Pectineus muscle, 516
Pectiniforme septum, 1086
Pectoral region, dissection of, 467
Pectoralis major, 468, minor, 470
Peculiar dorsal vertebræ, 127
Pedicles of a vertebra, 121
Peduncles of cerebellum, 774; of cerebrum, 750; of corpus callosum, 751; of pineal gland, 762
Peduncular fibres of cerebrum, 763; of cerebellum, 771
Pelvic fascia, 1145; parietal or obturator layer, 1146; visceral layer, 1146; girdle, 221; plexus, 865

Pelvis, 267, 1073; arteries of, 633; articulations of, 330; axes of, 269; boundaries of, 267; brim of, 267; cavity of, 268; diameters of, 269; false, 267; inlet of, 268; ligaments of, 330; lymphatics of, 707; male and female, differences of, 270; outlet of, 268; position of, 267; position of viscera at outlet of, 1142; true, 267; of kidney, 1062; surface form of, 270; surgical anatomy of, 271
Pelvis in fœtus, 270; about puberty, 270; after puberty, 270
Penis, 1085; arteries of, 1087; body of, 1085; corpora cavernosa, 1086; corpus spongiosum, 1087; development of, 116; dorsal artery of, 639; dorsal vein of, 691; nerve of, 849; suspensory ligament, 1085; lymphatics of, 707, 1088; muscles of, 464; nerves of, 1088; prepuce of, 1086; root of, 1085; surgical anatomy of, 1088
Penniform muscle, 384
Perforans Casserii nerve, 823
Perforated space, anterior, 748; posterior, 749
Perforating arteries, of hand, 613; from mammary artery, 597; from plantar, 564; from profunda, 652
Pericardiac arteries, 596, 618
Pericardium, relations of, 1014; diverticula of, 1015; structure of, 1015; fibrous layer of, 1015; serous layer of, 1016; nerves of, 1017; vessels of, 1017; vestigial fold of, 684, 1017
Perichondrium, 22, 31
Perilymph, 914
Perimysium, external, 36; internal, 36
Perinæum, in the male, 1139; in the female, 1144; abnormal course of arteries in, 1144; deep boundaries of, 1139; development of, 115; lymphatics of, 707; muscles of, 465; surgical anatomy of, 1137
Perineal artery, superficial, 638; transverse, 638; fascia, deep, 464, 1140; superficial, 461; nerve, 849; superficial, 849
Permeurium, 45
Periosteum, 25; internal, 25; of teeth, 923
Peripheral termination of nerves, 47
Peritoneum, lesser cavity of, 958, 962; greater cavity of, 958; ligaments of, 964; mesenteries of, 965; omenta of, 964; reflections traced, 958
Perivascular lymphatics, 58, 675
Permanent cartilage, 21; teeth, 923
Peroneal artery, 662; peculiarities of, 662; anterior, 663; nerve, 851; tubercle, 291; veins, 689
Peroneus brevis muscle, 533; longus, 533; tertius, 528
Perpendicular plate of ethmoid, 164; line of ulna, 240
Pes accessorius, 753; anserinus, 797; hippocampi, 756
Petit, canal of, 894; triangle of, 449
Petro-mastoid portion of temporal bone, 157
Petro-occipital suture, 188
Petro-sphenoidal suture, 188
Petrosal nerve, superficial or large, from Vidian, 788; small, superficial, 911; deep, large, 789; deep, small, 911; long, 911; process, 159; sinus inferior, 677; superior, 677
Petrous ganglion, 803; portion of temporal bone, 155
Peyer's glands, 980
Phalanges of cochlea, 918
Phalanges, hand, 256; articulations of, 357; development of, 259; foot, 300; articulations of, 300, 383; development of, 300
Pharyngeal aponeurosis, 941; arches, 93; artery, ascending, 566; clefts, 93; fascia, 406; ganglion, 859; glands, 942; nerve, from external laryngeal, 807; from glossopharyngeal, 803; from Meckel's ganglion, 790; from sympathetic, 858; from vagus, 807; plexus of nerves, 807, 858; spine, 143; tonsil, 942; vein, 672
Pharyngeo-glossus muscle, 415
Pharynx, 941; aponeurosis of, 941; arteries of, 566; development of, 109; mucous membrane of, 942; muscles of, 418; surgical anatomy of, 942
Phleboliths, 691
Phrenic arteries, 629; nerve, 819; plexus of nerves, 863; veins, 693
Phreno-colic ligament, 966
Pia mater, of brain, 726; of cord, 713; testis, 1093
Pigment, 21; of iris, 886; of skin, 63
Pigmentary layer of retina, 890
Pillars of external abdominal ring, 450, 1117; of diaphragm, 444; of fauces, 934
Pineal gland, 761; peduncles of, 762; recess, 759
Pinna of ear, 902; ligaments of, 903; muscles of, 903; nerves of, 904; vessels of, 903
Pisiform bone, 250
Piso-metacarpal ligament, 352
Piso-uncinate ligament, 352
Pit of the stomach, 219
Pituitary body, 749; development of, 94; fossa, 158; membrane, 875
Pivot-joint, 308
Placenta, 87
Placental sinus, 88; circulation, 103
Plantar arch, 663; artery, external, 663; internal, 663; fascia, 535; ligaments, 377; cutaneous nerve, 850; nerve, external, 851; internal, 850; veins, external, 689; internal, 689
Plantaris muscle, 530
Plasma, 5
Plasma cells, 18
Plates, tarsal, 897
Platysma myoides, 404
Pleura, 1046; cavity of, 1046; costalis, 1046; pulmonalis, 1046; reflections of, traced, 1046; vessels and nerves of, 1047; surgical anatomy of, 1047
Pleuro-peritoneal cavity, 81
Plexus of Nerves, 46; aortic, 865; brachial, 820; cardiac, deep, 861; superficial, 862; carotid, 856; external, 859; cavernous, 858; cervical, 818; posterior, 816; cœliac, 864; colic, left, 865; middle, 864; right, 864; coronary, anterior, 862; posterior, 862; cystic, 864; diaphrag-

Plexus of Nerves (*continued*)
matic, 863; epigastric or solar, 862; facial, 859; gastric, 864; gastro-duodenal, 864; gastro-epiploic, 864; left, 864; great cardiac, 861; hæmorrhoidal, superior, 865; inferior, 865; hepatic, 864; hypogastric, 865; inferior, 865; ileo-colic, 864; infra-orbital, 786; lumbar, 837; mesenteric, inferior, 865; superior, 864; œsophageal, 808; ovarian, 864; ophthalmic, 858; pancreatic, 864; pancreatico-duodenal, 864; patellæ, 843; pharyngeal, 803, 859; phrenic, 863; prostatic, 865; pulmonary, anterior, 808; posterior, 808; pyloric, 864; renal, 864; sacral, 845; sigmoid, 865; solar, 862; spermatic, 864; splenic, 864; superficial cardiac, 862; suprarenal, 864; tonsillar, 803; tympanic, 910; uterine, 866; vaginal, 865; vertebral, 860; vesical, 865
Plexus of cornea, intra-epithelial, 882; sub-epithelial, 882
Plexus magnus profundus, 861
Plexus of Veins. *See* Veins
Plica-epigastrica, 1123; hypogastrica, 1123; urachi, 1123
Plica semilunaris, 899
Pneumogastric lobule of cerebellum, 770
Pneumogastric nerve, 803
Polar globules of Robin, 73
Pomum Adami, 1032
Pons hepatis, 996
Pons Varolii, 734; Tarini, 749
Popliteal artery, 652; branches of, 655; peculiarities of, 654; surgical anatomy of, 655; surface marking of, 655; lymphatic glands, 704; nerve, external, 851; surgical anatomy of, 854; internal, 849; notch, 281; space, 652; surface of femur, 275; vein, 689
Popliteus muscle, 531
Pores of the skin, 67
Portal canals, 998; fissure, 996; vein, 695; 998, 1000
Portio dura or seventh nerve, 796; mollis, or auditory nerve, 801; inter duram et mollem, 797
Porus opticus of sclerotic, 880, 887
Posterior (*See under each separate head*)
Posterior and internal frontal artery, 581
Posterior choroid artery, 594
Posterior glenoid process, 152
Posterior vertebral veins of Rathke, 107
Posterior vesicular column, 722
Postero-lateral ganglionic arteries, 594; median ganglionic arteries, 594
Post-central sulcus, 739
Post-glenoid process, 152
Post-oral arches (fœtal), 92
Post-patellar bursa, 515
Pott's fracture, 545
Pouch of Douglas, 1104
Pouches, laryngeal, 1037
Poupart's ligament, 450, 1118, 1131
Præcentral fissure, 738
Precuneus lobe of brain, 744
Pre-oral arches (fœtal), 92
Prepatellar bursa, 515
Prepuce, 1086; of clitoris, 1100
Presternal notch, 211
Presternum, 211
Prevertebral fascia, 406
Prickle cells, 14
Primary areolæ of bone, 31; cerebral vesicles, 90
Primitive jugular veins, 107; trace, 76, 79; aorta, 104; sheath of nerve-fibre, 42; ocular vesicle, 97; otic or auditory vesicle, 99; fibrillæ of Schultze, 43
Princeps cervicis artery, 565; pollicis artery, 612
Processes or Process, acromion, 228; alveolar, 172; angular, external, 149; internal, 149
basilar, 143
ciliary, 884
clinoid, anterior, 161; middle, 158; posterior, 158; cochleariform, 157, 907; condyloid of lower jaw, 185; coracoid, 229; coronoid of lower jaw, 185; of ulna, 238; costal, 129
ethmoidal of inferior turbinated, 181
frontal of malar, 175
hamular of lachrymal, 175; of sphenoid, 162; of helix, 902
of Ingrassias, 161
jugular, 143
lachrymal of inferior turbinated bone, 181
malar, 172; mastoid, 154; mammillary, 129; maxillary of inferior turbinated, 181; of malar bone, 176; mental, 183
nasal, 172
odontoid of axis, 124; olecranon, 238; olivary, 158; orbital of malar, 175; of palate, 179
palatine of superior maxillary, 172; post-glenoid, 152; pterygoid of palate bone, 178; of sphenoid, 162
sphenoidal of palate, 179; spinous of tibia, 281; of ilium, 262; of sphenoid, 161; styloid of temporal, 157; of ulna, 242; of radius, 244
unciform, 253; of ethmoid, 165
vaginal of sphenoid, 160; of temporal, 157
vermiform of cerebellum, inferior, 770; superior, 769
zygomatic, 176
Processes of Ingrassias, 161
Processus ad medullam, 772; ad pontem, 772; brevis of malleus, 909; cochleariformis, 157, 907; e cerebello ad testes, 771; caudatus, 902; gracilis of malleus, 909
Profunda cervicis artery, 598; femoris artery, 650; vein, 672; inferior artery of arm, 608; superior, 608
Prohepaticus, 952
Promontory of tympanum, 907; of sacrum, 132
Pronator quadratus muscle, 485; radii teres muscle, 482; ridge, 240
Pronephros, 111
Pronucleus, female, 74; male, 74
Prosencephalon, 94
Prostate gland, 1083; lobes of, 1084; levator muscle of, 460, 1084; lymphatics of, 708; surgical anatomy of, 1085; vessels and nerves of, 1084
Prostatic plexus of nerves, 865; of veins, 690; portion of urethra, 1080; sinus, 1080
Protoplasm, 8

Protovertebræ, 81
Protovertebral column, 88; somites, 88
Protuberance, occipital, external, 141; internal, 143
Pseudostomata of sweat glands, 68
Psoas magnus muscle, 508; surgical anatomy of, 509; parvus, 508
Pterion ossicle, 167
Pterygo-maxillary fissure, 198; ligament, 399
Pterygo-palatine artery, 571; canal, 160; nerve, 790
Pterygoid arteries, 570; muscles, 401; fossa of sphenoid, 162; of lower jaw, 185; nerve, 791; notch, 162; plexus of veins, 670; process of palate bone, 178; processes of sphenoid, 162; ridge, 160; tubercle, 162
Pubic arch, 268; articulations of, 333; portion of fascia lata, 512
Pubis, os, 264; angle of, 264; crest of, 264; spine of, 264; symphysis of, 264, 333
Pubo-femoral ligament, 358
Pubo-prostatic ligaments, 1084
Pudendum, 1099
Pudic artery in male, 637; peculiarities of, 638; in female, 639; accessory, 638; deep external, 650; superficial external, 649; nerve, 847; vein, external, 688; internal, 690
Pulmonary artery, 547, 1052; opening of, in right ventricle, 1021; capillaries, 1052; nerves from vagus, 808; sinuses, 1022; veins, 666, 667, 1054; openings of, in left auricle, 1023
Pulp-cavity of tooth, 926; of spleen, 1010; of teeth, development of, 932
Pulvinar of optic thalamus, 759
Puncta vasculosa, 751; lachrymalia, 899
Pupil of eye, 885; membrane of, 887
Purkinje, axis-cylinder of, 42; vesicle of, 73; corpuscles of, 773
Pyloric artery, 624; inferior, 624; glands, 970; plexus, 864
Pylorus, 967
Pyramid in vestibule, 912; of cerebellum, 770; of thyroid gland, 1056; of tympanum, 907
Pyramidal cell or nerve corpuscle, 766
Pyramidalis muscle, 455; nasi, 395
Pyramids of medulla, 728, 730; decussation of, 729; of Ferrein, 1064; of Malpighi, 1062; of the spine, 137
Pyriformis muscle, 520

Quadrate lobe, 74
Quadratus femoris muscle, 522; lumborum, 458; menti, 397
Quadratus lumborum, fascia covering, 458
Quadriceps extensor cruris muscle, 513
Quadrigeminal bodies, 762

Racemose glands, 71
Radial artery, 609; branches of, 611; peculiarities of, 610; surgical anatomy of, 611; surface marking of, 611; lymphatic glands, 702; nerve, 830; recurrent artery, 611; region, muscles of, 486; vein, 681
Radialis indicis artery, 613
Radio-carpal articulation, 350; surface form of, 352; surgical anatomy of, 352
Radio-ulnar articulations, inferior, 349; middle, 348; superior, 347; region, anterior, muscles of, 481; posterior, muscles of, 488
Radius, 243; articulations of, 245; development of, 244; fracture of, 505; grooves in lower end of, 244; muscles attached to, 245; oblique line of, 243; sigmoid cavity of, 244; surface form of, 245; tuberosity of, 243; and ulna, fracture of, 506; surgical anatomy of, 245
Rami of the lower jaw, 184
Ramus of ischium, 263; of os pubis, 265; ascending of os pubis, 264; descending, 265
Ranine artery, 561; vein, 669, 672
Ranvier, nodes of, 43
Raphé of corpus callosum, 751; of medulla, 732; of palate, 934; of perinæum, 1139; of scrotum, 1089; of tongue, 868
Rathke, investing mass of, 91
Rathke, posterior vertebral veins of, 107
Receiving tubes of kidney, 1064
Receptaculi arteriæ, 577
Receptaculum chyli, 698
Recess, optic, 759; pineal, 759
Recessus labyrinthi, 99
Reciprocal reception, articulations by, 308
Recto-uterine ligaments, 1104
Recto-vesical fascia, 1146; fold, peritoneal, 1077
Rectum, 987; development of, 109; relations of, male, 987; female, 987, 1102; folds of, 989; lymphatics of, 708; surgical anatomy of, 990
Rectus abdominis, 453; capitis anticus major, 423; minor, 423; posticus major, 438; minor, 438; lateralis, 424; femoris muscle, 513; surgical anatomy of, 515; oculi, internus, superior, inferior, and externus, 393
Recurrent artery, interosseous, 615; radial, 611; tibial, anterior, 659; posterior, 659; ulnar, anterior, 614; posterior, 614; laryngeal nerve, 807; nerves to tentorium, 781
Region, abdominal, muscles of, 447; acromial, muscles of, 473; auricular, 389
back, muscles of, 426
cervical superficial, muscles of, 404; cranial, 387
epigastric, 947
femoral, muscles of, anterior, 509; internal, 515; posterior, 524; fibular, 533; foot, dorsum of, 536; sole of, 536
gluteal, muscles of, 518; groin, 1128
of hand, muscles of, 492; humeral, anterior, 477; posterior, 480; hypochondriac, 947; hypogastric, 948
iliac, muscles of, 507; infra-hyoid, 409
inguinal, 1128; intermaxillary, muscles of, 398; ischio-rectal, 1137
laryngo-tracheal, surgical anatomy of, 1044; lingual, muscles of, 413; lumbar, 948
maxillary, muscles of, inferior, 397; superior, 396
nasal, muscles of, 395
orbital, muscles of, 392

palatal, muscles of, 420; palmar, 492; palpebral, 388; perinæum, 1139; pharyngeal, muscles of, 418; popliteal, 652; pterygo-maxillary, muscles of, 401
radial, muscles of, 495; radio-ulnar, anterior, 481; posterior, 488
scapular, muscles of, anterior, 474; posterior, 475; Scarpa's triangle, 644; suprahyoid, muscles of, 411
temporo-maxillary, muscles of, 400; thoracic, 468; anterior, 468; lateral, 472; tibio-fibular, anterior, 525; posterior, 528
ulnar, 497; umbilical, 948
vertebral, muscles of, anterior, 423; lateral, 424
Regions of abdomen, 947
Reil, island of, 742
Remak, fibres of, 43
Renal afferent vessels, 1063, 1066; artery, 1066; inferior, 628; efferent vessels, 1063, 1067; plexus, 864; veins, 693, 1067
Reservoir of Pecquet, 698
Respiration, organs of, 1032; muscles of, 446
Respiratory nerves of Bell, external, 822; internal, 819; organs, development of, 110
Restiform bodies of medulla oblongata, 729
Rete mucosum of skin, 61; Malpighii, 62; testis, 1094
Reticular cartilage; 24; layer of skin, 63; lamina of Kölliker, 917
Retiform connective tissue, 19
Retina, 887; arteria centralis of, 581, 892; fovea centralis of, 891; limbus luteus of, 887; membrana limitans interna, 888; externa, 890; layers of, 888; structure of, 888
Retinacula of ileo-cæcal valve, 984
Retrahens aurem muscle, 390
Retro-pharyngeal space, 406
Rhomboid impression, 223; ligament, 335
Rhomboidal sinus, 93
Rhomboideus major, 431; minor, 430
Ribes, ganglion of, 854
Ribs, 214; angle of, 216; articulations of, 323; attachment of muscles to, 218; development of, 90, 218; false, 215; floating, 215; head of, 215; ligaments of, 323; neck of, 216; peculiar, 217; true, 215; tuberosity of, 216
Ridge, internal occipital, 143; mylo-hyoidean, 184; pterygoid, 160; superciliary, 148; temporal, 146, 151, 197
Rima glottidis, 1036
Ring, abdominal, external, 449, 1117; internal, 1121; femoral or crural, 1134; fibrous, of heart, 1025
Ring muscle, 887
Risorius muscle, 399
Rivini, ducts of, 937; incisura of, 906, 909
Robin, polar globules of, 73
Rods of Corti, 916; of retina, 890
Rod-granules of retina, 890
Rolando, tubercle of, 729, 731; fissure of, 738; topography of, 745; funiculus of, 729
Roof nuclei of Stilling, 774
Root of lung, 1050
Root sheath of hair, 65
Roots of spinal nerves, 812; of teeth, 923; of zygomatic process, 152
Rosenmüller, organ of, 114, 1111; accessory gland of, 899
Rostrum of sphenoid bone, 160; of corpus callosum, 751
Rotation, 310
Rotatores spinæ muscles, 437
Round ligaments of uterus, 1112; relations of, to femoral ring, 1134; of liver, 996
Rugæ of stomach, 970; of vagina, 1103
Rupture of urethra, course taken by urine in, 1139
Rust-coloured layer of cerebellar cortex, 773

Sac, lachrymal, 900
Saccular secretory glands, 71
Saccule of vestibule, 914
Sacculus laryngis, 1037
Sacra-media artery, 630
Sacral arteries, lateral, 641; canal, 135; cornua, 133; foramina, 133; ganglia, 861; groove, 134; lymphatic glands, 707; nerves, 843; anterior divisions of, 844; posterior divisions, 844; roots of, 843; plexus, 845; vein, lateral, 691; middle, 691; peculiarities of, 691
Sacro-coccygeal ligaments, 332
Sacro-iliac articulation, 330
Sacro-lumbalis muscle, 435
Sacro-sciatic foramen, greater, 263, 332; lesser, 263, 332; ligaments, 331; notch, greater, 263; lesser, 263
Sacro-uterine ligaments, 1105
Sacro-vertebral angle, 132; ligament, 329
Sacrum, 132; ala of, 134; articulations of, 136; attachment of muscles to, 136; development of, 135; peculiarities of, 135; structure of, 135
Sacs, dentinal, 930
Saddle joint, 308
Sagittal suture, 186
Salivary glands, 935; structure of, 938
Salpingo-pharyngeus, 421
Salter, incremental lines of, 928
Santorini, cartilages of, 1034
Saphena veins, surgical anatomy of, 689
Saphenous nerve, long or internal, 842; short, 850; opening, 512, 1131; vein, external or short, 689; internal or long, 688, 1128; surgical anatomy of, 689
Sarcode, 8
Sarcolemma, 36
Sarcoplasm, 37
Sarcostyles, 37
Sarcous elements of muscle, 38
Sartorius muscle, 412
Scala tympani of cochlea, 914, 916; vestibuli of cochlea, 914, 916; media, 916
Scalæ of cochlea, 916
Scalenus anticus, 424; medius, 424; posticus, 425
Scalp, skin of, 388
Scaphoid bone (hand) 246, (foot) 294; fossa of sphenoid, 162
Scapula, 225; articulations of, 230; attachment of muscles to, 230; development of, 230; dorsum of, 225; glenoid cavity of,

228; head of, 228; ligaments of, 338; muscles of, 474; spine of, 226; venter of, 225; surface form of, 230; surgical anatomy of, 231
Scapular artery, posterior, 596; notch, great, 228; region, muscles of, anterior, 474; posterior, 475
Scapulo-clavicular articulation, 336
Scarfskin, 61
Scarpa, fascia of, 448; foramina of, 173, 193
Scarpa's triangle, 644
Schachowa, spiral tubes of, 1064
Schindylesis, 307
Schlemm, canal of, 882; ligament of, 340
Schneiderian membrane, 875
Schreger, lines of, 928
Schultze, cells of, 777, 877; primitive fibrillæ of, 43
Schwann, white substance of, 42
Sciatic artery, 639; nerve, greater, 849; surgical anatomy of, 853; nerve, lesser, 847; veins, 690
Sclerotic, 880
Scrobiculus cordis, 219
Scrotal hernia, 1124
Scrotum, 1089; dartos of, 1089; development of, 116; lymphatics of, 707; nerves of, 1090; septum of, 1089; surgical anatomy of, 1091; vessels of, 1090
Sebaceous glands, 66
Second nerve, 778; surgical anatomy of, 779
Secondary areolæ of bone, 32; ocular vesicle, 98
Secreting glands, 70
Sella turcica, 158, 191
Semicircular canals, 912
Semilunar bone, 249; cartilages of knee, 366; fold of Douglas, 452, 455; fascia, 479; ganglion of fifth nerve, 782; of abdomen, 862; valves, aortic, 1024; pulmonic, 1022
Semimembranosus muscle, 525
Seminal cells, 1093; tubes, 1093; vesicles, 1095
Semispinalis muscle, 437
Semitendinosus muscle, 524
Senac, on structure of heart's valves, 1021
Senses, organs of the, 867
Septum auricularum, 1023; crurale, 1135; lucidum, 755; of nose, 203; artery of, 564; cartilage of, 875; pectiniforme, 1086; of Pons Varolii, 735; scroti, 1089; subarachnoid, 713; of tongue, 868; ventriculorum, 1024
Septum between bronchi, 1042
Serous glands of tongue, 871
Serous membranes, 68
Serratus magnus, 472; posticus inferior, 432; superior, 431
Serum, 1, 5
Serum globulin, 1
Sesamoid bones, 304; cartilages, 874
Seventh nerve, 796; surgical anatomy of, 801
Shaft of a bone, its structure, 119
Sheath of arteries, 53; of muscles, 36; of nerves, 43; femoral or crural, 1133; of rectus muscle, 455
Shin, 282
Short bones, 119
Shoulder, muscles of, 473; girdle, 221; joint, 339; surface form of, 342; surgical anatomy of, 342; vessels and nerves of, 341
Sigmoid artery, 627; cavity, greater of ulna, 238; lesser, of ulna, 240; of radius, 244; flexure of colon, 986; meso-colon, 966; notch of lower jaw, 185
Sinuses, cranial, 149, 667, 675; cavernous, 676; circular, 677; lateral, 676; longitudinal, inferior, 676; superior, 675; occipital, 676; petrosal, inferior, 677; superior, 677; straight, 676; transverse, 678
Sinuses of heart, of right auricle, 1019, of left, 1023; of coronary vein, 695, 1020
Sinuses of nose, 149; ethmoidal, 166; frontal, 149; maxillary, 171; sphenoidal, 159
Sinuses of Valsalva, aortic, 549, 1024; pulmonary, 1022
Sinus circularis iridis, 882
Sinus of external jugular vein, 671; of internal, 671
Sinus of kidney, 1061
Sinus of Morgagni, 419
Sinus pocularis, 112, 1080
Sinus prostaticus, 114, 1080
Sinus venosus, 106
Sixth nerve, 795; surgical anatomy of, 796
Skeleton, 119; number of its pieces, 119
Skin, *General Anatomy of*, 61; appendages of, 64; arteries of, 63; corium of, 63; cuticle of, 61; derma, or true skin, 63; development of, 100; epidermis of, 61; furrows of, 61; hairs, 64; muscular fibres of, 66; nails, 64; nerves of, 64; papillary layer of, 63; rete mucosum of, 61; sebaceous glands of, 66; sudoriferous or sweat glands of, 66; tactile corpuscles of, 49; vessels of, 63
Skull, 141, 189; anterior region, 199; base of, external surface, 193, internal surface, 190; fossa of, anterior, 190, middle, 191, posterior, 192; lateral region of, 196; tables of, 119; surface marking of, 204; vertex of, 189; surgical anatomy of, 206; vitreous table of, 120
Slender lobe of cerebellum, 770
Small intestine, areolar coat of, 976; mucous coat of, 976; muscular coat of, 976; serous coat of, 976; simple follicles, 979; valvulæ conniventes, 976; villi of, 977
Small intestine, 973; duodenum, 973; ileum, 975; jejunum, 975
Socia parotidis, 936
Soft palate, 934; aponeurosis of, 934; arches or pillars of, 934; muscles of, 420; structure of, 934
Solar plexus, 862
Sole of foot, muscles of, first layer, 537, second layer, 538, third layer, 539, fourth layer, 540
Soleus muscle, 529
Solitary glands, 979
Somatopleure, 81
Sömmerring, yellow spot of, 887
Space, anterior perforated, 748; axillary, 598; intercostal, 215; popliteal, 652; posterior perforated, 749
Spaces of Fontana, 882

Spermatic Artery, 629, 1090; canal, 1120; cord, 1090; arteries of, 1090; course of, 1090; lymphatics of, 1091; nerves of, 1091; relation to femoral ring, 1134; relations of, in inguinal canal, 1090, 1121; veins of, 1091; fascia, external, 450, 1118; plexus of nerves, 1091; of veins, 692; veins, 692, 1091; surgical anatomy of, 692
Spermatoblasts, 1093
Spermatogenic cells, 1093
Spermatogonia, 1093
Spermatozoa, 1093
Spheno-maxillary fissure, 197; fossa, 198
Spheno-palatine artery, 571; foramen, 180; ganglion, 788; nerves, 787; notch, 180
Spheno-parietal suture, 188
Sphenoid bone, 158; articulations of, 163; attachment of muscles to, 163; body of, 158, development of, 162, greater wings of, 160, lesser wings of, 161, pterygoid processes of, 162, rostrum of, 160; spinous processes of, 161; vaginal processes of, 160
Sphenoidal epithelium, 13
Sphenoidal fissure, 161; nerves in, 796; process of palate, 179; sinuses, 159; spongy, or turbinated bones, 162
Sphincter muscle of bladder, 1078; of rectum, external, 459, internal, 459; of vagina, 465
Spina bifida, 140
Spinal accessory nerve, 809; surgical anatomy of, 809
Spinal arteries, anterior, 592; lateral, 592; posterior, 592; median, 592; canal, 139
Spinal Cord, 714; development of, 88; arachnoid of, 713; arrangement of grey and white matter in, 716, central canal of, 717, central ligament of, 714, columns of, 716, dura mater of, 712, fissures of, 715, fœtal peculiarity of, 715, grey commissure of, 717, minute structure of, 718, ligamentum denticulatum of, 714, membranes of, 712, neuroglia of, 718, pia mater of, 713, sections of, 716, surgical anatomy of membranes of, 714, white commissure of, 716, white matter of, 716
Spinal foramen, 121, 139
Spinal nerves, 812; arrangement into groups, 812; divisions of, anterior, 813, posterior, 813; development of, 96; distribution of, 813; origin of, in cord, 812; ganglia of, 813; origin of roots, anterior, 812, posterior, 812; points of emergence of, 814
Spinal veins, 686, longitudinal anterior, 686, posterior, 687
Spinalis colli muscle, 436; dorsi, 436
Spindle, achromatic, 10; poles of, 10
Spine, 120; *General Description of*, 139; articulations of, 311; development of, 88; ossification of, 129: surface form of, 139: surgical anatomy of, 139
Spines of bones, ethmoidal, 158; of ischium, 263; nasal, 149; anterior, 173; posterior, 178; pharyngeal, 143; of os pubis, 264; scapula, 226
Spinous process of ilium, 262, of sphenoid, 161, of tibia, 281, of vertebræ, 121
Spiral canal of cochlea, 913; line of femur, 273
Spirem or skein, 10
Splanchnic nerve, greater, 860, lesser, 860, smallest or renal, 860
Splanchnopleure, 81
Spleen, 1008; capillaries of, 1011; development of, 110; fibro-elastic coat of, 1009; lymphatics of, 709, 1013; Malpighian bodies of, 1011; nerves of, 1013; proper substance of, 1010; relations of, 1008; serous coat of, 1009; size and weight, 1009; artery of, 1010; structure of, 1009; surface marking of, 1013; trabeculæ of, 1010; veins of, 1012; surgical anatomy of, 1013
Splenic artery, 625; distribution of, 1010; plexus, 864; corpuscles, 1011; pulp, 1010; vein, 693
Splenium of corpus callosum, 751
Splenius muscle, 432
Spongy portion of urethra, 1081; tissue of bone, 119
Spring ligament, 378
Squamo-sphenoidal suture, 188; parietal suture, 188; zygomatic portion of temporal bone, 157
Squamous portion of temporal bone, 151
Stapedius muscle, 910
Stapes, 909; annular ligament of, 909; development of, 99
Stellate ligament, 323; plexus of kidney, 1067
Stenson, foramina of, 173, 193
Stenson's duct, 936
Sternal end of clavicle, fracture of, 503; foramen, 211; furrow, 219; ligaments, 328
Sterno-clavicular articulation, 334; surface form of, 336; surgical anatomy of, 336
Sterno-hyoid muscle, 409
Sterno-mastoid muscle, 407; artery, 560
Sterno-pericardiac ligaments, 1015
Sterno-thyroid muscle, 409
Sternum, 211; articulations of, 214; attachment of muscles to, 214; development of, 90, 213; ligaments of, 328
Stilling, canal of, 893
Stomach, 967; alteration in position of, 968; alveoli of, 970; areolar coat of, 969; cardiac glands of, 971; curvatures of, 967; development of, 108; fundus of, 967; gastric follicles of, 970; ligaments of, 968; lymphatics of, 709; mucous membrane of, 969; muscular coat of, 969; orifices of, 967; pyloric glands of, 970; pyloric end of, 967; pylorus, 968; serous coat of, 968; splenic end of, 967; structure of, 968; surfaces of, 967; surface marking of, 972; surgical anatomy of, 972; vessels and nerves of, 971
Stomodœum, 93, 94
Straight sinus, 676
Straight tubes of kidney, 1064
Stratified epithelium, 14
Stratiform fibro-cartilage, 24
Stratum cinereum, 767; corneum, 62; lucidum, 62; opticum, 767, 778; gelatinosum, 766; glomerulosum, 766
Striæ longitudinales, 751; laterales, 751
Striæ medullaris vel acusticæ, 776

Striped muscle, 36
Stroma of ovary, 1110
Stylo-glossus muscle, 414
Stylo-hyoid ligament, 412; muscle, 412; nerve from facial, 798
Stylo-mastoid artery, 566; foramen, 157; vein, 670
Stylo-maxillary ligament, 321, 406
Stylo-pharyngeus muscle, 419
Styloid process of temporal bone, 157; of fibula, 285; of radius, 244; of ulna, 242
Subanconeous muscle, 480
Subarachnoid space of brain, 725; of cord, 713; fluid, 726; septum, 713; tissue, 713
Subcæcal fossa, 983
Subclavian arteries, 585; branches of, 591; first part of, left, 586; right, 585; peculiarities of, 588; second portion of, 587; third, 587; surgical anatomy of, 589; surface form of, 589; groove, 223; nerve, 822; triangle, 574; vein, 682
Subclavius muscle, 471
Subcostal angle, 211; artery, 619; muscles, 442
Subcrureus muscle, 515
Subcutaneous malæ nerve, 799
Subdural space, 713, 725
Sublingual artery, 561; fossa, 184; gland, 937; vessels and nerves of, 838
Sublobular veins, 998
Submaxillary artery, 564; fossa, 184; ganglion, 794; gland, 937; nerves of, 937; vessels of, 937; lymphatic gland, 701; triangle, 573; vein, 669
Submental artery, 564; vein, 669
Suboccipital nerve, 816; posterior branch of, 814; triangle, 439, 592
Subpeduncular lobe of cerebellum, 770
Subpleural mediastinal plexus, 596
Subpubic ligament, 333
Subscapular fascia, 474; angle, 225; artery, 604; fossa, 225; nerves, 823
Subscapularis muscle, 474
Substantia cinerea gelatinosa, 720; ferruginea, 776; gelatinosa centralis, 717
Sudoriferous glands, 66
Sulci of cerebrum, 736
Sulcus, frontal, inferior, 738; superior, 738; intraparietal, 739; occipital, inferior, 741; middle, 741; superior, 741; for olfactory tract, 738; orbital, 738; parallel, 741; post-central, 739; pre-central, 738; of Reil, anterior, 742; external, 742; posterior, 742; temporo-sphenoidal, middle, 741; superior, 741; tri-radiate, 738; sulcus longitudinalis medianus, 776
Sulcus spiralis, 916
Supercilia, 896
Superciliary ridge, 148
Superficial palmar arch, 616; cervical artery, 596; circumflex iliac artery, 649; epigastric, 649; external pudic, 649; perineal artery, 638; transverse ligament of fingers, 495; temporal artery, 567; surgical anatomy of, 567
Superficialis colli nerve, 818; volæ artery, 611
Superior maxillary bone, 169; articulations of, 174; attachment of muscles to, 174; development of, 173; changes in, produced by age, 174; nerve, 786
Superior mediastinum, 1048; meatus, 203, 876; medullary velum, 772; profunda artery, 608; turbinated crest, 172; of palate, 178; vena cava, 684
Superior thyroid artery, 560; surgical anatomy of, 561
Supinator brevis muscle, 489; longus, 486
Supra-acromial nerves, 819; artery, 595
Supraclavicular nerves, 819
Suprasternal nerves, 819; artery, 595
Supraglenoid tubercle, 228
Suprahyoid aponeurosis, 209, 411
Supramarginal convolution, 740
Supramastoid crest, 152
Supramaxillary nerves from facial, 800
Supra-orbital arch, 149; artery, 578; foramen, 149, 199; nerve, 784; notch, 149
Suprarenal arteries, 628; capsules, 1071; development of, 112; nerves of, 1073; vessels of, 1073; plexus, 864; veins, 693
Suprascapular artery, 595; ligament, 339; nerve, 822; notch, 228
Supraspinales muscles, 438
Supraspinatus muscle, 475
Supraspinous ligaments, 314; fascia, 475; fossa, 225
Supratrochlear foramen, 234; nerve, 783
Sural arteries, 655; veins, 689
Surface Form or Marking, of abdominal aorta, 621; of acromio-clavicular joint, 338; of ankle-joint, 376; of anterior tibial artery, 658; of axillary artery, 602
of bladder, 1079; of brachial artery, 607; of branches of internal iliac artery, 641
of carpus, 257; of cerebral convolutions, 744; of clavicle, 224
of common carotid artery, 557; of common iliac artery, 632; of cranium, 204
of dorsalis pedis artery, 660
of elbow, 346; of external auditory meatus, 905; of external carotid artery, 559
of external iliac artery, 642
of femoral artery, 647; of femur, 278; of fibula, 287; of fifth cranial nerve, 794; of foot, 302
of heart, 1027; of hip-joint, 361; of humerus, 236; of hyoid bone, 210
of intestines, 990
of kidney, 1068; of knee-joint, 370; of knuckles, 357
of larynx, 1044; of liver, 1003; of lungs, 1054
of mouth, 940; of muscles of abdomen, 457; of head and face, 403; of back, 440; of lower extremity, 542; of neck, 426; of upper extremity, 501
of palmar arches, 617; of palpebral fissure, 900
of pancreas, 1007; of patella, 280; of pelvis, 270
of plantar arch, 664; of popliteal artery, 655; of posterior tibial artery, 661
of radial artery, 611; of radio-ulnar joint, superior, 348; inferior, 350; of radius, 245

Surface Form or Marking (*continued*)
of scapula, 230; of shoulder-joint, 342; of skull, 204; of spleen, 1013; of spine, 139
of sterno-clavicular joint, 336; of sterno-mastoid, 409; of stomach, 972
of subclavian artery, 589
of tarsus and foot, 302
of temporo-maxillary joint, 322; of thorax, 219; of tibia, 284
of ulnar, 242; of ulnar artery, 614
of vertebral column, 139
of wrist and hand, 257; of wrist-joint, 352
Surgical Anatomy, of abdominal aorta, 621; of abducent nerve, 796; of acromio-clavicular joint, 338; of adductor longus muscle, 518; of ankle-joint, 376; of anterior tibial artery, 658; of arch of aorta, 551; of artery of the bulb, 639; of ascending pharyngeal artery, 567; of auditory nerve, 802; of axilla, 600; of axillary artery, 602; of axillary glands, 703; of axillary vein, 682, of azygos veins, 685
of base of bladder, 1143; of brachial artery, 607; of brachial plexus, 831; of bend of elbow, 605; of bones of face, 208; of branches of internal iliac, 641
of cavernous sinus, 677; of cervical glands, 702; of cervical vertebræ, 319; of clavicle, 224; of club-foot, 534; of common carotid, 557; of common iliac, 632
of deltoid muscle, 474; of dorsalis pedis artery, 660; of deep epigastric, 644; of descending aorta, 618
of extensor muscles of thumb, 492; of external carotid artery, 559; of external iliac artery, 642; of external jugular vein, 671; of eye, 895
of external ear, 905; of elbow-joint, 346; of Eustachian tube, 942
of facial artery, 565; of facial vein, 669; of facial nerve, 801; of femoral artery, 647; of femoral hernia, 1128; of femur, 278
of gluteal artery, 641
of hæmorrhoidal veins, 690; of hamstrings, 525; of forearm, bones of, 245; of foot, bones of, 302; of hand, bones of, 258; of hip-joint, 361; of humerus, 224; of hyoid bone, 210; of hypoglossal nerve, 812
of iliac fascia, 509; of inferior thyroid artery, 595; of inferior vena cava, 685; of inguinal hernia, 1115; of inguinal glands, 704; of innominate artery, 554; of intercostal nerves, 735; of internal carotid artery, 577; of internal jugular vein, 672; of internal mammary artery, 598; of internal iliac artery, 634; of internal pudic artery, 638; of intestines, 990; of ischio-rectal region, 1137
of joints of cervical vertebræ, 319
of kidneys, 1069; of knee-joint, 370
of lachrymal apparatus, 901; of laryngo-tracheal region, 1044; of larynx, 1044; of laryngeal nerves, 808; of leg, bones of, 287; of lingual artery, 562; of
Surgical Anatomy (*continued*)
liver, 1004; of lumbar plexus, 852; of lungs, 1055
of middle meningeal artery, 569; of motor oculi nerve, 781; of muscles of eye, 395; of muscles of lower extremity, 543; of muscles of soft palate, 422; of muscles of upper extremity, 503; of musculo-spiral nerve, 832
of nasal fossæ, 878; of nose, 878
of œsophagus, 944; of olfactory nerve, 778; of optic nerve, 779
of palmar arch, 617; of palmar fascia, 495; of pancreas, 1007; of patella, 280; of pelvis, bones of, 271; of penis, 1088; of perinæum, 1137; of peroneal or external popliteal nerve, 854; of pharynx, 942; of plantar arch, 664; of plantar ligaments, 378; of pleura, 1047; of popliteal artery, 655; of posterior tibial, 661; of pronator radii teres muscle, 482; of prostate gland, 1085; of psoas magnus, 509
of radial artery, 611; of radio-ulnar joint, 348; of rectus femoris muscle, 515; of ribs, 220
of saphena veins, 689; of scapula, 231; of Scarpa's triangle, 644; of sciatic artery, 641; of sciatic (great) nerve, 853; of scrotum, 1091; of serratus magnus muscle, 473; of shoulder-joint, 342; of skull, 206; of spermatic veins, 692; of spine, 140; of spinal accessory nerve, 809; of spleen, 1013; of sterno-clavicular joint, 336; of sterno-mastoid muscle, 409; of sternum, 220; of stomach, 972; of subclavian artery, 589; of superior thyroid artery, 561; of synovial sheaths of tendons of wrist, 493
of talipes, 534; of tarsal joints, 378, 380; of temporal artery, 567; of temporo-maxillary joint, 322; of testis, 1095; of thoracic aorta, 618; of thorax, 220; of thyroid gland, 1057; of tongue, 417, 872; of triangles of neck, 571; of triceps, 481; of trifacial nerve, 794; of trochlear nerve, 781
of ulnar artery, 617; of urethra, 1081
of vertebral artery, 593; of vesico-prostatic plexus, 691; of vesiculæ seminales, 1097
of wrist-joint, 352
Suspensory ligament of incus, 910; of lens, 894; of liver, 995; of malleus, 909; of penis, 1085
Sustentacular cells of spleen, 1010
Sustentaculum tali, 290
Sutura, 307; dentata, 307; harmonia, 307; limbosa, 307; notha, 307; serrata, 307; squamosa, 307; vera, 307
Suture, basilar, 188; coronal, 188; cranial, 186; frontal, 186; fronto-parietal, 188; fronto-sphenoidal, 188; intermaxillary, 199; internasal, 199; interparietal, 186; lambdoid, 188; masto-occipital, 188; masto-parietal, 188; occipito-parietal, 188; petro-occipital, 188; petro-sphenoidal, 188; petro-squamous, 188; sagittal, 186; spheno-parietal, 188; squamo-

parietal, 188; squamo-sphenoidal, 188; temporal, 155; transverse facial, 188
Swallow's nest of cerebellum, 771
Sweat-glands, 66
Sylvius, fissure of, 748; surface marking of, 745; aqueduct of, 761
Sympathetic Nerve, 46, 854; cervical portion, 856; cranial portion, 858; lumbar portion, 860; pelvic portion, 861; thoracic portion, 861; plexuses, 861; cardiac, 861; epigastric, 862; hypogastric, 865; pelvic, 865; solar, 862
Symphysis, 307; of jaw, 183; pubis, 264, 333
Synarthrosis, 306
Syndesmo-odontoid joint, 315
Syndosmosis, 307
Synovia, 306
Synovial ligaments, 306; sheaths, 306
Synovial Membrane, 69, 305; articular, 305; bursal, 306; vaginal, 306. *See also* Individual Joints
System, Haversian, 27
Systemic arteries, 546; veins, 666

Tables of the skull, 119
Tactile corpuscles, 48; of Grandry, 49
Tænia hippocampi, 755; semicircularis, 755; of fourth ventricle, 775
Tæniæ tectæ, 751
Tapetum lucidum, 890; nigrum, 890
Tarsal artery, 660; bones, 287; ligaments, 376; plates of eyelid, 897; ligament of eyelid, 391, 897
Tarso-metatarsal articulations, 380
Tarsus, 287; articulations of, 376; surface form of, 302; surgical anatomy of, 302; synovial membranes of, 381; development of, 300
Taste-goblets, 870
Teeth, 923; bicuspid, 924; body of, 923; canine, 924; cement of, 928; crown of, 923; crusta petrosa of, 928; cortical substance of, 928; cuspidate, 924; deciduous, 923; dental tubuli of, 927; dentine of, 927; development of, 929; enamel of, 928; eruption of, 933; eye, 924; false molars, 924; fang of, 923; general characters of, 923; incisors, 923; intertubular substance of, 927; ivory of, 928; milk, 923, 926; molar, 925; multicuspidate, 925; permanent, 923; pulp-cavity of, 926; root of, 923; structure of, 926; temporary, 923, 926; true or large molars, 925; wisdom, 925
Tegmen tympani, 155, 906
Tegmentum of crus cerebri, 750, 764
Tela choroidea inferior, 775
Temporal artery, 567; anterior, 567; deep, 570; middle, 567; posterior, 567; surgical anatomy of, 567
Temporal bone, 151; articulations of, 158; attachment of muscles to, 158; development of, 157; mastoid portion, 153; petrous portion, 155; squamous portion, 151; structure of, 157
Temporal fascia, 400; fossæ, 197; ganglion, 859; muscle, 400; nerves of auriculo-temporal, 792; deep, 791; of facial, 799; ridge, 146, 149, 197; suture, 155; veins, 669
Temporary cartilage, 23; teeth, 923, 926
Temporo-facial nerve, 799; malar, 786; maxillary articulation, 320; surface form of, 322; surgical anatomy of, 322; maxillary vein, 670
Temporo-sphenoidal lobe, 741
Tendo Achillis, 529; palpebrarum or oculi, 391
Tendon, central, or cordiform, of diaphragm, 444; conjoined of internal oblique and transversalis, 452, 1119
Tendon, structure of, 385
Tendons of wrist, relation of, 494
Tenon, capsule of, 879
Tensor palati muscle, 421; tarsi muscle, 392; tympani muscle, 910; canal for, 157, 907; vaginæ femoris muscle, 512
Tenth nerve, 803; surgical anatomy of, 808
Tentorium cerebelli, 724
Teres major muscle, 477; minor, 476
Terminal sinus, 103
Testes, 1091; coni vasculosi of, 1094; coverings of, 1092; development of, 113; tunica albuginea, 1092; vaginalis, 1092; vasculosa, 1093; gubernaculum testis, 1097; lobules of, 1093; lymphatics of, 708; mode of descent, 1097; rete testis, 1094; size and weight of, 1092; structure of, 1093; tubuli, seminiferi of, 1093; surgical anatomy of, 1095; vas deferens of, 1094; vasa efferentia of, 1094; vasa recta of, 1094; vas aberrans of, 1095
Testes muliebres, 1109
Thalamencephalon, 94
Thalami optici, 759
Thebesii venæ, 696; foramina, 696
Theca vertebralis, 712
Thigh, muscles of back of, 524; deep fascia, fascia lata, 510; superficial fascia, 510, 1128; muscles of front, 509
Third nerve, 779; surgical anatomy of, 781; ventricle of the brain, 759
Thoracic aorta, 617; surgical anatomy of, 618
Thoracic artery, acromial, 603; alar, 604; long, 604; superior, 603
Thoracic duct, 698
Thoracic ganglia of sympathetic, 860
Thoracic nerves, anterior, 823; posterior, or long, 822
Thoracic region, muscles of anterior, 468; lateral, 472
Thorax, *General Description of*, 1014; base of, 1014; bones of, 210; boundaries of, 210; cavity of, 1014; cutaneous nerves of, anterior, 734; lateral, 734; fasciæ of, 441; lower opening of, 211; lymphatics of, 709; muscles of, 441; parts passing through upper opening of, 1014; lower opening of, 1014; surface form of, 219; upper opening of, 210
Thumb, articulation of, with carpus, 354; muscles of, 495
Thymic artery, 553; lymphatic vessels, 711
Thymus gland, 1057; lobes of, 1058; lymphatics of, 1059
Thyro-arytenoid ligament, inferior, 1037; superior, 1037
Thyro-arytenoideus muscle, 1039
Thyro-epiglottic ligament, 1034
Thyro-epiglottideus muscle, 1039

Thyro-hyal of hyoid bone, 210
Thyro-hyoid arch (fœtal), 93; ligaments, 1035; membrane, 1035; muscle, 410; nerve, 812
Thyroid artery, inferior, 594; superior, 560; surgical anatomy of, 561; axis, 594; branches of sympathetic, 859; cartilage, 1032; foramen, 265; ganglion, 859; gland, 1055; isthmus of, 1055; lymphatics of, 711; veins, inferior, 684; middle, 672; superior, 672
Thyroidea ima artery, 553
Tibia, 280; articulations of, 284; attachment of muscles to, 284; crest of, 282; development of, 284; fracture of shaft of, 545; nutrient artery of, 663; spinous process of, 281; surface form of, 284; surgical anatomy, 287; tubercle of, 281; tuberosities of, 281
Tibial artery, anterior, 657; branches of, 658; peculiarities of, 658; surgical anatomy of, 658; surface marking of, 658; posterior, 660; branches of, 662; peculiarities of, 661; surgical anatomy of, 661; surface marking of, 661; lymphatic glands, 704; nerve, anterior, 852; posterior, 850; recurrent artery, 659; veins, anterior, 689; posterior, 689
Tibialis anticus muscle, 527; posticus muscle, 532
Tibio-fibular articulations, 371; region, anterior, muscles of, 525; posterior, 528
Tibio-tarsal ligament, 373
Tongue, 867; arteries of, 872; development of, 109; fibrous septum of, 871; frænum of, 867; mucous glands, 870; mucous membrane of, 868; muscles of, 413; nerves of, 872; papillæ of, 868; serous glands of, 871; surgical anatomy of, 872
Tonsillar artery, 563
Tonsillar nerves, 803
Tonsils, 935; nerves of, 935; vessels of, 935; of cerebellum, 770
Torcular Herophili, 143, 675
Trabeculæ of corpus cavernosum, 1087; cranii, 91; of spleen, 1009; of testis, 1093; of fœtal skull, 91
Trachea, 1041; cartilages of, 1042; glands of, 1043; relations of, 1041; structure of, 1042; surgical anatomy of, 1044; vessels and nerves of, 1044
Trachealis muscle, 1043
Trachelo-mastoid muscle, 435
Tracheotomy, 1045
Trachoma glands, 898
Tracts of cord, antero-lateral, 719; antero-lateral ground bundle, 720; of Burdach, 720; crossed pyramidal, 719; direct cerebellar, 719; direct pyramidal, 718; of Goll, 720; of Gowers, 719; of Lissauer, 720
Tractus intermedio-lateralis, 722
Tractus opticus, 778
Tragicus muscle, 903
Tragus, 902
Transitional epithelium, 15
Transversalis cervicis muscle, 436, *footnote*
Transversalis colli artery, 595; muscle, 435
Transversalis fascia, 1121; muscle, 453
Transversalis humeri artery, 595
Transverse arteries of basilar, 593; colon, 984; disc of muscular fibre, 37; facial artery, 567; vein, 669; fissure of brain, 756; of liver, 996; humeral ligament, 340; joint of foot, 375; ligament of atlas, 316; of hip, 360; of knee, 366; metatarsal ligament, 382; of scapula, 339; of shoulder, 340; superficial of fingers, 495; tibio-fibula, 372; mesocolon, 966; process of a vertebra, 121; sinus, 678; suture, 188
Transversus auriculæ, 903; perinæi, 462; perinæi (in female), 465
Trapezium, bone, 251; of pons, 735
Trapezius muscle, 427
Trapezoid bone, 251; ligament, 337
Treitz, muscle of, 953, 975
Triangle, inferior, carotid, 572; of elbow; 605; of Hesselbach, 1123, 1126; of neck, anterior, 572; posterior, 573; occipital, 574; Scarpa's, 644; subclavian, 574; submaxillary, 573; suboccipital, 439; superior carotid, 573
Triangular ligament of abdomen, 451, 1119; of urethra, 464, 1140; interarticular fibro-cartilage, 349
Triangularis sterni muscle, 442; menti muscle, 397
Triceps extensor cruris, 514; extensor cubiti, 480; suræ, *footnote*, 529
Tricuspid valves, 1021
Trifacial or trigeminus nerves, 782; surface marking of, 794; surgical anatomy of, 794
Trigone of bladder, 1078
Trigonum, acustici, 776; habenulæ, 759; hypoglossi, 776; vagi, 776
Tri-radiate sulcus, 738
Trochanter, greater, 273; lesser, 273
Trochanteric fossa, 273
Trochlea of humerus, 235; of femur, 275
Trochlear fossa, 150; nerve, 781; surgical anatomy of, 781
Trochoides, 308
Trolard, anastomotic vein of, 674
True pelvis, 267; ligaments of bladder, 1076; ribs, 215
Trunk, articulations of, 311; muscles of, 426
Tube, Eustachian, 908; Fallopian, 1108
Tuber, annulare, 734; cinereum, 749; ischii 263; omentale, 994
Tubercle, adductor, 275; carotid or Chassaignac's, 122; of the clavicle, 222; conoid, 222; deltoid, 222; of the femur, 275; genital, 116; of hyoid bone, 209; lachrymal, 172; laminated of cerebellum, 771; of Lower, 1020; of navicular, 294; for odontoid ligaments, 143; of the quadratus, 274; of rib, 216; of Rolando, 729, 731; of scaphoid, 249; of the tibia, 281; of ulna, 238; of zygoma, 152
Tubercles, genial, 183; mental, 183; of ribs, 216
Tubercula quadrigemina, 762
Tuberculum acusticum, 776; cuneatum, 729
Tuberosities of humerus, greater, 231; lesser, 233; of tibia, 281
Tuberosity, cuboid, 293; of ischium, 263; maxillary, 170; of the navicular bone, 294; of palate bone, 179; of radius, 243; of rib, 216

Tubes, bronchial, 1042; structure of, in lung, 1052
Tubular membrane of nerves, 43
Tubular secreting glands, 71
Tubular substance of kidney, 1062
Tubuli, dental, 927; of Ferrein, 1064; lactiferi, 1113; seminiferi, 1093; uriniferi, 1062
Tuft, vascular, in Malpighian bodies of kidney, 1063
Tunica albuginea, 1092; elastica externa, 53; of eye, 393; of ovary, 1110; Ruyschiana, 884; vaginalis, 1092; vaginalis propria, 1092; reflexa, 1092; vasculosa testis, 1093
Tunica intima of arteries, 52; media, 52; adventitia, 53
Tunica vaginalis oculi, 879
Turbinated bone, superior, 165; inferior, 180; middle, 165; crest, inferior, 178; superior, 178
Türck, fasciculus of, 718
Tutamina oculi, 896
Twelfth nerve, 809; surgical anatomy of, 812
Tympanic artery, from internal carotid, 577; from internal maxillary, 569; nerve, 803, 911; of facial, 798; plate, 153, 155, 905
Tympanum, 905; arteries of, 910; cavity of, 905; membrane of, 908; mucous membrane of, 910; muscles of, 910; nerves of, 910; ossicula of, 908; veins of, 910
Tyson's glands, 1086

Ulna, 238; articulations of, 242; coronoid process of, 238; olecranon process of, 238; development of, 242; fracture of coronoid process of, 246; of olecranon, 505; of shaft, 505; muscles attached to, 242; sigmoid cavities of, 238; styloid process of, 242; surface form of, 242; surgical anatomy of, 245; tubercle of, 238
Ulnar artery, 613; branches of, 614; peculiarities of, 613; surgical anatomy of, 614; surface marking of, 614; lymphatic glands, 702; nerve, 828; surgical anatomy of, 832; artery recurrent, anterior, 614; posterior, 614; vein, anterior, 680; posterior, 680
Umbilical arteries in fœtus, 88, 104, 634, 1028; how obliterated, 1031; cord, 88; fissure of liver, 996; region, contents of, 948; vein, 106; vesicle, 81
Umbilicus, 82, 456
Unciform bone, 252; process of, 253; process of ethmoid, 165
Uncinate lobe, 744; fasciculus, 764
Uncus, 744
Ungual phalanges, 257
Unstriped muscle, 39
Upper extremity, arteries of, 585; bones of, 221; fascia of, 467; ligaments of, 334; lymphatics of, 702; muscles of, 467; nerves of, 820; surgical anatomy of, 503; veins of, 679; surface form of muscles of, 501
Urachus, 86, 112, 1074
Ureters, 1069; muscles of, 1078; nerves of, 1071; vessels of, 1070
Urethra, development of, 116; male, 1080; bulbous portion of, 1081; caput gallinaginis, 1080; membranous portion, 1081; prostatic portion, 1080; sinus of, 1080; rupture of, course taken by urine, 1139; sinus pocularis of, 1080; spongy portion of, 1081; structure of, 1081; surgical anatomy of, 1081; verumontanum, 1080; female, 1101
Urinary organs, 1060; development of, 110
Urogenital sinus, 112
Uterine arteries, 636; plexus, 866; plexus of veins, 691
Uterus, 1103; appendages of, 1108; arbor vitæ of, 1106; broad ligaments of, 1105; cavity of, 1105; development of, 111; ganglia of, 866; nerves of, 866; in fœtus, 1107; fundus, body, and cervix of, 1104; ligaments of, 1104; lymphatics of, 708; during menstruation, 1108; in old age, 1108; after parturition, 1108; during pregnancy, 1108; at puberty, 1107; round ligaments of, 1112; shape, positions, dimensions, 1103; structure of, 1106; vessels, 1107; nerves of, 1107
Uterus masculinus or utriculus hominis, 112, 114, 1080
Utricle of vestibule, 914
Uvea, 885
Uvula of throat, 934; of cerebellum, 770; vesicæ, 1079

Vagina, 1102; columns of, 1003; lymphatics of, 708; orifice of, 1099
Vaginal arteries, 636; plexus of nerves, 865; plexus of veins, 691; portal plexus, 1000; process of temporal, 153, 157; processes of sphenoid, 160; synovial membranes, 306
Vagus nerve, 803; ganglion of root of, 805; of trunk of, 805
Valentin, ganglion of, 788
Vallecula Sylvii, 748
Valley (vallecula) of cerebellum, 768
Valsalva, sinuses of, 549, 1022, 1024
Valve of Bauhin, 983; coronary, 1020; of cystic duct, 1003; Eustachian, 1020; of gall-bladder, 1002; of Hasner, 900; ileo-cæcal, 983; of Kerkring, 976; mitral, 1024; of Vieussens, 775
Valves in right auricle, 1020; semilunar aortic, 1024; pulmonic, 1022; tricuspid, 1021; of lymphatics, 57; of veins, 56
Valvulæ conniventes, 976
Vas deferens, 1094; structure of, 1095; aberrans, 1095
Vasa aberrantia, from brachial artery, 606; afferentia of lymphatic glands, 698; brevia arteries, 625; veins, 693; efferentia of testis, 1094; of lymphatic glands, 698; vasorum of arteries, 53; of veins, 57; intestini tenuis arteries, 626; recta, 1094
Vascular area of blastodermic membrane, 82, 103
Vascular system, general anatomy of, 51; changes in, at birth, 1031; peculiarities in fœtus, 1028; capsule of lens, 99
Vaso-motor nerves, 46

Vastus externus muscle, 514; internus and crureus, 514
Vater, corpuscles of, 48 (*footnote*)
Veins, *General Anatomy of*, 55; anastomoses of, 666; coats of, 55; development of, 105; muscular tissue of, 56; plexuses of, 666; size, form, &c. 666; structure of, 56; valves of, 56; vessels and nerves of, 57
Veins or Vein, *Descriptive Anatomy of*, 666; of alæ nasi, 669; angular, 669; articular of knee, 689; auditory, 918; auricular anterior, 669; posterior, 670; axillary, 682; azygos, left lower, 685; left upper, 685; right, 685
basilic, 681; basi-vertebral, 687; of bone, 26; brachial, 682; brachio-cephalic or innominate, 683; bronchial, 686; buccal, 670
cardiac, 695; anterior, 695; left, 695, right, 695; posterior, 695; cardinal, 107; cava superior, 684; inferior, 691; cephalic, 681; cerebellar, 674; cerebral, 673; cervical, ascending, 672; deep, 672; choroid of brain, 674; circumflex, iliac, 690; superficial, 688; condyloid posterior, 672, 676; of corpora cavernosa, 1087; of corpus spongiosum, 691; of corpus striatum, 674; cystic, 695
deep, or venæ comites, 667; dental inferior, 670; digital of hand, 680; of diploë, 673; dorsi-spinal, 686; of penis, 691; dorsalis nasi, 669; pedis, 688
epigastric, deep, 690; superficial, 688; of eyeball, 894; emissary, 678; surgical anatomy of, 679
facial, 669; femoral, 689; frontal, 668
of Galen, 674; gastric, 694; gastro-epiploic, 693; gluteal, 690
hæmorrhoidal, 690; of head, 667; hepatic, 693
iliac, common, 691; external, 690; internal, 690; ilio-lumbar, 691; inferior cava, 691; innominate, 683; intercostal, superior, 684; interlobular, of kidney, 1067; of liver, 1000; intralobular of liver, 1000; interosseous of fore-arm, 682
jugular anterior, 671; external, 670; external posterior, 671, internal, 671
of kidney, 1067
labial inferior, 669; superior, 669; laryngeal, 684; lateral sacral, 691; lingual, 672; of liver, 998; longitudinal inferior, 676; lumbar, 692; ascending, 692
mammary internal, 684; masseteric, 669; mastoid, 670; maxillary internal, 670; median cutaneous, 681; basilic, 681; cephalic, 681; medulli-spinal, 687; meningeal, 670; meningo-rachidian, 686; mesenteric inferior, 693; superior, 693
nasal, 668
oblique cardiac, 696; obturator, 690; occipital, 670; œsophageal, 685; ophthalmic, 677; inferior, 677; ovarian, 692
palatine, inferior, 669; palmar, deep, 682; palpebral, inferior, 669, superior, 669; pancreatic, 693; pancreatico-duodenal, 693; parotid, 669; peroneal, 689; pharyngeal, 671; phrenic, 693; plantar,
Veins or Vein (*continued*)
external, 689; internal, 689; popliteal, 689; portal, 666, 695, 1000; profunda femoris, 690; pterygoid plexus, 670; pudic external, 688; internal, 690; pulmonary, 667
radial, 681; ranine, 669, 672; renal, 693, 1067
sacral, middle, 691; lateral, 691; salvatella, 680; saphenous external, or short, 689; internal, or long, 688, 1128; sciatic, 690; spermatic, 692; spheno-palatine, 672; spinal, 686; splenic, 693; stylo-mastoid, 670; subclavian, 682; sub-lobular, 998, 1000; submaxillary, 669; submental, 669; superficial, 666; supra-orbital, 668; supra-renal, 693; supra-scapular, 671; sural, 689; systemic, 667
temporal, 669; middle, 669; temporo-maxillary, 670; thyroid inferior, 684; middle, 672; superior, 672; tibial anterior, 689; posterior, 689; transverse cervical, 671; facial, 669; Trolard, great anastomic of, 674
ulnar anterior, 680; common, 681; deep, 682; posterior, 680; umbilical, 1029
vaginal of liver, 1000; vasa brevia, 693; vertebral, 672; Vidian, 672
Veins, plexuses of, ovarian, 692, 1112; pampiniform, 692, 1091, 1112; pharyngeal, 672; pterygoid, 670; spermatic, 692, 1091; uterine, 691; vaginal, 691; vesico-prostatic, 690
Velum pendulum palati, 934; interpositum, 758
Vena cava, superior, 684; inferior, 691; peculiarities of, 692; fœtal, 107
Venæ basic vertebræ, 121; comites, 667; hepaticæ revehentes, 106; advehentes, 106; salvatella, 680; Thebesii, or minimæ cordis, 696, 1020; vorticosæ, 884; interlobulares of kidney, 1067; rectæ of kidney, 1067
Venesection, 681
Venter of ilium, 262; of scapula, 225
Ventricle of Arantius, 730, 774
Ventricles of brain, third, 759; fourth, 774; lining membrane of, 776; fifth, 757; lateral, 752; of cerebellum, 774; of corpus callosum, 751; of heart, left, 1024, right, 1020; of larynx, 1037
Vermicular motion, 40
Vermiform process of cerebellum, inferior, 770, superior, 769
Vernix caseosa, 100
Vertebra prominens, 125; development of, 131
Vertebræ, 120; cervical, 121; development of, 129; dorsal, 125; general characters, 120; ligaments of, 311; lumbar, 127; sacral, 131; structure of, 129
Vertebral aponeurosis, 432; artery, 591; column, 137; surface form of, 139; articulation of, 311; ossification of, 129; ligaments, 311; region, muscles of, anterior, 423; lateral, 424; vein, 684
Vertex of skull, 189
Vertical plate of palate bone, 178
Verumontanum, 1080
Vesicle artery, inferior, 635; middle, 635; superior, 635; plexus of nerves, 865

Vesicle, auditory, 99; cerebral, 93; germinal, 73; ocular, 97; of Purkinje, 73; umbilical, 81
Vesicles, Graafian, 1110
Vesico-prostatic plexus of veins, 690
Vesico-uterine ligaments, 1104
Vesicula prostatica, 1080
Vesiculæ seminales, 1095; vessels and nerves of, 1096; surgical anatomy of, 1097
Vesicular nervous matter, 41; column of anterior cornu of spine, 722
Vestibular artery, 918; nerve, 802, 918
Vestibule of ear, 911; of nose, 877; aqueduct of, 156, 912
Vestigial fold of pericardium, 684
Vibrissæ, 874
Vidian artery, 571; canal, 161; nerve, 789
Vieussens, valve of, 772
Villi, 977
Viscera, position of, in abdominal regions, 947; pelvic, position of, at outlet of pelvis, 1142
Visceral arches (fœtal), 92
Vitelline membrane, 73; spheres, 74; circulation, 101
Vitellus, 73
Vitreous humour of the eye, 892; table of the skull, 119
Vocal cords, inferior or true, 1037; superior or false, 1037
Voice, organs of, 1032
Voluntary muscles, 36
Vomer, 181; alæ of, 181; articulations of, 182; development of, 182
Vortex of heart, 1026
Vulva, 1099; development of, 1116

Wagner, tactile corpuscles of, 48
Watney on the structure of villi, 978; of thymus, 1059
Weight of organs. *See* Individual Organs
Wharton's duct, 937
White fibrous tissue, 15
White substance of cord, 718; nervous, 41; of Schwann, 42
Willis, circle of, 583, 594
Winslow, foramen of, 958, 963; ligament of, 364
Wisdom tooth, 925
Wolffian body, 111
Womb. *See* Uterus
Wormian bones, 167
Wrisberg, cartilages of, 1034; ganglion of, 862; nerve of, 826
Wrist-joint, 350; surface form of, 257, 352; surgical anatomy of, 352
Wry-neck, 409

Xiphoid appendix, 213

Y-ligament, 359
Y-shaped centre of acetabulum, 266
Yellow elastic fibrous tissue, 16; cartilage, 24
Yellow spot of retina, 887
Yolk, 73; cleavage of, 74
Yolk sac, 81

Zinn, ligament of, 393
Zona, arcuata, 916; fasciculata, 1072; glomerulosa, 1072; reticularis, 1072; vasculosa, 1111; pellucida, 73; radiata, 73
Zygoma, 151; roots of, 152; tubercle of, 152
Zygomatic arch, 197; fossæ, 197; lymphatic glands, 699; process of malar, 176
Zygomaticus, major muscle, 397, minor, 397
