THE VALUE OF INTERNATIONAL CONGRESSES.—The Tenth International Congress at Berlin came to a successful closing, and its volumes of Transactions will bear witness to the value of the contributions there made. The special practical advantages to be derived from such international gatherings lies not so much in special work there

accomplished. The press, rather than the forum, is more serviceable in the promulgation of scientific truths; but the opportunity thus presented for the meeting of men of note, face to face, is one which will lend inspiration to their future efforts, and will give them an added value. Such meetings beget a world-wide interest in all medical questions; they develop a brotherhood of the profession; they broaden and strengthen the great work of scientific investigation which must be incident to medical progress. The profession will look forward with unwonted interest to the next great assemblage in the city of Rome, not soon forgetting the notable assemblage at Berlin, and the unbounded hospitalities which were so freely accorded.

THE PREVALENCE OF CHOLERA.—We have nothing of special import as to the spread of this disease beyond that which was noted in the last issue. It now prevails generally along the Arabian shores of the Red Sea, in Cairo, and along the southern shore of the Mediterranean. It has appeared in various provinces in Spain, advancing to the borders of Portugal. We hear nothing later of its supposed appearance in London.

AN ARMY MEDICAL BOARD will be in session in New York City, N. Y., during October, 1890, for the examination of candidates for appointment in the Medical Corps of the United States Army to fill existing vacancies. Persons desiring to present themselves for examination by the Board will make application to the Secretary of War, before October 1, 1890, for the necessary invitation, stating the date and place of birth, the place and State of permanent residence, the fact of American citizenship, the name of the medical college from whence they were graduated, and a record of service in hospital, if any, from the authorities thereof. The application should be accompanied by certificates based on personal knowledge, from at least two physicians of repute, as to professional standing, character, and moral habits. The candidate must be between 21 and 28 years of age, and a graduate from a Regular Medical College, as evidence of which his diploma must be submitted to the Board. Further information regarding the examinations may be obtained by addressing J. H. Baxter, Surgeon-General U. S. Army, Washington, D. C.

TOPICS OF THE WEEK.

RESULTS OF BACTERIOLOGICAL RESEARCH.

Upon this subject we quote the concluding portion of the able address of Dr. Robert Koch, at the late meeting of the International Medical Congress at Berlin. His words are as follows:

"Up till now I have purposely left one question untouched, although it is precisely the one which is most frequently, and not without a certain amount of reproach, addressed to bacteriologists. I mean the question of what profit all the weary labor which has up to the present been expended on the investigation of bacteria has been? Properly speaking, no such question should be asked, as true research follows its own way without being misled by the consideration whether its labors will yield immediate advantage or not. I cannot, however, deem this question utterly unwarranted in the present instance, as very few of those who occupy themselves with bacteriological research leave practical objects entirely out of sight.

"The practically available results obtained up to the present by means of bacteriological research are by no means so despicable as some askers of the above question think.

"I need only refer to that which has been accomplished in the domain of disinfection. Just at this point there was previously no foothold; men worked completely in the dark, and often enough large sums were spent in useless disinfection, leaving altogether out of account the indirect harm done in other ways by the neglect of hygienic precautions. Now, on the other hand, we possess certain knowledge by means of which we are able to test the efficacy of disinfectants, and if much still remains to be done in that province, we can at least affirm that the disinfectants now in use, so far as they have been tested, efficiently fulfil their object.

"Among the practical results might also be reckoned the application of bacteriological methods to the control of water filtration, as for that purpose nothing else can take the place of these methods. Connected herewith are the discoveries arrived at by means of bacteriological research as to the filtering properties of the soil, and the important consequences resulting therefrom as to the employment of ground water for water supply, and for the proper construction of wells. In the same way as in the case of water, bacteriological methods can be applied to the control of milk, especially as far as it is destined for the nourishment of children, as well as to the examination of other alimentary substances and other things in common use which are open to the suspicion of infection. The examination of the air in sewers, and the confirmation which the generally accepted opinion as to the injuriousness of sewer gas has thereby received; the examination of the air in schoolrooms, the recognition of pathogenic bacteria in alimentary substances, in the soil, etc., stand, as it is impossible to deny, in intimate relation with practice. Among the practical results I might further count the possibility which bacteriology has supplied of diagnosing sporadic cases of Asiatic chol-

era, and the first stages of pulmonary tuberculosis, the former being of importance for the prophylaxis of cholera, the latter for the timely treatment of tuberculosis.

"All these things, however, are advantages which can only indirectly be employed in the struggle against bacteria. We have hardly any directly acting, that is, therapeutical, agents to place beside the indirect ones. The only things which can be adduced in this connection are the results which Pasteur and others have obtained by means of protective inoculation in rabies, anthrax, quarter-evil, and swine erysipelas. With regard to antirabic inoculation, the only one which is applicable to man, it may be objected that the cause of rabies is not yet known, and probably may not be of a bacterial kind, and that this preventive inoculation should not be placed to the credit of bacteriology. Notwithstanding this, that discovery grew on bacteriological soil, and could not have been made without the antecedent discoveries of protective inoculation against pathogenic bacteria.

"Although in these directions, in spite of endless toil, bacteriological research has only such insignificant results to show, I am nevertheless not of opinion that this state of things will always continue. On the contrary, I am convinced that bacteriology will one day be of the greatest importance from the therapeutical point of view also. It is true, I look for relatively smaller therapeutical results in the case of diseases with a short incubation period and a rapid course. In these diseases, as for example in cholera, the chief reliance will always have to be placed on prophylaxis. I am thinking more of diseases of less rapid course, as these offer more points of attack to therapeutic enterprise. And there is scarcely a disease which, partly on this ground, partly on account of its far surpassing all other infectious diseases in importance, so challenges bacteriological investigation as tuberculosis.

"Moved by these considerations, very soon after the discovery of the tubercle bacilli, I set about seeking for substances which could be used therapeutically against tuberculosis, and I have pursued this search, which has, of course, been often interrupted by my other occupations, perseveringly up to the present. In the belief that there must be a remedy for tuberculosis, I do not by any means stand alone.

"Billroth has, in one of his last writings, expressed himself with all possible distinctness to the same effect, and it is well known that the same object is aimed at by many investigators. It seems to me, however, that the latter have not as a rule followed the right way in their investigations, inasmuch as they have begun their experiments on man. To that I ascribe the fact that everything which people have believed themselves to have discovered in that way—from benzoate of soda down to the hot-air treatment—has proved to be a delusion. Experiments must be made in the first place not on man, but on the parasites themselves in their pure cultures; even if substances have been found which have the power to check the development of tubercle bacilli in the cultures, man should not forthwith be chosen as the subject of experiment. But the question whether observations which have been made in a test tube hold good

also in living animal bodies should first be settled in animals. Only if the experiments on animals have proved successful, should the method be tried on man.

"Proceeding according to these rules I have in the course of time tested a very large number of substances to see what influence they would exert on the tubercle bacilli cultivated in pure cultures, with the result that not a few substances have the power, even in very small doses, of hindering the growth of tubercle bacilli. More than this, of course, a remedy cannot do. It is not necessary, as has often been erroneously assumed, that the bacteria should be killed in the body; in order to make them harmless to the body it is sufficient to prevent their growth, their multiplication.

"I have proved the following substances to be remedies which hinder such growth even in very small doses (to mention only the most important):—A number of ethereal oils; among the aromatic compounds, β naphthylamin, paratoluidin, xyloidin; some of the so-called tar dyes, namely, fuchsin, gentian, violet, methyl blue, chinolin yellow, aniline yellow, auramin; among the metals, mercury in the form of vapor, silver and gold compounds. The compounds of cyanogen and gold were especially conspicuous, their effect surpassing that of all other substances; even in a dilution of 1 to 2 millions they checked the growth of tubercle bacilli. All these substances, however, remained absolutely without effect if tried on tuberculous animals.

"In spite of this failure I have not allowed myself to be discouraged from prosecuting the search for growth-hindering remedies, and I have at last hit upon a substance which has the power of preventing the growth of tubercle bacilli, not only in a test tube, but in the body of an animal. All experiments in tuberculosis are, as everyone who has had experience of them has sufficiently discovered, of very long duration; my researches on this substance, therefore, although they have already occupied me for nearly a year, are not yet completed, and I can only say this much about them, that guinea pigs, which, as is well-known, are extraordinarily susceptible to tuberculosis, if exposed to the influence of this substance, cease to react to the inoculation of tuberculous virus, and that in guinea-pigs suffering from general tuberculosis even to a high degree, the morbid process can be brought completely to a standstill, without the body being in any way injuriously affected.

"From these researches I, in the meantime, do not draw any further conclusions than that the possibility of rendering pathogenic bacteria in the living body harmless without injury to the latter, which has hitherto been justly doubted, has been thereby established.

"Should, however, the hopes based on these researches be fulfilled in the future, and should we succeed, in the case of one bacterial infectious disease, in making ourselves masters of the microscopic, but hitherto victorious, enemy in the human body, then it will soon also be possible, I have no doubt, to obtain the same result in the case of other diseases. This opens up an oft-promised field of work, with problems which are worthy to be the subject of an international competition of the noblest kind. To give even now some encouragement to further

researches in this direction was the sole and only reason why I, departing from my usual custom, have made a communication on a research which is not yet completed.

"Allow me, therefore, to conclude this address with the expression of a wish that the nations may measure their strength on this field of labor and in war against the smallest, but the most deadly, foes of the human race, and that in this struggle for the weal of all mankind one nation may always strive to surpass the other in the successes which it achieves."

ROME AS A PLACE OF MEETING.

No city in the world can offer attractions to visitors to equal those of the Queen City of Europe. To mention the name of Rome is to evoke in the minds of those who are familiar with the historic glories, the artistic treasures, and the monumental grandeur of that city, memories of an ineffaceable delight, to renew which must in itself be an invincible attraction; while to those who are acquainted with the storied beauties and undying loveliness of the palaces, the galleries, and classic remains of the Eternal City, such a visit must be looked forward to with eager anticipation. Rome, too, is now a centre of great scientific and literary activities, the capital of an illustrious nation, and one whose aspirations and repute, not less than its enthusiasm and its sympathies, will not allow it to dream of being backward in the organization for the great reception, such as that of which London, Copenhagen, Washington, and Berlin have in turn afforded models. The invitation was all the more acceptable from being given by Baccelli, a former Minister of State, a President of the Italian Society of Medicine and of the Medical Academy of Rome, an orator, a statesman and a *savant*—one of the most brilliant of speakers, one of the most lovable of men, and one of the most distinguished of modern investigators. Under his invitation, and with the support which he is sure to find from the Government, from the municipality, and from his countrymen, we may be sure that the future Congress of Rome will have attractive features of its own, before which it is not improbable that all Congresses up to this date will pale their ineffectual fires.—*British Medical Journal*.

THE SURGICAL SECTION AT BERLIN

The London *Lancet* correspondent makes allusion to this Section as follows:

"The material submitted to this Section was perhaps on the whole more remarkable for quantity than for quality; no great or startling innovation in surgery has marked this International Congress. Without doubt the various hospitals in Berlin have undergone great and radical changes in the last ten years. Many of them were shown to the Section, and in all lavish expenditure was more than apparent. The new hospital is quite unsurpassed by any yet built in its arrangement and technical fittings. It is evident that the aseptic, as opposed to antiseptic, method of operating has obtained a firm foothold in Germany."

PRACTICAL NOTES.

ECZEMA OF DENTITION.

For eczema of dentition, treatment is to be directed to three indications (*Gazette Hebdom. in Annals of Gynecology and Pediatrics*, July, 1890).

1. To calm pruritus of the gums, frequent rubbing with the finger dipped in a solution of the following:

R. Cocaine hydrochlorat., gr. j.
Potass. Bromid., gr. x.
Glycerine.
Aqua destillat, āā f̄ss. ℥.

2. For insomnia a dessertspoonful hourly of—

R. Sodii bromidi, gr. xij.
Syrup aurant flor., f̄ssij. ℥.

3. For the local eczema the following:

R. Zinci oxid., gr. xx.
Vaselini, ʒj.

—*Buffalo Med. and Surg. Journal*.

ANTIPYRIN IN CUTANEOUS AFFECTIONS.

One of the symptoms which is most disagreeable in a large number of skin diseases, is the intense itching or soreness which causes scratching, with consequent injury to the parts involved. Many remedies are now added to the applications usually ordered to allay this troublesome state. Chief among these are carbolic acid, menthol, chloral hydrate, and cocaine, but even these often prove inefficient. According to Blaschko, of Berlin, antipyrin proves a most valuable remedy under such circumstances, and he recommends that for infants the following be given internally:

R. Antipyrin, ½ drachm.
Simple syrup, 1 oz. ℥.

Dose, half a teaspoonful at night before going to bed.

Sometimes large doses are needed, but excellent results are to be obtained by this means in eczema, urticaria, strophulus, pemphigus, lichen ruber and planus. Not only does it prove palliative, but often curative, probably by preventing scratching. Antipyrin may also be used for hysterical pruritus with advantage, but in adults must be given in full doses and frequently.—*Medical News*.

HYPNAL IN THE TREATMENT OF NEURALGIC INSOMNIA.

Dr. Fraenkel reports, in *Nouveaux Remèdes*, that he has prescribed hypnal in various cases at his clinic, and that sleep resulted as with chloral, and with the characteristics of the sleep produced by the latter drug—that is, a calm and refreshing sleep, without nausea or disagreeable sensations on awakening—and that the painful symptoms improved as they improve after the administration of antipyrin. Hypnal, or monochloralantipyrin, is a chemically well-defined compound that is less soluble than either chloral or antipyrin; in the

presence of a feeble alkali it is resolved into these substances, and this decomposition occurs in the blood or in the intestine. It has only a slight taste and odor, and is easily administered to children. It produces the hypnotic effect of chloral augmented by the analgesic action of antipyrin, and is especially valuable in insomnia caused by pain. It may be administered in capsules or powders, in doses of 15 grs., to an adult, that may be repeated if necessary. For a child the dose is from 1 gr. to 10 grs.—*N. Y. Medical Journal*.

FRUIT AT MEALS.

As a rule, a fruit dessert in the evening and after a mixed meal ought only to be lightly indulged in, for the average stomach will but rarely tolerate a heavy influx of such cold and usually watery aliment as fruit. This is not the case if the fruit is eaten before or between the meal courses. A ripe melon eaten with salt or butter, before or immediately after the soup, can be freely indulged in. Experience teaches us that stewed or raw fruit may be largely taken between the courses. In many parts of the Continent this custom prevails; the Germans eat stewed fruit with many meats, and in warmer climes such fruit as grapes, plums, figs, melons and sweet lemons are habitually eaten with all kinds of dishes as palate refreshers between the courses.—*Annals of Hygiene*.

ACETANILID IN EPILEPSY.

Dr. Theodore Diller, of Danville, has been using acetanilid in the treatment of epilepsy in nine cases in which bromides and other modes of treatment had previously been employed. He finds that in all the cases in which the drug was given continuously there was noted a reduction in the number of fits ranging from about 25 to 75 per cent., as compared with other months during which the patients were on bromide and tonic treatment alternately. The remedy was in all cases well borne, producing no apparent mental or physical depression, this forming a marked contrast to the depressant effects noted after a course of bromides. No skin eruption was produced. In spite of these results, however, he believes that in any given case, in which a great number of fits are occurring, and where it is desirable to control them as soon as possible, bromides would be of far more value than acetanilid. From the table appended to his paper it would appear that the beneficial effects of acetanilid were most marked only after the drug had been employed for over three months. In two cases no improvement followed the use of acetanilid.—*Lancet*. [Dr. Beaumetz proposed the use of exalgine in epilepsy, and Déferine is now testing the new drug at the Bicetre.]—*N. Y. Med. Abstract*.

SOCIETY PROCEEDINGS.

Tenth International Medical Congress,
Berlin, August, 1890.

DR. H. C. WOOD, of Philadelphia, delivered
before the Congress

AN ADDRESS ON ANÆSTHESIA.¹

He said: The most brilliant modern achievements of the science and art of medicine in the direct saving of life are connected with surgery. These great achievements have been rendered possible by two epoch-making discoveries—antiseptis and anæsthesia. The long array of fatal cases of poisoning by carbolic acid, by iodoform, by corrosive sublimate, and by other antiseptic agents; the hundreds of deaths from chloroform, ether, and other anæsthetics, all bear witness to the verity of that strange law, in obedience to which the progress of the human race is so often at the sacrifice of the individual. Antiseptis has outgrown the dangers of its youth, and to-day the measures that are meant to save very rarely kill. On the other hand, the death roll of anæsthesia is daily added to—added to, according to my belief, at a rate that has not changed in forty years. Though this be true, from far-off Australia comes the news that jury and judge have condemned to heavy penalty a chloroformist who had lost his patient; and in England itself a well-known medical journal lends support to such a verdict by affirming that “deaths from chloroform are preventable, that with due care they may be avoided,” and that, therefore, when they occur they are the result of ignorance and carelessness. If this be true, five hundred deaths and more—the result of ignorance or carelessness! Five hundred surgeons, including such names as Billroth, Jaeger, Simpson, McLeod, Agnew, Hunter McGuire, and others of equal rank, guilty of manslaughter! And still the carnage goes on. Surely, under such circumstances, the subject of anæsthesia is worthy of the attention even of this, the most learned medical gathering of the nations that the world can furnish. Antiseptis, the gift of the Old World to humanity; anæsthesia, the gift of the New World, which made the fruits of antiseptis possible—surely it is fitting that I, standing here to-day before you all as the representative of the newer civilization, should be the chosen mouthpiece for the renewed discussion of this old but pressing theme.

In attempting a fresh study of a well threshed-out subject, I propose to take advantage of the modern physiological methods, and to endeavor to discover by experiments upon the lower animals how anæsthetics kill, and what drugs or measures are most powerful in putting aside their lethal effects. This brings us face to face with

the question, How far is it possible to adapt experiments to the needs of practical medicine, and to reason from the dog to the man? A full discussion of this subject would not be opportune, but it does seem necessary for our purpose to devote a few minutes to the pointing out of certain general guiding principles.

It ought to be acknowledged as a fundamental axiom, that no amount of experiments can overthrow a clinical fact, although when a contradiction between experimental and bedside observation seems to arise, such contradiction challenges the correctness of the alleged clinical and experimental facts alike, and should lead to careful re-examination. No amount of failure to purge a dog by elaterium proves that elaterium does not purge man; whilst, on the other hand, the discovery that digitalis increased the blood pressure in the lower animal very properly led to doubt as to the correctness of the, at that time general, belief that digitalis acts upon man as a cardiac sedative, and finally to the recognition of the falsity of the clinical observation upon which such belief rested.

Whatever difficulties may beset the path of the experimental therapist, it is certain that law is throughout the universe supreme; that man, at least in his physical nature, is only an especially developed animal; and if drugs act differently upon different animals, such action must be in obedience to certain laws, to us known or unknown.

Any attempt to fairly discuss these laws would lead us too far afield for the present. One law, however, treads so closely upon the matter at hand this morning, that it requires statement. This law is, that when an apparatus or system is of similar function, and of similar functional activity in different animals, the difference in the action of remedies is very rarely, if ever, in kind, though it may be in degree. Throughout mammalia the heart has one general structure and one general function; the heart of the dog responds to the touch of digitalis precisely as does the heart of the man. The human brain is so much more highly developed than the brain of the lower mammal that it is, in fact, a new organ or apparatus, and its relation to drugs changes with the change of structure and of function. The scope of this law in regard to anæsthesia is not far to seek. The functions especially compromised in lethal anæsthesia are respiration and circulation. Surely these functions are similar throughout mammalia, and surely we ought to be able to safely reason concerning them from the dog to the man.

Recently, however, alleged clinical facts have been challenged by high authority, upon the strength of experimental results. Under these circumstances, nothing must be at once abandoned, everything must be re-examined. These

¹ British Medical Journal, August 16, 1890.

reëxaminations I have made, and I may be pardoned, perhaps, if I affirm that a complete study of the clinical and experimental evidence brings out, not a discord, but a most beautiful concord—that concord between experimental and practical medicine which so often fails to appear simply because we cannot fit together the fragments of truth in our possession.

Although numerous substances have been tried, there are to-day in use practically only three anæsthetics—nitrous oxide, ether, and chloroform. Of these, nitrous oxide stands apart, because it produces loss of consciousness, not by virtue of any inherent properties, but simply by shutting off from the nerve centres the supply of oxygen.

It has been asserted that the changes of circulation produced by the inhalation of nitrous oxide are essentially different from those of mechanical asphyxia, and that therefore nitrous oxide does not act as an asphyxiant. It must, however, be borne in mind that the phenomena of mechanical asphyxia are largely due to the presence of an excess of carbonic acid in the blood, whilst in the asphyxia produced by nitrous oxide there is no excess of carbonic acid, so that the phenomena present are simply the outcome of a lack of oxygen. It is, therefore, *a priori*, to be expected that the phenomena of mechanical and of nitrous oxide asphyxia should differ to a certain extent. To determine the way in which nitrous oxide inhalation affects the circulation, I have, during the past winter, in connection with my assistant and friend, Dr. David Cerna, made a long series of experiments. The result has been to show that usually the inhalation is followed by a rise of the arterial pressure, accompanied by a great disturbance of the pulse; the pulse at first becoming irregular and tumultuous, but by-and-by settling, so that when anæsthesia is complete the pulse wave is remarkably large and full, and the rate very slow. The rise and fall of the arterial pressure in nitrous oxide anæsthesia was found to vary remarkably, not only in different inhalations, but in different periods of the same inhalation. Sometimes the rise was sudden, sometimes it was slow and gradual; sometimes it was maintained until near death, sometimes it was interrupted very early; sometimes it was not very well marked, sometimes it was enormous.

In all our experiments respiration ceased while the heart was still in full activity. Indeed, instead of the gas acting as a cardiac depressant, it appeared to act as a cardiac stimulant, although it paralyzed the vasomotor apparatus. Thus, during complete anæsthesia, faradization of the sciatic nerve always failed to register itself in an increase of the blood pressure, although the heart was beating very powerfully, and although the pneumogastriacs had been previously severed; whilst late in the poisoning—at a time when the respiration had absolutely ceased, and the animal

was in this respect dead, and without the power of self-recovery, and when the arterial pressure also had fallen almost to zero—the pulse waves were frequently still nearly three times the normal.

We made but few experiments as to the action of artificial respiration upon the animal dying from nitrous oxide, but these experiments proved that even after complete paralysis of the respiratory function, artificial respiration is capable of rapidly bringing the animal back to life. The heart lives on through nitrous oxide anæsthesia long after the respiratory function has been abolished, and even when the strong, full pulse fails, and the heart has almost ceased to quiver, recovery is still hopeful, because the loss of function has been caused, not by the presence of a poison, but by the absence of oxygen; and although the paralysis may be complete, the life power sleeps before it dies, and is ready to awake at the touch of fresh oxygen.

These experimental results are in strict accord with clinical observations. The S. S. White Dental Manufacturing Company supply a very large, if not the largest, portion of the apparatus and material used for the administration of nitrous oxide in the United States; and, in answer to my inquiry, Dr. J. W. White, their President, writes me that a computation based upon their own sales, and a knowledge of those of their rivals, has reached “the somewhat appalling result, that anæsthesia by nitrous oxide gas is probably effected in three-quarters of a million cases annually in the United States.” Most of these inhalations have been given, not by trained physicians, but by comparatively untrained and often very ignorant dentists; have been given to patients in a sitting or semi-sitting posture; have been given apparently without thought or care to the general community, as the units presented themselves; to the healthy and to the diseased alike; and the result is, out of many millions of inhalations, only three deaths recorded as directly due to nitrous oxide. Could anything be safer?

A suggestive and very practical fact which came out in our experiments is that sometimes during an inhalation of nitrous oxide the rise of the arterial pressure is extraordinary and abrupt. Not long since, in the city of Philadelphia, a gentleman arose from the dentist's chair after an inhalation of nitrous oxide, staggered, and fell in an apoplexy. Is it not easy to perceive that when the arterial system is diseased the great strain of a sudden rise of blood pressure may produce rupture?

Some years since Dr. Kenderdine, a Philadelphia surgeon of local note, died of diabetes, which he insisted was produced in him by the inhalation of nitrous oxide. This is in accord with the researches of the French physician, Dr. Lafont, who reported a case in which sugar appeared in the urine twice in a patient after the inhalation

of the gas, and who also caused in himself, and in dogs, temporary glycosuria by such inhalations. Further, Dr. Lafont noticed in a case of mitral insufficiency temporary albuminuria.

I am not aware that these very suggestive statements of the French physician have given rise to any research, except five experiments made recently upon healthy men, with negative results, by two medical students of the University of Pennsylvania, Messrs. George S. Woodward and Alfred Hand, jun. I do not believe that ordinarily the inhalation of nitrous oxide is followed by sufficient disturbance of the circulation to register itself in the urine, but the negative evidence of Messrs. Woodward and Hand is not sufficient to render it improbable that in exceptional cases the inhalation of nitrous oxide may produce albuminuria or glycosuria. Such phenomena, if they occur, are in all probability not directly produced by the nitrous oxide, but are due to the disturbances of capillary circulation caused by it.

However these facts may be, it seems to me that great caution should be used in the administration of nitrous oxide to persons the coating of whose arteries is diseased, and it is probable that when widespread atheroma exists, ether is a safer anæsthetic than nitrous oxide.

When respiration has been suspended in nitrous oxide anæsthesia, the overwhelming indication is certainly for the employment of artificial respiration.

Notwithstanding the great safety and the many advantages which attend the anæsthetic employment of nitrous oxide, the gas can never be used for the general purposes of the surgeon, on account of the excessive fugaciousness of its influence.

The perfect anæsthetic will be a substance which has the power of paralyzing the sensory nerve trunks without affecting other functions of the body. If such drug exists it yet awaits the coming of its discoverer. Probably until such a sensory-nerve paralyzant is found chloroform and ether will maintain the complete supremacy which they now have; and in the further discussion of my subject I shall confine my remarks to them. Lack of time limits this discussion to:

1. The method in which these two drugs kill, both in man and in the lower animal, that is, whether they destroy life through the circulation or the respiration.
2. The comparative fatality attending the use of these two agents, and the reasons for the difference.
3. The comparative disadvantages between the two agents, and the best method of securing the desired results.
4. The treatment of accidents occurring during ether or chloroform anæsthesia.

In regard to the method in which anæsthetics

kill, my own teaching hitherto has been: First, that although ether in moderate doses acts as a stimulant to the circulation, yet, in overwhelming amount, it is capable of depressing the heart, but that such depression of the heart is always less than the depression of the respiration, and therefore ether kills always through the respiration; secondly, that chloroform may produce death by paralysis of the respiratory centre, or by a simultaneous arrest of respiration and circulation, but that primary paralysis of the heart may occur, and is especially prone to do so when the chloroform vapor has been given in concentrated form.

I think that these views are in accord with general professional belief, but it has recently been alleged that they are at variance with experimental evidences, so that a re-examination is necessary. What, then, are the clinical facts?

If any credence is to be attached to the statements of competent witnesses, who have recorded human deaths during anæsthesia, it is certain that in some cases, under the influence of chloroform, the pulse and respiration have ceased simultaneously; whilst in other instances the respiration has failed before the pulse; and in still other cases the pulse has ceased its beat before the respiratory movements were arrested.

Usually ether arrests respiration in man before it paralyzes the heart, but the collection of records made by Dr. J. C. Reeves certainly show that the fatal result may be produced by syncope. Thus Dr. Ernest H. Jacobs, in a report of a fatal case, asserts positively "the pulse ceased, the breathing continued." It would seem that we must allow that ether in the human subject may cause death in the same methods as does chloroform.

Such then are the clinical facts; or in other words, such are the results of observations made upon the human subject. What are the results of observations made upon animals?

The general teaching in regard to chloroform has been recently challenged by Dr. Lauder Brunton, who, as the result of 450 experiments made by himself upon the pariah dogs of India, has reached the conclusion, as published in the *London Lancet*, that however concentrated the chloroform may be it never causes death from sudden stoppage of the heart. In the physiological laboratories of the University of Pennsylvania, for some years, several hundred dogs have been used annually, and a very large proportion of these dogs have been, at the end of an experiment, killed by chloroform. The observations of Dr. Reichert, Professor of Physiology in the University, Dr. Hobart Hare, Demonstrator of Therapeutics, and myself, have been concordant in showing that chloroform is a cardiac paralyzant, and often does kill dogs by a direct action upon the heart or its contained

ganglia. The statements made concerning the Hyderabad Commission, however, led Dr. Hare and myself to a careful and thorough restudy of the subject. Some of our experiments were made by injecting chloroform into the jugular vein; others by administering it by inhalation in the usual way.

The action of the chloroform seems to be not seriously modified by the method of administration. We definitely proved that in the dog chloroform has a distinct, direct, paralyzing influence on both respiration and circulation; that the respiration may cease before the heart beat, or the two functions be simultaneously abolished; but that in some cases the heart is arrested before respiration. We have several times seen the respiration continue as long as one, and even two minutes after the blood pressure has fallen to zero, and the pulse has completely disappeared from the carotid artery.

The correctness of our experiments, we claim, must be acknowledged. The experiments have not only been witnessed by a number of persons, but I have with me to-day tracings which I will gladly show anyone especially interested in the subject. I do not desire to express any doubt whatever as to the correctness of the experimental data of Dr. Bruiton; I simply claim that both sets of experiments, although they have yielded different results, have been correctly and properly performed. It may be that the high heat or other climatic conditions surrounding the pariah dog make his heart less sensitive to the action of chloroform than is the heart of the dog bred in northern climates. That the thought of the different constitutions of animals in different climates is not absurd, is shown by the fact that some years ago—after I had affirmed before the Physiological Section of the International Medical Congress at London, that if certain asserted results were obtained upon European dogs, said dogs must differ from those of America, and had been met with a smile of incredulity—Dr. Brown Séquard rose and stated that he had experimented upon hundreds of dogs on both continents, and that there was a distinct difference between the animals, the vascular system of the European dogs being much more developed, and operations upon them being, therefore, much more bloody than was the case with the American dog.

A very curious parallel might be traced at this point between the experimental and clinical evidence in regard to the effect of climate upon the action of chloroform. In the Southern United States chloroform is used with great freedom, and with great alleged safety; and as long ago as 1878, Dr. Landon B. Edwards, editor of the *Virginia Medical Monthly*, wrote: "It is one of the most peculiar effects I have ever known in medical practice—the difference of

experience in Europe and the North with chloroform and ether as compared with that of the South—the high rate of mortality in the North, and the low rate in the South." Further, in a recent letter to me, Sir Joseph Fayrer affirmed the extraordinary safety of chloroform in India, and stated that he knew of no death from it as having occurred in that country, although its use is universal.

In a series of experiments which I have recently made myself to determine the changes in the circulation produced when ether anæsthesia is carried on to death, I have found that in the first periods of anæsthesia the blood pressure is usually elevated, and that it is usually quite high at a time when the respirations are very shallow and imperfect, and the dark color of the blood shows that it is heavily charged with carbonic acid. It is not, however, very rare for the blood-pressure to remain near the normal, and I have seen the blood-pressure begin to fall in the very first stages of ether anæsthesia; moreover, in at least two experiments, death occurred from syncope, the respiration continuing for one or two minutes after the complete cessation of the circulation. In an experiment in which the fall of blood-pressure was most pronounced, and the arrest of the heart most complete, the dog was sick from the mange, and it is possible that the weakened heart was more susceptible than is the normal heart to the depressing influence of ether.

So far, then, as concerns the method in which ether and chloroform kill, I claim most urgently that there is no contradiction between the results as obtained by the bedside and in the physiological laboratories, and that a complete broad study of the clinical and experimental evidence leads to one conclusion, namely, that chloroform and ether are capable of paralyzing the respiration and the circulation; that in some cases one function, in other cases the other function, is primarily arrested; but that ether is less prone to produce a primary arrest of the heart than is chloroform.

In the discussion of the second point which I have raised, namely, as to the comparative fatality attending the use of ether and chloroform, I shall not occupy time with any elaborate setting forth of the clinical evidence. In regard to the number of recorded deaths, I shall content myself with accepting the latest statistics at hand, namely, those collected by Dr. Lawrence Turnbull, who has found 375 deaths reported from chloroform, and 52 from ether. I do not believe that these figures nearly represent the total mortality; I doubt very much whether one-third of the deaths from anæsthesia are reported; certainly not one-third of the cases I have had personal knowledge of having been publicly recorded. Moreover, the pressure to conceal deaths from chloroform, is greater than when the lethal re-

sult is due to ether. The surgeon who uses ether feels that he has employed the safest anæsthetic, and that he will receive no blame if a death occurs from it, and feels also that he has a rare case to put on record, which will give his own name a permanent place in anæsthetic literature; whereas the surgeon who uses chloroform knows that if death occur from the anæsthetic, a very large proportion of the profession, at least in the United States, will condemn him either in public or in secret for the use of this drug, and that he will be fortunate if he escape being publicly condemned by a coroner's jury. Moreover, deaths from chloroform are only too common, so that the surgeon has nothing to gain and much to lose by publication of a chloroform death, and, if possessed of the average human nature, holds his peace.

It seems to me impossible to get at the exact number of anæsthetic deaths, or the proportionate fatality of ether and chloroform. Lyman considers that in regard to chloroform, the ratio of deaths to inhalations is one in 5,860; Richardson affirms that it is 1 in 2,500 to 3,000; Andrews puts it for ether at 1 in 23,204; and Lyman at 1 in 16,542.

Without claiming strict accuracy for any of these figures, I think that it can be asserted that the probable ratio of deaths from chloroform is three to five times that of deaths from ether.

When we come to study the effects of chloroform upon the lower animals, we find that it varies very distinctly in its action on the different species. The cat seems to withstand the fatal influences of chloroform with a power worthy of its reputed "nine lives." Many years ago, Professor Schiff called attention to the fact that the use of chloroform as an anæsthetic in the dog is usually attended with the loss of many animals. Prof. Martin, of the Johns Hopkins University, writes me that the margin between complete chloroform anæsthesia in the dog, and chloroform death, is a very narrow one. This certainly is our experience in the University of Pennsylvania; we have never been able to use chloroform as an anæsthetic without losing a very large proportion of our dogs.

(To be concluded.)

MISCELLANY.

HEALTH IN MICHIGAN.—For the month of July, 1890, compared with the preceding month, the reports indicate that cholera infantum, cholera morbus, cerebro-spinal meningitis, dysentery, whooping-cough, diarrhoea, typho-malarial fever, and inflammation of bowels increased, and that membranous croup, measles, pneumonia and influenza decreased in prevalence.

Compared with the preceding month the temperature was slightly higher, the absolute humidity and the relative humidity were less, the day ozone and the night ozone were less.

Compared with the average for the month of July in the four years 1886–1889, membranous croup, measles and influenza were more prevalent, and small-pox, puerperal fever, typho-malarial fever and typhoid fever were less prevalent in July, 1890.

For the month of July, 1890, compared with the average of corresponding months in the four years 1886–1889, the temperature was lower, the absolute humidity and the relative humidity were less, the day ozone and the night ozone were more.

Including reports by regular observers and others, diphtheria was reported present in Michigan, in the month of July, 1890, at 50 places, scarlet fever at 55 places, typhoid fever at 29 places, and measles at 72 places.

Reports from all sources show diphtheria reported at 8 places less, scarlet fever at 3 places more, typhoid fever at 1 place more, and measles at 36 places less in the month of July, 1890, than in the preceding month.

ANTISEPTIC DUELING.—In a recent duel with small swords, just as the principals were in position, a loud voice exclaimed: "One moment, gentlemen!" At the same instant a surgeon sprang forward with a bottle in his hand. This surgeon was imbued with modern ideas, and taking the swords he dipped their points in a solution of phenic acid, remarking as he handed them to the duelists: "Gentlemen, you may now kill each other without danger of purulent infection!"—*Medical Age.*

ALBUMEN IN URINE.—A solution of one part of acetic acid, and six parts of 1 per cent. solution of corrosive sublimate is prepared; to this the suspected urine is slowly added, which at once produces a distinct cloudiness. This test is not affected by peptones, uric acid, or the phosphates.

THE IMPORTANCE OF SURGICAL MEANS
APPLIED TO THE NASO-PHARYNX IN
THE RELIEF OF NASO-PHARYN-
GEAL, AND MIDDLE-EAR
CATARRH.

*Read in the Section of Laryngology and Otology at the Forty-
rst Annual Meeting of the American Medical Association,
Nashville, Tenn., May, 1890.*

BY C. W. RICHARDSON, M.D.,
OF WASHINGTON, D. C.

As a preface to the few remarks I am about to make I wish to offer a few words in explanation; not in apology. During the early part of the present year, at the invitation of your Secretary, I furnished him with the title of the present paper. Shortly after having written to Dr. Potter I received a copy of the *Journal of the Respiratory Organs*, containing that most excellent paper read by Dr. Daly before the New York Medical Society, carrying out, to some extent, the very idea and train of thought I intended following in presenting this subject for your consideration. I immediately wrote Dr. Potter requesting his permission to change my subject, to which he kindly consented, but, at the same time, urging me to continue its agitation. Concluding that the doctor's advice was well worthy of consideration, I decided to adhere to my original intention, and in a feeble way, lend my aid to the grand piece of "missionary work" already begun by that able exponent of rhinological wisdom, Dr. W. H. Daly.

In the presentation of this subject to-day it is not my intention to array the rhinologist against the otologist; but simply to insist upon the necessity of the thorough surgical treatment of certain conditions existing within the naso-pharyngeal cavities as an aid to the radical removal of, and in preventing the recurrence of, certain affections of the middle-ear. During the past decade the intimate relationship existing between, or rather dependence of, diseases of the middle-ear upon those of the naso-pharynx has been so thoroughly recognized as to cause a great increase to that class of specialists whose education, from its in-

completeness, has been such as to thoroughly imbue them with these ideas; whose education in the ear has been as thorough as in that of the nose and pharynx; whose education has been such as to cause them to view the diseases of the ear, in many cases, to be dependent upon an existing disease of these cavities; has caused them to search for these causes, to remove them when present, and thus thoroughly to relieve their patients, to this class of practitioners, and as an humble exponent of these ideas, I claim to belong. Dr. Daly in his presentation of the subject has handled the otologist from a rhinological point of view; and the otologists have accused him, and indirectly the rhinal surgeons, with an incomplete knowledge of diseases of the ear. These exponents having clashed arms it now remains for the auro-rhinologist to attempt to bring these warring factions to terms, bring harmony out of discord, and aid in showing the absolute necessity of the otologist being more of a rhinologist than ophthalmologist. I suggest that we aid in this good work because we are unbiased, we cannot be accused of wanting in knowledge of the use of the tuning fork; because, while being conservative, we do not hesitate in resorting to operative interference, when demanded; and, on account of having many ear cases presented primarily, we are better able to judge the relationship existing between diseases of the ear and those of the naso-pharynx.

During my short experience as an auro-rhinologist it has been my lot to have had under observation a number of aural cases that have previously sought relief at the hands of skilled auro-ophthalmologists in this vicinity and neighboring cities. These cases may be divided into two great classes, viz.: acute and chronic inflammation of the middle ear cavity. Among the acute cases were many of recurring middle-ear catarrh, non-suppurative and suppurative middle-ear inflammations. In all the above mentioned acute affections there existed various affections of the nasal and pharyngeal cavities, in many of which, their existence was so patent as hardly to escape the eye of the most non-observing layman. In some cases the aurist, who has been usually an ophthalmologist, while recognizing some disturbance of the normal functions of the naso-pharynx-

geal cavity, failing to appreciate its nature, has applied for its relief unscientific, inadequate, or inappropriate treatment showing an utter disregard, want of knowledge, and frequent dread of the only proper therapeutic measure for the relief of the condition present, naso-pharyngeal surgery. The surgical treatment of these cavities would not have in view only the restoration of them to a normal condition, but also, by the light of our present knowledge, aid in a restoration of the impaired organ of audition, and, acting as a prophylactic agent, by removing the cause, prevent the recurrence of subsequent attacks. In many of the acute affections of the ear, in which there had been numerous recurrences, in the hands of otologists, I have almost universally found some affection of the naso-pharyngeal cavity the relief of which, by operative measures, not only aided in affecting a rapid recovery, but also produced an absolute immunity from subsequent attacks. These facts are so thoroughly acknowledged by all auro-rhinologists as to have become an aphorism—to cause me almost to apologize for having given it mention, but having done so I shall cite several cases to illustrate this point.

About two years ago I had placed under my care, by an otologist of Washington, a young woman who had frequent recurring attacks of middle-ear catarrh. One attack would hardly be relieved before another would supervene. For years she had been under medical care for this annoying deafness, but invariably found that though exerting all due care she was certain to find her efforts futile. My friend sent her to me that I might treat her throat, at the same time advising me to continue attention to the ears. He was the first medical attendant who had ever suggested the care to nose and pharynx. The pharynx was, with its thick padding of mucus, the most disgusting sight I have ever seen; the tonsils were enormously hypertrophied; the vault studded with stalactite-like hypertrophies; and the anterior and post-nasal orifices blocked by hypertrophies of inferior turbinates. The whole picture was changed within a few days by intranasal and pharyngeal surgery. While patient was recovering from effects of active surgical procedures several inflations were made, and she was discharged, within a short period, with no catarrh of nose, pharynx or ear, and so remains at present writing.

Some time ago a patient was presented to me for examination. She had been under the care of various auro-ophthalmologists for several years for a chronic suppuration of the right middle-ear, but not having obtained relief her parents had desisted in treatment. I found considerable glandular hypertrophy at vault of pharynx, and suggested the removal of the same as a possible means of aiding in the relief of the suppuration of the ear; as the child was about to leave town

they did not consent to immediate treatment. Within six months an acute suppurative inflammation having occurred in the left ear patient was placed under my care. Removal of glandular hypertrophies at vault, with mild but effective treatment to ears, was followed within a few days with cessation of suppuration in the old, and within a couple of weeks in the recently affected one. I have seen this patient lately; hearing normal and no suppuration.

Several cases of chronic middle-ear catarrh have been under observation that have received the most decided negative prognosis from distinguished auro-ophthalmologists; in these I have found naso-pharyngeal disease of an obstructive character, the removal of which, with simultaneous and subsequent use of inflation, has been attended with the most satisfactory results. Acute inflammation of the middle-ear I seldom see without finding some obstructive disease of the nasal cavity or glandular hypertrophy at the vault of the pharynx. The simple treatment of the ear affection without any attempt to remove the producing cause, as is the course adopted by the majority of aurists, leaves the case half treated; it leaves the patient, to say the least, open to a recurrence at any moment. It would be unnecessary to give a long citation of individual cases drifting into our hands, who would show the insufficiency of simple otological treatment. In speaking as I do, I do so only with regard to the locality in which I live and its environs. In Washington and Baltimore the auro-ophthalmologist does not seem to recognize the great importance of naso-pharyngeal diseases as productive of affections of the ears. If they do, their actions belie their opinions, and one must acknowledge that they are rhinal therapeutic nihilists.

Obstructive disease in the naso-pharynx, hypertrophies, polypi, spurs, deflected septi, and hypertrophial glandular tissue at vault of pharynx, are the conditions usually observed by me as demanding treatment in most of the cases coming under my observation. The *modus operandi* in the production of disease of the middle-ear through obstructive disease of the naso-pharynx, whether by interfering with the ventilation of the middle-ear, by extension of catarrhal inflammation, by inflammatory infiltration into or paralysis of tubal muscles, are questions of minor importance as compared to the great truth, now universally acknowledged, that these conditions are productive of the affections mentioned, and that the only consistent, scientific, rational, and, therefore, proper treatment, consists in the primary removal of the causative agent as essential to the secondary treatment of disease thereby produced. Even should the above assertion be challenged in general, or as regards any individual case, one cannot but admit that many of these cases, in the hands of the aurist and auro-ophthalmologist are

allowed to continue suffering more or less inconvenience from unpleasant naso-pharyngeal affections which the auro-rhinologist would at once recognize, and, simultaneously with the aural affection, relieve. I cannot agree with the statement I have several times noted, made by a distinguished New York specialist, that atrophic rather than hypertrophic nasal catarrh is productive of the major proportion of middle-ear affections. Atrophic nasal catarrh, in which the nasal passages are extremely patulous, has presented the smallest per cent. of middle-ear affections in my practice.

In showing how inadequate the ordinary treatment of ear affections under the care of the auro-ophthalmologist is, I do not wish it to be understood that I am, to any extent, an aural nihilist. I am afraid a great many of my medical *confrères* are claiming too much for the independent use of the forceps, cautery, snare, drills and saw. I doubt very much of their curing all the ills to which the ear is subject unless they at the same time resort to a judicious use of aural therapeutic measures. Firmly convinced as I am of the value of naso-pharyngeal surgical methods, I have not yet thrown away the leech, douche, paracentesis knife, Pölitzer bag or catheter; our only safeguard is the judicious use of these means and the acknowledgment of their just therapeutic value. On the other hand, we must acknowledge the increased successfulness, or aid to success, in otological work rendered by the rhinal surgeon; but while acknowledging these achievements one must remember that there are a vast number of aural cases falling under our observation thoroughly independent of any change within the naso-pharyngeal cavity; the affection in the one being synchronous with but independent of the affection in the other; the relief of the one not arresting the retrogressive progress of the other. It is almost unnecessary for me to state that I refer to sclerotic changes within the tympanic cavity. These cases are usually present in persons manifesting little or no change in naso-pharyngeal cavity, with patulous tubes. What aid can the rhinologist here furnish? If the patient is to have relief it must be through aural therapeutic measures employed in the hand of the skilled otologist. It is nonsense for one to agitate ideas having in view the condemnation of otological therapeutic methods—they have a vast field of usefulness. The otological surgeon existed and filled a field of usefulness before the rhinal surgeon was born. It is not a question of the younger, but more thriving member devouring as it were the one which it claims to have so sorely afflicted, but rather a question of the more thorough amalgamation of the two branches; a more thorough appreciation of the dependence of aural affections upon naso-pharyngeal disease; a more thorough application of rhinal therapeutic

methods in the treatment of aural affections by the aural surgeon, the aurist becoming more of a rhinologist and the rhinologist more of an aurist; a more thorough inculcation of these views in the aural and rhinal clinics of this country and elsewhere. Contrary to expressed views, one does not find either in aural clinics that careful examination and treatment of the naso-pharyngeal cavity as is carried out in rhinal clinics, nor in rhinal clinics that same care and attention to the ears that one finds in aural clinics; and appreciation of the inadequacy of the routine treatment of the case as resorted to by the auro-ophthalmologist.

Independent of the direct relationship and import of naso-pharyngeal surgery as applied for the relief of affections of the middle-ear, it also has an important direct action when applied for the relief of naso-pharyngeal catarrh. Coming before a body of experts in naso-pharyngeal diseases, it would seem almost unnecessary for me to refer to the important rôle that glandular hypertrophy and bursitis play in the production and continuance of naso-pharyngeal discharges. It would seem unnecessary, I say, to call attention to these important facts were they universally acknowledged and duly regarded. Most authorities agree and acknowledge that glandular hypertrophy at vault of pharynx when existing in sufficient quantity to cause more or less interference with nasal respiration should be removed, but there is a want of unanimity when this tissue exists only in small quantity. There may be doubt in the minds of many as regards the advisability of the thorough removal of all glandular tissue at vault, possibly thinking that its existence there implies that it must perform some physiological function. In the normal condition, as shown by numerous examinations upon the living and dead, there exist no such excess of glandular tissue. I have been able in a number of cases to demonstrate the important rôle, slight glandular hypertrophy, and projecting knobs of adenoid tissue, play in the production and in the continuation of naso-pharyngeal catarrh. There exists also another condition at the vault in which there is, what might be called, an hypertrophical condition of the mucous membrane. The mucous surface, as noted at the choanæ, appears to be thrown into folds, and projects slightly beyond what appears to be normal; it is deeply injected, being well demarkated from the contiguous mucous surface. In other words, having very much the appearance of granulation-tissue as seen in the oral portion of pharynx. The lateral chains of lymphatic tissue occasioned add an element. Bursitis may or may not be acknowledged. There exists a condition at vault that bears all semblance to this condition, and the influence it has in the production of excessive post-nasal secretion cannot be overlooked or

underestimated. While insisting upon the important bearing the conditions just mentioned have in the production of excessive post-nasal secretions and their removal by surgical procedure, in the cessation of the same, I do not wish it to be understood that I offer them as the sole factors, or for an instant overlook other important elements in the production of this affection. What I wish to emphasize is the frequent dependence of post-nasal secretion upon local pathological changes such as those just mentioned, the removal of which will be attended with beneficial results. I do not insist upon any special surgical procedure; the forceps may be used with advantage in one case, the cautery in another.

In closing I must thank you for your kind attention, and apologize for the rambling nature of my remarks and want of strict adherence to the text as given.

ON THE DETERMINATION OF ASTIGMATISM WITH THE OPHTHALMOMETER (JAVAL-SCHIÖTZ).

Read in the Section of Ophthalmology, at the Fort-first Annual Meeting of the American Medical Association, Nashville, Tenn., May, 1890.

BY CARL KOLLER, M.D.,
OF NEW YORK.

It is almost a century since the great English philosopher, Thomas Young, discovered in his own eye an error of refraction due to different refraction of different meridians. For half a century the knowledge thus obtained did not influence the practice of prescribing glasses. It was almost exclusively astronomers, scientists and physiologists, like Young, Airy, Stokes, Fick and others who studied this asymetry of refraction in their own eyes, measured it and tried to correct it. The first to have used cylindric glasses to this end was Airy. A new impetus was given to the study of this imperfection of the human eye by the invention of Helmholtz's ophthalmometer. With the aid of this perfect instrument, invented to determine the curvature of different surfaces, Helmholtz, Donders and their pupils, as Knapp, Woinow, Middelburgh, Mauthner, etc., studied in all directions the dioptric system of the eye. Fundamental points were settled, as for instance that the refraction had nothing to do with the curvature of the cornea; that the curvature of the cornea is not changed by accommodation; that astigmatism is almost exclusively due to the form of the outer surface of the cornea, that all eyes, with a very few exceptions, have a certain degree of astigmatism; that the meridian of stronger refraction in the great majority of cases is the vertical one, and a great number of minor points. However, the ophthalmometer remained an instrument fit only to be used in a few laboratories by the hands of a few investigators. Practice

had to content itself with circumstantial and little exact devices of subjective tests, the great number of which is the best proof of how very unsatisfactory they are.

To the energy and perseverance of Javal, who made the study of astigmatism a task of his life, and who by this has established a claim upon the gratitude of mankind, we are indebted for an instrument, at the same time accurate and so perfectly fit for practical purposes, that it hardly allows any improvement. One cannot say that the instrument, for the time it has been made known to the profession—about ten years—is so generally known as it deserves. When it first came into my hands, about five years ago, I was assistant then at the eye hospital in Utrecht, under the management of Donders and Snellen. A very few exemplars were to be found at the European clinics, and when by the daily use of it I became convinced that it was superior to any other method of finding and determining astigmatism, it was my wonder why the profession did not avail itself of this superior means. When two years ago I came to this country, which is so very ready to adopt new and good methods, I found the ophthalmometer comparatively unknown. Only a few men had it in constant use, and contributed to its becoming known. These circumstances might excuse me when I bring before you an instrument which ten years ago was already perfect in its chief traits, although the new model represents some improvements on the old one. If I succeed in showing you the great advantages this way of determining astigmatism has over all the others, and so contribute to the spread of a valuable invention, I shall feel satisfied with the trouble I have taken.

Figure represents the old model of the instrument. In the new model a large disc containing the radiating lines and figures for designation of axis covers so much of the instrument as to render the drawing unintelligible.

The ophthalmometer of Javal-Schiötz has the object to determine the curvature of the cornea, and the instrument is arranged in such a way that the differences of curvature in the different

meridians of the cornea accurately and quickly can be detected. It is generally admitted nowadays that astigmatism, in the vast majority of cases, depends chiefly or wholly upon the asymmetry in curvature of the cornea. I shall deal later with this question, and for the present will assume the correctness of the statement.

The curvature of surfaces is most easily determined by the measurement of katoptric images; therefore, the instrument has to consist of an image-issuing object and an image-measuring part. Since the curvature shall be determined in different meridians, and in fact differences of curvature shall be measured, both parts must be revolving around a fixed axis. The image-measuring part is represented by a telescope, to which an arc immovable is fastened; the ray of this arc is 300 mm. and the center of its curvature is the eye to be observed. Two targets, one of each attached to one arm of the arc represent the image-issuing object. The size of an image reflected by a convex mirror—and the cornea acts here as a mirror—depends on three things: The size of the object, its distance from the mirror, and the radius of curvature of the mirror. Three of these things known you can calculate the fourth very readily. To determine the radius of the cornea you can put an object of a known size in a certain distance, measure the size of the image reflected and calculate the radius. But you can also follow another way: You can vary the size of an object standing at a definite distance until the mirror of unknown curvature reflects an image of definite size. If you now measure what the size of the object was required for that, you can easily calculate the ray of curvature. This way was adopted by Javal and Schiötz with their instrument.

The two targets attached to the arc are movable and so represent the out ends of an object to be varied in size by moving from or towards each other. In order that this supposed object might keep within the definite distance of 300 mm. from the cornea, the telescope with which the image is observed has an invariable focal distance, so chosen that when the images are seen through it the arc with targets is in a distance of 300 mm. from the cornea. Still the image is to have a certain size. This is attained by a double refrigent prism of Iceland spar placed in the telescope. The prism is cut in such a way that on its place within the telescope it has a doubling power of 3 mm. To explain this latter: If you look at one point through the telescope and the prism hidden in it you will see double images of this point—just distant 3 mm. from each other; and if you look at an object of 3 mm. size you will see double images of this object, one end of one image touching the other end of the other image. That gives you a means at hand to measure the size of smaller objects, in our case

of the katoptric image reflected from the cornea. When the image has just the size of 3 mm., the double images which the telescope gives you will touch each other with their outer ends; when the image is larger the ends will overlap each other, and when it is smaller than 3 mm. the ends of the double images will be as distant from one another as the image is smaller. All we have to do to measure the curvature of the cornea is: to place the eye in question on the right place in resting the chin of the person on the head piece, then to direct the telescope upon it by means of a screw and lateral motion and so look at the reflected images of the two targets. As already mentioned the two targets represent the out ends of an imaginary object which can be varied in size by moving the targets. The doubling action of the prism shows us four images of the two targets, two of each one; we observe only the two medium ones representing different ends of the same object and neglect the two outer ones. If the two middle images are just in contact, we know that the image of the imaginary object reflected by the cornea has the accurate size of 3 mm. In case they are distant or overlapping we have to adjust the targets in order to attain the required position. In measuring our object and making a simple calculation we will find the radius of the cornea. But this trouble can be spared, as a division of the arc gives us directly the corneal radius for the corresponding size of object. If the images by adjusting the targets are brought to contact, and remain so, as the arc is revolved about the axis, it may be concluded that the curvature of the cornea is the same in all its meridians and no astigmatism is present. Measuring the curvature in a number of meridians calculation would give us the amount of astigmatism, if any, present, and its chief axis. But owing to a particularity of astigmatic surfaces we can dispense with such a circumstantial measuring and figuring. The dioptrical and katoptrical images of cylindrical lenses and mirrors are displaced in a certain way, and the same holds good for all astigmatic surfaces that can be considered as a spherocylindrical combination. The image of a straight line is parallel to the object line only in the case that the direction of the line is coincident with one of the chief axis;—in every other case it is turned to a certain angle.

In my treatise about cylindrical lenses, "Graefes Arch.," 1887, I have given the theory of this fact in order to explain some very interesting phenomena based upon it. This very particularity of astigmatic surfaces enables us to find the axis of astigmatism by one turning of our instrument. Our image-issuing object extends chiefly in one direction, it is parallel with the arc and coincident with the doubling plain of the crystal within the telescope. Suppose the arc with its targets stands by chance just in the

meridian of strongest or weakest refraction; the katoptric images will be situated in the same plane where also the doubling action of the prism takes place. Therefore, the double images will stand in the same level, and we know we have found the meridian of one of the chief axis of astigmatism. But now suppose the arc does not stand in the meridian of one of the chief axis, the reflected image will not be parallel to its subject but turned in a certain degree. The doubling action of the crystal nevertheless takes place in the plane of the arc, and as a consequence thereof the double images will not stand in the same level. By a simple turning of the arc we can bring them to the same level and so find the chief axis. A large disk with radiating lines and figures for the meridians is fastened to the telescope. On its reflected image in the cornea we can read the position of the axis so found. In turning the arc and telescope by 90° we bring the instrument in the other chief axis in order to find the exact amount of astigmatism. It might be said in parenthesis that in this way we ascertain that there are cases of astigmatic curvature of the cornea—although they are very rare, which do not directly follow mathematical rules, as the chief meridians are not rectangular to each other but include smaller angles (until 70°)—contrary to the rule known as Sturm's law, which says that in three-axis ellipsoids the meridians at maximal and minimal curvature include an angle of 90° .

Double images of targets. 1, in contact. 2, overlapping.

The diagram of the targets is so chosen that from the amount of overlapping of images the amount of astigmatism in dioptics can be read without any further calculation;—for a certain increase in the size of the images corresponds to a certain increase in the size of the radius, that is, a certain amount of astigmatism. Strictly does this hold good only with eyes of one size, and eyes can be of very different size, notwithstanding they have the same refraction. Think, for instance, of a mouse's and an elephant's eye, both emetropic—an example which Javal himself at another occasion has used. For small eyes the part of the image corresponding to one dioptre ought to be smaller, for big eyes larger. But since we have to deal almost exclusively with eyes of the corneal radius 7.8 or 8 mm. the

arrangement as it is, is accurate enough and very expedient for practical purposes. Having found amount and direction of astigmatism, we have to verify this result by the glass test. The test with glasses is necessary and cannot be superseded by any other test, just as the determination with the ophthalmoscope can facilitate and abbreviate the glass test but cannot do away with it. The gain is enormous anyhow.

Beginning the examination of a patient as to his refraction there are a number of things which we do not know. We do not know if there is astigmatism; in case there is what its amount is, how the axis stand and which the refraction is. This concurrence of unknown makes the examination of refraction so difficult and often so tedious. The ophthalmoscope, with which every examination should begin, gives us a number of points, but still there remains sufficient uncertainty to make us feel often that we are at the mercy of the patient's intelligence. With the ophthalmometer of Javal-Schiötz we can settle some of those questions before we enter in the subjective test. We can find out if there is astigmatism or not; we can find its chief axis with exactness; we can find its amount with sufficient accuracy. And all that we do with a rapidity that is not approached by any other method. I have still to speak of the question already mentioned in beginning, if the assumption is just that astigmatism is solely or chiefly due to the cornea, and, therefore, measuring the astigmatism of the cornea will give us the astigmatism of the whole eye. In the first papers about astigmatism there was much spoken about the astigmatism of the lens and its relation to the whole astigmatism. Careful study through a number of years, examination of several thousand eyes with the aid of Javal's ophthalmometer, comparative researches with Helmholtz's ophthalmometer have resulted for me the following belief, which is also the opinion of most of the men who have directed their attention to this point:

1. Static astigmatism of the lens, that is astigmatism produced by the lens in its condition of rest is a comparatively very rare thing; very likely oblique position of the lens relative to the axis of vision is the cause. It is a remarkable occurrence that this condition was present in the eye of Thomas Young, the discoverer of the so-called regular astigmatism.

2. In the eyes of young people up to 35 years of age there is dynamic astigmatism of the lens present; that is astigmatism based upon involuntary irregular contractions of the ciliary muscle. This dynamic astigmatism of the lens is opposite to the astigmatism of the cornea so as to lessen its amount in a certain various degree. It does not change the axis of astigmatism, so that the axis of astigmatism of the whole eye is invariably coincident with that found in the cor-

nea. For older people with little or no accommodation, also in such young ones who have used correcting cylindrical glasses for a certain time, we find very little or no difference between astigmatism of the whole eye and astigmatism of the cornea; in these eyes the asymmetric spasm of the ciliary muscle has subsided. Similar to the spasm of accommodation in hypermetropes subsiding either by age or by constant use of correcting glasses.

3. I have found only a few single cases amongst a great number of eyes where the axis of the total astigmatism were not coincident with the axis of corneal astigmatism. This is due very likely either to oblique position of the lens or irregular swelling of the lens in beginning cataract.

I have to add a few words about the comparative merits of three objective tests for estimating astigmatism—retinoscopy, ophthalmoscope, ophthalmometer—letting aside all the subjective ones, which if not supported and preceded by one of the objective tests take up much of your time and do not give you the feeling of surety absolutely necessary in dioptric work.

Retinoscopy might be said to be the only really accurate objective method to estimate total astigmatism of the eye together with the refraction. However, it takes much time, and for detection of low degrees of optic errors considerable practice is necessary. The chief objection to me is the circumstantial proceeding of the test and the necessity of dilating the pupils with atropia or homatropia if an accurate result shall be obtained.

As to the ophthalmoscope it has its enthusiasts, who believe themselves able to determine astigmatism with the aid of this instrument. I admit that we can detect astigmatism with the ophthalmoscope, tell if the vertical or the horizontal meridian is the stronger refracting, and how much about the amount of the astigmatism might be. We cannot find the chief axis accurately; in some cases we cannot find the amount of astigmatism with sufficient accuracy. That refers to every observer, however skilful he might be in the use of the ophthalmoscope—and that because it does not depend on the skill but on the chance of circumstances. If vessels happen to run in the chief axis, one can determine the astigmatism. If they do not happen to run there, accurate determination of astigmatism with this method is not feasible.

The ophthalmometer does not require any dilatation of pupils and is not dependent on the chance of circumstances. In less than one minute you can tell with perfect accuracy if there is astigmatism in an eye, you know exactly within 5° how the axis is situated, you know very approximately the amount of astigmatism. You have nothing to do than to place the cylindrical glass—

it does not matter if positive or negative—in front of the patient's eye, and having so corrected the astigmatism you will find it easy to find the refraction.

Javal's ophthalmometer furnishes the greatest accuracy in combination with greatest rapidity of work, and, therefore, it is the instrument of the future.

ANTIRABIC INOCULATIONS.

SENSATIONS EXPERIENCED BY INOCULATED PERSONS. HOW IMMUNITY IS ATTAINED.

Read by Title in the Section of Practice of Medicine, Materia Medica and Physiology, at the Forty-first Annual Meeting of the American Medical Association, at Nashville, Tenn., May, 1890.

BY PAUL GIBLER, M.D.,

DIRECTOR OF THE PASTEUR INSTITUTE OF NEW YORK.

More than ten thousand people have been inoculated during the five years in which the Pasteurian inoculations have been practiced. Among the number were a few doctors; nevertheless, there does not, as far as my knowledge goes, exist any detailed narrative of the phenomena noticed in those who have submitted to the preventive treatment for rabies after having been bitten. I have therefore thought that it would prove interesting for the study of immunity in general, and as a contribution to the history of this system of treatment in particular, to make known some of my observations.

Following in the steps of several doctors, either directors or assistants in antirabic institutions, who did so to guard against a possible accidental inoculation during their daily manipulations of virulent matter, I inoculated myself as well as two of my assistants, Messrs. Roger and De Monchy. A young lad attached to the laboratory was likewise inoculated. But I must here and at once make the following remark, that whereas the lad complained only of local sensibility, of fatigue, and of a little nocturnal agitation, we, who are more accustomed to observations, made several which I think are worthy of record.

The series of inoculations which I practiced on myself and on my two aids, began March 27, 1890, with marrow of the fourteenth day, and ended on the 10th of April following, with matter of the second day.

The subcutaneous injections of the first four days were followed by a slight irritation, which, in one of us, extended so far as to redness of the tegumentum *in loco*, but without induration. During the night, sleep was somewhat disturbed by the sensitiveness of the lateral part of the lumbar regions, viz.: at the spot of the inoculations. During the first ten days, the symptoms were about the same. The temperature of the body rose slightly, but it cannot be said whether this slight febrile motion was caused through and by the injected matter, or whether it was the result of the

slight inflammation caused by the injection itself. These symptoms were considerably modified by hot baths of lengthy duration. Towards the tenth day, the tissues seem to have accustomed themselves to the injected liquid; the reaction was less acute, the pain decreased, and three days after the last injection there remained, so to speak, hardly any local traces of the fifteen injections made on each side.

Thus far, I have not said anything to explain the working of the immunity, but I will now take up the subject. How, then, is immunity obtained?

In a book I published last year ("Analyse des Choses," Dentu, éditeur, Paris) I propounded a theory which, according to my belief, may be of use to explain the hitherto mysterious property, common alike to man and to animals, of resisting the inroads of certain diseases when once attacked by them. In the living body, what is there that resists the development of the infectious figured elements which have reached the body from the outside? Evidently it is the figured elements which make up that body—in other terms, it is the living cell. For me, immunity is a phenomenon of cellular memory. The cellulæ are small individual beings, endowed proportionately with the constituting principles of the living being, such as we know it. As such, they enjoy the faculty of memory, and each time that they are attacked by a malady, they remember—automatically, if you like—but still they remember how they have gotten rid of the intruder (I mean the microbe) which attacked them, and when next assailed, they know immediately what measures are necessary to prevent the enemy from retaining a hold on them.

I do not desire to dwell any further on this theory. It is sufficient for my purpose to have indicated it; I will only remark that the recent works of Metchnikoff on the part played by the white globules in the case of inflammation produced by bacteria, certainly go to strengthen that theory. I will now try to show, by means of the three cases that I am about to analyze, that rabies, which is a malady affecting principally the nervous centres, is no exception to this rule.

In order that the nervous centres be protected against a mortal attack of rabies, it is necessary that, in order to forestall the progress of the microbe, other microbes of the same species, but attenuated, should be placed in contact with the cells of the spinal cord and of the brain. Let me make the passing remark, that the first subcutaneous injections are made with matter the prolonged desiccation of which has caused its virulence to disappear, but it is not unreasonable to admit that the nervous cell must be influenced, in a measure, by the ptomaines secreted by the hydrophobic microbe, and that this reasonably gives it a certain degree of power to resist (through being accustomed to its secretions) the attack of

microbes at first weak, then more and more virulent, when introduced by the successive inoculations. When, after having followed (as shown by experience) the nervous fibres which from the bitten spot go to the cord and to the brain, the infectious germ reaches the nervous cells of the cerebro-spinal axis, it finds them prepared, hardened against its attack, and it can do them no injury. Such is immunity.

What goes to demonstrate that during antirabic inoculation things take place as I have just described, is that my two assistants and myself experienced, during and after the inoculations, a series of phenomena indicating that certain departments of the nervous system were stimulated into activity by some unusual excitement. For my part, during the days when I took the last inoculation, and a few days after, I observed a greater activity of the salivary glands; several times a day I felt saliva welling from the submaxillary glands, and from the parotid canal, my mouth filled with saliva and I was obliged to eject it. During the night I was obliged to urinate, which is not my usual custom. These symptoms were the same in the case of my assistants, which evidently shows a sign of excitation of the medulla oblongata. I recall that in 1884, in a pamphlet on hydrophobia ("Recherches sur la rage et sur son traitement," Allatin and Houzeau, publishers, Paris), I have shown that *polyuria* was a frequent symptom of rabbits inoculated with the virus of hydrophobia, at the moment their nervous system was invaded by the germs. During the last week of the treatment, and the week following, I felt a certain heaviness of the head and an inability to work. These symptoms were equally experienced by MM. Roger and De Monchy, with these additional ones: On the fifth day (inoculated with the marrow of the sixth day), M. Roger complained of a sudden pain in the right side, lasting about half an hour. On the eighth day (inoculated with the matter of the fourth day), he experienced dizziness, which lasted intermittently for fifteen days. The twelfth day, he felt pain in the lumbar region, extending as far as the right testicle. On the fourteenth day the vertigo continued, accompanied by buzzing in the ears, which rendered walking difficult. But since this treatment, M. Roger assures me that he has been relieved of a chronic dyspepsia accompanied by pyrosis. The alvine functions are also more regular. M. De Monchy was more affected by nervous troubles. From the second injection, he felt pain in the nape of the neck; on the fifth day these pains spread into the brachial plexuses. After the ninth inoculation, some fulgurating pains were experienced in the region of the left crural nerve. On the twelfth day, he suffered a frontal cephalalgia and an exacerbation of the pains at the nape of the neck. These symptoms continued for about fifteen days after the

treatment, accompanied by unusual sexual excitement, sadness, undefined preoccupation, and unlocalized pains. The appetite was always good. Finally, MM. Roger and De Monchy were affected, on or about the fifteenth day following the last inoculations, by pains in the spots where the injections were made. These pains were so acute as to suddenly awaken them in the middle of the night. I call attention to this last fact, because in one case, where a person inoculated died of hydrophobia, in spite of the treatment, the adversaries of the Pasteur method took advantage of this fact—that the patient had complained of suffering at the spot of the inoculation—to pretend that hydrophobia had been communicated to him by these inoculations. One sees, however, that these injections are able to cause acute pain some time after they have been made, without determining hydrophobia.

To-day, May 19, nearly a month and a half after the last inoculation, we are, all three, in a state of health as satisfactory as possible. I will add that the sixteen persons who have been inoculated at the New York Pasteur Institute in the two months following its opening, are enjoying good health, whilst several domestic animals bitten by the same dogs that attacked several of these patients, have died of hydrophobia. A man bitten by one of these dogs, and not treated at the Institute, has also died of hydrophobia.

I am happy to make known these facts, and I shall be still happier if, by the application of the method of my illustrious teacher, M. Pasteur—the method which is so successful in Europe—I am able on this side of the Atlantic to preserve the greatest number of persons possible from the frightful death which is the consequence of hydrophobia.

A PECULIAR CASE OF ADDISON'S DISEASE.

Read in the Section of Dermatology and Syphiligraphy at the Forty-first Annual Meeting of the American Medical Association, Nashville, Tenn., May, 1890.

BY A. H. OHMANN-DUMESNIL,

PROFESSOR OF DERMATOLOGY IN THE ST. LOUIS COLLEGE OF PHYSICIANS AND SURGEONS.

Despite the fact that the literature of Addison's disease is vast and that much has been written upon this peculiar affection, its clinical characteristics and its pathology, each new case which is reported has a certain interest attaching to it which is certain to attract more or less attention. I do not purpose writing an exhaustive paper upon the subject, but merely wish to place upon record a case which proved interesting to me from the fact that a certain symptom presented itself which I have not found recorded in connection with this affection. I wish to state, however, that my search has been by no means exhaustive, and that similar cases might have escap-

ed me in my rather rapid review of a portion of the literature of the subject. This symptom to which I will call attention later on in a more explicit manner is one which I deem of some importance, as it confirms the view that Addison's disease is primarily and essentially an affection of the sympathetic nervous system. If we can positively determine this to be a fact there may be found some means of arresting the disease even if the pigmentation can not be caused to disappear. As the trouble is one which almost invariably terminates fatally, such an advance in the curative management would be a triumph in therapeutics.

That not more is known of Addison's disease is probably due to the fact that it is an affection not often observed. I have had an opportunity of observing but two cases, in one of which the history was such as we ordinarily find it, whereas in the other a few points existed which added interest and which have led me to present a short history and clinical record which is as follows:

Case 1.—On February 6 of this year I was requested by Dr. W. W. Graves, of this city, to see a case of Addison's disease. The patient was a man of forty-six who gave the following history: While employed in a grain elevator in Memphis, Tenn., he became aware of a general feeling of malaise. This "bad feeling" as he expressed it became so great, that as soon as he felt able to do so, he left for St. Louis. The beginning of this attack was about October 15, 1889. The bronzing of the skin was hardly noticed at this time but it progressed steadily. He arrived in St. Louis about December 20, and a week later it was noticed that he perspired very freely over the whole body and that the sweat had a most intense and disgusting odor. So marked was this that the doors and windows had to be opened. The whole house was permeated by this smell, which resembled that of carrion. The bromidrosis gradually disappeared and the amount of sweat diminished. Family history good.

At the time I examined the man I found him well developed—perhaps slightly emaciated, but not perceptibly so. Expression of face dull. He was still feeling rather weak although he had improved somewhat of late. He complained of a pain in the pit of the stomach, but pressure exercised in this region did not elicit any pain. He occasionally "bloated," and the tympanitis would become so great as to distress him much. He would be unable to put on his clothing, and he stated that it came on suddenly. Pressure in the back over the areas of the kidneys and suprarenal capsules did not elicit any pain. The patient was of a nervous disposition and had always been so.

Inspection showed that the man had a good supply of hair of a dark-brown color—almost black. He stated, however, and was corrobor-

ated in this by his sister, that before his present illness his hair was of a light color—that he was a blonde. The skin of this individual was apparently of normal thickness, no more than the usual moisture being perceptible. In fact it appeared perfectly normal with the exception of one thing—the color. The whites of the eyes and the mucous membrane of the mouth were devoid of any adventitious pigmentation.

The entire integument with the exception of that covering the head and the hands was of a marked brownish-bronze tint. The chest seemed to be of a somewhat slightly darker hue than the back. Disseminated throughout the affected area darker macules of various sizes could be observed. The areolæ about the nipples, the axillæ, perineum and internatal field was also darker than the general surface. On the other hand, that portion of skin lying over the scapulæ was lighter in color. A few small scars existed upon the chest and these were whitish. On the chest and back there existed numerous white macules of the size and shape of small oats. These were numerous, more particularly upon the chest and upon the forearms. The patient stated that these were small scars from wounds made by the grain which scratched him while at work in the bins of the elevator. While this appeared to be a very plausible explanation to account for the presence of these spots, close inspection failed to furnish any satisfactory evidence of their being scars; and, as excision of a portion of the integument was not permitted a resort to microscopical examination could not be made in order to obtain confirmatory evidence.

That Addison's disease is due to some disturbance of the sympathetic nervous system there seems to be no reason to doubt. The subjective symptoms which are noted are of a nature to point to such a cause, and the bronzing of the skin is another sequence dependent upon the same origin. It is pretty well established at the present day that many affections, characterized by an increase in the amount of pigment of the skin, are due to disturbed sympathetic innervation. Crocker states that the study of Addison's disease has made it highly probable that, whenever the abdominal sympathetic, especially the solar plexus, is irritated general pigmentation is likely to ensue. Greenhow and McCall Anderson do not look upon the symptoms as dependent upon destruction of the supra-renal capsules but upon the extension of the morbid process to the neighboring parts, especially to the solar plexus and semi-lunar ganglia. The general consensus of authorities of to-day is that there exists involvement of the sympathetic nervous system.

That this process is a severe one the general prostration and rapidly fatal termination of a certain number of cases show very plainly. But, in

addition to this, we have anatomical proof furnished in the profound alterations observed in the suprarenal capsules, in the greater number of cases in which necropsy has been performed. Addison was not far from the truth when he stated that the disease was due to these alterations in the capsules—he builded better than he knew. The remarkable investigations and demonstrations of modern investigators have conclusively shown that the suprarenal capsules are ganglia of the sympathetic nervous system directly connected with the solar plexus and semi-lunar ganglia. When we take into consideration the degenerative changes observed in the capsules, in some cases, there can be no room left to doubt that the involvement is a very serious one. This discovery also easily accounts for the fact that, at some post-mortem examinations, the capsules were found to have suffered no change, a circumstance which would seem to indicate that the process begins most probably in the ganglia situated higher up.

To make a short digression. It is admitted on the part of all authors that functional disturbances of the glands of the skin are also dependent upon disturbed sympathetic innervation. That sympathetic nerves preside over glandular functions is admitted and the glands of the skin are subject to the general law. This is especially true of those disturbances of function characterized by an increased amount of secretion. Prominent among functional cutaneous disorders is hyperidrosis, of which bromidrosis is merely a variety in the majority of cases. Whether the odor be due to the bacterium fœtidus, to chemical decomposition, or to direct nervous influence as maintained by E. Monin, we need not consider here. The main point to bear in mind is the increased amount of sweat. This, when universal, denotes a more profound implication of the nervous system than when localized in some particular area.

In the case which I have outlined above there existed for some little time a general bromidrosis, indicating a rather serious involvement of the sympathetic nervous system. The intensity of the odor also tended to show that the process was a severe one. The sudden onset and as sudden disappearance would further go to support the claim of its nervous origin. The presence of microorganisms or of chemical decomposition could hardly be claimed although either one would not militate against the assumption of a neurotic origin for the hyperidrosis.

The fact of the presence of this symptom is interesting on account of its rarity in connection with Addison's disease and because, as stated above, it shows the profound involvement of the sympathetic nervous system which must have existed in the case. We find then that the skin is pigmented and that the functions of a set

of glands are also changed. In other words, two manifestations of an entirely dissimilar character and which we are accustomed to study separately are here found to be coincident and, beyond any doubt, dependent upon a common origin.

The lack of time and opportunity have prevented my making a study of this question. There is no doubt, whatever, in my mind that other causes of a like nature have occurred, but the importance of the graver malady as well as its comparative rarity completely overshadowed the importance of the symptom which probably is one of frequent occurrence—the bromidrosis.

A feature which was observed and which might partially account for the fetid sweat is the fact noted in the history that there was no pigmentation of the mucous membrane of the mouth. The explanation that this would furnish would be that the energy usually directed to the mucous membrane had been diverted to other channels, or, in other words, the perverted innervation was transferred from the mucous membrane to its external congener, the skin. This process is not an unusual one. We observe it, for instance, in erythema nodosum in which the eruption rapidly disappears to give way to a bronchitis, and this in turn leaves to be followed by a recurrence of the eruption.

In this short clinical contribution I have merely desired to sketch an interesting condition, and, so far as I know, a peculiar case. While the literature of Addison's disease is plentiful there is really but little that is tangible. In the light of modern anatomical investigations, however, we can see the promise of great improvement in the future therapeutical measures to be employed, as well as in the more thorough and intelligent pathological investigations which will be made.

5 South Broadway.

NOTES ON A CASE OF TETANY.

Read in the Section of Diseases of Children at the Forty-first Annual Meeting of the American Medical Association, at Nashville, Tenn., May, 1890.

BY JACOB SCHNECK, M.D.,
OF MT. CARMEL, ILL.

Under the various names of tetany, tetanella, idiopathic muscular spasm, and carpo-pedal spasm, we find described a variety of cases which have, as prominent symptoms, more or less tonic contractions of the muscles of various parts of the body, beginning usually at the extremities and passing, in somewhat regular succession, to the muscles of the body and head. The consciousness of the individual is not disturbed during the paroxysm.

The symptoms of this disease trench closely on those of a number of the functional neuroses; and it is probable that many of the cases reported un-

der this heading are really spasms due to reflex irritation, caused by teething or a disordered condition of the alimentary canal; or to irritation produced in the nerve-centres by the distal ends of nerves, leading to them, being involved in cicatrices or other inflammatory products; these cases are permanently cured by removing the cause of the irritation. It is also probable that in this category cases have been reported which should be described under the title of hysteria.

The causes usually assigned as producing tetany are exceedingly numerous and various; chronic and debilitating diarrhœa, lactation and pregnancy, stand first, perhaps. Typhoid fever, rheumatism, measles, pneumonia, Bright's disease, small-pox, cholera, malaria, exposure to cold, anæmia, sexual excesses, alcoholism, excision of thyroid gland, intestinal worms, disordered stomach from undigested food, lead poisoning, and epidemic influences, have all been thought to be causes. In reading over the reports of some cases one is led to believe that many of the above named causes are only coincidences, and had nothing to do with inducing the disease. An important diagnostic point of this disease is the tendon-reflex action produced by pressing on the large vessels and nerves (Trousseau's symptoms). This is not always present, but in no other disease has it ever been recorded.

Chvostek was the first to direct attention to the increased mechanical excitability of the muscles and nerves in this disease; he found in many cases that during the latent period the calf-muscles were slightly contracted. During the paroxysms consciousness is intact; and the muscular spasms are tonic.

The present light on the pathology of this disease points to the nerve-centres as the site of disturbance.

Herz thought the disease was due to anæmia of the spinal cord. A. Jacobi attributes it to meningeal hyperæmia. Gowers teaches that it is probable that the primary pathological lesion is in the motor cells of the cerebral and spinal structures; and that thus is explained the tendon-reflex symptoms usually present in this disease. Whatever the pathology may be, there appears to be an inability to inhibit in the nervous and muscular organs.

I am induced to offer these notes on the following case for three principal reasons:

1. Tetany is a disease whose limits and symptomatology are not well defined.

2. The case which fell into my hands had the signs, usually given as belonging to this disease, well-marked. In addition there were other prominent symptoms, which I do not find given in any of the accounts of the disease which I have consulted, viz.: the absence of normal reflex excitability in the extensor muscles, as shown by the want of the tendon reflex action of the exten-

sors of both the upper and lower extremities. And also the Argyll-Robertson pupil; both of which signs improved and became normal *pari passu* with the diminution of the number and severity of the attacks.

3. For the purpose of putting on record the treatment and its result, so that the profession may give it a further trial.

Case.—Oct. 23, 1889, Clara I. Brine, of Grayville, Ill., was brought to my office; she being a well developed, bright and healthy looking girl of ten years. The mother and father, who accompanied her, were both above the average in size, of intelligent bearing, and barring a few slight attacks of unimportant sickness, had always been healthy. Their five other children were all well developed. Clara had been healthy until three years since, when she suffered from some ailment of the bladder, but which was of temporary duration. Near two years ago, while in her usual health, she was suddenly seized with a swimming sensation and fell backwards on the floor; not, however, losing consciousness. Attacks of this character occurred at frequent intervals for nearly one year. She usually avoided falling by holding to some object until the sensation passed off. The physician who treated her told the parents the attacks were caused by some heart disease. Gradually these paroxysms were ushered in, or preceded, by more or less tonic cramps of the lower limbs; felt most severely at the knees; when the feet were involved, the toes would be drawn together and towards the sole of the foot. Later the upper extremities, and finally the jaws, became involved in the tonic contractions; but as they did so, the dizziness became less and the cramps of the lower limbs grew lighter, and for the last six months had ceased entirely; while those of the upper extremities, neck, and jaws, had grown correspondingly more severe and more frequent; averaging about ten a day; being most frequent during the forenoon, but never occurring during sleep. In some of the most severe attacks there was decided opisthotonos. In all those attacks consciousness was never lost. During the past year she had been treated by a physician for epilepsy. During the time of her visit to my office, while I was familiarizing myself with a history of her case, she was seized with a severe paroxysm, while in the midst of a sentence, and when not in the least excited. It came without any premonition and involved both upper extremities, and the muscles of the neck and jaws, in the order named. The muscles were so rigid that she was unable to speak, swallow, or move the head; the elbow-joints were flexed and the arms held rigidly from the side; the right hand was closed into a hard fist; the fingers of the left were first irregularly over-extended, then drawn together, the two outer coming under the two inner ones, while

the thumb was drawn down to the palm, forming the obstetric hand. The face became full and flushed. This condition lasted near two minutes.

The paroxysm was accompanied by radiating pains in the parts involved. "A sharp pain, with other pains shooting out from it," was her expression. She complained, after the attack, of numbness and formication in the muscles affected, also of ringing in the ears. Examination revealed slight oedema of the hands and face; tendon-reflex of knees and wrist entirely absent; Argyll-Robertson pupil well marked; pulse 120 per minute, small and hard. Had always suffered slightly from constipation; appetite good; sleeps well and quietly; temperature normal. There was no tenderness along the spine or over the ovaries, or any other part of the body; not subject to excessive perspiration; nervo-muscular irritability could not be produced by raking finger-nail in front of ear; there was no nausea or vomiting after attacks; she had not been a bottle-fed infant; had never suffered from rickets or iaryngismus; did not pass large quantities of urine after paroxysms; pressure on the large blood-vessels or nerves did not bring on an attack; applying cold water to hands failed to cut short a paroxysm.

The treatment and progress of the case were as follows:

October 23, 1889.

R. Liquor potass. arsenitis, ʒj

Sodæ brom., ʒ ss.

Aqua, ad. ʒ iv. ℥.

Sig.—One teaspoonful after meals.

R. Antifebrin, gr. xxx.

Divide into 15 capsules.

Sig.—One capsule before meals.

October 31, symptoms very slightly improved; averaged five paroxysms per day since the former visit; pulse 120; tendon-reflex of the extremities imperceptible. Argyll-Robertson pupil still marked.

Thinking she might be afflicted with worms, I gave the following:

R. Hydrarg. chlor. mitis, gr. ij.

Sodæ bicarb. santonine, ʒā gr. vj.

Mix fiat chart No. vj.

Sig.—One powder at 4, 6 and 8 P.M. on consecutive nights.

Then to begin the following:

R. Fl. ext. conium, ʒj.

Sig.—Eight drops after each meal.

R. Glonoin, ʒ iv.

Sig.—Two drops two hours after meals.

Nov. 12.—Had passed no worms from santonine. During the first six days she had nineteen paroxysms, and none during the last five. Continues the two last prescriptions.

Dec. 4.—Had no paroxysm since last visit; tendon reflex of both upper and lower extremities nearly normal; pupil responds properly to light. Continued the nitro-glycerine and stopped the conium.

Feb. 3, 1890.—Had no attack since last report; continued treatment.

May 10, 1890.—Reports herself as entirely well, and has taken no medicine for two months.

DIAGNOSIS AND OPERATIVE TREATMENT OF GUNSHOT WOUNDS OF THE STOMACH AND INTESTINES.

Read by Invitation in the Surgical Section of the Tenth International Medical Congress, August 8, 1890.

BY N. SENN, M.D., PH.D.,
OF MILWAUKEE, WIS.

ATTENDING SURGEON MILWAUKEE HOSPITAL; PROFESSOR PRINCIPLES OF SURGERY AND SURGICAL PATHOLOGY IN RUSH MEDICAL COLLEGE, CHICAGO, ILL.

(Concluded from p. 363.)

2. *Treatment of Gunshot Wounds of the Stomach and Intestines.*

The propriety of surgical interference in cases of gunshot wounds of the stomach and intestines will depend on one of two things :

1. Dangerous internal hæmorrhage.
2. Visceral wounds of the stomach or intestines large enough to permit of extravasation and the escape of hydrogen gas on applying the diagnostic test.

Alarming intraperitoneal hæmorrhage furnishes an urgent indication for treatment by laparotomy irrespective of the existence of the visceral lesions of the gastro-intestinal canal. In these days of aggressive surgery it would indeed be unjustifiable to permit a patient to die slowly but surely from hæmorrhage from an intra-abdominal wound which in itself is amenable to successful treatment by prompt surgical means.

The signs and symptoms of profuse internal hæmorrhage come on soon after the injury has been inflicted, and are so plain and significant that they can hardly be misinterpreted even upon a brief and superficial examination. The progressive acute anæmia, the conditions of the pupils and pulse, and the complexus of nervous symptoms which attend alarming internal hæmorrhage present a clinical picture which, when once seen, is never forgotten and always recognized.

In such cases no time should be lost in looking for evidences of the existence of wounds of the gastro-intestinal canal, or in applying the hydrogen gas test, as the prime and most urgent indication is to gain access to the bleeding vessels by opening the abdomen in the median line, and then to arrest the hæmorrhage at once by compression until the bleeding points can be secured by ligation or the antiseptic tamponnade. After the hæmorrhage has been arrested, the whole gastro-intestinal canal, or such part of it as, from the course of the bullet, is known to have been exposed to injury, is tested by insufflation of hydrogen gas for the purpose of ascertaining in as

short a time as possible, the existence, location and number of perforations.

In cases in which, on account of the absence of dangerous hæmorrhage, the symptoms are less urgent, it is important to determine the necessity of treatment by laparotomy by resorting to the hydrogen gas test for the purpose of diagnosticating the existence and size of perforations of the gastro-intestinal canal. If through insufflation can be made, it is proof positive that no perforations exist, or, if present, that they are too small for extravasation to occur, and in the absence of other indications for abdominal section it is advisable to pursue a conservative course of treatment. Such patients are given an opiate to diminish the peristaltic action of the bowels; an absolute diet is ordered and rest in bed enforced for at least a week, while infection from without is prevented by subjecting the external wound to rigid antiseptic treatment.

If the hydrogen gas test, either by rectal insufflation or direct inflation of the stomach, yields a positive result, sufficient and reliable information has been gained to warrant laparotomy, as the surgeon has then satisfied himself that he has to deal with an injury which, if not properly treated, is almost certain to result in the death of the patient.

Laparotomy for Gunshot Wounds of the Stomach and Intestines.

I have already insisted that in every perforating gunshot wound of the abdomen, all necessary preparations for laparotomy should be made before the existence of visceral wounds of the stomach or intestines has been demonstrated by the application of the hydrogen gas test, as the latter procedure necessitates the administration of an anæsthetic. The stomach can be inflated without an anæsthetic and the existence or absence of perforations demonstrated before any definite plan of treatment is proposed, but rectal insufflation of hydrogen gas should never be undertaken in the diagnosis of gunshot wounds of the gastro-intestinal canal without complete anæsthesia.

Before I was able to demonstrate the existence of visceral wounds of the stomach and intestines without opening the abdominal cavity, I never succeeded in obtaining the consent of the patient and friends to make a laparotomy in cases of gunshot wounds of the abdomen; but since I have been able to tell the people that the course to be pursued will depend upon the result of the test, I have not met with a single refusal. The hydrogen gas flame at the wound of entrance is an argument more potent than words in convincing laymen of the necessity of active surgical interference. If the public understands that the abdomen will only be opened after the surgeon has satisfied himself and has demonstrated the existence of a mortal injury, the patient and his friends will be only too anxious to avail them-

selves of the benefits to be derived from the only resource which promises any hope of saving life.

Medico-Legal Responsibilities in the Performance of Laparotomy in the Treatment of Perforating Wounds of the Abdomen.

As in private practice the treatment of penetrating wounds of the abdomen always involves great medico-legal responsibilities, it becomes of the greatest importance to arrive at positive and reliable conclusions in reference to the character of the injury before the patient is subjected to the additional risks to life incident to an abdominal section.

We will suppose a case. In a quarrel a man is shot in the abdomen. The assailant is placed under arrest. The surgeon who is called establishes the fact that the bullet has entered the abdominal cavity, and from the point of entrance and its probable direction he has reason to believe that it has wounded some part of the gastro-intestinal canal, and he concludes to verify his diagnosis by an exploratory laparotomy; the operation is performed, the gastro-intestinal canal is examined in its whole length, but after the most careful inspection no visceral wound is found. Over an hour is consumed in the examination, during which time the peritoneal cavity is exposed more or less to infection. The wound is closed and the patient dies of shock in two or three hours, or of septic peritonitis on the third or fourth day. The attorney for the State charges the defendant with murder. During the trial the defense will very naturally raise the questions: "Did the man die from the effects of the injury or the operation?" "Shall the defendant be tried for assault and battery or for murder?" During the trial the attending surgeon is made a target for a volley of a medley of scientific and unscientific questions by the cunning attorney for the defense in the attempt to save his client from the gallows or a sentence of imprisonment in the State Prison for life, at the expense of the reputation of the surgeon and the respect and good name of the profession he represents.

This picture is not overdrawn. Such cases have happened and will happen again. It is entirely different if the surgeon can, by means of the hydrogen gas test, ascertain the existence or absence of fatal complications without subjecting the patient to any additional risks to life. If the test yields a positive result, the indications for an operation are clear, and are understood and appreciated by laymen who may serve on the jury.

If a laparotomy, performed in the treatment of a mortal injury, is followed by a fatal termination, the result must be charged to the person who inflicted the injury and not to the surgeon who failed in his attempt to save his patient from certain death. If the operation proves successful, the surgeon has not only saved a life, but

he has been at the same time instrumental in diminishing the severity of the sentence of the one who inflicted the injury.

Preparation of the Patient.

A patient suffering from a perforating wound of the abdomen should be properly prepared before he is subjected to examination by the hydrogen gas test, and, if this yields a positive result, to laparotomy. If the stomach is filled with food, a salt water emetic should be given for the purpose of evacuating the stomach. The rectum and colon should be emptied by a copious enema of lukewarm water to which may be added a tablespoonful of common salt. These precautions greatly facilitate the application of the hydrogen gas test, and guard against possible sources of error in diagnosis; at the same time they leave the gastro-intestinal canal in a better condition for operative treatment and a speedy repair of the sutured wounds. A hypodermic injection of one-fourth of a grain of morphia and one one-hundredth of a grain of atropia should be given shortly before the anæsthetic is administered, as these drugs in the doses specified assist the action of the anæsthetic, secure rest for the intestines and sustain the action of the heart. If the patient is much prostrated two ounces of whisky diluted with four ounces of warm water should be given *per rectum*. The external wound and the whole abdomen must be thoroughly disinfected.

Operating Room.

The room in which the examination is to be made, and possibly laparotomy performed, should be cleared of all draperies, pictures and unnecessary furniture, and the temperature should not be less than 80° F. It is a good plan to sprinkle the bare floor, walls and ceiling with a strong solution of corrosive sublimate or carbolic acid. An ordinary table covered with blankets and a clean sheet will answer for an operating table. Wash basins, dishes and pitchers are to be sterilized by heat. Plenty of aseptic sponges, clean towels, and hot sterilized water must be provided. A hypodermic syringe and the necessary stimulants must never be absent. A sufficient quantity of hydrogen gas can be generated in from five to fifteen minutes. The articles necessary for applying the hydrogen gas test are a stomach tube and a four gallon rubber balloon in which the gas is stored, which is connected by four or six feet of rubber tubing with the short rectal tube, for which the vaginal tip of an ordinary Davidson's syringe can be used. Wax tapers are useful in lighting the escaping gas.

Incision.

Great diversity of opinion still prevails in regard to where the incision should be made. In the majority of cases the median incision affords

advantages which give it the preference. It should always be selected in cases of gunshot wounds of the stomach, and where the wound of entrance is located near the median line, and where it is known that the bullet has taken an antero-posterior course. A median incision affords most ready access in the treatment of wounds of the small intestine.

The result of the hydrogen gas test will prove of much value in deciding the location of the incision. If, in gunshot wounds of the upper portion of the abdomen, direct inflation of the stomach through an elastic tube reveals the existence of perforation of this organ, the median incision should be selected. If rectal insufflation yields a positive result before the gas has passed the ileo-cæcal valve, the incision should be made over the wounded portion of the colon, which is usually indicated by the course of the bullet. A wound in the transverse colon can be found and dealt with most efficiently through a median incision, while perforation of the cæcum or ascending colon calls for a lateral incision directly over the wounded organ, while a lateral incision on the left side is indicated if from the direction of the bullet it is evident or probable that the colon below the splenic flexure is the seat of the visceral injury. In the treatment of a gunshot wound of the colon through a lateral incision it is absolutely necessary to make the incision sufficiently long so as not only to facilitate the finding and suturing of the perforation, but also to enable the surgeon to search for and treat additional injuries. By suturing the external wound with several rows of buried sutures there is but little danger of a ventral hernia following.

Laparotomy performed for the arrest of dangerous hæmorrhage should always be done by making a long median incision which will afford the most direct access to the different sources of hæmorrhage. Very often it will be advisable to make the incision in the line of the wound of entrance, more especially in cases where a lateral incision is indicated from the location of the wound, from the course of the bullet, and from the results obtained by application of the hydrogen gas test.

Arrest of Hæmorrhage.

In perforating wounds of the abdomen profuse hæmorrhage is more frequently of parenchymatous and venous than of arterial origin. Gunshot wounds of the liver, spleen, kidneys and the mesentery give rise to profuse and often fatal hæmorrhage. After opening of the peritoneal cavity it is often very difficult to find the bleeding points, as the blood accumulates as rapidly as it is sponged out, and it becomes necessary to resort to special means in order to arrest the profuse bleeding sufficiently to find the source of hæmorrhage.

One of two resources should be employed: 1. Digital compression of the aorta. 2. Packing the abdominal cavity with a number of large sponges. Digital compression of the aorta below the diaphragm can be readily made by an assistant introducing his hand through the abdominal incision, which in such a case must be larger than under ordinary circumstances. Compression of the abdominal aorta immediately below the diaphragm will promptly arrest the hæmorrhage from any of the abdominal organs for a sufficient length of time to enable the surgeon to find the source of hæmorrhage and carry out the necessary treatment for its permanent arrest.

Hæmorrhage from a perforated, lacerated kidney may demand a nephrectomy. A similar wound of the liver is cauterized with the actual cautery or tamponned with a long strip of iodoform gauze, one end of which is brought out of the external wound. A wound of the spleen, if the hæmorrhage cannot be arrested by the antiseptic tampon, necessitates splenectomy. Very troublesome hæmorrhage is often met with from wounds of the mesentery.

When multiple perforations of the mesentery and visceral wounds of the stomach or intestines are the source of hæmorrhage, it is a good plan to pack the abdominal cavity with a number of large sponges to each of which a long strip of iodoform gauze is securely tied, these strips being allowed to hang out of the wound in order that none of the sponges may be lost or forgotten in the abdominal cavity after the completion of the operation. The sponges make sufficient pressure to arrest parenchymatous oozing as well as venous hæmorrhage if they are placed at different points against the mesentery and between the intestinal coils. The sponges are removed one by one from below upwards and the bleeding points secured as fast as they are uncovered.

The ligation of mesenteric vessels, both arteries and veins, should be done by applying the ligature *en masse*. Thornton's curved hæmostatic forceps is the most useful instrument for this purpose. Catgut should never be relied upon in tying a mesenteric vessel, as this material, for several reasons which it is not necessary to mention here, is greatly inferior to fine silk. Troublesome hæmorrhage from a large visceral wound of the stomach and intestines is best controlled by hemming the margin of the wound with fine silk. If hæmorrhage is profuse this must be attended to before anything is done in the way of finding or suturing of the visceral wounds.

Search for Perforations.

If the hydrogen gas test has been employed with a positive result before the abdomen was opened, there will be no difficulty experienced in finding the first opening. If the stomach was inflated directly through an elastic tube and the

test has shown the presence of a perforation, a median incision is made from the tip of the ensiform cartilage to the umbilicus and the stomach drawn forward into the wound. If no perforation is found in the anterior wall, the insufflation is repeated, and the escaping gas will direct the surgeon to the perforation. After closing the perforation the stomach is again inflated, and if a second perforation exists it is readily detected by this test. The possibility of the existence of a third perforation should be remembered, consequently a third inflation becomes necessary. A second and a possible third perforation can also be detected by inflating the stomach directly through the first and second perforations.

If the wound implicates the abdominal cavity below the stomach, the hydrogen gas test is applied by insufflation *per rectum*. If the test has yielded a positive result, the lowest perforation is readily found by examining the intestine at a point where the distended and empty portions join, as the leakage of gas through the perforation prevents inflation higher up. In one of my experiments I carried the inflation so far that the intra-abdominal pressure caused by an immense free tympanites not only prevented the inflation of the intestine above the first perforation, but it also forced out the gas from the intestine below the perforation. If, however, the track of the bullet is enlarged down to the peritoneum, as should be done in the diagnosis of all perforating gunshot wounds of the abdomen before the hydrogen gas test is applied, such an occurrence is impossible, as the gas will escape through the external wound as fast as it enters the peritoneal cavity.

If the intestine is found distended below the first discovered perforation, it is an absolute proof that no perforations exist lower down in the intestinal canal, and hence that it is unnecessary to lose any time in looking for perforations in that direction.

As soon as the lowest perforation has been found, rectal insufflation should be suspended. If possible, the perforated portion of the intestine should now be brought forward into the wound, and after emptying the intestine below the perforation as far as possible of its gas, the bowel is compressed below the perforation by an assistant, and the intestine higher up is inflated through the wound. As a matter of course, a perfectly aseptic glass tube should be inserted into the rubber tube instead of the tube used in the rectum. The inflation is now carried as far as the second opening, when the first opening is sutured, and after disinfection the intervening portion of the intestine is replaced in the abdominal cavity. Further inflation is now made through the second opening, and if a third one is found, the second is sutured, and so on until the entire intestinal canal has been thoroughly subjected to the test. By

following this plan extensive eventration is rendered superfluous and the overlooking of a perforation is made absolutely impossible. Extensive eventration in the search for perforations, and undiscovered perforations figure largely as causes of death in gunshot wounds of the abdomen treated by laparotomy, and both of these sources of danger are avoided by a thorough and systematic employment of the hydrogen gas test.

Suturing of Wounds of the Stomach and Intestines.

Trimming the margins of the visceral wounds is not only superfluous, but absolutely harmful, as it requires a useless expenditure of time and may become an additional source of hæmorrhage. The same can be said of the Czerny-Lembert suture. All that is required in the treatment of a visceral wound of the stomach and intestines is to turn the margins of the wound inwards and bring into apposition healthy serous surfaces by a few points of interrupted sero-muscular sutures. Fine aseptic silk should be used for the sutures. It is sufficient to use from four to six sutures to an inch. Wounds of the stomach should be sutured in a line parallel with the long axis of the organ. Wounds of the intestine should be closed transversely, with a view of preventing constriction of the lumen. Defects an inch and a half in length on the convex border can be closed safely in this manner without fear of causing intestinal obstruction, while much smaller defects on the mesenteric side often necessitate a resection, not only because the vascular supply in the corresponding portion of the intestine would be inadequate, but also for the reason that a sufficiently sharp flexion might be produced at the seat of suturing to become a source of intestinal obstruction.

Enterectomy.

Enterectomy often becomes necessary in cases of double perforation, and in marginal wounds of the mesenteric border. If in cases of multiple perforations it becomes necessary to make a double enterectomy, and the intervening portion of the small intestine is not more than two or three feet in length, it is best to resect it at the same time, as the immediate effect of the operation will be less severe than a double resection with a corresponding double enterorrhaphy. The mesentery corresponding to the portion of intestine to be removed should be tied in small sections with fine silk before the bowel is excised.

Restoration of the Continuity of the Intestinal Canal after Enterectomy by Lateral Apposition with Decalcified, Perforated, Moist, Bone Plates.

Cases of gunshot wounds of the intestines requiring enterectomy are always grave, and anything which can be done to shorten the operation must add to the chances of recovery. Circular enterorrhaphy requires a great deal of time and is less certain in its results than lateral apposition

with decalcified bone plates, and for these reasons the latter procedure deserves the preference in uniting the bowel after resection for gunshot wounds of the intestine. For the full technique of this part of the operation I must refer the reader to my article read in the Surgical Section of the American Medical Association at its last meeting, and published in *THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION*, JUNE 14, 1890.

Omental Grafting.

If the bowel at the seat of suturing show evidences of contusion, the line of suturing and the damaged portion of the bowel should be covered by an omental graft, which is fastened in its place on the mesenteric side by passing two catgut sutures in the line of the mesenteric vessels through both ends of the graft and the mesentery, and tying them loosely. Before the graft is planted, the surface of the bowel and the surface of the graft which is to be brought in contact with it are scarified with the point of an aseptic needle.

Irrigation of Abdominal Cavity.

This is only necessary if fæcal extravasation or escape of stomach contents has occurred, an accident which, if it has not occurred before the abdomen has been opened, should be carefully avoided during the manipulation of the wounded intestines. Flushing the peritoneal cavity with warm sterilized water not only clears it of infections material, but acts at the same time as a stimulant to the flagging circulation. After completion of the irrigation the patient is placed on his side, and in this manner the fluid contents of the abdominal cavity are poured out. The cavity is then rapidly dried with large sponges wrung out of a weak antiseptic solution.

Drainage.

Cases which require irrigation also require drainage. Other indications for drainage are visceral wounds of the liver and wounds of the pancreas, spleen, and kidneys, where extirpation of the wounded part of the organ, or the whole organ is deemed unnecessary, and the existence of parenchymatous hæmorrhage which cannot be remedied by any of the different hæmostatic measures.

Closure of External Incision.

Incisions through the median line are rapidly closed by one row of silk sutures which include all of the tissues of the margins of the wound. Incisions made in any other place are to be closed by two or three rows of deep catgut sutures, and a superficial row of silk sutures.

After-Treatment.

Absolute rest must be strictly enforced. Opium must be given in sufficient doses to quiet the peristaltic action of the intestines. No food should be given by the stomach for at least forty-

eight hours. During this time brandy and water in small doses frequently repeated are agreeable to the patient, they quench thirst and exert a favorable influence upon the circulation. If more active stimulation is required to overcome shock and the effects of hæmorrhage, whiskey, ether, musk or camphor can be injected subcutaneously or *per rectum*, while the peripheral circulation is restored by applying dry heat to the extremities and trunk. Should symptoms of peritonitis set in, a brisk saline cathartic should be given at the end of forty-eight hours, as at this time the intestinal wounds will have become sufficiently united to resist the violent peristalsis provoked by the cathartic, while the removal of the intestinal contents and the absorption of septic material from the peritoneal cavity are not only the most efficient means of cutting short a fatal disease, but also of placing the wounds in the most favorable condition for rapid repair.

If the case progresses favorably, liquid food by the stomach can be allowed at the end of the second day and digestible solid food at the end of the first week. Under ordinary circumstances no effort is made to move the bowels until the end of the fourth or fifth day. If early feeding becomes necessary in marantic or exsanguinated patients, this can be done by rectal alimentation. Patients should not be allowed to leave the bed until the external wound has firmly united throughout, as any imprudence in this direction is liable to be punished by the formation of a ventral hernia. The sutures are removed on the eighth day and the patient is directed to wear an abdominal supporter for several weeks after he has left his bed.

SUGGESTIONS FOR THE CONSIDERATION OF MILITARY AUTHORITIES AND MILITARY SURGEONS.

The object of battle is to kill and disable the combatants until the question of victory is decided in favor of the army which exceeds in numbers, or is superior in courage or more skilled in warfare. Very little has been done so far in the way of aggressive surgical interference for heroes who fell mortally wounded in the line of battle in the defense of their country, their ruler, their families, their homes and their rights. The time has come when in case of war adequate provisions should be made on the field of battle near the rear line for the prompt treatment of perforating gunshot wounds of the abdomen. It is difficult to conceive how many valuable lives have been sacrificed on the field of battle during the innumerable wars recorded in the history of the world which now are within the reach of successful surgical interference. Thousands of lives have been lost from internal hæmorrhage alone which could now be saved by an early laparotomy.

In future wars it is the duty of every civilized

nation to do all that modern surgery can do in the treatment of perforating gunshot wounds of the abdomen on the battle field. Every soldier who has been in active military service can recall instances where comrades dropped in the ranks with a mortal bullet wound of the abdomen, who lived for several hours and died from hæmorrhage, often forgotten and uncared for in the excitement of the conflict. Justice, patriotism, humanity and the present status of abdominal surgery demand that in future wars enough men shall be detailed from each company to convey the severely wounded to the rear of the line of battle, where they can receive prompt and efficient surgical aid, and where, if die they must, the last hour of their life shall be peaceful, surrounded by those who will add to their comfort and administer words of consolation as the immortal spirit leaves the maimed body for the future world.

For the purpose of carrying into effect the modern aggressive treatment of perforating gunshot wounds of the abdomen in military practice, it will be necessary to erect a large tent for every brigade, in a safe place, but sufficiently near the line of battle to be within easy reach. This tent should be heated with gas stoves and provided with all the necessary instruments, dressing material and medicines required in the operative treatment of gunshot wounds of the abdominal viscera. One surgeon specially qualified for his work should be detailed to superintend the surgical work, assisted by a sufficient number of reliable assistants. This tent should be used exclusively for the treatment of perforating wounds of the abdomen.

If, as is so often the case in gunshot wounds of the abdomen made with bullets of large calibre, life is threatened by hæmorrhage, the abdomen, after rapid but thorough disinfection, should be opened at once, and after the bleeding has been arrested, visceral injuries of the gastro-intestinal canal should be sought for by applying the hydrogen gas test in the manner described above. The use of this test will not only shorten the time required in the completion of the operation, but it will also guard against two grave sources of danger—extensive eventration and leaving undiscovered and unsutured perforations. Enterectomy will be more frequently made necessary in military than private practice on account of the large size of projectiles used in warfare as compared with those used in private life. Restoration of the continuity of the intestinal canal after enterectomy for gunshot wounds of the abdomen should be done by a method which saves valuable time and secures the best results—advantages which are gained by the use of decalcified, perforated bone plates. Patients who rally from the operation should subsequently either receive the necessary after-treatment in hospital tents,

or should be later transported with the greatest care to the nearest hospital.

The Correct Diagnosis and Proper Treatment of Gunshot Wounds of the Stomach and Intestines Require a Degree of Skill and Dexterity which can only be Acquired by Experiments on the Lower Animals. Even the minutest descriptions of the details to be observed and applied in the diagnosis and treatment of gunshot wounds of the abdomen are utterly inadequate to prepare a surgeon to interpret correctly the symptoms and signs presented by penetrating gunshot wounds of the abdomen, or to meet the often unexpected emergencies in their treatment. Operative courses on the cadaver are valuable and useful, but they never can take the place of experiments on the living animal. This is more especially true in reference to the use of the hydrogen gas test as a diagnostic measure, and the manual dexterity required in the surgical treatment of internal hæmorrhage and visceral wounds. A certain amount of experimental experience is absolutely required in the preparation of the surgeon for the kind of abdominal work which requires not only courage, good judgment, and a thorough knowledge of every step in diagnosis and treatment, but also a manual dexterity which cannot be acquired in any other way.

CONCLUSIONS.

1. In gunshot wounds of the abdomen, in the absence of external fæcal extravasation and prolapse of the omentum, it is absolutely necessary to establish the fact that penetration has or has not taken place by enlarging the wound down to the peritoneum, if the bullet has entered the peritoneal cavity, or in non-penetrating wounds, sufficiently far to show conclusively that the peritoneal cavity has not been invaded.
2. In a fair percentage of cases a bullet which penetrates the abdominal cavity does not produce visceral injuries which require treatment by laparotomy, and such cases, as a rule, recover without surgical interference.
3. Absence of visceral lesions which require treatment by laparotomy is most frequently met with in perforating gunshot wounds of the abdomen, if the wound of entrance is at or above the level of the umbilicus, and if its course is in an antero-posterior direction.
4. In transverse and oblique gunshot wounds of the abdomen at a point below the level of the umbilicus, multiple perforations of the intestines may be confidently expected.
5. The general and local symptoms, with the exception of external fæcal extravasation, are of absolutely no value in the differential diagnosis between simple penetrating gunshot wounds of the abdomen and penetrating gunshot wounds of the abdomen complicated by serious visceral injuries which demand prompt surgical interference.

6. Alarming internal hæmorrhage caused by perforating gunshot wounds of the abdomen can be recognized by the symptoms which characterize progressive acute anæmia, and by the physical signs due to the presence of fluid in the free peritoneal cavity.

7. Dangerous internal hæmorrhage furnishes a positive and urgent indication for treatment by laparotomy. The incision in such cases should be ample and through the median line.

8. After opening the peritoneal cavity for the treatment of alarming hæmorrhage, temporary hæmostasis should be secured by digital compression of the aorta below the diaphragm, or by packing the abdominal cavity with a requisite number of large sponges until the bleeding points can be discovered and the hæmorrhage arrested by permanent measures.

9. The existence of wounds of the stomach and intestine large enough to permit the escape of the contents of these organs can be infallibly demonstrated by the application of the hydrogen gas test before the abdomen is opened.

10. Direct insufflation of the stomach through an elastic tube is preferable to rectal insufflation as a diagnostic test in all cases where, from the location of the wound of entrance and the probable course of the bullet, there is reason to believe that this organ is the seat of injury.

11. The existence and probable location of gunshot wounds of the intestines can be ascertained by rectal insufflation of hydrogen gas.

12. Through insufflation without evidences of free tympanites or escape of gas through the external wound demonstrates either the absence of perforations, or that if present they are too small for leakage to take place; consequently the result of the test is a strong argument in favor of non-interference.

13. The hydrogen gas test should invariably be relied upon in searching for the perforations after the abdominal cavity has been opened, as this method of examination, if properly and carefully conducted, makes extensive eventration unnecessary, and never fails in revealing every perforation.

14. After opening the abdominal cavity for the treatment of gunshot wounds of the intestines, the lowest perforation is pointed out by rectal insufflation of hydrogen gas, but in the search for additional perforations the inflation should be made directly through the perforation last sutured, while the portion of the intestines which has been tested and the perforation sutured is replaced in the abdominal cavity.

15. The external wound should never be closed until the whole length of the gastro-intestinal canal has been subjected to the hydrogen gas test, in order to guard against the possibility of leaving a perforation undiscovered.

16. The hydrogen gas test under ordinary

circumstances does not cause fæcal extravasation, and consequently does not increase the subsequent risks from peritonitis.

17. Pure hydrogen gas is most suitable for insufflation of the gastro-intestinal canal for diagnostic purposes, as this substance is non-irritating, non-toxic, and possesses valuable inhibitory antiseptic properties, while its exceedingly low specific gravity adds still more to its value when used for this purpose.

18. By following the indications furnished by the hydrogen gas test the surgeon relieves himself of all medico-legal responsibilities in the operative treatment of penetrating gunshot wounds of the abdomen.

19. A gunshot wound of the gastro-intestinal canal sufficiently large to permit escape of the contents of the stomach or intestines must, for all practical purposes, be regarded as a mortal injury, and on this account its treatment by laparotomy is urgently indicated.

20. Laparotomy in the treatment of gunshot wounds of the stomach and intestines should be performed as soon as possible after the infliction of the injury, and always before a septic peritonitis has had time to develop.

21. The closure of bullet wounds of the stomach and intestines is accomplished most speedily, and with a sufficient degree of safety by the application of one row of interrupted seromuscular sutures of fine aseptic silk.

22. If enterectomy becomes an unavoidable necessity in the treatment of gunshot wounds of the intestines, the continuity of the intestinal canal should be restored by making an anastomosis between the closed ends by lateral apposition with decalcified, perforated, moist, bone plates, as this procedure requires less time and accomplishes the desired result with a greater degree of safety than circular enterorrhaphy.

23. Flushing of the abdominal cavity is to be reserved for cases in which the peritoneal cavity has become contaminated by escape of the contents of the stomach or intestines.

24. Drainage becomes necessary in cases in which the peritoneal cavity has become infected, also in injuries of the liver, and in wounds of the spleen, kidney or pancreas not treated by partial or complete extirpation of the injured organ.

25. The adoption of adequate provisions for the prompt, aggressive treatment of perforating gunshot wounds of the abdomen in hospital tents in the rear of the line of battle, should receive the most serious consideration of military authorities, and military surgeons who will have charge of the wounded in the wars of the future.

26. The necessary diagnostic skill, and requisite manual dexterity in the operative treatment of gunshot wounds of the stomach and intestines, can be acquired only by experiments on the lower animals.

MEDICAL PROGRESS.

DISINFECTING POWER OF PEROXIDE OF HYDROGEN (H_2O_2).—DR. ALTEHOFER of Rostock, gives us, in the *Cent. f. Bakteriologie und Parasitenkunde*, a careful study of the disinfecting power of this substance, for which he claims the especial merit that it does not alter the appearance, taste or smell of water to which it has been added.

The first experiments were made with spring water, the second with hydrant water and a third with river water. The first contained 560, the second 180, and the third 1800 germs in each cubic centimetre. To these several waters were added H_2O_2 in the proportion of 1:5000 and 1:10000, and after an exposure of 24 hours inoculations of gelatine and agar-agar were made. In each case abundant colonies developed, but those from the weaker solution were in greater number and more vigorous.

A second series was made upon hydrant water to which sewage had been added in the proportion of two per cent. and one-half per cent. The solutions were not sterilized even when H_2O_2 was added in the proportion of 1:2500.

Observations were made upon solutions containing H_2O_2 in the proportion of 1:1000. Three samples of potable water were used containing respectively, as was ascertained by cultivation, 160, 600, and 6,000 germs per cubic centimetre. The results in these three cases were, at the end of the seventh day, for the first sample three colonies, the second two, and the third ten. While this shows that the peroxide, in the proportion of 1:1000, is not sufficiently powerful to destroy all the ordinary germs of drinking water, it will destroy the greater number. Solutions of this strength impart a slight metallic taste to water, but this disappears shortly after it has been added. To 100 cubic centimetres of sterilized water one-half ccm. of sewage was added and one ccm. of H_2O_2 . This mixture was found to be absolutely sterile at the end of twenty-four hours.

Experiments made with the typhoid and cholera bacillus showed that they were completely destroyed when H_2O_2 was present in the proportion of 1:1000.

The author recommends the disinfection of drinking water by this means in times of epidemics not only from its efficiency and cheapness, but also because the potability of the water is not altered.

THE GRIPPE CONSIDERED FROM A SURGICAL STANDPOINT.—The recent epidemic of la grippe has called into requisition the services of the physician rather than of the surgeon, but an article by PROF. VERNEUIL, published recently in the *Bulletin de l'Académie de Médecine*, shows that the disease presents many points of surgical interest.

M. Verneuil points out that in most of the surgical affections caused by the grippe, the main pathological feature is suppuration. Thus he observed suppurative inflammations of the eye, ear, joints, purulent pleurisy and pericarditis, the formation of superficial or deep abscesses of the skin and glands, and collections of pus in the antrum of Highmore and frontal sinus. These conditions were treated by appropriate surgical measures, but it was found that the prognosis was less favorable than under ordinary circumstances. This is not surprising, since the grippe, like other acute infectious diseases, causes marked depreciation of the patient's general health and therefore adds materially to the dangers of any surgical operation that may have to be undertaken. Aside from this, it was observed that when patients who were in the stage of recovery from an operation were attacked by the disease, the complication gave rise sometimes to serious consequences. M. Verneuil therefore lays down the rule that excepting the conditions above mentioned, where urgent surgical interference may be indicated, it is better to postpone all surgical measures until the patient has recovered from the grippe. Owing to the slow and tedious convalescence which characterized the disease, it may not be possible to delay the operation until recovery is assured, and in this case the best that can be done is to improve the patient's general condition as much as possible by appropriate medication.

According to the observations of DRs. BERGER and PEYRAT, surgical diseases ran the same course during the prevalence of the grippe as under ordinary circumstances. On the other hand, DR. WALTIER, of the Hospital de la Charité, states that patients who developed the grippe shortly after operations in which the wound was not immediately closed, as in the treatment of cold abscesses, exhibited a remarkable slowness of the healing process. Cicatrization was arrested to a certain extent, and was not re-established until several days after the complete cessation of the acute febrile symptoms. In the case of wounds sutured without drainage, healing was not interfered with, but usually two or three days after operation a sudden rise of temperature was observed. The cause of this fever could not be demonstrated, since on removal of the dressings the wound appeared perfectly healthy.

DR. DEMONS, of Bordeaux, mentions quite a number of surgical complications of the grippe which have come under his observation. Otitis, complicated by suppuration in the middle ear or mastoid cells, was met with in several instances. Severe inflammation of the eye occurred in some cases, while in still others an orbitis was suddenly developed without a previous history of gonorrhœa or contusion of the testicle. Fortunately, however, this disappeared as rapidly as it had appeared, without going on to suppuration.

There was also a formation of abscesses in the axilla, in the iliac region, and upon the leg, although none of the ordinary causes of suppuration could be found to exist. M. Demons states that all wounds in the wards of the hospital were slow in healing, and in many instances suppurated profusely. In his opinion, during an epidemic of the grippe it is necessary to abstain from all operative procedures, but especially those involving the buccal, nasal, pharyngeal and respiratory tracts, which are especially apt to be attacked by the disease.

Judging from these observations, the prognosis of operations performed during the grippe is worthy of careful consideration, and, if possible, all surgical measures should be postponed until the patient has recovered from the debilitating effects of the disease.—*International Journal of Surgery*.

CLOSTRIDIAL NEPHRITIS—A NEW FORM OF BRIGHT'S DISEASE.—DR. F. V. HOPKINS, of San Francisco, contributes an original, and apparently carefully carried out, bacteriological research to the *Pacific Medical Journal*. It is based upon the observation of a case of chronic nephritis, due, as he believes, to a peculiar microorganism which he terms "Clostridium renale." The description of the germ is as follows:

Circular cocci, 1.27μ in diameter; rods, with rounded ends averaging $.6 \mu$ in thickness by 3μ in length, sometimes enlarging characteristically to bear a sporangium, oval in form, and measuring $1.27 \times 2.5 \mu$. Spores circular, $.42 \mu$ in diameter. Filaments of indeterminate length, sometimes $.6 \mu$ thick throughout their whole extent, at others, 1.7μ at one end and tapering at the other into branches, whose ends separate by fission into the usual round-ended rods $.6 \mu$ thick by 3μ long. Non-motile, pathogenic, infests the blood and is carried by it to the capillaries of the principal organs, which it obstructs.

This organism produces a chronic affection of the kidneys and other organs of the body, characterized by nervousness, sleeplessness, flatulent dyspepsia, albuminuria, dropsy, dyspnoea, and heart-failure. The occurrence of the germs in the urine, free and in casts, is its pathognomonic symptom.

The particular case in question, upon which the description is based, was that of a woman who suffered from nervous depression, dyspepsia, insomnia, and cardiac weakness. Her urine contained various peculiar forms of albumen. Delafield gives tests by which six different varieties of albumen are distinguished. Dr. Hopkins' patient passed still other varieties than these. We are not told the specific gravity of the urine, its daily amount, or that of the albumen, and in this and some other respects there seems to be a lack of careful clinical observation. Casts were found, however, which were composed entirely of bacte-

ria, occurring in the form of rods with rounded ends. These bacteria were cultivated under proper precautions, and inoculations were made in rabbits with the result, invariably, of causing albuminuria, dropsy, and death, with the bacteria in the kidneys and other tissues. The patient died, but no autopsy could be made.

Dr. Hopkins' claim to have discovered a new and peculiar form of nephritis cannot be said to be absolutely established, but he has done a service in calling attention to the importance of the bacteriological study of renal casts. The similar studies in bacteriological nephritis which have been made by others are given by the author, thus:

Babes, in Cornil et Babes' "Bacteriologie," p. 373, Figs. 197, 198, has described the "Bacille de la nephrite bacterieuse." "Cylindrical rods, with rounded ends 0.8μ to 1μ thick, and of very variable length, sometimes 1.6μ to 2μ and sometimes 20 to 50μ , and sometimes curved. Habitat, in the urine and renal tissues of patients with diseased kidneys."

In 1880, Dr. Ballard reported a case of meat-poisoning that occurred at Welbeck, Nottinghamshire, England. Four died out of seventy-two that were affected. Bacilli were found plugging the capillaries of the Malpighian bodies in the kidneys, though the symptoms were choleraic. The tube-casts were of the hyaline variety (Klein, "Microorganisms and Disease," pp. 122-125).

The bacilli of swine-plague also attack the Malpighian corpuscles, but here the bacilli occupy the capsule, the capillaries being plugged with hyaline matter (*Ibid.*, p. 133).

Again, the bacillus anthracis may completely plug the capillaries of the glomeruli and of the renal cortex (*Ibid.*, Fig. 87, p. 160).

Bacillus tuberculosis also can obstruct the blood-vessels of the kidney (*Ibid.*, Fig. 92, p. 171).

The fungi *Aspergillus flavescens* and *A. fumigatus*, when injected into the peritoneum of rabbits, proved fatal by forming foci in the kidneys and other organs (*Ibid.*, p. 200; Lichtheim, in *Berlin Klin. Woch.*, 9 and 10, 1882).

Letzerich describes twenty-five cases of an acute dropsy of young persons, which he calls "nephritis bacillosa interstitialis primaria." This disease lasts from two to six weeks, and is due to bacilli which swarm in the urine. Twelve rabbits inoculated with pure cultures of these bacilli developed ascites in about fourteen days. The bacilli occurred "at the junction between the pyramidal and cortical portions of the kidneys" (*Zeitschrift für Klinische Medicin*, 1887).

Perhaps the criticism which may be more effectively made against Dr. Hopkins' claim to have discovered a new form of nephritis is that his case was one of general microbic infection, and that the kidneys were not the primary or chief centres of the morbid action.—*Medical Record*.

ON PSYCHOSES AFTER INFLUENZA.—KRÄPELIN (*Deutsche med. Wochenschrift*, 1890, No. 11) has observed a development of mental disorder after the departure of influenza in eleven instances. Among these were cases of simple psychical depression, of melancholia with delusions, acute states of exhaustion resembling the delirium of collapse, typical mania, and delirium tremens. The outburst of the psychical attacks regularly supervened at once upon the expiration of the bodily morbid phenomena; so also no elevation of temperature was ever noticed. The especially active causes of these psychoses was, therefore, apparently to be sought rather in the general enfeeblement of the organism than in the particular nature of the intoxication or toxæmia. The prognosis of these psychoses is very favorable; the treatment must be a generally strengthening one.

PLUMBISM AND ALCOHOLISM.—At a recent meeting of the Academy of Sciences, Paris, M. CHARCOT read a note on some experiments in plumbism carried out by MM. Combermate and François. They caused from one to five centigrams of carbonate of lead to be consumed daily by animals. At the end of about a month the nervous symptoms of saturnine poisoning made their appearance—such as epileptic fits, delirium, etc.—just as they are observed in man. This was, of course, not new; but the interesting point was that in certain of the animals experimented upon the administration of large doses of alcohol was found to hasten in a remarkable manner the advent of the nervous symptoms. The same thing was noticed when others of the animals were subjected to any abrupt emotional shock, such as fear. These facts were worthy of note, for in man a similar precocity of the nervous phenomena of plumbism was observed whenever those already suffering from lead poisoning were subjected to a moral shock or became addicted to alcohol.—*Lancet*.

OSTEOGENESIS.—On Tuesday, August 5, PROFESSOR OLLIER, of Lyons, read a paper on this subject at Berlin. He began by considering the growth of bone in general, and gave a full account of his researches into these questions, in which by a series of experiments performed on animals, as well as in consequence of the numerous operations which he had performed on man, he had been led to the following conclusions: New bone could in reality be formed from the periosteum alone, and only under certain well-known conditions. It was perfectly hopeless to expect any complete and permanent growth of bone to take place unless the periosteum surrounded it. It was, indeed, true that if the parts were aseptic for a time, the new bone, or implanted bone, as the case might be, seemed to grow,

but this was only for a time. Within six months necrosis took place, and the dead bone, if loose, was thrown off, or might remain encysted in some instances, and, if it did no harm, was certainly of no advantage to its possessor. This was a fact which had been known for many years, and there was, he believed, notwithstanding what had been said to the contrary, no exception to it. If a more minute examination were made of the implanted bone, it would be seen that the changes which took place in it were as follows: It was penetrated by blood-vessels from the surrounding bones and tissues, but these vessels played no part in its nutrition, but served only to further its absorption. Perhaps no more striking evidence of the value of the periosteum could be given than the following: On one of his patients, a young woman, he had operated three times, resecting her elbow-joint on each occasion, but the periosteum had been retained, and on each occasion she had made an excellent recovery. Practically there were three kinds of plans which might be employed, which might be styled: 1, autoplasmic, in which the same bone was used to repair some deficiency in itself, and the bone was only partially severed from its connections—as, for example, where a piece of bone was turned down from the forehead to make a new nose; 2, the second of these plans was well described as homoplasmic—that is, when the graft is taken from the same individual, but not from the same bone; 3, the third, or heteroplasmic, plan is applied to those cases in which a bone of some other individual or animal is made use of. The first and second plans were all but useless, and the third quite so—that is to say, the implanted bone could not ever grow. With regard to the question of excisions, it was, of course, a case for either movement or ankylosis. He had nothing to say, except that in the lower limb we must always have ankylosis, and in the upper movement, though an exception might, perhaps, be made in the case of the wrist, where a fixed or partially fixed joint would be more useful to the patient than a movable one.—*Brit. Med. Journal*.

SALT IN MILK FOR CHILDREN.—DR. A. JACOB (*Arch. of Ped.*) says that the addition of sodium chloride prevents the solid coagulation of milk by either rennet or gastric juice. The cow's milk ought never to be given without table salt, and the latter ought to be added to a woman's milk when it behaves like cow's milk in regard to solid curdling and consequent indigestibility. Habitual constipation of children is influenced beneficially, since not only is the food made more digestible, but the alimentary secretions, both serous and glandular, are made more effective by its presence.

SATURDAY, SEPTEMBER 13, 1890.

EMPHYEMA.

The impunity with which the peritoneum is subjected to operative interference depends not so much upon antiseptic methods as upon the germicidal action of the peritoneum itself. This action has been shown by RINNE¹ to be sufficient to remove, every few days, a few cubic centimetres of injected pus. The experience of operators also leads them to place the greatest reliance on the uninjured peritoneum to remove small amounts of infective material. Although the investigations of KNECHT² show that the healthy pleuræ of animals absorb with ease small amounts of pure cultures of pyogenic bacteria, the germicidal action of these surfaces is noticeably less than that of the peritoneum. The pericardium and the serous surfaces of the meninges offer almost no resistance at all to infection. This phenomenon the writer holds is due to an immunity acquired by the peritoneum through its proximity to infective material within the intestinal canal. The danger of the pleural cavities to infection is less, and therefore less resistance has been evolved, while the opportunity of the remaining serous cavities to infection is so small that their resistance is at a minimum.

Next to the peritoneal, then, the pleural cavities offer the greatest opportunity for, and the greatest hope in operative treatment. The history of empyema is one full of mournful disasters. Its diagnosis has often been delayed or mistaken. Usually secondary, it has been confounded with

every condition which it follows, and the unhappy patient has been allowed to die and be buried with a mistaken diagnosis. Phthisis (pulmonary tuberculosis) has not only had cases added to its mortality, but records some of its most remarkable recoveries through these errors, and mania and insanity have suddenly been cured by the evacuation of a suppurating pleura.

During the past half year, an unprecedented number of cases of suppurative pleuritis have been observed. In Cook County Hospital only two cases of empyema were treated in 1889, while during the first six months of 1890 fifteen cases were admitted with this diagnosis. Almost every practitioner could report a similar condition of things in his own private practice, and a careful examination will show that the influenza was the primary disease in the great majority of cases.

The origin of these empyemas may be set down something in this manner: General infection of the blood with influenza and consequent saturation of its germicidal quality; invasion of portions of the lung with pneumonia-producing parasites, and consequent interruption of the lymph-currents from the pulmonary pleura over the affected area, resulting in serous pleuritic effusion; invasion of the lymph spaces in the pneumonic area by pus-producing bacteria which advance from the larger to the smaller bronchioles to the lymphatics, and then are carried in the lymph in its abnormal course into the pleural cavity. Here the bacteria multiply in the effused serum until the pleural surfaces are so modified by the products of bacterial growth that absorption is arrested and these surfaces become one continuous pyogenic membrane.

Suppurative disease in the pleuræ is of the same destructive and progressive nature which is so well recognized elsewhere, and it should be attended with the same prompt and radical treatment. The peculiar contractile power of the lung which causes it to collapse as soon as the atmospheric pressure is admitted through a defect in the thoracic wall, has led to the surgical neglect of this region. However, the indications in cases of empyema are well defined: evacuation of the pus, arrest of the suppuration, and restoration of the function of the parts.

The early evacuation of the pus with the aspirator accomplishes the first and last indication temporarily; and, when continuous aspiration

¹ Langenbeck's Arch. f. Klin. Chir., 1889.

² Inaugural Dissertation, Greifswalde, 1889.

after the manner of BULAN is practiced, it meets all the indications better than any method yet proposed. But the patient requires constant trained attendants, and his intelligent and patient cooperation is necessary to success. The method, moreover, is inapplicable to cases of fibrinous or fibrino-purulent pleurisy, and it is liable to serious interruptions and accidents when successfully initiated. Nevertheless it is the only method that can be thought of in bilateral empyema, and in unilateral empyema with loss of function of the opposite lung from pneumonia or other cause. Even if it be followed by incision of the thoracic wall and open drainage, it may limit the cavity so that the lung will suffer trifling collapse.

For cases removed from the possibility of constant trained assistants, the excision of a portion of rib and free drainage through the defect, is much to be preferred and it can be relied upon in most cases. Its application is so well understood that further mention is unnecessary. It is the only method which can be practiced in tubercular empyemas and in cases accompanied by permanent collapse or extensive gangrene of the lung, and in pneumo-pyothorax from perforation into a bronchus. It may frequently be necessary to supplement it in the worst of these cases with ESTLANDER'S operation.

Simple incision between the ribs can not be recommended as a safe procedure. It has been tried, with and without drainage tubes, for years, but with the most disastrous results. While it gives temporary relief, it offers, except in children, small hope of permanent recovery. Nevertheless, WM. E. QUINE has lately so modified this operation that it has in his hands given the greatest hope of usefulness. The incision is made into the center of the empyemic cavity at upper border of a rib. The pus is washed out once or twice daily with the most scrupulous antiseptic precautions. The thorough disinfection of the cavity is all the time kept in mind. When, after a week or ten days, more or less, the discharge becomes serous, the antiseptic irrigations are redoubled in amount and care for a few days, and then, after one grand attack on any remaining infection, the tube is removed and the incision stopped with a mass of iodoform, and the thoracic wound covered with an occlusive antiseptic dressing for two weeks. Under this treatment he has repeatedly had large tympanitic

thoracic cavities close in ten days, all the air being absorbed as well as any serous or purulent discharge, and what infective material the antiseptics have spared. The writer, on the suggestion of Prof. Quine, has practiced this method on a boy seven years old with the most happy results. A cavity holding at least three ounces, after daily antiseptic irrigation for two weeks, was permanently closed and the boy has remained well for three months. The writer believes that in proper cases and in proper hands this will be found a most satisfactory treatment. It must be instituted early. It must be conscientiously carried out until an approximately aseptic condition of the cavity is secured, or, better, until the absorptive power of the pleural surfaces is restored. Then the incision must be so closed that all ingress of air is prevented by the coaptation of the lips of the incision while the air within the cavity is absorbed, or forced out of the incision by coughing.

THE CRIME OF OVER-STATEMENT.

In the candid study of reported cases, there is apparent to the critical mind, an element of incredibility, which will not down at the bidding. We are ready to admit that this is not a constant factor, but merely that with all the hedging that it is quite frequent enough to deserve criticism. There is somehow an over-writing, a curious blending of the probable with a suggestive caution lest the tale be too well told. These are the arts of the shrewd writer, well up in the tricks of his craft. Parallel instances do not and are not expected to yield like results in other hands. Failure is to be attributed to lack of skill, knowledge or judgment.

Much may be allowed for the enthusiasm of the advocate of a new mode or principle, but there is altogether too much glossing and too much of the spirit of self-complacency to yield results of permanent value. This strife for immediate recognition, and this pushing to the front at all hazards, although for a season successful to the individual, only resolve themselves into examples of disaster to science at large. Men shake their heads and take refuge in a general disbelief, which stifles progress.

Now we hold that much more is to be learned from confessed errors of logic and mistakes in

diagnosis, than by any pandering to a personal vanity or assumption of infallibility. An unsuccessful issue, incapable of any avoidance in reality benefits more, when, conscientiously stated, than the most brilliant jumping at conclusions. We desire to give to this expression the utmost force, especially if the prevarication be deliberate. In all contributions to the medical press, the ideas involved may be worthy of perpetuation; then more is the pity if they be over-stated. What harm, therefore, if the foresight and ingenuity of other investigators bring to the task of unravelment a fresher mentality and more unprejudiced views. Any truth may be spoiled by too much drapery. Facts, in this our age, where BACON holds such a sway, can well afford to stand without propping. Facts, too, none of us need be told, are the known quantities in our mathematics, no less than in other departments of learning. HIPPOCRATES as an observer of the phenomena of disease will stand the test of ages yet to come; and DARWIN as a classifier of facts, will stimulate thought as long as the language in which he wrote is known. Why such enthronement? Why, because, in both the cardinal virtue was honesty.

In this, our writing, we are hinting at no delinquents in particular, but are disposed to denounce tendencies, customs and motives. Offenders are legion, and worst of all unconscious of their faults—they only know their neighbors, whom they would willingly punish. We admit that the temptations for a cheap acquirement of fame are various, that patience in classification is ignored, and that much latitude is given to fiction; but there can be no excuse for misleading the trusting by claims that are extravagant. We also allow that testimony is fallible, but cannot yield the point that falsehood, either deliberate or suggestive, can ever be utilized for any good. Let us have clear, succinct histories devoid of attempts at embellishment, and those artifices of concealment which mar rather than strengthen; let us not depend upon any one instrument of precision, nor let our vista be limited by any one field. When we become convinced of the more truthful methods of procedure, we shall come to comprehend broader laws, and to anticipate some of the grander discoveries, which may have been intended for reservation to posterity. Our moral is obvious, less self-appreciation but more labor for the general good.

GOVERNMENTAL INVESTIGATION REGARDING SPIRITUOUS LIQUORS.

An official enquiry by PROF. LYON PLAYFAIR'S committee on British and foreign spirits and their adulteration, at the laboratory of the Inland Revenue Department, has been made unusually interesting from the fact that one of the members, MR. HEALY, obtained specimens, from the House of Commons refreshment bar, of the Scotch and Irish whisky dealt out to the honorable members. The report of the analysis has not been published. But there has been published the evidence of DR. BELL, principal chemist at the laboratory above mentioned, regarding the brandy obtainable at the drinking places in London, to the effect that only four out of five were genuine, the other samples consisting of purified spirit flavored and colored. The mellowing of whisky, according to Dr. Bell, is a very uncertain element. He has seen a three-year old specimen which had lost none of its fusel oil, although generally speaking the time required in the mellowing process depends mainly on the amount of that oil present when the liquor is fresh from the still. Hence it is, as might be expected, that a great difference can be detected between the products of different distilleries. The chemical changes, which attend the mellowing of whisky, are not fully understood, although they are known to consist in part in the breaking up of fusel oil into aromatic ethers, but the same changes will certainly not always occur in different samples kept under conditions closely analogous. Dr. Bell states that he obtained fifty samples from the lowest public-houses in various British towns, and his analysis resulted in showing that the spirits were satisfactory in regard to purity, and that the injurious adulteration of alcoholic beverages is far less frequent than is commonly reported.

ELEMENT OF CONSENT IN SURGICAL OPERATIONS.

Apropos of a recent editorial in the *Medical Record* on "The Responsibility of the Physician for Experiments upon Patients, even with the latters' Consent," we are reminded of the exhaustive discussion upon "The Medico-Legal Relations of Abdominal Surgery" held in the Section on Jurisprudence at the last meeting of the American Medical Association. In that dis-

cussion, the necessity of obtaining the consent of the patient and friends, before proceeding to open the abdomen, was especially insisted upon by several speakers, and from this the discussion branched to the element of consent generally in surgical operations. The view most readily accepted in that meeting was that more than simple consent was required in surgical operations—while that was essential; the operation itself must be in the line of approved surgical procedure. A case was quoted in which a young man had his testicles removed because of amorous proclivities. He subsequently married and sued the physician for malpractice, notwithstanding the fact that the operation was undertaken with his full consent, indeed it was solicited. The case was settled out of court by the payment of a round sum on the part of the physician.

Responsibility in these cases is a complicated legal question. But we incline to the view that the mere element of consent is not sufficient to absolve the medical man from responsibility, unless the operation is within the recognized limits of medical or surgical procedure. It will not protect the physician in performing bizarre operations, or in reckless experimentation.

While we sympathize with the physician, mentioned by the *Record*, who was mulcted in small damages, we are not unmindful of the painful abscesses in the paralyzed limbs of the too credulous patient.

EDITORIAL NOTES.

PROF. SILAS H. DOUGLAS, M.D.—Dr. Douglas, says the *American Lancet*, died at his home in Ann Arbor, August 26, aged 74. He was for thirty-three years Professor of Chemistry in Michigan University. His genius organized the chemical laboratories of the University. For many years these had no equal in the United States. Much of the special value of the medical course was due to the exceptional advantages of these laboratories. Following Dr. Douglas Houghton in his occupancy of the Chair of Chemistry, he had the fullest opportunity to carry out his plans of teaching. He will doubtless be long remembered by his connection with the famous Douglas-Rose controversy, that kept at a white heat scientific, social, educational, and political interests of

the dominant power in the State. He was an exceptionally good business man for a doctor and a professor, and so was enabled to leave a large estate.

DEATH FROM POST-MORTEM ACCIDENT.—Dr. John Henry Love, formerly Health Officer at Wolverhampton, England, lost his life in consequence of an unusual accident in the post-mortem room. In the course of an autopsy he was engaged in opening the calvarium, when the hammer he was using slipped from the head of the chisel, and he received a sharp blow on the thumb of his left hand. The wound thus caused was immediately sucked and other treatment employed, but not sufficiently well to prevent septic infection, with cerebral symptoms, which resulted fatally three months after the accident. Perhaps the most important point of information to our readers, in this narration, may be in the fact that the lethal hammer-blow was given by one of those instruments that have one end of the head sharp and the other flat, and that in delivering the stroke the operator unfortunately had the sharp end towards the head of the chisel. Not unnaturally the hammer slipped, with the distressful results above described; all of which goes to show how life may hinge on a trifle of want of care and attention. In the post-mortem room, especially, these trifles must be rated as extra-hazardous.

THE MEDICAL EDUCATION OF WOMEN IN RUSSIA.—The reopening of the Woman's College of Medicine at St. Petersburg has been ordered by the Government. A building belonging to the municipality has been set apart for its temporary occupancy, and an annual grant amounting to about \$15,000 will be contributed by the city towards its support. The hospitals of the city will be accessible to the female students. The donations of private citizens will be relied upon, in considerable measure, to establish the college on a substantial basis. The college has already graduated not far from 700 lady physicians. The decision of the municipality to open the institution anew was brought about in consequence of a favorable report by Dr. Archangelsky, who has observed the good results of the work done by eleven female medical inspectors, employed by the city, to have oversight of the public schools and the *pauvres faubourgs* of St. Petersburg. Some of

these Russian ladies have found their way to Smyrna and other cities of the Orient, but far the greater number have remained in their own country, which suffers under a dearth of practitioners of medicine.

DR. FRIEDRICH ARNOLD, the eminent pathologist, died in Heidelberg on the 7th ult. No German professor is better known in America, nor one who has taught personally so many of the younger generation of medical men.

CHOLERA IN SPAIN; MALTREATMENT OF THE GOVERNMENTAL PHYSICIANS.—The strange behavior of the Spanish peasantry towards the medical men, who have been sent among them to save their lives, is like a page out of some mediæval chronicle. If the facts have been truly related to us by the cable despatches, not less than three cholera physicians have been killed by the mob, and many have been violently assaulted without cause. The health physicians have, in some places, refused to go on with their work unless protected by the military. Wherever they have gone, in the country districts, they have encountered the same wild panic-like antagonism, although their errand is plainly declared by them to be to save the lives of other people, at the risk and exposure of their own.

THE REPUTED CASE OF CHOLERA IN LONDON.—Great excitement prevailed in London recently following the announcement that a typical case of cholera had occurred in the person of a sailor landed at the Victoria Docks. On admission at the Poplar Hospital he was suffering marked collapse, cyanosis, cramps and violent vomiting. While these clinical symptoms point to Asiatic cholera, still the fact that there were no other cases during the voyage, and that no new cases are being developed, leads to the conclusion of his medical attendants, who have given the case every attention possible, that it is one of cholera nostras or cholera morbus, and not Asiatic cholera.

THE AUSTIN DISTRICT MEDICAL SOCIETY will hold its twelfth quarterly meeting at Austin, Texas, on Thursday, Sept. 25, 1890. A full programme of papers is published, and an interesting meeting of Texas physicians is assured.

THIRTY-TWO physicians of Bordeaux have volunteered for service at the frontier in preventing the spread of cholera.

CHOLERA.—The advices with reference to this disease during the current week have been favorable. Though prevalent in the provinces of Spain, the adjacent territories of France and Portugal are still exempt. It is less fatal in the localities previously infected, and in its progress westward it has been nearly at a stand. The report of a case in London proves to be ill-founded, and the advance to Western Europe by way of the Black Sea seems less and less probable. The heat of summer past, we may reasonably anticipate that for winter, at least, its general westward progress will be controlled.

PERSONAL UNCLEANLINESS AS A FACTOR IN THE CAUSATION OF CHOLERA.—In the *Gazette Médicale d'Orient* Dr. Gabuzzi cites Rochefontaine's experiments going to show that the microphyte of cholera is sterile within the patient's organism, and that, in order to be rendered capable of conveying the disease, it must find a nutritive soil on being cast off from the system. The urine, he thinks, often constitutes a medium in which it may attain pathogenic powers, and uncleanness, which favors the mixture of urine with the bacillus, may therefore be regarded as a predisposing cause of cholera.

CHOLERA IN JAPAN.—This disease has become prevalent in various parts of Japan, and it is quite possible that it may reach this continent by the western route rather than by the way of the Atlantic ports. Cases are reported in Tokio, and in Yokohama, the great center of commerce, a number of cases are reported.

PARIS is now receiving milk directly from the provinces, in sealed glass jars. This not only prevents contamination, but also fraud on the part of the retail dealer.

PROF. V. NUSSBAUM, of Munich, has, through ill health, been compelled to resign the position of director and professor at the University surgical clinic. Prof. Augerer has been intrusted with its provisional conduct.

SINCE 1866, 202 women have received diplomas in France, of whom 35 were doctors of medicine, 67 bachelors of letters, 69 bachelors of science, 13 licentiates, and 2 pharmacists.

IN the rue Fessart, Paris, there has been established a house of refuge for women, modelled somewhat after the plan of industrial homes.

TOPICS OF THE WEEK.

PAST CONGRESSES.

The Berlin correspondent of the *British Medical Journal* prefaces his report of the late Medical Congress with the following brief references to the past Congresses:

"Before proceeding to give an account of the scientific and general work of the great medical gathering now being held at Berlin, it may be well to glance backwards for a moment at the similar meetings which have taken place in past years. The history of this important periodical event in the world of medicine is interesting as showing its almost casual mode of origin, and the way in which it has developed from comparatively humble beginnings into one of the most powerful factors in the advance of knowledge and the promotion of community of effort, professional solidarity, and good-will among the members of our body throughout the world. Although an international hygienic congress was held at Brussels so far back as 1852, the International Medical Congress, as we now know it, is of much more recent date. Our French neighbors claim the merit of having originated the idea, but the first meeting which was held at Paris in 1867 appears to have been little more than an accidental expansion of the annual Congress of French medical men, which was being held in the ordinary course, by the addition of a considerable foreign contingent formed by the medical visitors of various nationalities who had gone to Paris at the same time to see the great exhibition of that year. The scientific guests, who numbered about 500, were received by their French hosts with all the courtesy characteristic of the *grande nation*, and representative men of the different leading nationalities were chosen Vice-Presidents, among them, it is interesting to recall, being Professor Virchow, some of whose later utterances recently furnished Dr. Huchard with a text for a vehement call to all patriotic Frenchmen to boycott the Berlin Congress. The proceedings at the Paris Congress were almost purely scientific, with little or none of the festive element, which has been so prominent a feature in most of the subsequent gatherings. Moreover, French was the only language recognized at the meeting. The assembly, such as it was, however, was so successful that on the motion of an Italian physician, Dr. Pantaleoni, it was determined to make an International Medical Congress a regular institution, the meetings to be held every two years. In compliment to Dr. Pantaleoni, Italy was fixed upon as the place for the next meeting. It had at first been intended to hold the second Congress at Rome, but as there were some doubts as to the willingness of the Papal Government to furnish facilities for the meeting, Florence was chosen, and a gathering was held there in 1869, in which 87 foreign practitioners took part. Owing to the outbreak of the Franco-Prussian war, the third Congress was not held till 1873, when a successful meeting took place at Vienna, again contemporaneously with a Universal Exhibition. The veteran pathologist Rokitsansky was the president on that occasion, which is memorable in the annals of medicine for the part assigned to discussions on important hygienic questions,

such as the prophylaxis of cholera, compulsory vaccination, etc. At Vienna, also, it was decided that at future meetings there should be three official languages, namely, German, French, and English. The fourth Congress was held at Brussels in 1875. The King of the Belgians took so much interest in the proceedings that he was present at many of the sittings. It was at this meeting that the Congress was first divided into Sections. The fifth gathering was at Geneva in 1877, under the presidency of the illustrious biologist, Karl Vogt; the sixth at Amsterdam in 1879, under the presidency of Donders, whose death ophthalmology and physiology will long continue to deplore. The next meeting, which was held in London in 1881, marks an epoch in the history of the Congress. Some 3,000 practitioners, including about 1,000 foreigners, took part in it. It was divided into sixteen Sections, which held 190 sittings, giving a total of 293 hours of work. The number of communications amounted to 325. The social aspects of the London Congress were not less brilliant than the amount and quality of its scientific work. Of the meetings at Copenhagen in 1884, and at Washington in 1887, it is needless to say anything more than that, though very successful, they did not eclipse the splendor of the London gathering."

LIGHT IN THE SICK ROOM.

Still a custom prevails despite all our sanitary teachings, that the occupant of the sick room in the private house should be kept at all hours in a darkened room.

Not one time in ten do we enter a sick room in the day time to find it blessed with the light of the sun. Almost invariably before we can get a look at the face of the patient, we are obliged to request that the blinds may be drawn up that the rays of a much greater healer than the most able physician can ever hope to be, may be admitted. Too often a compliance with this request reveals a condition of the room which, in a state of darkness, is invariably one of disorder everywhere; foods, medicine, furniture, bedding misplaced; dust and stray leavings in all directions.

In brief, there is nothing so bad as a dark sick room. It is as if the attendants were anticipating the death of the patient; and, if the reason for it be asked, the answer is as inconsistent as the act. The reason usually offered is that the patient cannot bear the light, as though the light could not be cut off from the patient by a curtain or screen, and as though to darken one part of the room it was necessary to darken the whole of it.

The real reason is an old superstitious practice which once prevailed so extensively that the sick, suffering from the most terrible diseases—small-pox, for instance—were shut up in darkness, their beds surrounded with red curtains during the whole of their illness. The red curtains are now pretty nearly given up, but the darkness is still accredited with some mysterious curative value.

A more injurious practice really could not be maintained than that of darkness in the sick room. It is not only that dirt and disorder are the results of darkness; a great remedy is lost. Sunshine is the remedy lost, and the loss is momentous. Sunshine diffused through a

room warms and clarifies the air. It has a direct influence on the minute organic poisons, a distinctive influence which is most precious, and it has a cheerful effect upon the mind. The sick should never be gloomy, and in the presence of the light the shadows of gloom fly away. Happily, the hospital ward, notwithstanding its many defects (and it has many), is so favored that it is blessed with the light of the sun whenever the sun shines. In private practice the same remedy ought to be extended to the patient of the household, and the first words of the physician or surgeon on entering the dark sick room should be the dying words of Goethe: "More light, more light!"—Dr. B. W. Richardson.—*Tenn. Health Bulletin.*

CHOLERA PROPHYLAXIS IN ITALY.

Among the nations of the Continent, Italy has hitherto been conspicuous for her belief in quarantine and sanitary cordons as the most effective means of averting cholera from her shores. And even now, when their efficacy has been shown, by her highest hygienic authorities, to be more than doubtful, she continues to favor them if only for the "sense of security" they give to her uneducated populace. Concurrently, however, with these traditional, if not exploded, measures, she is developing activity in a far more promising direction—that is, in a vigilant censorship of the food-supply. For years past the meat, the vegetables, and the alcoholic beverages have been, in many large towns throughout the peninsula, sold to the poorer classes when in a state unfit for consumption; but, thanks to the new Sanitary Code, the public health officers have been most stringent in the exercise of the powers given them by that enactment for the confiscation of such articles, and the punishment of their vendors. How far the evil had been allowed to go may be inferred from the fact that one can hardly open an Italian newspaper without coming on one or more announcements of the sequestration of food or liquor stores, which, if permitted to be sold, must have injured the health of the consumer. The *Opinione*, for example, a leading Roman journal, tells us that in one fortnight the *Ufficio d'Igiene* has sequestered in that city 245,300 chilograms of fish, 1,742 of vegetables, 2,750 of fruit, and 32,700 of mushrooms, while the tradesmen in whose shops these articles were on sale have had their names and addresses published in the most conspicuous fashion possible. Similar seizures of confectionery and fancy beverages, such as are largely consumed throughout Italy in the summer season, are also reported in a Florentine journal—the *Nazione*—again with the names and addresses of the fraudulent vendors. All this should have a salutary effect on the Italian poorer classes, not only in view of cholera invasion, but of the maintenance of health at a high standard. In the memorable visitation of cholera in 1884, the ravages it made among the Neapolitan proletariat were distinctly traced not only to panic, but, primarily, to the unsound macaroni and the putrid vegetables, which made them "candidates" for the disease. Now this source of danger is in a fair way of being minimized—all the more that, as we see from an official rescript, the *personnel* of the sanitary office is

being rigidly supervised, so as to obviate the temptation not unknown in poor countries—of the enforcer of the law conniving, for a "consideration," at breaches of the same. Italy, indeed, is doing now what she should have done long ago, and will reap the reward, not only of keeping epidemics at bay, but of receiving a larger measure of that tourist population whom her backward hygienic system has hitherto tended to warn off.—*Lancel.*

THE INTERNATIONAL CONGRESS FROM AN ENGLISH STANDPOINT.

In a leading editorial in the *British Medical Journal* of August 16, there occurs the following reference to the recent Congress at Berlin:

"*Congressus haud impar*—Berlin has had to sustain the stress of a gathering of medical men of all nations, in numbers hitherto unprecedented. They invaded the metropolis of the German Empire in hosts from every part of the world. They came; they saw; and they admired. Nothing could have exceeded the overflowing hospitality, the generous and cordial welcome, the thoughtful courtesy, and the minutely elaborate preparations with which the social and scientific needs of the invading hosts were met. All were alike made to feel this welcome; so that whether for its remarkable assemblage of the most eminent representatives of cosmopolitan medical science, or for its endless round of scientific and social activity, the Berlin Congress must be pronounced to have far exceeded any which has preceded it; and it will certainly be difficult in the future for any capital to surpass the feat which Berlin has accomplished."

THE MEDICAL CHARITIES IN EDINBURGH.

A series of elaborate articles have appeared within the past week in the *Scotsman* on the Charities of Edinburgh. These are dealt with in great detail, and compared with similar reports published twenty-five years ago in the same paper. The charities first treated are the medical charities, and some of the results are sufficiently startling to be worth noting here. The sum annually spent in healing the sick in Edinburgh amounts to £45,000, irrespective of the sum paid for the support of the City Hospital for Infectious Diseases. The most startling result of the investigations upon which these articles are based is the number of persons who receive gratuitous medical advice from the city medical charities, the number reaching a total of rather over 103,000 persons, and this in a population a little over 236,000. The articles recommend that additional precautions should be taken to prevent persons availing themselves of such gratuitous help who are quite able to help themselves. At present the principle upon which most of the institutions are conducted is to help whoever presents himself, without asking any questions. And the writer fairly remarks that the temptation to abuse help so readily given is very great, and that it is not altogether wonderful that the numbers are large, especially when, owing to the amount of medical teaching done in Edinburgh, there is always a certain demand for patients. It is almost needless to state that this represents an enormous amount of gratuitous service by the profession.—*Lancel.*

PRACTICAL NOTES.

THE USE OF BUTTERMILK IN VOMITING.

Dr. Stanley M. Ward writes in the *Therapeutic Gazette* that he has found fresh buttermilk very serviceable in relieving vomiting of various forms, even at times the vomiting of pregnancy. The remedy is administered ice cold, in doses of about half a teaspoonful repeated every fifteen or twenty minutes. In the case of children with cholera infantum he has often succeeded in quieting the stomach by interdicting everything else and using a few drops of fresh ice-cold buttermilk at intervals varying in length according to the severity of the case.—*Medical Record*.

METHOD OF APPLYING ANTISEPSIS IN THE TREATMENT OF RECENT ANTERIOR URETHRITIS.

Dr. J. William White has obtained the best results in this disease by frequent injections with a large syringe of a solution of sulpho-carbolate of zinc (10 grains to the ounce of the mixture) in a 10 to 15 per cent. lotion of peroxide of hydrogen. In addition to this treatment, or often entirely omitting local treatment, six to eight capsules a day were given by the mouth, each containing:

Salol, $3\frac{1}{2}$ grains.
Oleoresin of cubeb, 5 grains.
Para balsam of copaiba, 10 grains.
Pepsin, 1 grain.

Of fifty-three cases of recent urethritis thus treated, and of all grades of severity, a distinct and unmistakable effect was produced upon the discharge in every instance but two, in which a violent indigestion prevented a thorough trial of the capsules. In about two-thirds of the whole number the discharge almost or entirely disappeared during the first week after treatment was begun. In but one case of the whole number did gonorrhoeal rheumatism develop. This was especially noteworthy in three cases which had never before been free from joint trouble during an attack of gonorrhoea.—*Medical News*.

LYSOL.

At a meeting of the Society of Physicians of Vienna, May 23, 1890, Dr. V. Gerlach spoke of a new disinfectant, lysol, derived from tar oils by boiling with alkalis and fats. Comparative tests as to the germicidal powers of lysol, carbolic acid, sulphurous acid, and creolin upon the spores of anthrax bacilli, the staphylococcus pyogenes, and cocci of erysipelas, showed the former to be possessed of special advantages. Lysol appears to be perfectly innocuous, and has been administered

subcutaneously to rabbits in amounts of half a drachm daily during fourteen days without causing death. It has been successfully employed in surgical operations, and for vaginal and uterine irrigation. On wounds it has no irritant effects, but when applied to mucous surfaces in $\frac{1}{2}$ per cent. solutions it causes slight transient burning. A 0.3 per cent. is sufficient to destroy all the organisms present in wounds within thirty seconds, and a 1 per cent. solution is a good general antiseptic. In 3 per cent. solutions, it has the properties of a soap, and acts as an excellent disinfectant of the hands.—*Wiener Medicinische Wochenschrift*, No. 22, 1890. *International Journal of Surgery*.

IODOFORM EMULSION IN THE TREATMENT OF COLD ABSCESSSES.

In the Polish Journal, *Gazeta Lekarska*, Dr. R. Jassinski reports the results he has obtained in the treatment of cold abscesses with iodoform emulsion. He opens an abscess only when it has become "residual," that is, when the primary focus in the vertebral column has healed or is separated from the abscess cavity. He has used iodoform emulsion in eighty-six cases, with the following results. A certain number of abscesses healed after a single injection, others after two or more injections. In eleven cases the abscesses burst spontaneously after injection, and much pus, mixed with emulsion, escaped. Healing occurred without further surgical interference. In nineteen cases aspiration was impossible, owing to blocking of the trochar; the opening was therefore dilated, and the cavity washed out with a 3 per cent. carbolic acid solution. Iodoform emulsion was then injected, and the wound stitched up. Occasionally a drainage tube had to be inserted, and the injection frequently repeated. Dr. Jassinski has never seen symptoms of poisoning, though he has injected 180 grams of a 10 per cent. iodoform emulsion at once.—*British Medical Journal*.

ANTIPYRIN IN ERYSIPELAS.

Dr. Favre, of Fribourg, relates an unusually severe case of erysipelas, showing the high curative value of antipyrin. A woman, aged 30, suffered from facial erysipelas accompanied by somnolence, vomiting, constipation and high fever. In spite of the local application of cold, carbolic acid, ichthyol, corrosive sublimate, strips of adhesive plaster, etc., the morbid process gradually spread over the scalp, neck, chest, upper extremities, abdomen and buttocks. On the tenth day the administration of antipyrin was commenced, with the result that fever at once markedly decreased, the patient's subjective state greatly improved, and the erysipelas soon ceased to spread.

SOCIETY PROCEEDINGS.

Tenth International Medical Congress,
Berlin, August, 1890.

DR. H. C. WOOD, of Philadelphia, delivered
before the Congress

AN ADDRESS ON ANÆSTHESIA.

(Concluded from page 376.)

Clinical and experimental results, namely, the results of experiments made in the physiological laboratory upon the lower animal, and the results of experiments made in the amphitheatre upon the higher animal, man—are again concordant. Chloroform is much more inimical than ether to animal life. The cause of this singular fatality is not, however, chiefly the cardiac action of chloroform. Chloroform is more apt to cause cardiac arrest than is ether, but it is also much more prone than is ether to cause death by failure of the respiration. Almost invariably, when ether is withdrawn before the dog is absolutely in the grasp of death, recovery occurs; but over and over again have I noticed that although the chloroform was taken away whilst the respirations were still being maintained with regularity, the arterial pressure much above zero, and the pulse very apparent, yet the symptoms of cardiac and respiratory failure continued to increase until the fatal issue was reached.

It seems to me that certain general facts or principles in regard to anæsthesia must be considered as established:

1. That the use of any anæsthetic is attended with an appreciable risk, and that no care will prevent an occasional loss of life.
2. That chloroform acts much more promptly and much more powerfully than ether, both upon the respiratory centres and the heart.
3. That the action of chloroform is much more persistent and permanent than that of ether.
4. That chloroform is capable of causing death either by primarily arresting the respiration, or by primarily stopping the heart, but that commonly both respiration and cardiac functions are abolished at about the same time.
5. That ether usually acts very much more powerfully upon the respiration than upon the circulation, but that occasionally, and especially when the heart is feeble, ether is capable of acting as a cardiac paralyzant, and may produce death by cardiac arrest at a time when the respirations are fully maintained.
6. Chloroform kills, as near as can be made out, proportionately three to five times as frequently as does ether, partly, no doubt, because it is more powerful in depressing the heart, but largely because it lets go its hold much less rapidly than does ether when inhalation ceases. Is it not possible that this "holding on" is

because it is less volatile than ether, and can we not here get a hint why chloroform is less deadly in the South than in the North? The diffusibility of vapors or gases is in inverse proportion to the square of their densities, and the vapor of chloroform would certainly diffuse itself with far greater rapidity at 90° F. than at 70° F.

The comparative advantages and disadvantages of the two anæsthetics in practical medicine are so well known, that only one or two points seem to force themselves upon our present attention. I cannot see that the surgeon is justified in putting the life of the patient to unnecessary risk of chloroformisation, except under special circumstances. I believe, moreover, that much of the unpopularity of ether is due to its improper administration. It is so easy to embarrass the respiration seriously by the folded towel, as commonly used, that not only are the struggles of mechanical asphyxia almost invariably produced, but probably death itself sometimes caused. Especially is there danger of death being thus caused mechanically in the advanced stage of etherization, when the patient is too thoroughly etherized to struggle, and when the attention of the etherizer is, it may be, attracted by some novel and difficult operation. I confess myself to once having nearly killed a patient in this way.

A proper apparatus is certainly preferable to a folded towel. Various have been invented, but, as the time is short, I shall only mention one, which seems to me a practically perfect mechanism, although it is probably little known on this side of the Atlantic.

The inhaler invented by Dr. O. H. Allis is based upon the theory that the patient to be etherized should be supplied with a full abundance of air saturated with the vapor of ether. It consists essentially of a series of foldings of muslins on a wire framework, arranged almost like the gills of a fish, so as to allow the air to pass freely through, but everywhere come in contact with ether. It should be placed upon the face of the patient dry, and the ether gradually poured on from a bottle with a tight cork, pierced by two small glass tubes, one short for the entrance of the air, the other long, and reaching nearly to the bottom of the bottle for exit of ether. When properly used, the Allis inhaler practically does away with the sense of suffocation, and the consequent struggles which have made etherization alike so repulsive to patient and surgeon.

In order to determine the rapidity with which etherization can be produced by this inhaler, Dr. M. H. Wilson kept for me notes of thirteen consecutive cases in the clinic of the Jefferson Medical College Hospital in Philadelphia. The average time required for the production of complete unconsciousness was 8 minutes. The average time during which anæsthesia was fully

maintained was 32 minutes; and the average amount of ether used during this time was $7\frac{1}{2}$ ounces. In twenty-one surgical cases occurring this spring in the clinical service of Professor J. William White, of the University of Pennsylvania, the average time for the production of complete anæsthesia with ether, used through Allis's inhaler, was $7\frac{1}{6}$ minutes. The results arrived at in these two clinics are so close that 8 minutes must be considered as the average time required for full etherization by this apparatus.

In discussing the treatment of the accidents of anæsthesia, the results obtained at the bedside naturally press forward for careful consideration; but in going over the subject from this point of view, I have found so little that was novel, and so little that was satisfactory to myself, that I shall not occupy the time of this Congress with any conclusions drawn from reported cases, or personal experience in chloroform accidents. I do not think myself that the problem can be solved by any such study of cases. Death is so near and so terrible, time so absolute, moments so important, that no surgeon would be willing or justified in waiting for the effect of any one remedy; and when a man is dosed with alcohol, nitrite of amyl, hypodermic injections of ether, digitalis, atropine, and other powerful agents; faradised, slapped, douched, stood on his head, subjected to chest movements for artificial respiration, and various other measures too numerous to mention; who can tell, if by chance he recover, why he has done so? or who can point out, if by chance he die, what is the remedy whose omission or commission has led to the fatal result?

The problem is a very complex one, not to be worked out amidst the excitement and responsibilities of the amphitheatre. Only in the physiological laboratory can its various elements be separated and studied each by itself, without regard to the individual life which is at stake.

In the physiological laboratory two distinct paths open, each promising to lead to some positive knowledge. We may, on one hand, enter upon the study of the minimum fatal dose of the anæsthetic, and of the results by consentaneous or subsequent administration of its supposed physiological antagonist; or we may investigate the effect of remedies upon functions that are failing under the influences of the anæsthetic.

The objections to the first of these methods have been, in the present instance, overwhelming. The accidents seem to be independent of the amount of anæsthetic inhaled; and such a method of investigation would have required far more time than was available after I had had the honor of being asked to address this body. Death is produced by chloroform and ether through paralysis of the respiration and the heart, and the method of experimental study which I have employed consisted in a study of the action of power-

ful agents upon these functions when oppressed by chloroform. I have selected chloroform chiefly because it is the more powerful agent of the two anæsthetics, and the more certain in its lethal results.

The experiments have all been made upon dogs, by one plan. The carotid artery and also the trachea, having been connected with a recording drum, so that the movements of the circulation and the respiration could be consecutively recorded, the animal was anæsthetised, and when the blood pressure had fallen almost to zero, and the respiration had ceased, or nearly ceased, as the case might be, the remedy to be tried was injected into the jugular vein, through a canula which had been previously inserted.

The more important remedies which have been used by clinicians for the averting of threatened death during anæsthesia are ether, alcohol, ammonia, nitrite of amyl, digitalis, atropine, and caffeine, alterations of position, and artificial respiration.

Although, at least in America, hypodermic injections of ether have been frequently employed even in ether accidents, such use is so absolutely absurd that it does not seem to me to require any experimental evidence as to its futility. Ether in the blood acts as ether, whether it finds entrance through the lungs, through the rectum, or through the cellular tissue; and the man who would inject ether hypodermically into a patient who is dying from ether, should, to be logical, also saturate a sponge with the ether and crowd it upon his unfortunate victim.

Instead of simply stating the results obtained in my experiments, I have thought it would be more interesting to show reproductions from some of my tracings. The first drug that I shall report upon is caffeine. I have injected it during the cardiac failure produced by chloroform, in doses varying from 3 to $7\frac{1}{2}$ grs., and have never been able to perceive any distinct alteration in the arterial pressure, and no consistent distinct change of the pulse either in number or force. So far as the experiments go, they certainly indicate that the drug has no influence upon the heart that is being overpowered by chloroform. I may also state here, that it is not possible in any of my tracings to make out any influence exerted by caffeine upon the respiration.

With atropine, I have made a few experiments, the results being almost as negative as with caffeine. Ten cubic centimetres of a 2 per cent. solution of the atropine injected into the jugular vein of a chloroformed animal, altered the rate of the pulse beat, but had no apparent effect or influence upon the arterial pressure, or upon the respiration, and in no wise prevented final cardiac arrest.

Of all drugs, that which I think is most relied upon by clinicians as a cardiac stimulant in anæ-

thetia, as in other cases of heart failure, is alcohol. The chemical and physiological relations of alcohol to ether and chloroform are, however, so close, that many years ago I became very doubtful of the value of this drug as a stimulant to a heart depressed by anæsthesia.

These doubts continually grew stronger from what I saw and read as to the effects of the administration of alcohol during anæsthesia, and were finally changed into conviction by the experiments of R. Dubois,¹ who found that in the animal to which alcohol had been freely given, much less chloroform is required than in the normal animal, to anæsthetize or to kill; or, in other words, that alcohol intensifies the influence of chloroform and lessens the fatal dose.

In my own experiments with alcohol an 80 per cent. fluid was used, diluted with water. The amount injected into the jugular vein varied in the different experiments from 5 to 20 cubic centimetres, and in no case have I been able to detect any increase in the size of the pulse, or in the arterial pressure, produced by alcohol, when the heart was failing during advanced chloroform anæsthesia. On the other hand, on several occasions the larger amounts of alcohol apparently greatly increased the rapidity of the fall of the arterial pressure, and aided materially in extinguishing the pulse rate.

The effects of ammonia upon the failing heart of chloroform anæsthesia have been in my experiments uncertain; sometimes distinct, although very fugacious, and sometimes imperceptible. Twenty cubic centimetres of a 10 per cent. solution of aqua ammoniæ fortior (United States Pharmacopœia), in some instances produced an immediate rise in the arterial pressure, and even fugaciously registered itself in the respiratory rate, but perhaps more frequently it failed in its influence.

The influence of injections of digitalis has been in a number of experiments very pronounced in producing a persistent gradual rise of the arterial pressure, with an increase in the size of the individual pulse rate. In several instances death was apparently averted by its injection, and I saw in one or two cases, where large amounts of the digitalis had been employed, sudden systolic cardiac arrest, indicating that digitalis, if in sufficient amount, is able to victoriously assert itself in opposition to chloroform. Moreover, when I have given chloroform to dogs whose hearts were already under the influence of digitalis, there has seemed to be a peculiar steadying or sustaining power combating the circulatory depression naturally produced by the anæsthetic, and I believe that in all cases of weak heart in man, a full dose of digitalis before the administration of chloroform would greatly lessen the danger of cardiac collapse.

With the nitrite of amyl four experiments were made; in some of these from 4 to 10 drops of the nitrite of amyl were injected in the jugular vein; in others the nitrite was used by inhalation. No distinct effect upon the arterial pressure was in any instance produced, and usually no alteration in the size of the pulse waves, although sometimes the pulse did appear to be a little fuller.

Of all my experimental results, those which have been reached with strychnine have been the most surprising. The injection of strychnine into the jugular vein usually produced a gradual rise of the arterial pressure, and always caused an extraordinary and rapid increase in the rate and extent of the respiration. Thus I have seen the respiration, which had practically ceased for ten seconds, suddenly, under the influence of an injection of $\frac{2}{100}$ of a gr. of strychnine, become at once very large and full, and reach a rate of 130 a minute.

A series of elaborate experiments made upon the effect of the change of position of the animal on the blood pressure in the carotid and other arteries, has very clearly proved that the body of the animal whose circulation has been paralyzed by chloroform acts in a measure like a tube filled with fluid. Thus, if the feet of the dog were raised vertically above the head, whilst the latter remained upon the table, an immediate rise of pressure occurred, even though the heart had ceased beating entirely; provided that the head of the animal was kept upon a level with the table. If, however, the head of the animal was depressed below the level of the table for a distance equal to, or greater than the length of the body of the animal, a decrease of the arterial pressure occurred at once, although the animal was in a vertical position. The phenomena observed were precisely such as would have been produced if the canula had been inserted into a tube filled with fluid, instead of the carotid artery, and the elevation and depression of this tube had registered itself on the recording drum, in obedience to the ordinary laws of hydrostatics. The phenomena were entirely independent of any beat of the heart, and were readily produced when the animal was dead, provided the death had not occurred too long previously. Sometimes, even a very few minutes after the cessation of the heart beat, it was impossible to produce the changes of pressure on the drum. This I believe to have been due to coagulation of the blood occurring very early after death to a sufficient extent to interfere with the liquid properties of the fluid. In no case was any effect upon the respiration produced by change of position in the animal. In a number of cases, however, when the feet were elevated, the heart, which had entirely ceased beating, recommenced its work, and I have several times seen a pulse entirely disappear when the animal was taken from the vertical to the

¹ Progrès Méd., 1883, xi, 951.

horizontal position. On the other hand, very frequently it was impossible to affect the cardiac action by changing the position of the animal. Nevertheless, the phenomena spoken of occurred too frequently to be a mere outcome of chance, though I several times noted that the heart was usually more affected by alternately elevating and depressing the feet of the animal than by keeping it in a steadily elevated or horizontal position.

When the circulation has practically ceased, under the depressing influence of an anæsthetic, inverting the body must cause the blood which has naturally collected in the enormously relaxed vessels of the abdomen, to flow into the right side of the heart and distend it, and this distension—this increase of pressure—appears at times to have a sufficient momentary influence to stimulate the failing organ.

The theory which has been advocated by some therapeutists—that inversion of the body is of value in the accidents of anæsthesia, because it causes the vital centres of the brain to be supplied with blood—is probably incorrect. The respiration in anæsthesia fails, not through want of blood in the respiratory centres, but because the blood contains a poison which paralyzes these centres.

The most remarkable results which I have reached in bringing about recovery of animals to all ordinary intents and purposes dead, were obtained through the use of artificial respiration. Thus, I have seen an animal, in which no respiratory movements whatever had taken place for two minutes, and in which, during that time, no movements of blood had occurred in the carotid artery, and in which, therefore, the heart had ceased its beat, rapidly and permanently restored by artificial respiration.

At one time in these researches, it appeared as though after any dose of chloroform by inhalation, the animal could be resuscitated by artificial respiration, even though heart and lungs were completely paralyzed by the drug; but finally I did find a case in which artificial respiration failed.

The results of my experiments with the lower animals may be summed up: that nitrite of amyl, caffeine and atropine are of little or no use in chloroform poisoning; that alcohol, when given in small amounts, has no influence, but that when given largely, materially assists in paralyzing the heart and producing fatal results; that ammonia has some little influence upon the heart, but that of all substances tried, digitalis was by far the most powerful in stimulating the failing circulation; indeed, my experimental results indicate that it is the only known drug which is of any real practical value in such cases. Next, or perhaps even before digitalis, strychnine seems to be of value in the accidents of anæsthesia, because, whilst having some influence on the circulation, it affects powerfully the respiration. For many years chloro-

form has been used in practical medicine as the physiological and practical antagonist to strychnine, and it seems rather odd that strychnine should never have been employed as the practical antagonist to chloroform.

The one measure which in practical value far surpassed all others for the restoration of the dying animal was artificial respiration, and I have no doubt that a great majority of the deaths which have occurred in man from anæsthesia might have been avoided by the use of an active artificial respiration. The difficulty with artificial respiration, as it has been hitherto practiced upon man, after the Sylvester or other methods, is its inefficiency; whereas the artificial respiration which I used on animals was very active, indeed, much more efficient than natural breathing in causing circulation of air through the lungs, and therefore in removing excess of the anæsthetic from the residual air of the lungs and from the blood.

The use of what may be called "forced" artificial respiration by the physiologist, so naturally suggested a similar practice in man, that the celebrated John Hunter invented for the purpose an apparatus which consisted of a bellows so constructed that when it was extended one compartment drew in air from the lungs, whilst the other drew air from the atmosphere; and when it was closed the process was reversed, the fresh air being thrown into the lungs, the foul air into the atmosphere. In 1867, Richardson, of London, invented an apparatus more elegant and portable, although identical in principle with that of John Hunter's; but I have not found that either Hunter or Richardson treated by forced artificial respiration an actual case of disease or poisoning. In 1875,² Dr. John Ellis Blake reported a successful case of aconite poisoning, in which life was apparently saved, although there was no pulse for over three hours, by artificial respiration, with the use of oxygen. In this case Marshall Hall's method was at first used, but later, a small rubber tube was connected directly with a copper reservoir of condensed oxygen, the other end of the tube terminating in a small nozzle, which was inserted in one nostril. Four hundred gallons of oxygen were thus used, but how far the force of the compressed gas was employed to dilate the lungs is not very clear; and it is doubtful whether this case should be considered as one of forced respiration. The first physician to use forced respiration in actual human poisoning, with a clear idea of its value and power, so far as my reading goes, was Dr. George E. Fell.³

It is plain that the bellows constructed by John Hunter and by Richardson are unnecessarily complex and faulty in principle. There is no need whatever of drawing the air out of the fully-

² Boston Med. and Surg. Journal, vol. xxi.

³ International Medical Congress, Washington, 1887.

filled lungs. Every physiologist knows that when the muscular system is completely paralyzed by curare or even by death, the chest walls have sufficient elasticity to force air out of the lungs, and all ordinary laboratory apparatus for artificial respiration is based upon this fact. For forced artificial respiration in man, an ordinary bellows of proper size is all that is required for the motive power.

The real difficulty—the point to be especially investigated and studied—is as to the connection between the bellows and the lungs. Hunter and Richardson simply placed a tube in one nostril, closing firmly the other nostril and the mouth of the subject.

Dr. Fell at first used a tracheal tube, the insertion of which, of course, necessitated the performance of tracheotomy. In one case, however, a simple mask covering the mouth and nostrils was a perfect success. I have had no opportunity of trying the apparatus on the living, but have made a series of experiments upon dead bodies, which have demonstrated that usually a face mask is all that is necessary for the performance of artificial respiration. Before using the mask, the tongue should be well drawn forward, and, if necessary, fixed in this position by an ordinary piece of silk suture run through it, which can be held in the hand of the operator. If in any individual case the mask fails, an intubation tube may be introduced into the larynx. I do not believe it will ever be found necessary to perform a tracheotomy.

Dr. Fell's apparatus consists of a pair of foot-bellows by which air is forced into a receiving chamber, which is connected with an apparatus for warming the air, and a valve which can be opened and shut by a movement of the finger. This valve in turn leads to the tracheal tube. When the valve is opened the air rushes through the chamber into the lungs and expands them; the finger is lifted, the valve shuts, the lungs contract; and so the respiration goes on. I have no doubt that this apparatus is efficient in practice, but it is open to the serious objection of being unnecessarily complex and costly.

A much simpler, cheaper, and probably equally efficient apparatus may consist simply of a pair of bellows of proper size, a few feet of india-rubber tubing, a face mask, and two sizes of intubation tubes. There should also be set in the tubing a double tube, with opening similar to that commonly found in the tracheal canula of the physiological laboratory, so that it is in the power of the operator to allow for the escape of any excess of air thrown by the bellows. This whole apparatus can be prepared at a very trifling expense, and it seems hardly necessary to point out its probable value in various narcotic poisonings, and other accidents, in which death is produced by a paralysis of the respiratory centres of

temporary nature. The proper use of it—at least with the face mask—could be taught to persons without special medical skill, so that it not only ought to form a part of the surgeon's outfit, but might be of great service in life-saving stations, about gas works, etc.

In conclusion, I may be allowed to state that if the results and deductions arrived at in this address are, as I believe, correct, the rules for the proper treatment of accidents during anæsthesia can be summed up in a very few words:

Avoid the use of all drugs, except strychnine, digitalis, and ammonia.

Give the tincture of digitalis hypodermically.

Draw out the tongue, and raise up the angle of the jaw, and see that the respiration is not mechanically impeded.

Invert the patient briefly and temporarily.

Use forced artificial respiration promptly, and in protracted cases employ external warmth and stimulation of the surface by the dry electric brush, etc., and, above all, remember that some at least, and probably many, of the deaths which have been set down as due to chloroform and ether have been produced by the alcohol which has been given for the relief of the patient.

DOMESTIC CORRESPONDENCE.

The New York State Examining Board.

To the Editor:—Dr. William Warren Potter—who gives his own name and address so fully that it is unnecessary for me to reciprocate the favor which he does me in that respect—apparently misapprehends both the intention of my criticism and the provisions of the Act which he defends, inasmuch as he confines the principal part of his argument to the function of the State Medical Society in "nominating to the Regents of the University one of the boards of medical examiners to be created," whereas my objection concerned the decree that this board shall be "composed exclusively of members of the same medical society."

I am aware of the distinction which Dr. Potter so clearly draws between "members" and "delegates" (although he subsequently confuses them altogether as members), and I am also aware that eligibility to membership is a very different thing from membership, as but two per annum out of the many "eligibles" could be elected until recently. Accepting Dr. Potter's statement that there are now 229 members, the Act declares that from what I must still call "a small circle" must be "exclusively" appointed the examining board to represent the regular medical profession.

Furthermore, I entertain strong doubt of the safety of the assertion that a quorum of members

and delegates can be trusted to speak for a constituency of "upwards of 4,000 physicians." They certainly did not so speak when, in 1882, without preliminary warning to the profession, fifty-two of them enacted a "new code" of ethics, cutting the society loose from the national Association, with the result of eliciting protests from forty out of the sixty county societies. They were not so speaking in 1884, when, out of 5,002 physicians, but 1,040 expressed themselves in favor of this "new code." Nor are they more entitled so to speak to-day.

THE JOURNAL'S "editorial commendation" was, I suspect, misapplied to the society in question by a *lapsus pennæ*, and intended for the New York State Medical Association, founded for the maintenance of the national code of ethics, since its "plan of organization" alone provides the system of district branches which was commended.

ALFRED L. CARROLL.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from August 30, 1890, to September 5, 1890.

First Lieut. Theodore F. DeWitt, Asst. Surgeon U. S. A., is granted leave of absence for one month, to take effect September 15, 1890. S. O. 76. Hdqrs. Dept. of Texas, San Antonio, Tex., September 1, 1890.

APPOINTMENT.

Col. Jedediah H. Baxter, Chief Medical Purveyor, to be Surgeon-General, with the rank of Brigadier-General, August 16, 1890. Vice Moore, retired from active service. A. G. O., Hdqrs. of the Army, Washington, September 1, 1890.

Official List of Changes in the Medical Corps of the U. S. Navy for the Week Ending September 6, 1890.

Surgeon J. C. Wise, detached from Torpedo Station, and to the U. S. S. "Alliance."

Surgeon Paul Fitzsimons, ordered to the Torpedo Station, Newport, R. I.

Surgeon George A. Bright, detached from the U. S. S. "Constellation," and to Naval Academy.

Asst. Surgeon F. W. Olcott, promoted to be P. A. Surgeon, U. S. Navy.

P. A. Surgeon A. R. Wentworth requests to withdraw resignation—granted.

P. A. Surgeon M. H. Crawford, detached from the U. S. S. "Monongahela" and granted two months' leave of absence.

Asst. Surgeon James F. Keeney, detached from the U. S. S. "Richmond," and granted two months' leave of absence.

Asst. Surgeon Chas. H. T. Lowndes, detached from Naval Academy, and ordered to the U. S. S. "Richmond."

Official List of Changes of Stations and Duties of Medical Officers of the U. S. Marine-Hospital Service, for the Two Weeks Ending July 5, 1890.

Surgeon W. H. H. Hutton, ordered to Washington, D. C., for special duty. July 23, 1890.

Surgeon W. H. Long, granted leave of absence for thirty days. July 2, 1890.

Surgeon H. W. Austin, when relieved at Chicago, Ill., to report in person to the Supervising Surgeon-General. July 5, 1890.

Surgeon Fairfax Irwin, to proceed to Biloxi, Miss., on special duty. July 2, 1890.

Surgeon F. W. Mead, relieved from duty at St. Louis, Mo., to assume command of the Service at Chicago, Ill. July 5, 1890.

P. A. Surgeon S. T. Armstrong, granted leave of absence until August 7, 1890. June 24, 1890.

P. A. Surgeon P. C. Kalloch, relieved from duty at San Francisco, Cal., to assume command of the Service at St. Louis, Mo. July 5, 1890.

Asst. Surgeon T. B. Perry, granted leave of absence for ten days. July 2, 1890. Upon expiration of leave, to proceed to Norfolk, Va., for temporary duty. July 5, 1890.

Asst. Surgeon J. O. Cobb, to proceed to St. Louis, Mo., for temporary duty. July 5, 1890.

Asst. Surgeon B. W. Brown, to proceed to San Francisco, Cal., for temporary duty. June 23, 1890.

RESIGNATION.

P. A. Surgeon S. T. Armstrong, resignation accepted, by direction of the President, to take effect August 7, 1890. June 24, 1890.

APPOINTMENT.

Asst. Surgeon B. W. Brown, commissioned as an Asst. Surgeon by the President. June 23, 1890.

OMITTED FROM PREVIOUS LIST.

Surgeon P. H. Bailhache, to proceed to Eureka, Cal., and Astoria, Ore., as inspector. June 5, 1890.

FISTULOUS ESCAPE OF LIGATURES
AFTER PELVIC OPERATIONS.

*Read in the Section of Obstetrics and Diseases of Women at the
Forty-first Annual Meeting of the American Medical Association,
held in Nashville, Tenn., May, 1890.*

BY MARIE B. WERNER, M.D.,
OF PHILADELPHIA.

As the science of abdominal surgery advances, we feel it is not a report of successful operations alone that establishes a reputation, but the number of absolute cures makes the successful surgeon.

Since the days of Listerism, when Lister first laid down the rules for antisepsis, which in turn gave birth to the crowning aid to surgery, thorough asepsis, the rate of mortality has diminished in a remarkable manner.

The number of abdominal sections for various lesions increased, and with the number of recoveries the dread for such surgery was diminished. Those earnestly engaged in effecting lasting cures, soon began to see that it was not always recovery from an operation which meant a cure. The patient was not safely lauded; fistulæ, secondary adhesions, painful stumps, or unfinished operations, marked the shoals upon which the hopes for an entire recovery might be wrecked; like the successful navigator, it becomes our duty to study these shoals in detail, and, if possible, place the danger signal conspicuously in our minds, in order to be able to avoid a second exposure to similar dangers.

The most successful operations reported, prove that aseptic, rapid work, with as few instruments and sponges as possible; a clean, good stump; light ligatures, applied closely to the uterus, cut ends, short, thorough irrigation avoid many of these complications. If much oozing from torn adhesions, or if pus is present, the drainage tube becomes a valuable aid, provided it is properly cared for (cleaned at intervals of twenty or thirty minutes with syringe, and removed as soon as the effusion becomes serous and less than a drachm).

Last, but not least, comes the importance of including the muscle and fascia in closing the abdomen. The fact that various gynecological societies have taken up the discussion of the be-

havior of ligatures after the removal of diseased uterine appendages induces me to place on record two cases, the first my own, the second, one who subsequently placed herself under my care three months after operation.

Knowing full well there must always be a cause for unexpected happenings, I was anxious to satisfy myself in these cases, and think I succeeded.

Case 1.—Operation in March, 1887. Right ovarian cyst; cyst walls friable, adhesions, ligature Chinese twisted silk, medium size, Staffordshire knot, drainage five days; recovery good. With the exception of an occasional pain in the region of the stump, patient was well and attended to her household duties. Fifteen months later, however, the patient brought the ligature, claiming to have discharged it from the urethra after much tenesmus at micturition; giving a history of much pain previous on right side over the bladder, and frequent desire to urinate. Examination showed slight tenderness of stump and a tendinous cord leading to bladder. After a few weeks all tenderness gone, patient well.

Case 2.—Operation in May, 1887, by Dr. R. S. Hunt. I was present at the operation; cyst of broad ligament on left side. Ligature braided silk, No. 9, Staffordshire knot, no drainage. Aside from several stitch abscesses, recovery good, patient up in four weeks. During latter part of August of same year, patient experienced great pain in scar, shooting down toward the right side. A small abscess formed in the scar, was lanced, washed, probed and found to extend down toward the stump. In about two weeks the ligature was expelled and in a short time all had healed.

Case 1 presents two factors, each of which may account for the discharge of the ligature: First, the friable condition of the cyst wall, part of which helped to make stump, the want of vitality of surrounding tissues, failing to encapsulate or absorb the ligature; second, the length of time the drainage tube was left *in situ*, owing to my inexperience regarding their use, this being my first drainage case. I left it in long enough to become an irritant and had some difficulty in healing the track (three weeks).

Case 2 was undoubtedly due to the size of the ligature, the tumor being small and the pedicle short in consequence, allowed the ligature to slip

over the button the moment shrinkage of the stump took place.

In connection with this subject, I have endeavored to collect as many cases as possible, with a brief history of each. It is only by concentrating our forces that we are able to win the battle, hence the study of cause and effect becomes most necessary.

Dr. Thomas Keith, in his little book on "Contributions to the Surgical Treatment of Tumors of the Abdomen," relates his experience with catgut ligatures, (on page 17) he says: "Twice I have had hæmorrhage happen in ovariectomy, and on both occasions catgut ligatures were used, in one some thick catgut ligatures had been used to a very thick omentum. Several of the knots came away through the wound, and after weeks of horrible suffering from cystitis, a thick knot of catgut, with the loop but little absorbed, was passed by the urethra."

Dr. Matthew D. Mann tells us in his report of 160 abdominal sections (*Buffalo Medical and Surgical Journal*, April, 1890), that the causes of fistulæ are either an abscess in the pelvis from some foreign substance, or the use of the drainage tube, and cites an experience in which a fistula resisted all attempts at healing for four years; he feels confident that it is due to a silk ligature. This induced him to try catgut, which proved more satisfactory—indeed, he feels so secure about its harmlessness, that he was comparatively at ease when he found a fistula and discharge of pus follow the use of the drainage tube, feeling sure there was no infected silk at the bottom of the sinus. Later, two knots of catgut came out of this sinus, after which it readily closed.

In a communication from Dr. H. A. Kelly he writes the following: "I have had a number of cases in which the ligatures have all been cast off through the abdominal walls, except one case of hydrosalpinx and ovarian tumor, in which the patient afterward had cellulitis. This suppurated and was drained through the vagina and the ligature discharged. It has frequently happened in cases of pyosalpinx, where long continued drainage was necessary. I have observed it very constantly in cases in which the pyosalpinx has already ruptured, or been on the point of rupturing into the bowel, these cases always requiring prolonged drainage.

"Ligatures of twisted silk, figure of eight doubled, were used. These have been cast off from two or three months to a year after operation. I never use heavy strands of gut, as there is considerable doubt as to our ability to disinfect them satisfactorily. In all cases there has been drainage for four or five days. I clean the tube at intervals not longer than twelve hours. No sort of antiseptic injections are ever used in any of my abdominal sections."

Dr. Kelly's remark regarding the use of heavy strands of catgut seems of importance. We are never sure of healthy membrane, hence, in spite of antiseptic precautions we may often use septic gut. Dr. Matthew D. Mann's statement that gut shrinks one-tenth its length when wet with water, requires some consideration in tying, since too much pressure may cause some necrosis of stump.

The causes of fistulæ can be summarized as follows: Adhesion to the bowel may, in being loosened, cause thinning and subsequent sloughing. Heavy ligatures on small stump. Ends of ligature left too long. Ligature not thoroughly aseptic. Part of stump consisting of unhealthy tissue. Prolonged use of the drainage tube may set up localized inflammation, resulting in abscess of stump, or surrounding tissue.

Drainage, however, seems too valuable an aid to discard lightly, for we may meet with just as serious difficulties in closing up the abdomen where there is danger of oozing, which may accumulate and decompose, giving rise to troublesome secondary symptoms.

Among the secondary adhesions most commonly found, may be mentioned omental and intestinal with the stump or abdominal incision as a focus. Such a case was reported by E. Sinclair Stevenson before the British Gynecological Society, April 24, 1889, in which intestinal obstruction called for a second operation. The omentum was found twisted like a loose rope, dipping into the abdominal cavity, glued to coils of intestine, its extremity firmly attached to a coil deeply seated. The importance of careful inspection regarding torn surfaces of omentum or peritoneum, and obviating adhesions by stitch or removal, spreading out the omentum toward the left just before tying the abdominal sutures, becomes at once manifest.

Omentum caught in the holes of the drainage tube, is another unpleasant complication, but can be avoided by using the tubes of small calibre with small perforations, as advocated by Dr. Joseph Price.

Intestinal adhesions to stumps or open surfaces left from torn adhesions, are best overcome by free purgation and the avoidance of opium.

Painful stumps may be due to an uncovered ligature, to unhealthy tissue left in stump, or, as Dr. B. C. Hirsch has shown us, by too much ligature, added to an unfinished operation. This brings us to the last point of importance: Under this head I have had an unpleasant experience with two cases some years ago; and have profited by it. One case in particular, in which a pus tube was so tightly adherent to the uterus and pelvic walls that my courage failed me and, contenting myself with one side removal, I closed the abdomen, only to see my patient three months later with a sharp attack of septic peritonitis, and

TABLE OF CASES.

OPERATOR.	OPERATION.	LIGATURE.	DRAINAGE.	REMARKS.	HISTORY OF FISTULÆ.
Dr. Ashton. Annals of Gynecology, April, 1890.	January, 1888, abscess of right ovary and tube.		Yes.	Track of drainage tube did not close. In finding one ligature, after flushing a fistula resulted, necessitating a third operation in Feb., 1889, with complete closure; the following August, however, the fistula reopened and discharged a ligature.	October, 1888, a second section resulted in finding one ligature, after flushing a fistula resulted, necessitating a third operation in Feb., 1889, with complete closure; the following August, however, the fistula reopened and discharged a ligature.
Dr. B. F. Baer. (Personal com.)	Ovariectomy.	Chinese twisted silk, figure of 8.	Two days, tube cleansed with syringe every half hour.	Intraligamentary adhesions to descending colon and small intestine.	Facial fistula caused by sloughing of bowel and drainage tube; ligature came away two weeks after operation.
Dr. J. M. Baldy. (Personal com.)	Extra-uterine pregnancy. Local peritonitis.	Twisted silk, figure of 8.	8 to 12 days, tube cleansed with syringe every hour.	General adhesions; beginning gangrene of sac.	Fistula at site of drainage tube; ligature came away in 13 weeks; healed spontaneously.
Dr. H. Beates, Jr. (Personal com.) Dr. B. has had three cases from other operators, in whom "fishing out the ligature" resulted in a cure. Ligatured twisted silk No. 4 in one, smaller in the other two.	Salpingitis.	Twisted silk No. 3. Staffordshire knot.	1 to 2 days, injections of bichloride 1-10000, cotton capillary dressing.	General adhesions.	Fistula at site of drainage tube; ligature came away in 12 weeks; healed.
	Pyosalpinx.	Same as above.	Same as above.	General adhesions; patient in bed five weeks.	Fistula; ligature came away in 11 weeks; healed.
	Pyosalpinx.	Same as above.	Same as above.	General adhesions; patient in bed five weeks.	Ligature came away in 14 months.
	Ovariectomy. Multilocular cysts.	Same as above.	Same as above.	No complications.	Ligature expelled through abdominal fistula in 10 weeks.
Dr. Wm. Goodell reports to the Philadelphia Obstetrical Society, March 7, 1889; the following three cases.	Removal of intraligamentary cyst.			Compelled to reopen wound for bleeding, 5 days after a fistula resulted.	1½ years since operation; fistula still remains; the only annoyance to the patient is an escape of gas.
	Pelvic abscess.		Prolonged.	A counter-opening may yet be necessary per vaginam.	Fistula caused by the prolonged use of drainage tube.
	Recurrent intraligamentary cyst lying in a large abscess cavity.		Yes.	Fistula resulted from a previous operation in which a clamp had been used many years ago.	Fistula still present at time of report; was then trying to heal with iodine applications along the entire tract.
Dr. B. C. Hirst. (Personal com.) Two cases.	Pyosalpinx.	Twisted silk, figure of 8.	No.	Patient was easily managed, out of bed 3 weeks. Excessive hemorrhage necessitated passing two foreign ligatures at base of tube, broad ligament. The ligatures were not surrounded by lymph accessible to sight and touch; pain which had followed previous operation disappeared after removal.	Fistula of a year's standing; after discharge of ligature fistula healed.
Dr. Joseph B. Deaver. (Personal com.) Two cases.	Removal of a former stump, one-fourth ovary and four ligatures.			Many adhesions.	Fistula at site of tube track; ligature expelled 4 weeks after operation.
	Double pyosalpinx.	Twisted silk, figure of 8.	Yes.	Patient had been tapped a number of times, making dense adhesions.	Fistula in tube track; ligature expelled 6 weeks after operation.
Dr. Hannah T. Croasdale. (Personal com.)	Ovariectomy for large multilocular purulent cyst.	Cable twist No. 3, Staffordshire knot.	Eight hours.	Extensive adhesions prevented removal of appendages of other side.	Patient in bed from Jan. 2 to Feb. 9; ligature discharged Jan. 31; rapid improvement; wound healed Feb. 4.
	Removal of a tube and ovary. Local peritonitis.				
Dr. Joseph Hoffman. One case from his own practice, the other under observation. (Pers'l com.)	Pyosalpinx.	Chinese silk twist No. 3, figure of 8.	Tube cleansed with syringe at short intervals.	General intestinal adhesions. Local peritonitis.	Ligature discharged in about 3 months; patient remained in bed 6 weeks.
Dr. H. A. Kelley. Reported in the British Gynecol. Soc. by T. B. Jessett, Oct. 23, 1889.	Pyosalpinx.	Same as above.	Yes.	General intestinal adhesions; general peritonitis; pus.	Ligature discharged in about 3 months; patient in bed 2 months.
	Left ovarian dermoid cyst.	Chinese silk.		Dr. Kelly reports that "in her convalescence she had a large hæmatocoele, ante-uterine, which is slowly undergoing contraction."	Mr. T. B. Jessett finds, 5 mos. after operation, an abscess in the anterior wall of vagina; opens, drains, and finds a Chinese silk double ligature; negative history regarding rigors or high temp.
Dr. D. Longaker. (Personal com.)	Hydrosalpinx, puerperal. Local peritonitis.	Plaited silk, medium size, figure of 8.	36 hours.	Extensive adhesions; sinus following drainage track.	After a few months one ligature, at end of sixth month the second came away; fistula failed to heal for one year; was finally curetted and injected with nitrate of silver; healed.

OPERATOR.	OPERATION.	LIGATURE.	DRAINAGE.	REMARKS.	HISTORY OF FISTULA.
Dr. Charles D. Penrose. (Personal com.)	Case 1. Double ovariectomy.	Twisted silk No. 3, figure of 8.	No.	Both ovaries cancerous, one presenting a large tumor of about 20 lbs., the other the size of a large orange; general condition poor.	Dr. P. has had two cases in which a sinus lasted several months, one due to syphilis, the other to tuberculosis; never has had a case of discharged ligatures in abdominal sections.
Dr. W. H. Parrish. (Personal com.)	Case 2. Removal of appendages on both sides.	Black silk, fig. of 8 of one side, shoemaker's knot the other.	Yes.	Syphilitic colored woman, confirmed drunkard, unruled; walked across ward second day, glass in situ; fistulous opening in lower angle of wound.	Fistula; two months later shoemaker's ligature discharged and fistula closed spontaneously.
Dr. Charles M. Wilson. (Personal com.)	(Per. Ruptured ectopic gestation of six months).	Rather large Chinese ligature, fig. of 8.	Staffordshire knot.	Nine mos. after operation removed one ligature with hooked end of small probe; subsequently a counter-opening was made per vaginam, by another gentleman; no avail; later, laparotomy by a third resulted in death.
Dr. H. M. Weeks. (Personal com.)	Extra-uterine pregnancy, Nov., 1888.	Twisted silk No. 3, figure of 8.	Prolonged; tube cleansed by irrigating with the long syringe; distilled water.	Six mos. later one of the ligatures ulcerated its way out through the abdominal cicatrix.
Dr. H. T. Hanks. Reports N. Y. Obstetrical Society, Jan. 7, 1890.	Ruptured extra-uterine pregnancy.	Yes. Irrigation twice daily.	The R. broad ligament through which the large hysterocele had ruptured was very friable, and the suture had a strong tendency to cut through.	Ligatures came away 5 months after operation. Ten days after operation two ligatures were removed from the sinus; patient made a good recovery.

die five months after; her abdomen literally filled with multiple abscesses. The second unfinished case was of a similar nature, though not so far advanced; the adhesions again intimidated me; patient recovered promptly, in spite of hot July weather, was temporarily relieved. The following winter I was called in to treat a localized peritonitis on the side where I had left the pus tube. She recovered, but has since passed out of my hands. I have learned that to open an abdomen and leave pus there is productive of as much censure as to know of its presence and not attempt its removal; and have since endeavored to remove the cause of sepsis even though the ideal operation was out of the question, and the results have been more satisfactory.

This leads me to an important question which has agitated my mind of late, and which is best illustrated by a brief account of two cases from my practice, both unilateral hydrosalpinx. In both I removed the affected tube and ovary—one in March, 1887, the other in February, 1888; the remaining appendages apparently normal. Both recovered promptly and improved in health. Former symptoms returned to the other side—Case 1 in eighteen months; Case 2 in six months.

Case 1.—Reported three months ago. Found painful mass on right side; when told she made preparations at once for a second operation. Operation March, 1890. Some omental adhesions to incision, tube and ovary adherent, cystic, left stump was healthy. Patient recovered promptly, now seven weeks since operation; no pelvic pains, intestinal functions normal.

Case 2.—Operation May 9, 1890. Omental adhesions to abdominal wall. Intestinal adhesions to the stump, uterus and abdominal wall; ovary and tube adherent; decided constrictions of tube near ostium internum. Removed tube and cystic ovary; separated all adhesions except those to the stump, fearing more grave complications. May 18, patient doing well.

This leads to the question: Is it the proper course, to remove an apparently normal ovary and tube when there is hydrosalpinx on one side, or shall we let the patient run the risk of a possible second operation?

Is there the same danger as in pyosalpinx? Should this last question receive an affirmative answer, it certainly behooves us to explain such dangers fully to the patient and gain her consent to remove, if necessary, even an apparently healthy-looking ovary and tube; so she may not be exposed to the dangers of a second operation.

IN China eight varieties of leprosy are recognized, and the disease is considered contagious, infectious and hereditary, but is said to disappear in four generations. There are leper villages, to which all suffering from the disease are sent.

FACIAL AND THORACIC DEFORMITIES INCIDENT TO OBSTRUCTION BY ADENOID HYPERTROPHY IN THE NASO-PHARYNX.

Read by Title in the Section of Practice of Medicine, Materia Medica and Physiology, at the Forty-first Annual Meeting of the American Medical Association, May, 1890.

BY W. E. CASSELBERRY, M.D.,

PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS, AND OF LARYNGOLOGY AND RHINOLOGY, IN THE CHICAGO MEDICAL COLLEGE.

The disease which occasions the particular form of obstruction, prone to result in the series of deformities about to be described, is variously known as "adenoid hypertrophy in the naso-pharynx," "adenoid vegetations" and "hyper-trophic naso-pharyngitis;" and in multiplicity of cases, gravity of consequences, facility of operative treatment, and the brilliancy of results, it may be said to outrank any other affection of the upper respiratory tract.

At the vault of the pharynx a number of muco-lymphoid follicles are grouped together forming a compound gland, analogous to the tonsils and known as the third tonsil, the pharyngeal tonsil or the tonsil of Luschka. In the normal state this is not of sufficient size to deserve such appellation, but when hypertrophied, as it frequently is, it bears some resemblance to the faucial tonsil in a state of enlargement.

In form, contour, and consistency the growth presents many gradations from the soft stalactitic "adenoid vegetations" up to the dense and more fibrous individuate variety, in which the mass is made up, in large part, of but a single neoplasm, of firmer consistence, smooth surface, and more or less irregular contour, according to size and degree of impaction. Fig. 1, accurately drawn

Figure 1.

from nature, is a typical representation of an average case in which the naso-pharynx is seen to be occupied by a fimbriated adenoid mass, which occludes, in large part, the posterior nasal choanæ, and so presses downward the upper lip of the tuber of the left Eustachian orifice as to practically close the channel to the middle ear.

Etiology.—The disease is frequent among children, not uncommon with adolescents, and not at all rare during early adult life. Children of inherited syphilitic or tuberculous diathesis, and

those perhaps otherwise the victims of scrofulosis, are predisposed to it. It is unnecessary to discuss the relationship between these diatheses. Whether as a result of inheritance of one or more of them, or of acquisition through bad hygienic influences, we recognize in the state called scrofulosis a debilitated constitutional condition, one of the characteristics of which is a pronounced tendency toward hyperplasia of the lymphatic and lymphoid structures. The reason therefore one can not state any more than one can formulate a full explanation of the normal cell proliferation. It concerns that of which we know naught—the ultimate essence of life itself. Climatic inequalities furnish adequate exciting causes. Repeated acute congestion from "cold" acting upon a structure already the subject of diathetic predisposition to hyperplasia, serves to establish a chronic hypertrophy of the group of muco-lymphoid glands in the naso-pharynx. This mass is then constantly swathed in a viscid muco-purulent, readily decomposable secretion, the product of its own elaboration, which, by exciting and maintaining irritation, further conduces to the development of the growth.

Symptoms.—The space of the naso-pharynx is, by nature's law, designed to be free, and to serve as a common area of air communication between the five openings which enter it.

The Eustachian tubes open into it, one on each lateral wall posterior to the nasal choanæ, and upon perfect patency of these openings, together with free nasal respiration, the power of hearing is dependent, for ventilation with normal air pressure in the cavity of the middle ear, is essential to correct auditory sense. Deafness, therefore, is frequently a deplorable symptom, and one which is liable to become permanent unless speedy relief be afforded.

Into this space open also the posterior nares, the natural respiratory passage being *via* the nose and naso-pharynx. Adenoid hypertrophy therefore serves as a plug to the posterior nasal openings, and obstructs nasal respiration completely or in part according to the degree of glandular enlargement. From this point we find it a matter of exceeding interest to trace the origin and development of each successive step in the series of deformities consequent upon this condition. The plugging up of the posterior nares necessitates oral breathing, and the constantly open mouth interferes with the normal adaptation of certain facial muscles, which in turn effects radical changes in the contour of the soft and developing bones of the face, the whole resulting in a physiognomy characterized by a vacant, stupid, almost idiotic expression of countenance, which can be better illustrated by photographs from nature than described. (Fig. 2.)

The hanging lower jaw causes the face to appear elongated. The nose is pinched or its alæ

distended, while the angles of the mouth and eyes have a drawn appearance.

Figure 2.

Moreover, as pointed out by Henri Chatellier,¹ of Paris, cited by Hooper,² of Boston, the air cavities in communication with the nose, as the frontal, maxillary, sphenoidal, and ethmoidal sinuses, which are essential to the proper expansion of their respective bones, cease to develop when the circulation of air through the nose is interfered with, thus altering nature's intent regarding the dimensions of the face and head, and still further deforming the physiognomy. Dr. Hooper has also described and illustrated the next link in the chain of deformities—the high-arched hard palate and V-shaped indenture. The naturally rounded arch of the roof of the mouth is formed, in large part, by the palate process of the superior maxillary bone, which also constitutes a corresponding portion of the floor of the nose. Augmentation of atmospheric pressure upon the buccal surface of the palate process and the impact of air currents to and fro during mouth-breathing, together with diminution of intra-nasal air pressure incident to nasal obstruction, gradually force upward the centre of the hard palate, and change thus the obtusely rounded Romanesque arch into one of Gothic shape—the pointed or high-arched palate invariably existing in association with long continued and excessive adenoid development during childhood. (Fig. 3.)

Elevation of the palatal arch lessens the transverse diameter of the jaw and causes it to grow pointed in front—the so-called V-shaped indenture—and with the resulting contraction of the alveolar process, the teeth, especially those near the point, are crowded into various grotesque ag-

gregations, or are rotated on their axes—a condition depicted in Fig. 5, drawn from a typical case, in which the two central incisors overlap, and the two lateral incisors undergo a quarter rotation and stand at right angles to the alveolar process.

Dentists have long recognized what they call the "habit" of mouth-breathing as a prolific source of irregular indentures, and S. C. G. Watkins, in a recent number of the *Ohio Journal of Dental Science*, says: "I know a child which at birth and up to the third year had a perfectly formed and normal arch; but it acquired the habit of breathing through the mouth, and the arch is becoming narrow—so much so that you cannot do more than place your finger in the centre of the arch. Now, at the age of 9 years, there has been a radical change in the shape of the mouth, and from no other reason than oral breathing."

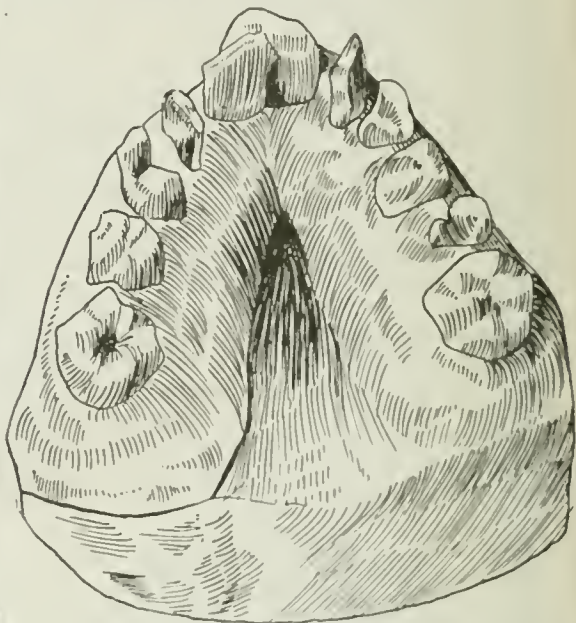

Figure 3.

We would advance a step and assert that mouth-breathing is but rarely a mere "habit." It conduces to so much discomfort that even the babe would feel inclined to close this aperture could he secure the requisite amount of air through the nose and naso-pharynx. Aside from greatly debilitated states, it is occlusion to some degree of these passages which necessitates the habit.

Next, elevation of the palatal arch must produce contortion within the nose. Deflections of the septum are rarely congenital; indeed, the only part of the septum which is ossified at this period is the vomer, the whole ethmoid bone, including the vertical plate, being in a soft cartilag-

It is proper to state that other dental authorities deny this influence of oral breathing in the causation of deformed indenture, and attribute the latter solely to a perverted formation of the permanent set of teeth. The association, however, between adenoid vegetations and the high-arched palate is so constant that an etiological relationship must exist.

¹ Des Tumeurs Adenoides du Pharynx, Paris, 1886.

² "The Mechanical Effects of Adenoid Vegetations in Children." Reprint from Medical and Surgical Report of the City Hospital of Boston, Fourth Series 1889.

inous state. Traumatism, as shown by Robertson in the investigation of 217 cases, cited by Delavan,⁴ cannot fairly be made to account for much over half the number. Now, the septum, composed of the vomer, the perpendicular plate of the ethmoid bone and its cartilaginous portion, is unequal in power of resisting compression to the bones by which it is incased. Designed by nature to fill vertically the natural space between the roof of the nose and its floor, the abbreviation of this space by elevation of the palatal arch through the instrumentality of naso-pharyngeal adenoid hypertrophy cannot result otherwise than in forcing the septum to provide for itself by bending and curving laterally in various directions—a condition which is diagrammatically represented in Fig. 4, and which explains the etiology of the remaining moiety of cases of deviation of the septum narium. Furthermore, guided by the contorted septum, even the external nose may be twisted to one side—a deformity common enough in its milder aspects, and not unfrequently seen in aggravated forms. Within the nares also the septal deflection acts as an additional impediment to nasal respiration and drainage, and becomes a potent factor in the evolution of hypertrophic rhinitis, or that form of nasal catarrh characterized by enlargement of the turbinated bodies. (Fig. 5.)

Figure 4.

Finally, not only, as before said, do these unfortunates *look* stupid, but they really *are* stupid and exhibit abundant evidence of mental hebetude, with inability to fix the attention to learn, to memorize, or to reason, the whole evidencing an impairment of cerebral function which Dr. Guye,⁵ of Amsterdam, has recently described under the name of *aprosxia nasales*. Indeed, we hold it not illogical to believe that in extreme cases of long duration, associated perhaps with deafness, such alteration of cerebral function might ensue as to result in absolute idiocy.

Three varieties of thoracic deformity are observed to accompany obstructive naso-pharyngeal adenoid hypertrophy, the association of one or

other form, in advanced cases, being so constant that a direct causal relationship, although difficult of absolute demonstration, can reasonably be assumed.

For the induction, however, of two of these forms, the "pigeon-breast" deformity and the "barrel-shaped chest," the intermediation of still another symptom—bronchitis, seems essential.

The influence of hypertrophic rhinitis and obstructive deflection of the septum narium in the causation of certain cases of bronchitis is now a matter of common observation. Plethora of the blood-vessels of the nasal mucous membrane tends to develop a like plethora in the bronchial mucous membrane, and anæmia induced in the turbinated tissues tends to effect an anæmic state of the bronchial tubes. The physiological relationship between the two regions—the nasal erectile tissues being designed to warm and moisten the inspired air—demands, through the vaso-motor system, an intimate correspondence between their blood supplies. As might therefore be expected, a pathological correspondence also obtains, and without entering into a discussion of the hypothetical details of nervous mechanisms, we simply state the oft-observed fact, that turgescence and vaso-motor paresis of the nasal erectile tissues may occasion vaso-dilation, congestion, and inflammation of the bronchial mucous membrane.

Figure 5.

Now, we have just seen how adenoid vegetations, persisting through early childhood, can occasion obstructive deflection of the septum with hypertrophic rhinitis, and, in many instances, chronic bronchitis is thereupon superinduced.

Furthermore, adenoid hypertrophy is, in itself, an etiological factor in the production of chronic bronchitis. Especially in neurasthenic individuals, it is exquisitely sensitive to reflex producing impressions, and its irritation may result, reflexly, in spasm of the glottis, cough, asthma, and parietic vaso-motor bronchitis.

Miss A., for instance, was affected by large adenoid vegetations, and suffered also with profuse bronchitis and from alarming, rapidly recurrent attacks of spasm of the glottis. On two occasions we were able to excite the glottic spasm

⁴ Reference Handbook of the Medical Sciences, Vol. v, p. 213.

⁵ "On Aprosexia," by Dr. Guye, Professor of Otology in the University of Amsterdam. Journal of Laryngology and Rhinology, December, 1889.

in our office by simply titillating the adenoid mass by a probe. They culminated with extreme suddenness and endured for a couple of minutes, the second paroxysm being so severe as to suggest hasty preparations for tracheotomy and to cause us to desist from further experimentation in this direction. Surgical removal of the adenoid growth, somewhat incomplete for want of time, resulted in a disappearance of the bronchitic symptoms, and in such amelioration of the glottic spasms that they ceased to be a serious inconvenience.

Again, for example, in the case of a young boy who suffered from chronic bronchitis with frequent asthmatic paroxysms, the removal of an associated adenoid mass from the naso-pharynx resulted in an immediate disappearance of all symptoms for a period of five months, but with subsequent rarer and milder recurrences. Indeed, in all cases of chronic bronchitis with children, adenoid hypertrophy should be sought for, as the upper and lower respiratory tracts constitute one continuous surface, having intimate nervous and vaso-motor connections, and the removal of adenoid vegetations, if present, will eliminate at least one, and possibly the chief, source of irritation.

With the continuance of bronchitis during the early developing years, the irregular convulsive action of the respiratory muscles incident to cough and dyspnea is productive of the thoracic deformity known as "pigeon-breast," in which the sternum protrudes, the antero-posterior diameter being lengthened at the expense of the transverse diameter. The same symptom is influential also in the production of the emphysematous or "barrel-shaped" chest, as the coughing spells and powerful expiratory efforts, by forcing the air to the superior part of the lungs, serve to distend the antero-posterior diameter of the chest at this point.

The culmination, under like conditions, of one or other of these two deformities, is seemingly determined, with some by age—young subjects being little prone to emphysema and the deformity tending toward "pigeon-breast;" and with others, by the existence primarily of any degenerative change in the alveolar walls which might predispose to emphysema and in consequence to the "barrel-shaped" deformity.

The third variety of thoracic deformity—the "flat chest," is due directly to obstruction by the adenoid growth itself, and is an indrawing of the chest walls, especially a shortening of the antero-posterior diameter which results from an insufficient air supply to the lungs. The impairment of the normal respiratory relations by exclusively oral breathing, is such that complete expansion of the chest does not occur and a sufficient amount of air cannot be obtained, a fact which any one can test for himself by comparing the ease of deep inspiration through the nose with the laboriousness and incompleteness of similar efforts continued through the mouth alone.

The chest in these cases becomes flat and thin (Fig. 6, after Hooper), has a sunken appearance over the lower part of the sternum, perhaps a deep concavity at the ensiform cartilage with depressed intercostal spaces—a permanent, mild degree of the retraction observed during the dyspnea of membranous croup, and due, as Löwenberg,⁶ cited by Hooper,⁷ has explained, to excess of atmospheric pressure on the outside of the chest, together with the labored action of the diaphragm and intercostal muscles in efforts at inspiration.

Figure 6. After Hooper.

Such deformities must result in pulmonary asthenia, and we might proceed to trace therefrom predispositions to pneumonia and tuberculous infection, but we have said enough—sufficient to reiterate that herein lurks one of the most formidable enemies of early life, and to demonstrate that if one would save to the adult his face, his figure, yea, even his reason, one must give to him in childhood a clear respiratory passage.

70 Monroe St.

A SIMPLE AND RELIABLE ASTIGMOMETER.

Read in the Section of Ophthalmology at the Forty-first Annual Meeting of the American Medical Association, held at Nashville, Tenn., May, 1890.

BY F. C. HOTZ, M.D.,
OF CHICAGO.

PROFESSOR OF OPHTHALMOLOGY CHICAGO POLICLINIC, AND
ATTENDING SURGEON TO ILLINOIS CHARITABLE
EYE AND EAR INFIRMARY.

It is an old saying that "haste makes waste;" and every medical man will do well to have these three words inscribed in golden letters over his desk; for three-fourths of all the mistakes made in medical practice can be traced to hasty examination. But while we should spare no time in

⁶ Tumeurs Adenoides du Pharynx nasal, Paris, 1879.

⁷ The Mechanical Effects of Adenoid Vegetations in Children. Reprint from the Medical and Surgical Reports of the City Hospital of Boston, 1883.

order to obtain a correct diagnosis, we do not like, on the other hand, to waste any time unnecessarily in the busy hours of the consulting room. While our examination should never be hurried, it often can be quick or slow, short or long, the time consumed being dependent a great deal on the method we employ; the one method may give us the desired information in five minutes, which we cannot get by another method in less than fifteen minutes.

In this respect the examination for astigmatism furnishes us a good illustration, and if we make quickness and precision the essential conditions for the best practical test for astigmatism, the methods at our disposal show a great difference in their practical utility.

When we examine for astigmatism we wish to find out first, of course, whether the eye is astigmatic; and if it is, we want to know the exact position of the two principal meridians. If this point is established with precision it is an easy task to ascertain the refraction of either meridian, and thereby the degree of astigmatism, and to select the proper glasses.

Now, we can diagnose astigmatism by the direct ophthalmoscopic examination, but you will admit this is not a quick and easy way. Much quicker and easier is the shadow test; but neither method can determine with precision the direction of the principal meridians.

We may often succeed in detecting the astigmatism very quickly by rotating a cylinder glass before the eye, but just as often our patient's answers are so vague and misleading that a great deal of time is consumed before we are reasonably certain whether astigmatism exists, and where the meridians are located.

And as to the so-called astigmatic fan, or clock, and all its modifications, this test demands a degree of accurate observation the fewest of our patients possess. Especially with children (and they constitute no small proportion of our cases), this test is very tedious and unsatisfactory; but even grown persons seldom are quick in observing any marked difference in the lines unless their astigmatism is of a high degree. I have often tested patients upon this point after their astigmatism had been established by other means; and the most of them could not see any difference in the lines until I pointed out those lines which, according to their astigmatism, had to be the most distinct, and told them to compare them with those lines which had to be the least distinct; then, and not until then, they began to appreciate the difference. But in the examination, of course, it would never do to lead the patient in this way, because if you ask them whether they do not see certain lines more distinctly than others, nine out of ten will imagine to observe a difference which they do not see, and make you diagnose an astigmatism which does not exist.

Dr. Culbertson's prisoptometer is a very ingenious instrument to detect anomalous refraction; but it, too, puts a greater demand upon the observing power than a great many patients can meet. I, at least, have found that it is impossible for many patients to appreciate slight variations in the contact of the two discs so that they could tell with precision whether the contact remains exactly the same during the rotation, or at which angle of rotation it is disturbed the least, and at which the most.

It would be tiresome to review all the methods and costly instruments which have been devised for the examination of astigmatism; they are no better than those I have mentioned. These, I believe, are the most popular methods, and I have shown that none of them fulfils our conditions of quickness and precision in establishing the presence of astigmatism and the direction of the principal meridians; especially for the lower grades of astigmatism they are not very reliable.

Now, it has always seemed so strange to me that we should waste our time with these elaborate methods, when we have a much simpler and more sensitive test, which will tell us quickly whether an eye is astigmatic, and at the same time also give us the correct position of the faulty meridians. This test is the retinal image of a distant point of light.

Since the rays coming from such a point which pass through the meridian of greatest refraction are focussed sooner than the rays which pass through the meridian of least refraction, the image upon the retina can never be a sharply defined luminous point. If the retina is at or near the anterior focal line, the image will be elongated in the direction of the meridian of least refraction, and if the retina is at or near the posterior focal line, the image is drawn out in the direction corresponding with the meridian of greatest refraction. Whenever, therefore, a patient sees a distant point of light elongated we know he is astigmatic, and the line of elongation gives us at once the direction of the one, and indirectly also that of the other, meridian, because they are always at a right angle to each other. And as it does not require a keen power of observation to tell the approximate shape of a small hole, this test is as quick as it is sensitive and precise; for it is very easy even for a child to determine whether the light looks round (like a pea or marble), or oblong (like an egg, an almond, or half moon), or whether it has no definite form (like a star).

Theoretically this distant point of light should appear elongated to every astigmatic eye, with the exception of such cases of mixed astigmatism where the myopia of the one meridian is about of the same degree as the hypermetropia of the other principal meridian; for, under these circumstances, the retina being about in the centre of

the focal interval, receives a round, though indistinct, dispersion image.

In persons over 40 or 45 years of age you will find the results of the test agree with the theory. But among younger persons with active accommodation you will find a great many who, though astigmatic, see the hole perfectly round, because their astigmatism is corrected by the unequal contraction of the ciliary muscle. I have found, however, that if such patients look steadily at the light hole they notice its form is constantly changing from round to oval, and back to round again. This observation shows how sensitive this test is, and at the same time furnishes us an interesting evidence of the unequal contraction of the ciliary muscle.

(+ or — as the case may be) which corrects the ametropia of one meridian and thus reduces the compound to simple astigmatism will produce a better defined image and reveal at once the elongation of the light point. And in the same way we can reduce mixed astigmatism to the simple kind, and obtain the distinct oval image by our test. Sometimes a patient will see the light hole double instead of oblong; and in this case, one hole above the other, or to the side of the other, indicates the meridian just as well as the vertical or horizontal elongation does.

I began using this test in 1872, when I had a little instrument made for this purpose, which, in want of a better name, I baptized "astigmometer," although I employ it more for *detecting* than for

But, fortunately, we have in the mydriatics the effectual means of eliminating the disturbing influence of the ciliary muscle; and I never consider the examination for astigmatism in a young patient completed unless the accommodation has been suspended. When this is done, the light hole will always appear elongated in simple astigmatism, and in all cases of compound astigmatism, provided the refraction of one of the meridians does not depart from emmetropia by more than one-half or one dioptre. With higher degrees of ametropia in both meridians the retinal image is so blurred that the patient cannot make out any definite shape; but the proper spherical glass

measuring astigmatism; but you can measure its degree with it just as well.

*Description of the Astigmometer.*¹—The instrument which I take pleasure in showing you now consists of a blackened metal screen 20 cm. (8 inches) square; in its centre it has a round aperture (B); and the semicircle of a protractor is fastened to it so that the 90 degree mark is exactly perpendicular over the round hole and the 180 degree mark exactly on a horizontal line with it. Between the protractor and the central hole a semicircular slot 10 millimeters wide is cut into the screen, but is covered in front by a round

¹ For sale by Sharp & Smith, 73 Randolph street, Chicago.

metal disc which can be rotated round the central opening, and which has near its periphery a round hole (A), so arranged that it travels exactly along the slot when the disc is rotated. Just over this second hole (A) the edge of the disc is drawn out to an arrow-like point which reaches the concave margin of the protractor. This point and the centres of the two holes are exactly in a straight line, and therefore the angular degree of the protractor to which the arrow points, will always show the radius in which the movable hole (A) is situated. Both holes are exactly the same size; on the front side they have a diameter of 4 millimeters, but on the other side they are much larger. This was done to make sure that no shadows could interfere with our observations; for the metal around the holes (especially around the central one) is so thick that if they had the same size on the posterior as on the anterior face the posterior edge might cast a shadow when the hole is illuminated from behind, and this shadow might make the hole appear to the spectator in a different than its true form, though he be not astigmatic. Finally, in order to avoid any glaring light and to make the outlines sharp and distinct, the holes are filled with small bits of ground glass so that they light up with a uniform mellow light. Diametrically opposite the arrow there is a small knob, by which the disc can be conveniently rotated, if necessary.

How to use the Astigmometer.—The instrument may be set in a window shutter or placed in front of a gas or lamp light. My instrument is set into a movable bracket which is fastened to the wall near the gas light. When not in use it is turned to the wall and thus it is out of the way; when I wish to use it I swing the bracket so that the screen stands exactly perpendicularly and about six or eight inches in front of the gas light, which stands just a little higher than the central hole. The screen is so high from the floor that the holes are about on a level with the eyes of the patient sitting (if an adult) or standing (if a child) 15 feet away. Especial care must be taken that the plane of the screen is exactly at right angle to the visual line of the patient. The room is then darkened, the gas light turned on just enough to light up the holes, and the patient is directed to look at them, with one eye at the time, and to tell whether he sees them distinctly enough to make out their form. Never ask a leading question like this: "Do you see these round holes?" because the *suggestion* of the round form implied in the question, will make the patient see the holes round, even though they actually appear to him oblong. Let the patient describe what he sees, and you will easily and quickly find out whether the holes appear indistinct, or round or oblong.

The great advantage of this instrument is that

as soon as, with or without spherical glasses, the holes appear drawn out, we do not only know the eye is astigmatic, but we also know, and at once, the exact direction of the faulty meridians. If the patient declares the elongation is straight up or straight across we know of course the two meridians are vertical and horizontal. But if the elongation occurs in an oblique direction the patient can seldom estimate accurately the angle of inclination; and just here this apparatus is of the greatest value, for it will determine the inclination quickly and precisely. While the patient is looking at the holes we have only to turn the round disc to the right or left until the peripheric hole (A) is moved to a point where its long axis (as seen by the patient) makes one straight line with the long axis of the stationary central hole. The degree to which the arrow then points gives the exact angle or inclination of the meridian. For instance, if the patient sees the holes drawn out obliquely up to the right, I must move the peripheric hole, if it stands at 90 degrees, down to the right to bring it into the line of inclination. Before doing this, I explain to the patient, by means of two pencils, what I wish to accomplish and what I mean by "bringing the two ovals into the same line;" when he understands it and I begin rotating the disc he is to tell me to stop when the holes are in line. This done, I look at the indicator, it points to 45 degrees, and I know at once the one meridian is inclined 45 degrees, and the other, of course, 135 degrees.

Dr. G. M. Burnett, who, as far as I know, is the first author since Donders, giving a description of this test, says:² "But while this gives us the direction of the principal meridians, it furnishes no information as to the form of the astigmatism, the light spot being drawn out in the same direction in M. and H." This is true, but if you wish to get this information, you can quickly have it by a few trials with spherical glasses. Suppose, for instance, the light holes appear elongated vertically and a + 1D. makes them still longer, but at the same time broader and less distinct, while a — 1D. reverses the elongation and draws the holes out horizontally, you know at once there is myopic astigmatism in the vertical meridian; and if you like, you can determine even the exact degree of the M. by that glass which changes the light spot to a horizontal line.

Whether you like to determine separately first the refraction of the meridians by this test, and then to find out the visual acuteness by means of glasses and the test-types, or whether you prefer to ascertain the refraction and vision in each meridian at one and the same time with the aid of the stenopaic slit;—this is perhaps a matter of personal choice. I, for my part, use the stenopaic

² Treatise on Astigmatism, p. 76.

slit and test-types as soon as the astigmatometer has furnished the direction of the meridians; for in this way I can find out the quickest which glasses will give the patient the best possible eyesight, and this is, after all, the practical and final problem our examination for astigmatism has to solve, and which it can solve only by means of the test-types and lenses. All the other methods are useful only in preparing the way for this final test. And among these preliminary tests I regard the distant point of light as the most useful one. It is probably the oldest test for astigmatism; for Prof. Donders, as we all know, has used it extensively in his classical investigations on astigmatism. In 1873 Dr. W. L. Purves spoke of its merits in Graefe's *Archiv* (xix) and described an instrument very similar to the one which I had made for my own use a year previously. But as I have not seen it used by any one else, and having tested its reliability and practical value these 18 years, I cannot longer resist the desire to see it more generally employed; and I feel convinced you will find it, as I did, a most useful addition to your office outfit and a time-saving instrument in your practical work.

103 State street.

RHEUMATISM, AND ITS TREATMENT BY TURKISH BATHS.

Read in the Section of Practice of Medicine, Materia Medica and Physiology at the Forty-first Annual Meeting of the American Medical Association, at Nashville, Tenn., May, 1890.

BY CHAS. H. SHEPARD, M.D.,
OF BROOKLYN, N. Y.

At what time the disease called rheumatism first made its appearance is not known. The name was first applied in 1642, in a treatise on the subject by one of the most celebrated physicians of his time, M. Guillaume de Baillou, who was an author of several medical works of great merit.

No disease has proved more perplexing. Its uncertain course at times seems to baffle the physician at every point. Volumes have been written concerning its character, and other volumes still have been devoted to the various systems of treatment, which from time to time have held the favor of the medical world. Nor is the subject exhausted. While much is unsatisfactory, and many new facts are continually discovered, opportunity yet remains for the investigator to discover more. Every new thought advances the welfare of mankind. It is the purpose of this paper to suggest some conclusions on the treatment of this disease which a somewhat extensive study, together with a practice of nearly thirty years' duration, have developed.

Rheumatism exists in three forms: the acute, the sub-acute, and the chronic. The prominent symptoms are well known. One most character-

istic of acute rheumatism is inflammation, attended with intense pain in and around the joints, and with marked febrile and nervous conditions that indicate a disturbance of the nerve centres. Another noted symptom is the presence in the blood of an excess of lactic acid, which has a decidedly stimulant action on the cutaneous surface. Subacute rheumatism is a milder form of the same disease. Chronic rheumatism is a name which is loosely applied to many ailments not really of rheumatic origin. Properly speaking, it is a milder form of the subacute variety.

The pathology of rheumatism is acknowledged to be obscure, and consequently there is great diversity of opinion regarding its essential nature. These different conditions are the expression of but one morbid process with varying forms of intensity. At one time rheumatism was regarded as a general or infectious disease; at another, as a fever; and again, merely as a peculiar inflammation of the joints and other structures. Of theories now in vogue, perhaps the most prominent one is that lactic acid accumulates in the body, and that the symptoms are directly traceable to the action of this poison upon the system. There is the nervous theory, the germ theory, and also the malarial theory.

Rheumatism is a constitutional disease, evolved in the system, the culmination of excretory products. The freedom from rheumatic symptoms immediately following a single attack strongly indicates the expulsion of noxious matter from the system. As man is but the product of his environments, no valid claim can be made that any one cause is sufficient to account for all the disorder that this disease produces. It would be nearer the truth to call rheumatism the sum of all the transgressions of its victim. Lactic acid is a normal product of tissue metamorphosis. The morbid action which constitutes rheumatism gives rise to an excess of the acid, and this excess and the rheumatic symptoms both result from the same cause.

It is reasonable to suppose that the special poison of rheumatism may find its principal obstruction while circulating through the tense fibrous tissue of the joints, and thus by pressure on the nerves of those parts produce the pain characteristic of the disease. Retained excreta exercise two distinct actions: one, a stimulant action on the organ by which they are naturally eliminated; the other, a disturbing action on the tissues which supply the materials of their formation, and there is always danger from every arrest of the nutritive changes of the system.

Of the predisposing causes of rheumatism, one of the most importance is inheritance, which can be traced in 27 per cent. of all cases. Some bring it on by overwork or exposure in damp or unsanitary surroundings. All nerve exhaustion tends to lower the vital reaction of the individual, so

that a slight occasion often culminates in this disease; but in most cases the attack is induced by error or excess of alimentation. Indigestion is a frequent cause of rheumatism in the aged, and there is no doubt that tobacco and alcohol are responsible for a large amount of this as well as other disease. The action of tobacco on the nervous system, which is mistakenly supposed to be a tonic, is in reality only a toxic effect, and alcohol, by preventing the elimination of waste material, helps to aggravate every weakness and increase every predisposition to disease. Those alcoholic drinks that contain lime salts are particularly injurious to rheumatics.

Rheumatic fever is simply a crisis, in other words, a means of expelling morbid material from the system, and instead of trying to suppress it, we should aid nature in all her efforts to eliminate this poison. Disease, in whatever form it may appear, is but an effort of nature to free itself from some offending material in the system.

There is probably no disease to which so many different modes of treatment have been applied. Until about the middle of this century, bleeding was considered the sheet anchor in the treatment of acute rheumatism. Facts, however, tended to show that patients recovered more rapidly and satisfactorily when they were not bled, and the practice generally was abandoned, for rheumatism as well as other diseases. Purgatives, diaphoretics, sedatives, and many other remedies have had their day. Then came the lactic acid theory, which naturally led to the alkaline treatment. Lemon juice also found favor for a time, with results quite as good as those from the alkalis. Of all these remedies, not one can be confidently relied upon. Indeed, it has been stated by good authority, that we have no remedy for acute rheumatism. Even the salicylates, salol, colchicum, iodide of potassium, etc., have proved a disappointment in many cases.

So unsatisfactory did all known remedies prove, that about thirty years ago some physicians gave up all treatment, simply kept the patient warm in bed, ordered a light simple diet, and administered a placebo. Dr. Flint published, in 1863, an account of thirteen cases treated on this plan, with good results. Two years later Dr. Sutton, of Guy's Hospital, gave an equally good report of forty-one cases which were treated medicinally with mint-water only. This expectant treatment was adopted by many with results as satisfactory as those from more active measures.

For the treatment of a constitutional disease, we must needs have a constitutional remedy, and this is furnished us in the modern Turkish bath. Having devoted over thirty years to the study of preventive medicine, and having been during that time in an institution in daily contact with rheumatism, our opportunities have been exceptional. Of over three thousand cases of this dis-

ease under treatment, at least 95 per cent. have been either entirely relieved or greatly helped. Some, who were treated over twenty years ago, have stated that they have not had a twinge of rheumatism since. Under this treatment swollen joints have resumed their normal size, acute pains have been eradicated, and the patient restored to general good health. Men are to-day actively engaged in business who were brought to us by their physicians, who acknowledged that ordinary medication had failed to reach their case. The records of every establishment using this remedy will bear out the statement that no rheumatic can submit to the process without deriving great benefit, and that remarkably few have persevered in its use without experiencing permanent relief.

It therefore needs no apology for bringing to the notice of the profession a remedy that has been almost invariably successful, and that is, *heat*; the simplest, the easiest, and the most effective of remedial agencies. It is an all-important fact, that we have perfect command over the blood circulation by subjecting the skin organism to the influence of artificial heat, and on this the whole sanative virtues of the bath depend.

This opens a new field, and offers results that are well worth investigation and trial. Every physician should know what a Turkish bath is, and acquaint himself with its practical workings. It is no new-fashioned remedy of to-day. Its history dates back to tradition. We read of it in the early records of the Romans. In the Augustan period, the bath flourished in its greatest magnificence. All the resources of science and art were made contributory to its completeness. When Rome overran Gaul and Britain, the bath attended her progress, and ruins of the splendid structures then erected are now to be seen in many places, notably at the Hotel Cluuy in Paris, and at the city of Bath, in England. The success of the Roman armies was due in a large measure to the bath, which was to them the hospital and the pharmacopœia. Traces of this bath are also found in ancient Mexico, in Ireland, and in many other countries.

For its modern revival we are indebted to David Urquhart, of honorable memory. He was an enthusiastic Englishman, who had represented his country in Turkey, and there became enamored with the bath as an institution. One chapter of a book which he wrote, entitled the "Pillars of Hercules," and which was published just forty years ago, was devoted to the Turkish bath, and first called attention to the subject.

The Turkish bath of to-day is a most desirable resort, where all modern improvements have been brought into subjection for the comfort and enjoyment of the bather. Treatment by the Turkish bath immediately becomes a luxurious method of getting well. It is a sweating process, and

heat is its vital principle. This can be used as high as 200° Fahr., and over, in cases of emergency. It would be impossible for bacteria, or disease-germs of any kind, to live in such a temperature, and it can be readily seen that with the circulation constantly coming under the influence of such an action it would soon be purified and vivified. By this bath we can destroy personal contagion. This has been demonstrated in many cases.

A few moments in the hot room brings a positive degree of comfort to the rheumatic patient, and soon so much relief is given by the heat, that he will almost imagine that the disease has left him. Every pore of the skin is made an open sluiceway for the discharge of a large amount of perspiration, disease-germs included. The good effect of the manipulation which immediately follows is intensified by this heated condition of the body. Certainly nothing can purify the external and internal man more than this process, nor can any agency better assist the vital energies in the struggle against disease. The circulation is invited to do its perfect work, and as the improved action of any organ only comes through a quickened circulation of the blood in that part, so we find that every function, influenced by this natural stimulus, quickly takes on a normal condition. When the body is thoroughly heated, and the circulation most active, the reaction from a cold application is most agreeable and salutary. Inflammation necessarily implies a want of proper circulation. Some cause has plugged up the finer terminal vessels of the part inflamed. A condition of stasis has been brought about. By applying heat, we relax the tissues so that the circulation can pass on, and the offending material be thrown out through the usual excretory channels. Whether or not this theory be true, the fact remains that thousands have experienced entire relief by this process.

In ordinary treatment it is observed that while the rheumatic patient may complain of the unpleasant effect of the perspirations, he never complains of their weakening effect, such as is observed in hectic fever. On the contrary, he may describe them as bringing great relief to the bodily condition.

The perspiration and increased circulation brought about by the heat are not at all exhausting or debilitating, for there is no drain on the vitality, and there is an essential difference in this respect from the perspiration brought about by exercise.

That this bath is weakening or in any manner debilitating, is thoroughly controverted by many facts, among others that the sham-pooers, who work in the heat several hours daily, never lose a day from its effects. On the contrary, they are examples of good health and vigor. Invalids, weakened by disease, and not able to sit up all day, have been subjected to this treatment once,

and even twice, daily, for months at a time, the result being a constant improvement in health, strength and flesh. In fact, the more desperate the case, the more active and persistent the bath treatment. Many trades find it necessary for their workmen to labor in a temperature considerably above 100° Fahr., and the men are far from being injured thereby. Prof. Carpenter, in "Human Physiology," endorses this same idea, and Chabert, the "Fire King," was in the habit of entering an oven whose temperature was from 400° to 600° Fahr. In fact, the whole weight of testimony disproves the notion that this bath is in any way enervating.

For those disposed to rheumatism, a careful and well selected dietary should be chosen. Sufficient only should be eaten, and that thoroughly masticated; the food being plain and simple. By a thorough *régime* of this kind, and a systematic course of treatment by the Turkish bath, all may be freed from any liability to this most uncomfortable disease.

Much has been and can be done by the private practitioner in the way of expectant treatment, or the let-alone policy, by preventing the patient from injurious dosing or troublesome friends, and mainly by making him comfortable and simply assisting nature to throw off the disease as fast as possible. The cold bath has a wonderful tonic effect, but the greatest relief is brought about by the sweating bath followed by the cold dash. The change from hot to cold has an invigorating effect upon the nervous system, and this is in line with the Turkish bath treatment. A little ingenuity will often enable the physician to improvise what will answer the purpose for the time being, in the patient's home. Wet compresses to the inflamed joints sometimes give great comfort. It is plainly impossible, however, in private practice, to have all the facilities to handle this disease as comfortably, or to relieve as quickly, as in an institution where all these arrangements are made a specialty. Therefore, when it is practicable, it is advisable to at once remove the patient to an institution where the Turkish bath and its accessories can be secured. The advantages of medical care, proper diet, and the regulation of the treatment to the condition of the patient by one who has had experience in the matter, are desirable.

Out of the multitude of rheumatic patients that have come under our care it would be unnecessary, and not to the purpose, to give the history of even a tithe of them. We have, however, selected six typical cases, simply to illustrate the treatment.

Case 76.—H. W. W., aged 44, was brought to the institution January 29, 1867, helpless from acute rheumatism, having been under regular treatment over six weeks. He was unable to move a joint in his body without much suffering,

and was obliged to have an attendant sit up to help him turn over during the night. He was given one treatment daily, and for one week was carried to and from his room to the bath. After that time he could walk unaided, and continued to progress till February 25, when he returned to business, gradually taking on his full duties. He had then received but twenty treatments. He has continued the use of the Turkish bath once every week since, and to this day, May 20, 1890, he has had no return of rheumatism.

Case 84.—T. B., Jr., aged 35, came to the institution April 25, 1867, suffering from rheumatism partly developed. After two treatments the rheumatism was so acute that he was unable to move without great pain, attended with high fever. After six days, during which he took two treatments a day, he was able to return to business, and has not been troubled with rheumatism since.

Case 251.—C. R., aged 20, a young German, was brought to the institution suffering from acute rheumatism, unable to walk or help himself. He was given two treatments a day, and for two days he was apparently no better; thought himself that he was worse; but in one week he was able to go up and down stairs without help, and in three weeks he left for home without an ache or pain.

Case 2248.—H. L. R., aged 55, case of rheumatism in right shoulder, reported that after the first treatment he had the best sleep of any time during the previous fortnight, and with daily treatment improvement continued to a quick recovery.

Case 2806.—W. H., aged 21. A severe case of chronic rheumatism which had existed for months. Brought to the institution by his physician. He was anæmic and much emaciated, weighing but 100 pounds. Pulse 120, temperature 101°. Only able to take a few steps with much suffering, and that with the aid of a stout cane. There was enlargement of both knees and ankle-joints, and the synovial membranes distended by effusion. After three months he was restored to health, having taken two treatments daily, and gaining in that time seventeen pounds in weight.

Case 3375.—Mrs. J. F. Y., aged 40, was brought to the institution helpless from a severe attack of acute rheumatism. Any motion of the limbs caused intense pain. After one week of daily treatment she was able to go to and from her room unaided, and improvement continued till at the end of two months she was in better health than she had been for years before.

The one thing most prominent in the treatment of rheumatism by the Turkish bath is the fact that it works in consonance with every physiological law, and that it tends only to place the system in harmony with itself. When we se-

cure a harmonious interchange and natural action of every function, we have the highest condition of health that the individual is capable of attaining.

Inasmuch as rheumatism is all-pervasive and all-prevalent, and the Turkish bath is its most perfect antidote, the more we spread the knowledge of its good work and help to popularize and promote its general adoption, the more we help on the better time coming, by adding to the length of days of man.

SOME NOTES ON THE NAILS.

Read in the Section of Dermatology and Syphilography, at the Forty-first Annual Meeting of the American Medical Association, at Nashville, Tenn., May, 1890.

BY JOHN V. SHOEMAKER, A.M., M.D.,
OF PHILADELPHIA, PA.

In the early days of the world, before man had learned to utilize the stores of nature, the nails were of far more importance than at present. As the first weapon of attack and defense, the first implement of digging in the soil, or cutting or preparing the food, a healthy finger nail was one of the necessities for a healthy existence.

Even at the present time, they are of the utmost importance as an ornamental and useful appendage of the skin.

They preserve the delicate and sensitive nerves of the posterior terminal portion of the fingers from contact with irritative substances. They protect the sense of touch in the tips of the fingers from becoming dull by constant contact and perform a thousand other useful offices. It will thus be seen that attention to their health is of paramount importance. Fortunately for both physician and patient, diseases of the nails are comparatively limited in number. This is due to the fact that they are composed entirely of flattened epithelial scales which contain neither blood-vessels or nerves. They are, therefore, practically precluded from being the subject of either inflammation or neuralgia. They are, of course, liable to all forms of external injuries, but unless the injury extends to the structures beneath or adjacent to them, the result is not serious. The treatment of wounds or injuries to the nails is in fact a treatment of the structures which are wounded or injured at the same time. If the nail alone is fissured or broken or torn, there can be nothing done except to trim the surface down and wait for all trace of the injury to grow out, as it will do in all cases except when the matrix or root of the nail, is destroyed.

In that event the nail will not be reproduced, but the integument will become hard and cicatricial like.

One of the diseases with which the nails are liable to be affected and to which I wish to refer,

is known as onychogryphosis, or hypertrophy of the nails.

This disease consists of an abnormal increase of either, or both, the length or thickness of the nail. It is due to an excessive proliferation of the cells of the root. It may be uniform, affecting the whole nail, or only certain portions. In the form most usually observed the hypertrophy or excessive cell deposits occur principally in the central portion of the toe nail, elevating it there and producing an upward curvature. As a result the edges of the nail are depressed, and forced into the soft structures of the toe, producing more or less irritation and inflammation. In neglected cases the inflammation may lead to very serious consequences, requiring, at times, excision of the entire nail. This form of the disease is generally the result of prolonged pressure, as from tight fitting shoes, and is seldom observed anywhere except in the nails of the toes, especially the big toes. It is sometimes observed on the fingers in persons who from their occupation, or in obedience to fashion, are in the habit of wearing tight fitting gloves. Idiopathic cases sometimes occur as the sequelæ of rheumatism, scarlet fever and other diseases. This is, however, rarely noticed. The treatment of hypertrophy of the nail consists in removing the cause of the disease, and restoring the natural condition of the parts.

No remedies will do any permanent good if the cause be allowed to continue. If, as is usually the case, the disease is limited principally to the nail of the big toe and the adjacent soft parts, the patient must be ordered to remove the pressure, by either cutting out a piece from his ordinary foot covering, or to discard it for a slipper, until cured. When this is done the edges of the nail will no longer be forced down into the sensitive inflamed flesh, and relief will be given at once. The free edges of the nails should then be trimmed down as close as possible, and a mild sedative and astringent ointment applied to the painful parts. One of the best applications is a 5 per cent. ointment of the oleate of tin, or if there be much inflammation a 10 per cent. ointment of the oleate of lead.

Another excellent application is tannic acid 1 part, bismuth sub-nitrate 1 part, adipis 12 parts. If there be much pain 5 grains of powdered opium should be added to each ounce. In some cases the best results are obtained from applying pure carbolic acid directly to the raw surface. A momentary burning sensation is produced, which is quickly succeeded by entire relief from pain. A solid stick of nitrate of silver may be used to accomplish the same purpose. Another analgesic ointment is composed of salicylic acid 20 grains, ext. belladonna, 10 grains, adipis 1 ounce. In chronic cases, where the surface remains raw for days after the pressure

has been removed, reparative action can usually be promptly produced by abandoning the use of ointments and dusting the surface with powdered cinchona bark, or pure tannic acid, or oxide of zinc, or bismuth sub-nitrate. If the nail remains thick, or continues to increase in thickness after the removal of all sources of pressure or irritation, its surface should be softened by frequent applications of liquor potassæ, and then gently scraped with a knife or abraded by a file until it returns to its natural condition. Nightly applications of salicylic acid ointment or plaster over the nail are also serviceable.

Internal medication is seldom required unless the pain be extremely severe, or there is some constitutional disease present. In the former instance, full doses of morphia are indicated to allay pain and procure sleep. In the latter case appropriate anti-syphilitic, anti-strumous, anti-rheumatic or other needed remedies should be freely given. If the hypertrophy is due to parasitic infiltration, it may be necessary to destroy or remove the greater portion of the diseased nail surface.

SOME ABNORMAL CONDITIONS DUE TO REFLEX NERVE ACTION.

Read before the Spokane County Medical Society, July 3, 1890.

BY R. L. THOMSON, M.D.,

LATE PROFESSOR OF ANATOMY IN THE KENTUCKY SCHOOL OF MEDICINE; HOUSE SURGEON OF MANHATTAN EYE AND EAR HOSPITAL, NEW YORK CITY, 1887; EDITOR WEEKLY MEDICAL REVIEW, ST. LOUIS, 1888-9; SEC'Y OF THE MISSISSIPPI VALLEY MEDICAL ASSOCIATION, 1889; PRESIDENT SEC'Y OF SPOKANE COUNTY MEDICAL SOCIETY, MEMBER OF THE AMERICAN MEDICAL ASSOCIATION.

My purpose in reporting the cases detailed in this paper, is to give some additional testimony as evidence of the importance in practice, of keeping constantly before us one of the first principles in the treatment of disease, namely, the removal, so far as possible, of the *cause* of every abnormal condition that we are called upon to treat.

Disease in its various forms exhibits so many phenomena for which we can find no adequate cause, it is not a matter of wonder that we at times fall into a routine practice of treating symptoms.

At the same time, we are justly proud of our superior methods of diagnosis that have enabled us to acquit the liver of many sins of other organs; to stop some supposed "consumption coughs" by checking the discharge from the posterior nares; to relieve many cases of so-called fever by evacuating pus cavities in various portions of the body, and in a hundred other ways to alleviate suffering, and cure patients who would have been left by our predecessors, to endure the pain and discomfort, and in some instances to perish.

It is safe to assume, as a fact, that there is no effect without a cause, and my experience justifies the belief that there is more to be learned of the etiology of disease than has yet been made known to us. The scarcely less than marvelous advances made in the past few years toward reducing the practice of medicine and surgery to a science, should stimulate us in our exertions to achieve new successes.

Cases of vesical tenesmus due to fissure of the anus; of intense pain in the knee due to arthritis of the hip-joint; of pain under the shoulder-blade from abscess of the liver; of cough due to gastric irritation, and many other forms of reflex nerve action are familiar to us all. The cases which I now report are of a similar nature though not so generally understood by the profession.

Case 1.—Miss M. G., æt. 18, applied to me for something to strengthen her eyes. She stated that frequently while walking in the street, or sitting in the theatre, hot tears would flow almost in a stream down her cheeks. I made a careful examination of her eyes and found that they were perfectly healthy, and her vision was normal in each. The mucous membrane of her nose was somewhat hypertrophied and hypersensitive. By making applications to this membrane, I stopped the excessive lachrymation.

Case 2.—Miss K. M., æt. 24, was brought to my office by a physician. Her vision for distance was $\frac{2}{3}$ or less than one-half that of normal. As seen by her, the smaller letters on the test card were so blurred that she could not make them out. She read diamond type on a card held in her hand, but said that if at any time she continued such exercise longer than a minute or two, the letters ran together, and a severe headache was sure to follow. For eighteen months she had scarcely known what it was to be without a headache, which at times was so severe as to cause her to keep her bed. An ophthalmoscopic examination showed her eyes to be emmetropic, and they were absolutely free from disease. I examined her ears, and there was nothing wrong with them. She stated that she had no trouble with her nose, but upon inspection I found the right nasal passage plugged by hypertrophy of the tissue covering the turbinated bones. With instruments, I opened the occluded nostril. From this time on my patient had no headaches. At the next visit to my office she read $\frac{2}{5}$ with each eye, and stated that she could use her eyes for reading, writing and sewing, for as long a time as she wished. Some months later when I saw her last, there had been no return of her trouble.

Case 3.—D. R., æt. 30, applied to me for glasses. He stated that each day on his return from a morning ride in the Park, the left sleeve of his coat was wet with water from his left eye.

The lachrymal passages were not closed, as there was no overflow of tears except while out riding. I could find nothing about his eye to account for this annoying symptom. The mucous membrane of his nose was hypersensitive. I treated the nose and the excessive lachrymation ceased.

Case 4.—Miss V. B., æt. 20, was brought to me by her physician, who stated that he had been trying for some months to build up her health, but that his remedies had failed. The patient had been subject to headaches for many months. Her lips had scarcely more color than her anæmic-looking face and hands. Her tongue was coated and her appetite bad.

I found her vision in the right eye to be $\frac{2}{15}$ or better than that of the average good eye. Vision of left eye was $\frac{2}{30}$ + or somewhat less than that of the average good eye. I placed her eyes under atropia and found that the right eye needed no glass; the left required a plus cylinder of one-half a dioptré, which brought the vision up to $\frac{2}{5}$. Over the right eye I placed a plain glass; over the left, the weak plus cylinder. From the day on which my patient began to wear these glasses, she had no more headaches, and in a short time she was restored to perfect health.

Case 5.—I was called in consultation to see J. L., æt. 19, who was unable to raise the upper lid of his right eye. He stated that three weeks previous to the time of my seeing him, while working around a wheat thresher he had felt something strike his right eye. The next day he applied to a physician, who treated the case as one of conjunctivitis. At the end of two weeks, the patient found that his eye was not getting well, so he consulted another physician, who everted the lid, but not finding a foreign body concluded that the ptosis must be due to a tumor in the cranial cavity. Upon examining the patient, I found some œdema of the lid, and that it could be everted only with great difficulty. There was a local conjunctivitis in the upper cul-de-sac. The ptosis was due to a tonic spasm of the orbicular muscle of the eye, which in turn was caused by some peripheral irritation. Had the drooping of the lid been due to paralysis of the nerve supplying the elevator muscle of the lid, I would have met with no resistance when I attempted to evert the lid. The symptoms seemed to clearly indicate that there was a foreign body either in the upper cul-de-sac or in the substance of the upper lid. I wrapped a small piece of cotton around a probe, dipped it in warm water, everted the upper lid and swept the entire length of the cul-de-sac twice. The second time, I brought away a piece of a beard of wheat, about half an inch in length. The patient experienced immediate relief, and his ptosis was instantly improved. I did not see him again, but I am quite sure he made a good recovery.

IMPERFORATE AUDITORY CANALS.

Read in the Section of Laryngology and Otology, at the Forty-first Annual Meeting of the American Medical Association, at Nashville, Tenn., May, 1890.

BY SETH S. BISHOP, M.D.,

SURGEON TO THE ILLINOIS CHARITABLE EYE AND EAR INFIRMARY,
CHICAGO, ILL.

American medical books on the ear contain so little on the subject of congenital and traumatic anomalies of the external auditory canal, that it seems fair to infer that they are of uncommon occurrence in this country.

Only the following four cases of complete and permanent imperviousness of the external meatus have come under my observation during a practice of fourteen years, eight of which have afforded me quite a respectable experience in hospital and dispensary work.

Case 1 was a man 32 years old, who applied for treatment August 15, 1883. Several years previously he had been run over by a railroad train, that severed the auricle from the head. The surgeon in attendance is said to have had no hopes of the man's recovery, but sewed the auricle to the side of the head, to make the subject appear more presentable at his funeral. The result was that union of the parts took place in such a manner as to completely close the external auditory canal, and deprive the patient of any use of that ear. However, the fact that the auditory nerve had retained its integrity was established by a careful application of the hearing tests. I therefore cut away the scar tissue sufficiently to obtain a channel of nearly the natural size. There was only a slight discharge following the operation, and when the patient left the city for his home two weeks later, his hearing in that ear was good for ordinary conversation.

The result showed that the drum and auditory nerve had been uninjured by the accident, and nothing was needed to restore the usefulness of the organ beyond opening the door for the admission of sound.

Case 2.—A girl 8 weeks old was brought to my clinic October 10, 1885. There was a congenital deformity of one auricle, and absence of the external auditory meatus of the same ear. The auricle was rudimentary, and doubled forward upon itself. It appeared shrunken and pinched, and had a large, hard nodule and several indentations in that part of the helix that corresponds to the key-stone of an arch.

It is interesting to note, in this connection, that the mother attributed the deformity of the auricle to the fact that, about the fifth month of gestation, her elder child bit the mother's ear severely, at just that point that corresponds to the greatest auricular deformity in the baby.

At the point where the canal ought to have been, there was a depression or cul-de-sac that yielded to pressure, and imparted to the touch an

impression as if there were an opening in the bone beneath.

Four months later, careful tests led me to believe that the child could hear with that ear. I operated to correct, as far as possible, the deformity of the auricle, and to ascertain if there were any bony meatus. On cutting down into the cul-de-sac where the canal should have been, I found nothing but a depression in the bone. No bony canal could be found, and I did not consider that further operative interference would be justifiable. However, I maintained a sufficient opening to give quite a respectable appearance of an external meatus.

Case 3.—An infant 14 months old, healthy and apparently normal, except in respect to one ear. There was no opening where the external canal should have been, and, although the patient appeared to hear on that side, the parents were unwilling that an exploratory opening should be made. I saw the case several years ago, but have never heard from it since.

Case 4.—Locomotive engineer, 32 years old, was referred to me through the courtesy of Dr. Fitch, of Rockford, Ill. When 3 years old he was run over by a wagon, that detached the auricle and tore off part of the cheek. The auricle was stitched over the meatus, and completely closed it with dense fibrous tissue. The patient stated that he had never since been able to hear with that ear, but the tests showed that the nerve was sensitive to sound.

About ten years ago, he suffered intense pain in the ear for two weeks. This was followed by a purulent discharge from a pin-hole perforation in the adventitious tissue at the highest point of the mouth of the external meatus. The discharge had continued ever since, being copious and malodorous. The exit for pus was so minute that accumulations produced considerable pain. At such times he pressed above and in front of the ear, and alternately pulled and pushed the auricle in a sort of pumping process, to work the pus out. He succeeded in this manner, and by the aid of the Valsalvian experiment, in evacuating the pus cavities.

I operated by means of the paracentesis needle, followed by a triangular-shaped bistoury. The meatus was filled with tough cicatricial tissue for about three-fourths its depth. After opening up the canal and cauterizing it with chromic acid, I inserted a vulcanized rubber tube, and retained it in position by antiseptic dressings.

After the operation he could hear my watch 11 inch, and ordinary conversation 11 feet distant. After several treatments with the Eustachian catheter and external applications, the patient resumed his occupation. When he returned again the canal had contracted, and granulations had extruded the rubber tube by one-half its original insertion. Under a 10 per cent. solution of cocaine I curetted

and cauterized the canal, and recovered the ground lost. Subsequently, however, the same experience was repeated, and the canal was allowed to close; but by this time the discharge had diminished to a few drops in the twenty-four hours, and the foul smell had disappeared.

I had already begun dilating the old perforation. Through this I could pass a probe upward into the mastoid cells, and inward parallel to the roof of the external meatus, to the tympanic attic. I proposed a more radical operation for the excision of all the occluding tissue, which would enable me to discover and remove any carious bone that might be present; but he was so well satisfied with the almost complete cessation of the discharge, that he refused, and returned to his vocation.

We found that after dilating the original opening, he retained his hearing nearly, though not quite, as well as it was through the tube.

The remarkable circumstance in this case is, that the perceptive apparatus and the conducting mechanism should retain their functions after twenty-nine years of apparent disuse. But I apprehend that, although the patient was unconscious of any hearing power in this ear, it was sufficiently responsive to sound-vibrations of a major character to give the conducting apparatus exercise, and to keep the nerve sensitive. The nature of his business lends color to this view, for its environments abounded in vibrations which would be imparted to every organ in his body. If anything in nature is calculated to arouse a dormant auditory nerve, I should imagine that nothing but Gabriel's trumpet would surpass the clanging of bells and the tooting of whistles.

Some of our authorities speak of imperforate external auditory canals as though they might be of frequent occurrence; but among the records of the Illinois Charitable Eye and Ear Infirmary at Chicago, embracing more than 8,000 cases of diseases of the ear, I find but one case of closure from exostosis, three cases of congenital absence of the meatus, and three of traumatic closure. Of course, we have found numerous cases of narrowing, and various irregularities of the canal, from causes that are not uncommon.

A reference to the following authorities will bear me out in my inference that congenital and traumatic anomalies of the external auditory canal are infrequent in America:

Roosa mentions the occurrence of congenital absence of the canal, but does not treat of traumatic closure. He records no operations to form an external meatus.

Burnett speaks of the possibility of closure, but cites only membranous and osseous formations as the cause. None of my cases were of that kind, two being congenital and two traumatic.

Green's edition of Schwartze speaks of congenital atresia, or imperforation, and stenosis, or con-

striction, of the canal, as "specially frequent."

Turnbull mentions congenital absence of the meatus, rudimentary auricle, and exostoses, but not as being frequent.

Mittendorf does not treat of the subject.

Jones also ignores it.

Pomeroy does not deal with the subject, although he mentions exostoses.

Sexton's book on the ear is silent on the subject.

Von Troeltsch has seen congenital absence of the meatus, speaks of the difficulties of operation, and discourages it, unless one can with certainty find the bony canal.

Buck has nothing on the subject, but mentions membranous closures.

Congenital cases have been reported by the following authors: Moos, Knapp, Jäger, Welcker, Robb, Hessler, Zaufall, Steinbrügge, Zuckerhandl and Michel.

Politzer's classical work on the ear advises an "operation in congenital atresia of the external auditory meatus only when it has been with certainty ascertained, by careful examination, that it is a case of congenital thin-walled septum at the entrance to the ear. When the atresia extends far inwards, so that the canal cannot be made out, or only a solid cord, operation must be avoided, as irrational and dangerous.

Virchow's Archives, Bd. 30, S. 221, and Bd. 32, S. 518, says: "Congenital anomalies of the external ear and its neighborhood are to be referred to early disturbances in the closure of the first branchial cleft, and are often associated with fistulæ of the other branchial clefts, cleft palate, and other forms of arrest of development in the facial bones—as, for instance, with unilateral atrophy of the face."

MEDICAL PROGRESS.

TOXICITY OF BORIC ACID.—By some authors boric acid is considered not more toxic than table salt, and it has been extensively employed as a disinfectant in the preparation and canning of foods. That it is occasionally poisonous has been recently demonstrated in the journals, and now we have the communication of DR. G. LEMOINE (*Gazette de Paris*) describing four additional cases.

The first case was that of a paralytic, with a bed-sore that was dressed with a powder containing boric acid; on the fifth day there appeared an eruption which gradually covered the whole body. The temperature rose, pulse frequent, severe headache, sleeplessness and delirium, with vomiting. After changing the dressing there was improvement in all the symptoms, and at the end of the sixth day the eruption had disappeared. After some days the boric acid was again employed,

and was followed by similar symptoms that disappeared after its discontinuance.

Dr. Vincent describes two similar cases, in one after washing out the pleural cavity with a 4 per cent. solution there was vomiting, urticaria, delirium; these symptoms disappeared when the cavity was cleansed with pure water, and returned when the boric acid was again used. In the second case, one of bladder operation, the boric acid caused similar poisonous symptoms, but without the vomiting and urticaria. In another case, a laparotomy (Prof. Dubar), severe poisonous symptoms developed, with an erythema of the abdomen and thighs, that lasted twelve days. There was also fecal incontinence. The pulse and temperature were not materially altered.

It is noteworthy that the first case had chronic heart trouble and interstitial nephritis. The last case also had albuminuria. This may be the possible explanation why poisonous symptoms are so rarely noted in the use of boric acid. By the healthy kidney it is rapidly eliminated, but when they are diseased it accumulates in the system and causes poisonous symptoms.

ASEPTIC OPERATIONS. — FRITSCH (*Deutsche Med. Wochenschr.*) claims that the most important discovery in modern antisepsis is that carbolic acid and sublimate are not needed in fresh, clean wounds; that dirty wounds must be cleaned, goes without saying, but clean tissues are only injured by antiseptics. Fritsch has of late used only 0.6 per cent. sterilized solution of sodium chloride, in all operations, even the severer ones in the abdominal cavity. When this cavity is irrigated with solutions of carbolic, salicylic, or boracic acids, depressed heart's action and collapse frequently appear. A directly opposite condition is produced by irrigation with warm salt solution; indeed, this method may be used to prevent the more serious symptoms of surgical collapse.

RESECTIONS OF THE STOMACH AND INTESTINES. — At the recent Medical Congress, PROFESSOR BILLROTH read a paper on resections of the stomach and intestines. One hundred and forty cases were recorded which comprised the whole of those that had come under the Professor's own hands. The technique of the operation was scarcely alluded to, as it had already before been published. The plan of suturing adopted was that known as the Lembert or Czerny-Lembert plan, the latter being seldom adopted, whilst occasionally the plan had been adopted of inserting one piece of intestine into another. Practically about half the patients had recovered from the operation, though, as will be seen from the subsequent account, the mortality is far greater in certain classes of operations, and more particularly is this the case when the upper part of the small intestine

is affected. Of pylorus resections, about twenty cases had been operated on by him, half of which died from the operation itself. All of the cases in which this operation was performed were the subject of cancer, though some were far more favorable to operate on than others, as the disease was not at the time of operation very infiltrating in character, but was chiefly confined to one spot, where considerable ulceration had taken place. Where there was much infiltration of the surrounding parts, an operation was almost impossible. Of those that survived the operation, some four or five had lived in comparative comfort for a few months; two cases had survived from one year to a year and a half; one case had survived two years, and one was alive five years after the operation. Twenty cases of gastro-duodenostomy were recorded, one half of which had been performed by Wöfler's method (in front of the transverse colon), and one-half by Hacke's (behind the transverse colon). They had nearly all been attended by temporary success, which of course was all that could be expected. Of ten cases of resection of the small intestine with the formation of artificial anus, all recovered from the operation. On eight or ten occasions the cæcum had been removed, but it was a difficult operation, and did not yield satisfactory results. It was best to insert the small intestine into the large after such an operation. In two cases of cancer of the descending colon he had attempted resection, but both had died. In the case of the rectum the results were remarkably good; none had died directly after the operation. In two instances a portion of the rectum had been excised, and the upper and lower end of the bowel brought together. Senn's plates had never been used by him on the human subject, but he had employed them on the dog, and was satisfied with their efficacy.—*British Medical Journal*.

TREATMENT OF DYSENTERY WITH INJECTIONS OF BICHLORIDE OF MERCURY. — LEMOINE (*Bull. gén. de Thé.*) has had an opportunity to treat 102 cases of dysentery in the military hospital of Oran. Fifty-four were treated with sublimate clysters, and only those who could not take calomel owing to some disturbance of the stomach; 21 with calomel, with a beginning dose of 1 gram followed in the next two or three days by smaller doses; 11 with ipecacuanha; and 16 in the beginning with ipecacuanha, and later, as it did no good, with mercury. No deaths were noted, and ordinarily 1 gram of calomel was sufficient to check the slimy and bloody stools. In 28 of the cases, the favorable results were immediate. The clysters, consisting of 200 grams of a 5 per cent. solution, were commonly retained about ten minutes, and worked rapid improvement in the tenesmus and slimy discharges. In some cases, owing to the sensitiveness of the anus, it had to be

painted with a solution of cocaine. In many cases the calomel was given in connection with the clysters. Poisonous symptoms were not noted in any case. The author refers the favorable action of mercury in these cases to its antiseptic power.

ON THE OCCASIONAL FAILURE OF CASTS IN THE URINE.—DR. ERNST SEHRWALD (*Deutsche Med. Wochenschr.*) says that occasionally cases present themselves in which a urine, rich in albumen, contains no casts. If the urine is examined in separate portions or each hour, it will be found that the different parts will differ in the number of contained casts. How is this difference explained? The one that naturally presents itself is that some portion of the kidney more involved than the balance, has secreted that portion rich in casts. If this were true, the amount of albumen would also vary, but this is not the case. The author thinks he has found the true explanation, in that the casts have been destroyed by the pepsin contained in the urine, it exerting its proteolytic action in the acid urine. The proportion of pepsin is always greater in the urine containing the less number of casts.

LATE SYPHILITIC INFECTION.—M. CHARLES MAURIAC communicated to the French Society for Dermatology and Syphiligraphy (*Annales de Dermatologie et de Syphiligraphie*) an authentic case of infection four years and nine months after the primary accident. He was consulted in 1885 by the patient and treated him for a primary lesion. The secondary symptoms were not marked and soon subsided, but for the next two years there were occasional appearances. At this time the patient expressed a strong desire to marry, providing that he could be assured that he would not infect his wife. At this time he occasionally had slight herpetic eruptions, and the danger of these, from an infectious point of view, was described. The patient had a fixed idea that he would infect his wife, but at the end of four years and nine months from the date of primary infection married. Unfortunately, his prediction proved to be true, for a short time after marriage his wife presented all the appearances of recent syphilitic infection—roseola, mucous patches, etc.

In the discussion M. Hardy said it was very difficult to fix a time with certainty, when a syphilitic would not infect a wife or child. Fournier placed the time at five years and over.

THE MEDICO-LEGAL ASPECT OF ABDOMINAL SECTION.—The technique of abdominal operations has attained so high a degree of excellence that it would seem that little remains to be accomplished to render it absolutely perfect. Unfortunately, the same cannot be said of our diagnostic resources in conditions of disease within

the abdomen, which are still far from being adequate. Every now and then we read of cases occurring in the practice of careful and skilled surgeons, where errors of diagnosis have led to the performance of abdominal operations attended sometimes with fatal results. If these errors have been made by men of acknowledged diagnostic ability, they are much more likely to occur in the practice of surgeons of less skill and experience.

It is therefore a matter of importance to determine how far the surgeon can be held responsible for these diagnostic errors, since the greed of attorneys and the avariciousness of the patient's relatives not infrequently place him in the disagreeable position of defendant in a civil or criminal law suit. At the last meeting of the American Medical Association two interesting and instructive papers were read by Drs. Vanderveer and Wile, on the subject of the "Medico-Legal Aspect of Abdominal Section," which are reported in the *Journal of the Association*. Dr. Vanderveer states that in the trial of medical men for malpractice, charges to juries have been uniformly that gross neglect or gross ignorance, or both, must be shown on the part of the prosecution, beyond a reasonable doubt, before conviction can be had. It should be borne in mind, however, that it is impossible to make precise distinctions between negligence and ignorance, and gross negligence and ignorance; for that which under some circumstances would be ordinary skill, in other circumstances would be ignorance, and in still other circumstances gross ignorance. The responsibility which the surgeon should assume in the class of cases under consideration is well stated in Dr. Wile's paper: "Laparotomy to-day is, in skillful hands, a recognized operation, and there are certain conditions of disease or accident which can be reached only through abdominal section. The surgeon must be certain, as far as possible, from his diagnosis, that a given condition, or conditions, warranting exploration, exist. He ought to be accurately informed as to the correct method of reaching the parts through operative interference. He should know just when the operation ought to be performed in order to obtain the best, or safe results. Beyond this the responsibility lies with the patient or patient's friends. They should be informed of the danger of the disease as it exists unrelieved; they should be informed as to the gravity of the operation, and its risks, and they should be warned that in the event of unfavorable result, either through failure of the vital powers to stand the shock, or from a too great extent of diseased parts to permit successful manipulation, or even in the case of a possible mistaken diagnosis after sufficient consultation has been had, the doctor shall not be blamed."

It is an unfortunate fact that suits of malpractice against surgeons are tried before juries of

laymen, who are unacquainted with the mere rudiments of the surgical art. Moreover, the prosecution is frequently permitted to adduce, as expert testimony, the opinions of men who have never performed a surgical operation of magnitude, and who are perfectly ignorant upon the subject on which they are asked to testify. The experts testifying in these cases should be appointed by the State, and selected from among men of acknowledged surgical skill and ability. By the adoption of some plan like this the accused party would be certain of a fair and impartial investigation of the points at issue. However comforting the reflection may appear that the unjust decisions of juries are usually reversed by the superior courts, it must not be forgotten that the accused surgeon has been subjected to a large expense and loss of time, not to leave out of consideration the anxiety and worry inseparable from every law-suit. And we would heartily re-echo the sentiment expressed by Dr. Vanderveer, that the laws should be so modified that surgeons may have better protection in the recovery of time, for expenses they have been put to, when it is proved that the case was urged by some disreputable lawyer, or by those personally malignant, within or without the profession.—*International Journal of Surgery.*

EFFECT OF OPERATION WOUNDS ON THE HEART.—DR. J. TANSINI has made a number of experiments on animals with a view to determine the effect upon the heart's action of operation and other wounds of the skull, the pleura and the abdomen. In operations of the skull he finds that the heart is less affected by the use of the trephine than by that of the chisel. The latter may, however, be employed with impunity even upon a skull that is still entire, if an instrument of small size be used, and if it be inclined at an angle of 30° with the surface. When an opening has already been made into the cranial cavity, the use of the chisel appears to exert no disturbing action on the heart. A plug outside the dura mater is much more prejudicial than one applied directly to the brain substance. Venous hæmorrhage can always be arrested by the latter without any serious interference with the heart's action. Washing out the lateral ventricles produces but little effect on the heart if there is a free exit provided for the liquid. Ten experiments were made on the pleura, from which it appears that an opening of either the right or the left thoracic cavity has a very serious effect on the heart, causing at first irregularity and subsequently diminution of the movements. Continued washing out of the cavity with cold water at 11° C., or even at the body temperature, slows the heart to a more marked degree, and causes the animal to die more rapidly. The various antiseptic solutions do not appear to behave differently from plain water, with the ex-

ception at least of those that are definitely poisonous. Wounds of the abdomen, producing prolonged irritation of the abdominal nerves appear to slow, and ultimately to arrest the heart's action.—*Lancet.*

HYPNOL OR MONOCHLORAL-ANTIPYRIN.—DR. SCHMIDT, of Nancy (*Les Nouveaux Remèdes*), presented to the Biological Society his observations upon two new compound substances—the monochloral-antipyrin and bichloral-antipyrin. As a soporific he found that 1 gram of the former was equal to .55 gram chloral, and the latter to .60 gram. Both substances produced a fall of temperature, the bichloral being more energetic than the mono. Their action upon respiration was not sensibly different from that of chloral hydrate. They diminish the force and frequency of the heart's action, but to a less degree than chloral hydrate administered by the stomach. Both substances are toxic, due to their contained chloral. Monochloral-antipyrin has several advantages over chloral hydrate, as it is easier taken, and soporific effects are obtained with a minimum disturbance of the heart and circulation. The question of the analgesic property of these drugs was distinctly reserved.

DISINFECTION OF THE HANDS.—BALL (*Deutsche Med. Wochenschr.*), has studied carefully several methods, and has come to the conclusion that that recommended by Miculicz is the safest and best. It consists essentially in: 1. The removal of visible dirt from the finger-nails with knife or shears. 2. Then the hands are washed and brushed for three minutes, in warm water with potash soap. 3. One-half minute in 3 per cent. carbolic acid solution, and then rinsed in a 1:2000 sublimate solution. 4. Lastly, the space under the nails and the root of the nail are rubbed with damp iodoform gauze for about one minute.

Ball has made some experiments with pure cultures of the staphylococcus aureus, with which he infected his hands, and then applied this method. The results showed that it was a certain means of sterilizing the hands, it being a matter of indifference whether they were previously infected or not.

PILOCARPINE IN DERMATOLOGY.—DR. H. G. KLOTZ, of New York, in a paper read at the annual meeting of the American Dermatological Association, on the 2d inst., gave a review of the history of pilocarpine in dermatology. The author had employed this remedy in a few cases, including some of eczema, pruritus of the anus, and affections with dryness and irritation. The result had been such as to encourage him to give it a further trial. It might be given internally or by hypodermic injection, small doses, long continued. A tenth of a grain was likely to prove sufficient to keep the skin moist.—*Boston Med. & Sur. Jour.*

SATURDAY, SEPTEMBER 20, 1890.

THE TREATMENT OF SYPHILIS.

This always interesting topic was discussed at the recent International Medical Congress at Berlin, with the result of but little new information being added to our knowledge of the subject; although a review of methods of treatment and a comparison of results obtained, is not without value to new workers in any branch of medical science.

DR. M. H. LELOIR considered that the physician was justified in excising the primary syphiloma: 1. When the chancre was seen at its commencement; 2. When the chancre was situated where excision was easy and without danger (labia, prepuce, etc.); 3. When it was not yet accompanied by adenopathy; 4. When a unique chancre, or several chancres, could be removed easily; 5. When the patient was not diabetic, albuminuric, etc. Excision may be a means of aborting or of attenuating syphilis; and the facts on which these statements rest are sufficient to prove that, contrary to well known opinion, the chancre is not the first of the secondary accidents, and does not introduce the infection into the system but, in reality, produces it. Where excision does not abridge infection it may be because it is insufficient, and does not remove the entire area of sclerosis. Specific treatment should not be commenced until the appearance of the secondary symptoms, because the diagnosis of primary syphiloma is not always an easy thing; and to preventive treatment in the beginning may be ascribed the non-appearance of secondary symptoms, so

that certain patients—believing themselves syphilitic—affect their health by using mercurials and iodides, while others—actually syphilitic—totally neglect treatment. His statistics of cases treated with mercury *ab initio*, and of those treated on the appearance of the secondary symptoms, show that late accidents have not been more frequent in one class than in the other; in fact, some of the most refractory cases of cutaneous and mucous syphilides were in patients placed on mercurial treatment when the chancre appeared. The chancre should be treated locally with VIGOS' plaster, of the French codex, or the emplastrum hydrargyri of UNNA; with lotions applied twice a day. From 2 to 4 grams of mercurial ointment are applied for fifteen days, then an interval of from fifteen to twenty days is allowed to pass, and this alternation is continued for a year. Certain rebellious cases of cutaneous syphilis may need general baths, containing 7 grams of bichloride of mercury. Hygiene of the mouth, general hygienic and tonic treatment, and occasional trips to the country or seashore, are required. During the second year the frictions are given for ten days, at intervals of from three to six weeks; and if there is freedom from syphilitic symptoms the inunction may be used, during the third and fourth years, only in the spring and fall. He avoids mercury internally whenever possible, on account of the digestive trouble it may cause; while he uses it hypodermatically only in hospital cases, because such patients neglect their medicine.

DIDAY gives $\frac{1}{2}$ gr. of protiodide of mercury three times a day, with iron and iodide of potash in anæmia. He believes things proscribed are more important than things prescribed. DRS. SCARENZIO and LANG use hypodermatic injections of mercury; while NEUMANN conservatively holds the necessity of considering the individual conditions and following an active case by preventive treatment, or by symptomatic treatment, or by intermittent treatment, continued no longer than two years.

It seems to be agreed by the participants in the discussion that excision of the chancre may, at least, attenuate the disease; this experience has not been corroborated by American syphiligraphers, and we believe is but rarely practiced in this country. So with adenopathies; excision of the glands does not obliterate the many lymph channels that are conveying the syphilitic poison.

The consensus of opinion seems to be that there is no advantage in commencing treatment until the secondary infection is manifest; a conclusion that is generally practically applied among us. But the hypodermatic treatment has not as yet been generally adopted, largely on account of the intolerance of patients; and inunction has the disadvantage of uncleanness, aside from its liability to cause skin affections, as well as uncertainty of dosage of mercury absorbed. As VIRCHOW has said, the treatment that is best tolerated may be dangerous; and in nothing, more than the treatment of syphilis, is eternal vigilance on the part of the physician the price of the patient's liberty from tertiary manifestations of disease.

THE INFLUENCE OF NEWSPAPERS ON THE HEALTH OF THE COMMUNITY.

At the late meeting of the Social Science Association at Saratoga, DR. F. W. RUSSELL, of Winchendon, Mass., read a paper pointing out the evils of sensational descriptions of crime and accidents in the daily press. He asserted that minute descriptions of crime were an educational power to weak minds to commit similar acts in the same way. This was proven by the similarity of particular crimes, that had been minutely detailed in the daily press. In one instance a suicide had devised an ingenuous apparatus for hanging. This was given in sensational detail by a daily paper, and within a few months four similar cases were noted in which the same apparatus were used, showing that they had been copied from the first description.

Many similar instances will be apparent to any one who studies the histories of crime as given in the daily press, especially if it has attracted much attention. The similarity of detail as to method and manner of execution, shows that the press has educated the criminal and pointed out the methods of committing the crime.

The sensational descriptions of cyclones was mentioned as particularly dangerous to a certain class who, on the approach of any storm, gave way to the most morbid impulses of fear and alarm. The most alarming symptoms of nervous prostration followed the appearance of any approaching storm, that resembled the description given in the papers. In cases of accidents the doctor had noted a marked change in the health

of persons who had read the details minutely.

In asylums the influence of these sensational accounts were exceedingly dangerous, and all such papers had to be excluded. The effect on the mind of comparatively healthy persons of the sensational details of crime, and casualties, was always bad, and especially on nerve exhausted and defective brain organizations.

To young persons it is practically worse and more disastrous than obscene literature or pictures. The morbid impressions it produces and shock to the higher nerve centers, leaves a permanent enfeeblement that is traceable. The cheap novel, however sensational, was more or less unreal to the reader, and could not enter so minutely into his daily life, but the newspaper accounts of atrocities were accepted as positive histories, that roused, excited, and became a large part of the thought of the reader for the time, forming naturally a degree of education to govern all future conduct.

Some very interesting illustrations were given of the effect of journalistic sensationalism and its far-reaching disastrous effects on all communities. The doctor concluded that the remedy was to appeal to the press to publish no details of crime, and thus raise the tone of its readers, and also to withdraw all patronage from papers of sensational character. The comments on this paper by the press have been in most instances very kindly. The defense was that details of crimes and accidents are demanded by the public, and this publicity has a deterrent influence in most cases, preventing crime for fear of publicity. It is evident that many of the cheap sensational dailies are not only bad but dangerous in their influence on the minds of the readers. The morbid glorification of criminals is the direct result of minute exaggerations of his life and crime. The same detailed accounts of his crime create an air of superiority that is fascinating to many minds. It is also evident that medical men have a duty to correct and educate public sentiment in this regard. There are mental influences at work in all communities that are as potent for harm as poisonous germs, and the physician should be the counsel and adviser.

Dr. Russell's paper suggests a new field of study and observation. If it can be shown from facts gathered over wide sections of country, that detailed histories of great crimes stimulate crime of like character, as in the case of the "James boys,"

a remedy for the evil is demanded at once. It is asserted that a history of the "James gang" has produced several similar organizations, whose depredations were such close imitations, as to suggest the inspiration from this history alone.

The effect of any horrible event, when given in detail, on the minds of the community opens up a wide field of psychological study of great interest. The observations and conclusions reached by Dr. Russell, have been made before, but they came to-day with peculiar interest, and have a larger significance than ever. Sensational journalism has attained great proportions, and the dime novel and trashy story is put in the background. How far does this journalism influence public health? How far does it cultivate crime, and morbid mental states, dangerous to the community? How far does it stimulate disease and disease conditions? How far does it pervert and damage all healthy mind and brain growth?

These are only a few of the questions which the profession should be prepared to answer.

EDITORIAL NOTES.

THE MISSISSIPPI VALLEY MEDICAL ASSOCIATION.—In previous issues of *THE JOURNAL* we have called the special attention of our readers to the fact that the next annual meeting of this prominent medical society will convene at Louisville, Ky., on the 8th of October. The medical profession of that city have made every possible provision for a most successful meeting. Special arrangements have been made at the hotels and reduced rates have been secured on many of the railroads, and we shall be greatly surprised if the medical men of the Mississippi Valley and their friends from less favored regions are not largely represented in that meeting. The very efficient Chairman of the Committee of Arrangements is Dr. I. N. Bloom, of Louisville, who will be glad to render any needed service or information.

A CORRECTION.—Referring to the cause of the death of the late Dr. Robert Stephenson, of Adrian, Mich., while in attendance at the Medical Congress at Berlin, the associated press seems to have been guilty of a serious misrepresentation. So far from being true that he died from an "overdose of morphine," the facts, as the result of careful post-mortem examination, reveal that he died from cerebral hæmorrhage from a rup-

tured vessel in the pons varolii. A sensational report should never attach to a name so fair and so honored as his, and the press, if it be not more discreet in the selection of its correspondents, is guilty of a crime.

A WORLD-WIDE BROTHERHOOD.—It is a significant fact that medical science knows neither geographical boundaries nor national restraints. Millions of men may be under arms for the preservation of international peace, and yet the devotees of medicine from every land may meet in any domain, and under any flag, heartily reciprocate the kindest courtesies, and labor as brethren in a common effort for the alleviation of human ills, receiving on every hand a heartfelt welcome.

To the honor of the medical profession be it said, that the world has never seen such another manifestation of international comity as has just been witnessed at Berlin. The representation from all the principal nations was such as to command profound respect everywhere, and the influence upon the nations represented must have its beneficial influence. The courtesies awarded by the Germans to their French visitors will be sure of a generous response; America will surely be accorded a name and a place upon this planet, and the fact that the centre of medical achievement seems to be nowhere, and that its circumference is everywhere, will lead the way to more and more generous recognition of *genuine* work and worth regardless of clime or previous condition.

One of the mighty agencies for the unification of the nations will be the unification of their medical men. The international congresses are simply heralding the advance.

THE SANITARY CONDITION OF CAIRO.—The want of proper action on the part of the British Government with reference to the sanitary condition of Cairo is being severely criticised. The Internal Board of Health, appointed some seven years ago, seems to have accomplished little or nothing in the way of sanitary improvement. Its water-supply is said to be filthy, and a heavy death-rate prevails at the Egyptian capital. Cholera prevails in the city, and at neither of the quarantine stations, where pilgrims are detained, are adequate provisions made for the patients themselves, or for preventing the further spread of cholera in Egypt. Favoritism and nepotism are said to be responsible for the neglect. Expert

service is demanded at such a crisis as this, and no time should be lost in the correction of such a criminal neglect. The British government owes it to herself and the world to place the City of Cairo under the best possible sanitary surveillance, and that at once.

DEATH OF DR. VON JELENFFY.—This distinguished Hungarian laryngologist became suddenly sick after attending but a single session of the Congress at Berlin, and has since died. Most of the members of the Section on Laryngology who remained in the city were in attendance at his funeral, at which Dr. Fraenkel, the president of that Section, presided.

HIPPOPHAGY IN BERLIN.—The *Lancet* says: "It is stated that, in compliance with the public wish, a horse-meat restaurant has been established at Berlin, wherein a large trade is carried on." It seems remarkable that the meeting of the Medical Congress should so soon be followed by a meat famine.

MURDER OF THREE PHYSICIANS.—According to a Dalziel's telegram from Madrid, dated the 27th ult., the physicians at work in the cholera-infected districts continue to receive ill-usage from the peasants, who are opposed to the precautionary regulations upon which they insist. Notwithstanding that the physicians are provided with military escorts, they are still subjected to violence. In Valencia a physician has been killed by a stab in the back; at Mogente another doctor had his head split in two by a hatchet wielded by a woman; while a third was set upon and killed by an infuriated mob near Lerdo.

ADULTERATION LAWS IN RUSSIA.—The Russian government has recently enacted some very stringent laws against the adulteration of food and drink. Any person guilty of adulterating any article of food will be liable to a fine of \$200, or imprisonment for three months, for the first offense, double this penalty for the second, and deprivation of all rights as a citizen for the third. What a sweeping revolution would follow the enactment of such a law in the United States. As a question of profit and loss, it would be simply stupendous.

DEDUCTIONS FROM EXPERIMENTS WITH DRUGS.—The *Progrès Médical* states that Dr. Huchard

recently read a paper on "The Physiological and Therapeutical Action of Drugs" before the *Société de Thérapeutique*, calling attention anew to significant differences in the action of certain drugs in the well and in the sick and in various forms of disease. For example, it was stated that quinine lowered the temperature in typhoid fever, but had no such effect in erysipelas. The lesson to be drawn from such facts is that it is not safe to make sweeping therapeutic deductions from observations of the physiological action of drugs; to use the author's words, "physiology should not enslave medicine."—*N. Y. Med. Journal*.

CHOLERA INTELLIGENCE.—Cholera is still prevalent in Spain. The infected provinces are Valencia, Alicante, Castillon, Tarazona, Badajoz, Carthagen and Toledo. The total number of recorded cases up to the date of August 23 was 2,314, of which 1,167 had proved fatal. Over 20,000 persons have emigrated from Spain to France, but thus far no cases of cholera have been reported from any part of the French domain. Reports to August 25 state that up to that date 2,727 deaths from cholera had occurred at Mecca, and 1,083 at Jeddah. The disease is prevalent also in Japan, and the report of its appearance in Tokio is confirmed. The near approach of cold weather leads us to hope that its present severity will be mitigated, and that its progress will be stayed.

THE BRITISH WARSHIP *Buzzard*. which recently arrived at Halifax from Jamaica, is reported to have had nineteen cases of yellow fever on board. The report adds that one man died on the voyage, and was buried at Port Royal. Five of the men, it is expected, will recover.

SEVERAL cases of leprosy have, it is reported, been discovered in Englishtown, Cape Breton Island. The victims are said to have been in constant association with the other inhabitants.

THERE would appear to be a recurrence of influenza in Vienna. Several cases are stated to have occurred in the hospitals there. In Paris also the disease is said to be reappearing.

SMALL-POX EPIDEMIC.—A telegram received from Pernambuco states that 4,000 cases of small-pox had occurred there, with an average of fifteen to twenty deaths a day.

TOPICS OF THE WEEK.

THE POWER OF CREATION.

In whatever department of thought we find it occupied, the very nature of science is hostile to uncertainty. Facts, indeed, are not its constant possession, but its object, nevertheless, is always to know the truth as true beyond possibility of doubt. Nothing therefore can, in strict conformity with its character, be received on mere trust. All that is accepted must be capable of proof, and anything that cannot be thus verified, though true it may be, is to science a thing not known. In reference to all such matters, its position is that of the agnostic, properly so-called; not, that is to say, of a mere creedless bigot, but of an expectant and cautious investigator, accepting in belief only that which he has proved. In virtue of this very position, however, the description here given is but a partial one. It applies rather to a purpose than an actual condition. It is a true portrait of exact science only, and it leaves untouched the illustration of that far-reaching principle by which every branch of knowledge is made subject to the law of development, and passes through doubts, conjectures, and shrouded truths to the brightness of clear understanding. Science is no exception to this rule. It has its tentative theories, its mutable facts, and provisional acceptances, and its position would be logically untenable if it were to deny to other modes of thought a share in that charitable consideration which allows time for its own conclusions, however crude, to be planned, marred, recast, and slowly matured. The assumption of such a position would indeed be suicidal, for it implies a fatal schism among the forces concerned in philosophic inquiry. Science and philosophy, it must be remembered, are not contraries. They are merely the obverse and the converse of the same intellectual process, the former objective, the latter subjective as to its rational method. Either may, in the wider acceptance of its meaning, be taken to include the other, and it is only the prominence of one, the physical application of scientific study, which has associated the former with what we call matter, as distinct from spirit or mind, the natural sphere of the latter. However diverse they may seem to be, distinction between mind and matter is, in the present state of our knowledge, impossible. We are as yet without experience or information respecting the separate condition of one or another. At all points matter is instinct with incorporated properties which constitute the law of its being, though whence derived its atoms cannot tell us; and mind, on the other hand, can only confess itself through its physical manifestations. Though we should penetrate, if it were possible, beyond the earliest known traces of our world, we might still be as far as ever from a solution of the mystery, but at no stage could we expect to pass beyond the age at which these two became united. Everywhere we still find, whether in vital activity or in the buried vestiges of old-world existence, the sure signs of cause and effect. The design may vary, but its evidences are never wanting. Some, perhaps, may prefer to regard it as the essential possession of matter, and to dignify this with the

attributes of a creator. We cannot but think, however, that the very diversity of material forms, and their infinite variation in conformity with some discoverable purpose in each case, mark them out rather as the vehicles of some compelling force implanted in them. That this force is not purposive, but fortuitous in its action, is incredible. Given a certain stage in the progress of development, circumstances may, indeed, accomplish many modifications, as the laborious genius of Darwin has abundantly proved; but even these are governed by strict limitations, are apt to be transient in character, and are rather differences of degree than alterations in type. The argument for intelligent design is not seriously impaired, in our opinion, by such evidence of a merely material agency, and there is every reason to believe that this view is yearly gaining ground among the more scrupulous thinkers in physical science. It is significant to find an authority like Professor Tyndall, despite his belief in matter and force as primary factors in the production of life, admitting the probable existence of a "power of creation," which he associates with evolution, and proposes to invest with some feeling akin to worship. Professor Huxley's condemnation of materialism as "the most baseless of dogmas" is also—at least constructively—suggestive of a disposition to include within the beliefs of natural science the existence of a supreme directing intelligence.—Editorial, *London Lancet*.

MEDICAL SCIENCE IN THE LAY PRESS.

"Save us from our friends!" would probably be the exclamation of Dr. Vaughn of Ann Arbor, Michigan, when he took up his daily paper about the middle of last month. Dr. Vaughn's work in connection with ice-cream poisoning and tyrotoxin, and his *brochure* on animal poisons, are both so well known that an inflated newspaper paragraph can scarcely do him much harm; but the system of lay press eulogy and advertisement that has grown up under the fostering care of those whose knowledge is somewhat limited, but whose desire for public recognition is an inverse ratio, would not protect from the derision of right-thinking men many so-called scientists. Dr. Vaughn has probably published, or there will be published through some other channel than the lay press, the results of his work on cholera infantum and typhoid fever. He has followed up the work of Hankin, Brieger, and Fraenkel, Roux and Yersin, and others, and he has added another to the list of tox-albumoses. The work that he has done is probably both thorough and sound, and we shall anxiously await the arrival of the record of such work in this country. It seems rather hard in his case that his fellow countrymen should in their hysterical excitement so magnify the work that they speak of Dr. Vaughn as a rival to Jenner. That the work is "a triumph to the States" will be fully admitted, more, however, from the fact that it adds another to the many proofs of the existence of a number—a number that is rapidly increasing—of highly educated, thoughtful, and skilful scientific medical men in a country where, not many years ago, the standard of medical education could not be said to be very high, and

where, even at the present, it is lower among the general practitioners than in any civilized country. America is the home of short curricula, and the happy hunting ground of the various "pathists" and quacks, but that there is an ardent desire for better things the very fact that such an article (ludicrous though it is in many respects) as that before us could be written, and could be acceptable to the readers of the *Ann Arbor Argus* of July 15, 1890, and the *Philadelphia Record* of an earlier date, is evidence. We have got beyond the extravagant stage in this country, but it would be well if many of the so-called medical articles that appear in our lay papers were suppressed.—*Lancet*.

COURT RECEPTION AT BERLIN.

By command of the Emperor, a Reception and Garden Concert was given at Potsdam, at which Prince Leopold, of Prussia, the Emperor's cousin, received the guests, attended by Count Caprivi, Court Marshal Count Bülensberg, Herr von Gossler (Minister of Education), and other high officials. Invitations were issued to 500 guests, selected from many of the leading British delegates and members. At the reception, which took place in the Shell Room, the guests were arranged according to their nationalities, and Prince Leopold, in walking round the circle, caused a number of the representative visitors to be specially presented to him, addressing to each of them a few words of courteous welcome. Subsequently a concert was held in the garden, in the course of which Prince Leopold mixed with the visitors, and conversed with them on subjects likely to interest each. Refreshments were served, and the party returned, being taken back to Berlin by the special train which had brought them. Everything was done to make the medical guests of Germany feel that the German Emperor fully participated in the cordial and generous welcome which had been given to them by the municipality, citizens, and the profession of Berlin, and desired to mark his gracious goodwill to the Congress and its members. Happily the weather on this as on all the other days of the Congress was peculiarly favorable, and the Court function was in every way an interesting and successful one.

FRENCH DEFENCE OF ILLIBERAL MEDICAL LEGISLATION.

Galigani's Messenger, of July 21, replying to the arguments of *The Lancet* attempts to defend the projected illiberal law of the Republic requiring foreign medical practitioners, including English, holding diplomas of good repute, to pass a French examination before being allowed to practice in France, even among their own countrymen. The attempt is lame and inadequate as regards our diplomas. It is chiefly based on three points: first, some of our English examinations are so bad as not to compare with the French. As an illustration of the accuracy of our contemporary's information we will give one specimen. He speaks of the licence of the Apothecaries' Society being gained by 97 per cent. of those who seek it. We know no ground for this asser-

tion. The facts of the examination of the Society for the last year are before us and are as follows: At the first examination 12 were rejected and 17 passed; at the second, 14 were rejected and 25 passed; at the final, 53 were rejected and 125 passed. The examinations have been inspected by the General Medical Council and declared to be sufficient. Our contemporary admits that we practically allow Frenchmen to practice in England without let or hindrance, but says that we do so because the privilege is of no such value as the corresponding privilege to Englishmen in France. This is ungracious and weak. Let the liberal Republic at least be as liberal as we are and enjoy the praise of being more disinterested. Meantime can anything be more ungenerous than to refuse English people, resident in France, medical advisers of their own country, certified by its medical authorities. We shall not answer the less polite insinuations and even assertions of our contemporary that, with some few exceptions, English representatives of the profession in France are eminently unsatisfactory. His elaborate argument against their admission is a fair presumption that they are no mean competitors for practice even among Frenchmen.—*Lancet*.

ANTISEPTICS AMONG THE ANCIENT GREEKS.

Prof. Andreas Anagnostakis, of Athens, gives in the *Deutsche Medicinische Wochenschrift* some interesting facts in reference to the employment of antiseptic measures among the ancient Greeks. Hippocrates and Galen were aware that an unclean condition of wounds retarded healing. They were also well acquainted with the fact that by thorough hæmostasis, suture and the employment of antiseptic measures, infection of wounds might be prevented. Hippocrates warned his disciples against the use of moist dressings, on account of the danger of suppuration, and forbade the employment of drugs before the wound was dry. Above all, says Galen, avoid dirt, as it prevents healing. The ancient Greeks boiled their water before applying it to wounds. Sponges were avoided, and charpie recommended in their stead, which was to be destroyed after use. One of the principal antiseptic substances then in use was wine, which was usually heated before using, and with which, according to Hippocrates, all wounds were to be washed. Dressings dipped in wine were also applied to the wound. Salt was in very general use, either in solution or in the form of sea-water. The solutions were rendered aseptic by boiling. Sulphate of copper was relied upon as an antiseptic for foul wounds, and was also put into use as a hæmostatic. Tar was highly praised for its antiseptic virtues, and was either applied in the form of a dressing or directly poured upon the wound. Besides these, many aromatics and bitters were in daily usage, among which were thyme, rosin, asphaltum, etc., used as dressings, or in the form of plasters. Galen was acquainted with catgut, and advised the use of non-putrefying substances for sutures. Prof. Anagnostakis declares that all this was not empiricism, but an antiseptic method founded upon some knowledge of the principles governing the healing of wounds.—*Druggists' Circular*.

PRACTICAL NOTES.

HYPOGASTRIC PUNCTURE OF THE BLADDER.

Dr. Deneffe (*Journal de Médecine de Paris*) says that too serious a view is taken of hypogastric puncture of the bladder in cases of retention. It ought not to be considered as dangerous, and as a last resource. He quotes a case of hypertrophied prostate which prevented micturition and catheterism, in which the patient was punctured seventeen times without suffering any inconvenience. The seventeenth time, the trocar was allowed to remain, and ten days afterward micturition took place spontaneously through the urethra. Nevertheless, the trocar was allowed to remain twenty-nine days, when it was removed. The fistula was closed in four days, and the patient recovered permanently.

Hypogastric puncture is considered a mild operation by Dr. Deneffe, and he states that he has performed the operation on three hundred and one patients, with a mortality of oily two and a half per cent. A patient suffering from enlarged prostate or stricture suddenly cannot micturate, and this is usually due to a sudden spasm of the posterior portion of the urethra being superadded to the original lesion. Catheterism is not adapted to reduce a spasmodic contraction, and the urethra affected by spasm can only be benefited by the contact of irritating urine being removed.—*Medical Record*.

THE EFFECT OF ICED TEA.

Dr. G. W. Bar writes, in the *Therapeutic Gazette*, that iced tea has none of the physiological action of theine if it is kept ice-cold for a short time. He says that he has known a man of nervous temperament, who is kept awake all night by a single cup of tea, to drink a half-gallon of iced tea during the evening and sleep soundly at his usual time of retiring. Others, made very "nervous" by hot tea, have been able to drink large quantities of iced tea with no appreciable effect. If the tea-grounds are allowed to remain in the liquid, the iced tea is usually kept long enough before drinking to dissolve more tannin than is usual in hot tea; hence the tea should be strained as soon as removed from the fire.

COCAINE IN THE PTYALISM OF PREGNANCY.

Carlson, in *The Clinique* says: A young and very fleshy woman who was pregnant for the first time suffered extremely and became rapidly emaciated. She had the worst form of ptyalism with incessant running from the mouth, obliging her to have a spittoon by her bed or couch all the time. She also had a very distressing nausea, but with little vomiting. She was highly scrofulous, and had formerly had some eruption about the anus, under the arms, on the eyelids,

and on the neck, for which she had received treatment from a physician previous to her marriage. Beside the usual treatment I tried the effect of local cauterization of the uterine cervix with carbolic acid, which old expedient has benefited some of my cases very decidedly, but it did nothing for her. I then gave three hypodermics of five drops each of the five per cent. solution of cocaine at intervals of three days, keeping her quietly in bed meanwhile. The relief was direct and complete, and, although still very weak, she got up and went about without any further trouble. She was safely delivered of a nice boy on the 16th day of July.—*Times and Register*.

A REMEDY FOR TENDER FEET.

A remedy for tender feet is cold water—about two quarts, two tablespoonfuls of ammonia, one tablespoonful of bay rum. Sit with the feet emersed for ten minutes, gently throwing the water over the limbs upward to the knee. Then rub dry with a crash towel, and all the tired feeling is gone. This is good for a sponge bath also.

PHENACETINE IN TYPHOID FEVER.

I have just discharged my third case of typhoid fever with phenacetine treatment. Duration of each case, twenty-one days. All the drugs used was an opening dose of calomel, and then gave phenacetine, 3 grains, and sulphate of quinine, $\frac{1}{2}$ grain, every four hours, to a boy eleven years old. The skin was moist throughout. To adults I give 8 grains of phenacetine, with 1 grain of quinine. It kept the temperature below 101° eight hours.—W. S. Cline, *Medical World*.

FOR IRRITABLE BLADDER.

Dr. W. P. Chunn writes to the *Maryland Medical Journal* that the following prescription has been found to allay incessant desire to urinate, and irritable bladder when due to phosphatic deposits in the urine:

R. Acidi benzoici, ʒ ij.
Sodii boratis, ʒ ij.
Aque, f ʒ xij.

℞. Sig. Tablespoonful three times a day.

This mixture has upon two occasions acted so efficiently in what was thought to be cystitis that cystotomy was dispensed with.—*N. E. Medical Monthly*.

NITRATE OF COCAINE IN THE TREATMENT OF URETHRAL DISEASES.

Lavaux thinks that the nitrate of cocaine should replace the hydrochlorate as a urethral anæsthetic, previous to the application of nitrate of silver. The nitrate may be prepared by pouring a solution of the hydrochlorate into a solution of nitrate silver. An absolute precipitate of chloride of silver falls, and nitrate of cocaine remains in solution.

SOCIETY PROCEEDINGS.

Allegheny County Medical Society.

Special Meeting, August 19, 1890.

W. S. FOSTER, M.D., PRESIDENT IN THE CHAIR.

EXHIBITION OF SOME URETHRAL INSTRUMENTS.

DR. STEWART: The first instrument is the urethragraph. A year ago last July I exhibited my first urethragraph. I have made a number of changes. This instrument is for the purpose of recording a diagram of the urethra, giving the exact circumference at every point. The next instrument I will show you resembles the first one. It is almost the same in principle. It is for a different purpose; it is a combined urethrameter and urethratome, so made that it will either measure the urethra or cut a stricture. This instrument is inserted into the urethra as far as you may desire, usually to the bulbous portion. If you desire to cut a stricture, you first ascertain the size of the healthy portion of the urethra, the part you do not wish to cut, then permit the blades to open to the size you desire to cut. Having done this, fasten the screw on the upper surface and withdraw the instrument. The third instrument is the urethroscope, the fourth an urethral syringe.

DR. THOMAS: I have had no experience with the doctor's instruments. I did have a little experience in the doctor's presence with his first urethragraph. At the time it was not perfected, so that my experience will not serve in my remarks at present. The principle of the instrument is doubtless correct. I have been using the urethrameter of Professor Otis, which I have considered the best in the market. The difficulty I found was this: that you had to cover the instrument with a gum tube, the gum tube always giving more or less resistance. After passing the urethrameter down as far as it would go to the bulbous portion, and then opening its arms to the full calibre of the urethra, then in withdrawing it when you would come to a stricture, of course the instrument would cease. Then in order to pass through the stricture, you had to reduce the calibre until it would cut through the stricture, but in bringing it through the stricture you could not tell where the stricture ended. You might pull your instrument anterior to the stricture. Now, that is the trouble with the Otis urethrameter. In the doctor's urethrameter, if the spring has the proper sensibility to come and go with the inequalities of the urethra, then it is a typical instrument. But the question is to me whether you can get a spring sufficiently graduated to come and go as you withdraw the instrument.

DR. STEWART: As Dr. Thomas has suggested,

the spring in the instrument we used together was weak; this has been remedied.

DR. WERDER reported:

FIVE LAPAROTOMIES.

Case 1. Intra-ligamentous Cyst.—Aged 22 years; epileptic; typhoid fever in October last, followed by bad health. Noticed a tumor growing since, reaching from one to one and one-half inches above the umbilicus down into the vagina, bulging out Douglas' *cul-de-sac* and pushing down the anterior wall of the rectum, in fact almost completely filling out the pelvic cavity. The tumor was immovable, fluctuating and distinctly pulsating both over the abdomen and in the vagina, suggesting the possibility of an aneurism. Exploratory laparotomy, March 29, exposed an intra-ligamentous cyst, which had to be peeled out of its capsule. It was a tedious and difficult task. Drainage. Patient made an excellent recovery, without rise of temperature and notable increase of pulse-rate. Had an epileptic attack immediately after operation, then none for a week, though previous to operation she had a number of them every day. After first week they returned at intervals of several days.

Case 2. Pyosalpynx.—Miss M. D., 26 years of age, had poor health for several years; about a year ago she was obliged to go to bed, when an abscess ruptured into her rectum, which continued to discharge for several months. After the discharge had ceased, her health improved and she gained flesh, but six weeks later she experienced great pain in her right side, and when she entered the Mercy Hospital another abscess had ruptured into the vagina. She was extremely emaciated and anæmic. Laparotomy performed April 6. The anæsthetic used was the "mixture." Immediately after opening the peritoneal cavity she became asphyxiated. Respiration and pulse were arrested for fully five minutes; artificial respiration was performed, head and chest lowered, and hypodermics of whisky administered. Probably ten to fifteen minutes passed until the respiration and pulse became normal and the operation could be continued. On introducing my hand into the pelvis, I found one large mass from which neither uterus, ovaries or tubes could be distinguished. After a great deal of trouble I succeeded in freeing the right tube and ovary from their adhesions; both contained pus-cavities. The left tube was also removed with the greatest difficulty; its ovary, however, could not be found. A drainage tube was inserted. Twenty-six hours after the operation a fecal odor was detected in the discharge from the drainage tube. The following day she commenced to discharge fecal matter in large quantities, and from now on most of her feces passed through the tube and on the sides of it, continuing to do so for a week. The wound was kept clean by enemata, which were

immediately returned through the fistulous opening. During this time her appetite was poor, and vomiting very frequent, so that she became exceedingly weak. The fistula gradually closed up, so that at the time of her discharge from the hospital, there was only (sometimes at intervals of several days) a slight discharge of flatus. The occurrence of this fæcal fistula can easily be explained by the fact that the left tube distended with pus had become adherent to the rectum and discharged its contents through the latter. In separating this tube from its old adhesions to the rectum, the old rectal fistula of necessity was reopened, and as a consequence, by virtue of the life-saving drainage tube, the fæcal matter found its way through the external wound.

Case 3. Pyosalpinx.—Mrs. A., three years married, aged 30 years, had one child at eight months, and was never in good health since. Had three attacks of pelvic peritonitis since; with the last one she was brought into the Mercy Hospital. A very tender mass could be felt on both sides of her uterus, which was diagnosed as a double pyosalpinx. Laparotomy, April 29. Tubes and ovaries on both sides very firmly bound down to the pelvic floor and adherent to loops of intestines. They were brought up with considerable difficulty and tied off. Ovaries on both sides were firmly attached to their corresponding tubes, each ovary and tube forming one abscess-sac. Drainage. Patient rallied badly from the operation, and vomited incessantly. She had taken ether very badly, a very large quantity being needed to keep her relaxed. The incessant vomiting was therefore attributed to the ether. It kept up for forty-eight hours; for thirty hours her pulse was about 160 and very feeble; had Cheyne-Stokes respiration and an ashy color about her face. She was fed and stimulated freely by rectum, and forty-eight hours after operation she was much improved, her convalescence being then uninterrupted by elevation of temperature and with a good pulse; appetite was good, and she was sitting up in bed, when on the evening of the twelfth day a sudden change came over her; she complained of pain about the chest and of loss of appetite. Had shown symptoms of hysteria a day or two previous to this. I examined her carefully; her pulse was 100; temperature perfectly normal; abdomen flat without the slightest tenderness. She rested well during the early part of the night, but towards morning she became very restless, and died suddenly at 6 A.M. on the thirteenth day after the operation. A *post-mortem* examination could not be obtained. Her death was entirely unexpected and its cause very obscure, though I have reasons to suspect pulmonary embolism.

Case 4. Solid Tumor of Right Ovary and Ascites.—Mrs. S., æt. 45, no children, consulted me

about an abdominal tumor, situated on right side of uterus, hard, irregular, freely movable, and reaching midway between the anterior superior spinous process of the ilium and the umbilicus. Lately she had suffered so much pain, that she had to be kept under the influence of opiates constantly. The diagnosis was either solid tumor of right ovary or subperitoneal fibroid of uterus with long pedicle. Laparotomy, May 6. On opening abdomen a considerable quantity of ascitic fluid escaped. The operation was extremely simple, as there were no adhesions whatsoever. Patient made an uninterrupted recovery, the temperature never being above normal. The tumor, of the size of a large cocoa-nut, had become partly cystic and appears to be a fibroid of the right ovary.

Case 5. Abscess of Left Ovary.—Miss Annie C., æt. 24, has been in bad health for over a year. I was called to see her about a year ago, and found a large mass to the left of her uterus, not very tender to the touch, and fluctuating. She was greatly reduced in flesh and very weak. Under treatment her general condition improved, but her local trouble remained the same, though local treatment was conscientiously employed for four months. I then advised laparotomy following my diagnosis of left pyosalpinx, but the operation was refused. She then placed herself under the care of another physician. Two or three months later, while going to her physician's office, on getting off the street car, an abscess ruptured through her vagina, and this was followed by a severe attack of pelvic peritonitis. At this time I was again called in, and found the mass on her left side considerably larger and exceedingly tender. She was now very anxious to have the operation performed. Laparotomy, June 16. Removed a large ovarian abscess containing about a pint of pus. The sac was adherent to the omentum, intestines, anterior surface of bladder, and had to be peeled out; on doing this, the tube, firmly attached to it and to the pelvic floor, was broken off; the remaining portion was then brought up with great difficulty. The ovary was one large abscess cavity, and the tube also contained pus. The right tube and ovary were, contrary to the usual rule, not removed, as the patient's condition was such as to make it dangerous to perform a second operation on her, especially as they seemed perfectly healthy. In breaking up the adhesions around the abscess-sac I accidentally ruptured it, and the pus poured freely into the abdominal cavity. This was thoroughly and repeatedly washed out with hot water and a drainage tube introduced. Her recovery was uninterrupted, the temperature and pulse remaining perfectly normal, except on the day after the operation, when the temperature rose to 100°. She is now in perfect health and has gained much in flesh.

DR. MACFARLANE: It is gratifying to see so many patients relieved of tumors who do well. I

do not say that it occurs in the hands of all operators, but very frequently the patient is left in a condition nearly as bad as that in which she was prior to the operation, the only effect being to prolong life for a time.

DR. WERDER: I will simply state that it is very unfortunate when the patient is left in the condition spoken of by Dr. MacFarlane. It is very important, in performing a laparotomy, not to make your abdominal incision larger than is necessary. A small incision only is needed, not more than 3 inches. Now, if this is united very carefully, and the stitches put in at proper intervals, I think herniæ will not occur very often, though they cannot always be prevented. In regard to fistulæ, those are things that will often occur from septic ligatures. If you have not your ligatures absolutely aseptic, it is very likely that a fistula will follow, but with perfectly aseptic material, it should be a very rare occurrence to have a fistula.

CASE OF TYPHOID FEVER.

DR. KEARNS: A boy twelve years old, in the third week, ceased to speak even in monosyllables, and this condition continued for about ten days. During this time there was no apparent impairment of intellect. Sitting at the bedside of the patient and telling him to put out his tongue, he did it instantly. Telling him to look toward me that I might examine his eyes, he did it instantly. The pupils of his eyes were markedly dilated. Then, at the expiration of these ten days, the case assumed the very opposite condition and became loquacious; he would take up any conversation which occurred in the room and follow it up repeatedly. This condition continued day and night with some short intervals of rest for ten days, when it gradually stopped. The pulse was accelerated during this period of excitation. It was at a normal stage during the period of quietude. All this time the stomach had been in good condition. Now here are two extremes. What condition of the brain and nervous system is involved in these conditions of two extremes in the same patient and the same disease? This cerebral excitation was very difficult to control. The simple remedy which appeared to have the desired effect was calomel. I administered a grain $\frac{1}{4}$ of calomel every two hours, then when the bowels began to run off, in smaller doses. To me this was a very interesting case, and I ascribe the nervous symptoms to a complicating meningitis.

DR. THOMAS: During the month of April, I saw a patient with typhoid fever. The boy was thirteen years old. He had been sick about a week. The fever ran an ordinary course. About the twenty-first day there was defervescence, and I presumed the case was going on the convalescence. I visited the boy as long as I remained in the city, and in the meantime he would not

speak a word until the day before I went away, I got him to say one word. I did not feel uneasy about him, his temperature not being above normal. He went into the hands of Dr. McNeil. On my return I found the boy all right, and was told that in speaking to his grandmother, in whose care he was, upon his beginning to talk again, the first word he said was "cracker." He said: "Cracker, cracker, cracker," for three or four minutes; then he ceased calling for crackers. I looked upon it as caused by anæmia of the brain.

DR. STEWART: I remember a case where a man lost the power of the right arm. The loss was progressive, and then he had convulsions. The convulsions were in the arm affected. Subsequently they became general and he would become unconscious. The convulsions became very frequent, several times a day. An operation was performed under the supposition of lesion in that area. The man had had syphilis. Iodide of potassium had no effect on the case. The brain was uncovered and only a localized meningitis was found. Incisions were made into the brain and nothing was found. The man ultimately recovered the use of his arm and had no more convulsions.

DR. MCKENNAN: I find that it is not at all uncommon to have peculiar mental states following typhoid fever; mental weakness and also very frequently mental exhilaration. I have seen many cases of insanity which have been traced to typhoid fever. I have never seen a case of meningitis in a child with typhoid fever. The whole weight of authority goes toward the supposition that the lesion is purely of a functional character and that there is rarely any structural lesion, although some authorities state the possibility that there may be embolism which could only involve one artery.

DR. LANGE: No matter what cerebral symptoms we may have in typhoid fever, there is no justification for the assumption of meningitis. No matter how violent or how peculiar are the cerebral symptoms, the assumption of meningitis is not correct, is not justified. I do not know that typhoid fever and meningitis are incompatible, but I mean to say that *post-mortem* examinations in cases of typhoid fever which presented most violent and most strange ataxic symptoms have so invariably proven the absence of meningitis and of all inflammation, that such symptoms cannot be correctly assigned to meningitis or to any structural lesion, but are to be considered only as the toxic effects of the typhoid fever poison. Neither can I understand how the speech center can be affected by a meningitis without previous and greater injury to the motor areas, which being in closer opposition to the meninges than the centre of speech, would primarily, and to a greater extent, be subjected to meningeal pressure.

DOMESTIC CORRESPONDENCE.

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

Summer Homes and Hospitals for the Poor—What the St. John's Guild is Doing to Help the Movement—The Children's Aid Society—Health Resorts in New York State—Miscellaneous Gleanings.

The movement for enabling the poor of the city to enjoy the benefits of fresh air in the summer, which was inaugurated less than twenty years ago, has now extended to enormous proportions and ramified in many directions. Originally started to relieve the children in the crowded tenement districts during the heated term—by day excursions—it has been extended by the establishment of a large number of summer homes and hospitals, at the seaside and in the country, which are fitted up with the best sanitary appointments, and where the children, both sick and well, are often kept for weeks at a time. Besides this, many children are annually cared for in the country, free of expense, by farmers and others who take them into their homes, and the fresh air fund work has further been extended by various churches and societies; so that, while a vast number are thus reached through charity, summer resorts have also been provided where those of moderate means, especially young working girls and women of refined tastes, may secure a summer outing at a very low cost.

For many years one of the most prominent organizations in this fresh air work has been the St. John's Guild, to which Dr. Charles A. Leale, Dr. William Thurman and others have unselfishly devoted much time and thoughtful attention. The Guild owns a large seaside hospital at New Dorp, Staten Island, and a floating hospital which makes salt water excursions, loaded with women and children four times a week during the summer season. Free admittance to these excursions is given to poor sick children and their mothers, the tickets for which can be had at all the dispensaries and from the physicians of the summer corps of the Board of Health. A warm dinner is served on board, and there is an abundant supply of fresh milk for the children. Besides, free baths are furnished to as many children as can be accommodated in the bathing department. Of course, no cases of contagious disease are admitted, and a physician is always at the dock to examine each child that is brought to the boat. The less serious cases stay on the upper deck. The more serious ones are kept on the lower deck, and they have the privilege of going to the seaside hospital for such a length of time as the circumstances of each require.

When the floating hospital reaches the lower bay, it is moored amidstream opposite the seaside

hospital, and the number of flags displayed on the flagstaff of the latter indicates to those on board how many vacant beds there are and how many women and children can be accommodated. The seaside hospital has two pavilions, with a central executive building, and the wards extend the entire length of the pavilions. A staff of two physicians and three trained nurses are in constant attendance. A pleasant beach is near the hospital, and the patients have the benefit of sea bathing, as well as sea air.

Last year 30,057 sick children and mothers were carried on the floating hospital on free fresh air excursions. Thirty-three trips were made from July 9 to September 6, 2,056 salt water baths were given on board under medical supervision, and the cost *per diem* for maintenance of the hospital was 21¼ cents *per capita*. Each trip of the barge involves an aggregate cost of about \$250, and the trips are made alternately from the east and the west sides of the city. At the seaside hospital 1,013 sick children and 500 weary or invalid mothers were admitted to the wards, and after being well fed and cared for for a suitable period, were generally returned to their homes with restored health and vigor. In twenty-three years St. John's Guild has sent out 398,915 children and mothers on its excursions.

A very large work in this guild is done by the Children's Aid Society, which conducts a Health Home at West Coney Island, and a Summer Home at Bath, Long Island. The Health Home has pleasant cottages and dormitories for the reception of mothers with children under five years of age, where a week's stay is allowed. Each week a party of from 60 to 100 mothers and sick infants are taken to the Home, and last week there were cared for at it 1,838 children and 1,048 mothers for a week, and 2,955 women and children who remained for from one to three days. The Summer Home at Bath was bought several years ago by Mr. A. B. Stone, for \$20,000. Each week during the summer parties of from 250 to 300 little children from the tenement districts are taken down there to enjoy its rest, comforts and pleasures. There are also day picnics from time to time at this Home.

The subject of fresh air is suggestive of health resorts in general, and New York State is especially fortunate in having within its borders, and readily accessible from the large cities, so admirable a mountain sanitarium as the Adirondack Forest region. No one has done so much to call public attention to the peculiar virtues of the Adirondacks from this point of view as Dr. Alfred L. Loomis, who a number of years ago was himself cured of serious pulmonary disease by a residence of some months among them. Within the last few years it has been conclusively demonstrated that many persons in the incipient stage of phthisis, for whom medical science could

do very little elsewhere, might, by a longer or shorter sojourn in that region, pretty certainly have the progress of the disease checked, and in a considerable percentage of cases be entirely restored to health. The Adirondacks are accordingly now recognized by the profession and the public in general as possessing curative properties for consumptives to be found in but few other places in the world. In the United States a portion of Colorado and the mountain region of Asheville, North Carolina, are apparently the only ones having such properties in anything like so high a degree.

The chief of these is fresh air, and the character of the Adirondack region seems admirably adapted to secure this. It contains a vast elevated plateau with rolling surface, which secures perfect drainage and freedom from miasmatic poison. The soil over a large portion of the country is light and sandy, and, by quickly absorbing excessive moisture, helps to secure a dry atmosphere. There are many miles of unbroken forest, largely of pine, balsam and other evergreen trees, from which the air comes not only purified, but laden with resinous aromas which are themselves powerfully disinfectant and antiseptic. The results of these and other favorable conditions have been found by actual test to be so satisfactory that a constantly increasing multitude of invalids now resort thither, while a considerable number of individuals, finding that they cannot enjoy health elsewhere, have made this region their permanent home. Rigorous as is the climate in winter, it has been found that with the clear, dry, bracing air of the cold months, the advantage to consumptives of residence there are even greater at that season than in the summer.

Many of the general considerations that influence the minds of those seeking a health resort appear to favor the Adirondacks. A change in air and surroundings is often deemed necessary, and almost any change that is not decidedly for the worse is apt to prove advantageous to the debilitated. A change merely for the sake of change is thoroughly defensible; but the Adirondacks fortunately afford not only a change from the ordinary life in the city and country, but a decided change for the better. There are new scenes, new surroundings, and new, pure air, with a perfectly healthful general environment. As compared with a city life, there is quiet instead of noise, and leisure instead of hurry and bustle. All cause for the high nervous tension maintained in the teeming centres of business disappear; so that the visitor drops out of one kind of world and finds himself in another of an entirely different sort. There is complete change and a chance for complete rest. But rest is not always found in idleness, and the surroundings met with do much to furnish means of occupation and recreation. There is the most picturesque scenery

with exquisite walks and exhilarating mountain climbing. Beautiful lakes and streams abound for boating, and in the winter one has plenty of sleighing and skating. For those inclined to sports there are hunting and fishing, with abundance of game and fish in their season. Finally, there is camping, which is such a prominent feature of Adirondack life, and is universally recognized as most efficacious in the renovation of worn-out humanity. Consumption, being peculiarly a disease of civilization, is nourished by bad air and over-work amid insalubrious conditions, and a recurrence under favoring conditions to some of the features of aboriginal life, therefore, appears to be often the best possible treatment for it. But if the Adirondacks are unequalled as a health resort for actual invalids, they are also equally valuable to those who need not to be cured, but only invigorated or carried over a hot month.

The most noted health resort in the Adirondacks is the village of Saranac Lake, which is rapidly growing in importance and in popular favor, and for the past two years has been the terminus of the Chateaugay Railway, which affords as yet the only means of reaching the heart of the Adirondack region by rail. It is beautifully located amidst the most charming scenery, and its situation and the hygienic conditions existing there are believed to be especially favorable. It has a large population in the winter as well as the summer, and, in addition to numerous boarding-houses and private cottages, a large, first-class hotel, fitted up with all the modern luxuries, is now kept open all the year round. The fact that so many persons with pulmonary trouble are here seeking relief has caused them to be recognized as a distinct class. In the slang of the town they are known as "lungers," but as it is upon the money which they spend that the prosperity of the place in a great measure depends, they are naturally treated with the utmost respect.

An institution at Saranac which is accomplishing much good and is meeting with constantly increasing appreciation and encouragement, is the sanitarium for consumptives founded a few years ago by Dr. Edward L. Trudeau, formerly of New York, who, in consequence of suffering from phthisis himself, removed to the Adirondacks. Having become permanently cured, he has since continued to reside there, and, being an ardent student of the pathology and treatment of the disease, he has devoted himself largely to original research, and from time to time has added contributions of substantial value to our knowledge of this subject. With very limited financial means at his command, he commenced the work of the sanitarium in a very small way, and for a time it had a hard struggle for existence. He lost no opportunity, however, in interesting people with whom he came in contact in the institution, and

gifts began to come in. The contributions from well-to-do visitors to the Adirondacks now amount to a good many thousand dollars, and several separate cottages have been built, each by the gift of a single individual. Two such cottages are now in course of erection; one of them being given by the wife of Dr. Loomis. Mrs. A. P. Stokes, of New York, has also proved a generous friend to the sanitarium, and a pavilion is now in process of erection at her expense which is to be especially devoted to the recreation of the inmates, being fitted up with billiard tables, and other appliances for amusement, and provided with ample piazzas, which can be inclosed with glass in cold or stormy weather. The various contributions have not only increased the capacity of the sanitarium, but have also provided free beds for those unable to pay the regular charge of \$5 a week. The generous spirit shown of late has made it pretty certain that the sanitarium will be permanent, and in fact, the hope is now entertained that an endowment fund large enough to pay the necessary expenses will soon be secured.

The institution has never paid but one salary, and that is to the matron, who acts as general superintendent. Until the past year it has not had a resident physician. For a considerable time Dr. Trudeau was the only attending physician, but more recently he has been efficiently aided in this work by Dr. C. F. Wicker. The sanitarium now has about fifty inmates, and it is not only full, but has a list of names on hand of applicants who desire to enter as soon as there is room for them. As it was established "for the cure of pulmonary diseases," and to aid those of insufficient means, admissions are naturally restricted as far as possible to hopeful cases and to persons unable to pay all their own expenses. The history of most cases of consumption, it is believed, shows that there is a time when restoration to health might take place if the patient could for a while give up his occupation and care, and obtain a change of climate and surroundings. It is, accordingly, the intention to restrict admissions to persons in the incipient stage of phthisis; but such intention is not easily carried out, and certain cases of a different character are sometimes admitted. Some of the results met with in the institution may be judged from the following extract of the last annual report:

"From February 1 to November 1, 96 patients have been treated. Of these, 1 died in the institution, 11 continued to lose ground and returned to their homes, 17 have temporarily improved, while in 17 the disease was arrested, and they were sufficiently restored to resume their occupations, and 8 have been cured. The remaining 42 are still under treatment."

One of the chief features of the treatment is, of course, the keeping of the patients in the open air, and making sure that they shall have per-

fectly pure air when indoors. To this end the ventilation of the cottages is carried to the utmost degree of completeness. Patients are required to be outdoors several hours every day, winter and summer, and opportunities are afforded for riding, as well as for walking and other exercise. The sanitarium is picturesquely situated on a hillside overlooking the Saranac River, and having an elevation of 2,000 feet above sea level, the air is dry nearly all the time. It is said that not more than four or five times a year is any deposit of moisture found on the cottage piazzas in the morning. The cottages, which are tastefully constructed, are all small; accommodating only from two to five persons each.

The great natural advantages which the Adirondacks afford as a health resort and breathing-place for the people, which are now becoming so generally appreciated, render it imperative that they should be supplemented by all that art can do to make them permanent and accessible. Already the vandalism of lumbermen, charcoal burners, and railroad projectors has laid waste vast districts of noble forest; and not only should these forests be preserved, but every step taken toward opening roads and settlements should be under capable supervision. The best intelligence and skill that the State can command should certainly be employed to make this great natural State park a park indeed, the attractiveness and usefulness of which should be increased, rather than diminished, as time goes on.

The last monthly bulletin of the State Board of Health announces that 11,083 deaths were reported in the State during the month of July. According to the bulletin, July has uniformly the largest death-rate of any month in the year. The average number of reported deaths per month for the past five years has been 7,866, while that of July has been 10,252. The infant mortality is also highest in July, more than half of the deaths being of children under 5 years of age, the average of the rest of the year being about one-third. For July of this year the infant mortality is a little below the average, but is much higher than in June. Of the total number of deaths, 4,254 occurred in New York City, and 2,219 in Brooklyn. The deaths under 5 years were 2,609 in the former, and 1,384 in the latter.

A Chinese laundryman, of Hoboken, having consulted a physician of his own nationality for some abdominal trouble, the exact nature of which is not now of importance, was informed that it would be necessary for him to undergo an operation by a "Melican doctor." Under these circumstances the patient considered life no longer worth living, and, rather than submit to the surgical procedure, he made his will, set his house in order, and quietly threw himself into the Hudson River, whence his body was fished out a few days afterward.

MISCELLANY.

HEALTH IN MICHIGAN.—For the month of August, 1890, compared with the preceding month, the reports indicate that dysentery, typho-malarial fever, typhoid fever, cholera infantum, and cholera morbus, increased, and measles, puerperal fever, whooping-cough, and cerebro-spinal meningitis decreased in prevalence.

Compared with the preceding month the temperature was lower, the absolute humidity was less, the relative humidity was slightly more, the day ozone and the night ozone were less.

Compared with the average for the month of August, in the four years 1886-1889, scarlet fever and influenza were more prevalent, and puerperal fever, whooping-cough, typho-malarial fever, erysipelas and cerebro-spinal meningitis were less prevalent in August, 1890.

For the month of August, 1890, compared with the average of corresponding months in the four years 1886-1889, the temperature was lower, the absolute humidity was less, the relative humidity was about the same, the day ozone was slightly less and the night ozone was slightly more.

Including reports by regular observers and others, diphtheria was reported present in Michigan, in the month of August, 1890, at 49 places, scarlet fever at 48 places, typhoid fever at 61 places, and measles at 24 places.

Reports from all sources show diphtheria reported at 1 place less, scarlet fever at 7 places less, typhoid fever at 32 places more, and measles at 48 places less in the month of August, 1890, than in the preceding month.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from September 4, 1890, to September 12, 1890.

By direction of the Acting Secretary of War, First Lieut. Nathan S. Jarvis, Asst. Surgeon, is relieved from duty at Ft. Verde, Ariz. Ter., and will report in person to the commanding officer, San Carlos, Ariz., for duty at that station. Par. 4, S. O. 208, A. G. O., Washington, September 5, 1890.
Major A. A. Woodhull, Surgeon, is granted leave of absence for one month, on surgeon's certificate of disability, with permission to go beyond the limits of the department. Par. 1, S. O. 122, Hdqrs. Dept. of the Missouri, St. Louis, Mo., September 5, 1890.
First Lieut. Leonard Wood, Asst. Surgeon, is hereby granted leave of absence for one month, to take effect on or about October 20, 1890, with permission to apply for an extension of one month. Par. 1, S. O. 74, Dept. of California, San Francisco, Cal., August 30, 1890.
Capt. Edward C. Cutter, Asst. Surgeon U. S. A., is granted leave of absence for one month. Par. 2, S. O. 108, Hdqrs. Dept. of the Columbia, September 6, 1890.

Official List of Changes in the Medical Corps of the U. S. Navy for the Week Ending September 13, 1890.

Medical Director Theoron Woolverton, ordered to U. S. S. "Philadelphia" September 15.
Medical Inspector Thomas N. Penrose, detached from the U. S. S. "Richmond."
P. A. Surgeon J. E. Gardner, detached from the U. S. F. C. Str. "Albatross."
P. A. Surgeon N. H. Drake, detached from the U. S. C. S. Str. "McArthur," and to the U. S. F. C. Str. "Albatross."
P. A. Surgeon T. A. Berryhill, detached from the hospital, Mare Island, Cal., and to the U. S. C. S. Str. "McArthur."
P. A. Surgeon A. C. Heffinger, ordered before Retiring Board October 1, 1890.

Official List of Changes of Stations and Duties of Medical Officers of the U. S. Marine-Hospital Service, for the Three Weeks Ending September 6, 1890.

Surgeon John Vasant, granted leave of absence for thirty days, to take effect upon return of Asst. Surgeon J. C. Perry to duty. September 5, 1890.
Surgeon Walter Wyman, to proceed to Cape Charles Quarantine Station, on special duty. August 25, 1890.
Surgeon Geo. W. Stoner, granted leave of absence for four days. August 19, 1890.
P. A. Surgeon D. A. Carmichael, leave of absence extended fifteen days. August 26, 1890.
P. A. Surgeon R. P. M. Ames, to proceed to Memphis, Tenn., on temporary duty.
P. A. Surgeon S. C. Devan, leave extended five days on account of sickness. August 12, 1890.
P. A. Surgeon L. I. Williams, granted leave of absence for thirty days. September 5, 1890.
Asst. Surgeon H. F. Goodwin, granted leave of absence for thirty days. August 21, 1890.
Asst. Surgeon J. O. Cobb, to proceed to Marine-Hospital, Detroit, Mich., for duty. August 16, 1890.
Asst. Surgeon S. H. Hussey, granted leave of absence for thirty days. August 19, 1890.
Asst. Surgeon J. C. Perry, granted leave of absence for twenty days, to take effect when relieved. September 3, 1890.
Asst. Surgeon G. B. Young, to rejoin his station at St. Louis, Mo., when relieved. September 3, 1890.

APPOINTMENT.

Asst. Surgeon Milton J. Rosenau, commissioned as an Asst. Surgeon by the President, August 25, 1890. Ordered to Chicago, Ill., for temporary duty. August 27, 1890.

ADDRESSES.

THE CARE AND TREATMENT OF THE
INSANE IN THIS AND OTHER
COUNTRIES.

Being the President's Address, delivered before the Ohio State Medical Society, June, 1890.

BY JOHN CURDY, M.D.,
OF YOUNGSTOWN, O.

The manifestations of a diseased brain have always made a deep impression upon the sane, and those impressions have called forth the most contradictory impulses.

We find that mental culture or scholastic attainments alone have never done anything for the protection, comfort and cure of this class. The treatment received at their hand has been so unjust, oppressive, tyrannical and so often brutal as to shock the coarsest natures of to-day. We find no record where the man whose head only has been educated ever lifted a sorrow or a burden from their breaking backs, or extended the hand of protection, encouragement or consolation to this helpless class.

Looking far back to the point where history and legend inseparably blend we find mental culture and ripe scholarship for the times, but no help for the insane save where it was blended with the devotional, the spiritual and the worship of the Divine or the Divinities.

Only when the religious and reverent instinct, the cultivation of the heart, the affections and the sympathies were developed do we find the insane cared for and comforted. While Egypt, from one hoary century to another, was the seat of so-called culture her insane were unpitied outcasts, the persecuted and the reviled, as possessed of devils or any demoniacal spirits the jeering and brutal populace saw fit to inhabit them with. Only when the devout worshipers of the Gods met in the temples did the insane find rest, or find those who had a rational conception of their actual condition. The same is true of Greece, with all her pure, classical tastes. Only in the temples of Asclepia, a priestly craft educated as physicians and taken an oath to keep sacredly the mysteries of medicine, and who claimed to be descendents of the god Æsculapius, were they ad-

mitted and treated swiftly and agreeably as was the order of their great founder.

The first asylum built for the insane was by monks of Jerusalem, in the fifth century, and also in Spain the first efforts to establish their treatment on the basis of disease was by the monks of Saragossa. The first hospital ever established in England was by private subscription of philanthropic individuals, in 1751.

During the fierce conflict of brute force and ignorance, known as the "dark ages," the only place the demented got a shelter from the scourings and imprisonments was in the monasteries and the homes of the worshipers.

Truly the coarseness and asceticism of the times entered into these havens, but forbidding as they were they held about all the comfort, sympathy and love to be found. It cannot be pleaded that places for the relief and care of the sick and wounded were not known in the early ages, for we cannot go back to the time when hospitals for lepers did not exist, and when brotherhoods and sisterhoods who vowed to devote their lives to works of charity and mercy, for wounded and sick did not exist. Even the mighty hospital "Hotel Dieu," of Paris, was established in the seventh century. Coming now down to the times when our present forms of government were put in practice we see the politician cared no more for his insane brother than the barbarian of former ages.

In Ireland, that land so full of helplessness and infirmities, the record is that it was modern society that compelled their statesmen to provide hospitals for the insane. The Irish practice had been to tie ropes around their arms and fasten them to carts and compel them to walk the whole distance to the asylums; and so great was the resistance and savagely secure the tying that one arm in five had to be amputated from the mutilation that resulted, and when they reached these places all who could pay were compelled to do so. The testimony before a commission of inquiry was as follows: "One house contained twenty-three—fourteen men and nine women—chained to wooden boxes six by two and one-half feet. Once a week they were taken into the open air and the straw changed; and they were so dirty that a careful inspection was impossible. The

physician in charge said he treated them by bleeding them twice a year, gave a vomit once a week, and then purged them, and that had been the treatment for years before his time." It is with pride we refer to our young nation as giving birth to the practice of treating these afflicted ones as diseased—and put it into practice in Philadelphia in 1750. The first asylum that could be called curative was that established by the Friends, of England, for the insane of their own denomination—the famous York Retreat—the principal treatment being *moral over mechanical* methods. Again we find that comparatively small body of Friends, whose hearts are ever attuned to the spiritual and not literal lessons of the Revealed Will, were the first to buy fifty acres of land as early as 1817, near Philadelphia, and there established a retreat for this class, where they could feel they were not outcasts and abandoned, but yet friends and brothers.

The humane and cultivated people of old England waged a determined warfare for the rights of the insane, getting their first hospital built in 1547. In 1742 the legislature took some steps in their interest, but their struggles were against a forlorn hope and they generally suffered defeat, as the mad-houses provided were of the most revolting kind. Even down to within a few years—1842—an old jail was considered good enough for an insane asylum, and at the old Bedlam considerable money was made by the keepers exhibiting the unfortunate inmates as wild beasts chained and caged, and tormented by instruments thrust against and into their bodies by their keepers. Only fifty-two years ago, when Dr. Hill wished to treat the insane by kindness and the taking off of their shackles, the authority and opposition were so fierce he was compelled to resign. But to-day, behold the changes that have flashed like sheets of electricity over this same land. The wildest flights of Jules Verne scarcely equal the actual progress made. Now the entire bosom of this old mother of Christian civilization is beautified with the grandest homes for these unfortunates where love, kindness and affection is ever present. Every thought, impulse and plan that promises good are tried with eager earnestness, and Colony Hatch, Caterham, Hayward's Heath, Brookwood, Wakefield, Wadswell, Hanwell Asylum, Baunstead, Leavesden, Prestwick, Wittingham and Birmingham are grand monuments to the sanctified hearts and cultivated brains of the English people.

Whether the classes are rich, poor or medium, all are treated by the most thoroughly educated and progressive alienists. The rooms, halls, apartments of every kind are made home-like and even elegant by the hangings, pictures, curtains, books, furniture; everything betokens quiet repose, refined comfort. An alienist of our own State and member of this society, of whom we

are proud, Dr. Orpheus Evarts, says: "*Comfort means cure.*"

Truly to-day we can answer yes, when the question is asked, "Canst thou not minister to a mind diseased, pluck from the memory a rooted sorrow, raze out the written troubles of the brain, and by some sweet oblivious antidote cleanse the stuffed bosom of that perilous stuff that weighs upon the heart?"

In this favored land the patients are classified; the chronic, the harmless and the quiet are not disturbed by the frenzies of the maniacal or the threatened dangers of the violent. Everything in the shape of dungeons, bars, high walls and appliances for bodily restraint or either wholly removed or reduced to a minimum. The tastes of the occupants are carefully considered and fostered. Many are employed in farming, gardening, stock-raising, dairying and horticulture; while others do sewing, cooking, laundering, housework, etc., etc. Although land is held at exorbitant prices in England, yet so great is the zeal for the care and cure of this class that large tracts are purchased and in use by most of the asylums.

The early treatment of the insane in Scotland is but a repetition of England's, with, perhaps, a little deeper shading, their infirmities being considered evidence of possession by devils or witches, and some were publicly burned as witches as late as 1722. Centuries after this heroic little nation prided itself not only on its military prowess but its advanced so-called civilization, at Inverness the space between the arches of an old bridge was converted into a repulsive vault, used at first for a jail, then a mad-house. Into this place the insane were thrust one generation following another, as late as 1815, and was not abandoned until the last victim was devoured by rats.

In an uncertain and halting way some improvements were made for this class, but the shocking truth remains that until yesterday—1855—and not until America produced Miss Dix, that woman so full of Christian zeal and philanthropic impulses, who visited that land and pleaded with that people did they sweep forever from all their valleys and heather-covered mountains these haunts of cruelty. And this land is, in my opinion, to be carefully studied and imitated in its way of providing quiet, liberty and pleasant abodes for its old, feeble and harmless insane, as well as its boarding-out and probationary discharge system.

Scotland may well point to her asylums at Woodilee, Midlothian and Morningside with honest pride.

In Ireland's case the same holds good that the student of the spiritual and museen first opened his heart to the mentally dethroned, and their first ray of comfort reached them in the little St.

Patrick Hospital of Dublin, established by Dean Swift in 1745, which to-day is still a shelter and port of peace for this class.

The same neglect, cruelty and inhuman punishments inflicted in the countries named, as they were in Germany, France and Russia, were practiced in poor, badly-governed and restless Ireland. Therefore, nothing more will be said on this part of the subject.

The number of mentally diseased in Ireland is about one to three hundred and thirty-three, while in our country it is about one in six hundred and eighteen. The Irish heart is very impressible, and considering the misfortunes of this beautiful island, its poverty, famines and discontent, the migratory character of its people and never ending rebellion against its government, this class is well provided for. Its aims and plans are comprehensive and thoughtful, and its strivings are ever after the most humane and advanced methods known. Its medical officers and attendants take a prominent place for scientific and effective management. It has sixteen government hospitals and many private asylums, and it can well point with pride to its asylums at Cork, Belfast, Donegal and Dublin. All are full, and for many of its unfortunates the poorhouses are their only homes.

Great prominence and much praise have been given the plan pursued in Belgium as carried out in the Colony of Gheel. Here again we find the religious instinct is the foundation of this famous retreat. Its history is wrapped in legend. It covers a territory of about forty square miles. The legend is that the lovely daughter of one of Erin's kings in the seventh century became converted to Christianity, and being persecuted by her unnatural father, fled with her spiritual adviser, and they found a refuge where Gheel now stands. Her father pursued, found and murdered her and her adviser. It is believed this lovely maiden, now St. Dymphna, not only forgave her father, but believed him insane and greatly desired to alleviate madness in others. Pilgrims came and implored her intercession. Her tomb is sacredly guarded, elevated upon short pillars, that persons can pass under it upon their knees. Through these long centuries the weary feet and knees of pilgrims who have sought relief from their afflictions have worn the stone pavement very smooth. The long custom was when arrivals came for a priest to say mass and read prayers to them for nine days, and then in company with some children, to pass around and inside the church three times, and each time the tomb was reached they prostrated themselves and passed under it upon their knees. Should the new comers be too violent to do this some children were hired to do it for them.

There are about three thousand houses in this colony and about one-third of them are boarding

houses for the insane. All live in poor, or but middling cottages, and while moderate thrift is seen, an air of poverty is everywhere marked. About twelve thousand form this colony and about seventeen hundred are insane. A board of commissioners has control of all matters pertaining to the insane, and in addition to this there is a permanent committee which enforces all regulations. Universal unrestraint does not exist. All applicants for admission pass through a hospital and those unfitted for family life are refused admission. Although mechanical restraint is used, consisting of padded welts, waist-bands, padded rooms, etc., they are used as seldom as possible. Even in this vaunted home, through the long centuries of its existence up to 1803, its inmates suffered grievous wrongs from coarse and brutal officials, and so oppressive were they that Dr. Parigot, sent as inspector, reported that their treatment was, even more cruel than that of negroes he had seen in South America. Even up to a few years ago—in 1851—Dr. Pliney Earle says he saw in the streets of Gheel a man with his waist encircled with an iron belt, to which his hands were secured by wristlets, and in the suburbs and among the farms several were fettered with iron, the chains between the ankles being eight inches long, and in some cases the rings around the ankles had abraded the skin and occasioned bad ulcers. It was not until 1856 these abuses were removed by the appointment of Dr. Bulckens. Fourteen hundred of these people are paupers and divided into three classes, according as they can care for themselves, partly care for themselves, or cannot care for themselves, and the prices charged the communes that send them is, for the first \$1.09, for the second \$1.22, and for the third \$1.43 respectively per week. There about two hundred and thirty-eight private patients who pay from \$11.00 down to \$1.60 per week. The pauper class is compelled to work to partly pay for their keeping, and as the whole colony is low, flat and wet, with roads in bad weather almost impassable, and with stables, manure heaps, privies and cesspools in close connection to the abodes, with their floors of earth, the majority of these poor people is yet wretched. This colony does not receive all cases as do the asylums of this and other countries. With the many proofs of paucity to me the greatest is that of the medical staff. One physician with one assistant looks after each section, but does not give all his time as he has private practice. The rule is they visit each patient once a month, and troublesome cases whenever necessary; acute cases at least once a week; the register showed that ten weeks intervened between visits, and until within a few years ago—1879—the medical officer was only required to visit the patients three or four times yearly. There is also a medical director who makes a general visitation.

Beer is freely sold to all, and the only injunction is that they must not drink "too much," and the beer seller, who tries to make the most out of his business, is the one who determines the limit.

The American who visited this place was struck with the lack of bathing facilities, ventilation, pure water, and numerous other comforts, and the number of idiots among this population seemed large and out of proportion, and the liberty given certain classes of the insane, as the young women whose maladies assumed the erotic form, was far from being humane or safe, and the shocking exhibition of person seen daily upon the streets must have a demoralizing effect on the vast number of children who witness them, and, as might be expected, illegitimate births occur.

It is with eagerness and a sense of comfort we turn from this colony of so much squalor and poverty to that most delightful and cheerful home in Saxony, Alt Scherbitz. How changed everything. Scrupulous cleanliness, ample room, perfect sanitation, quiet, good food, flowers, lawns, with broad and fertile fields, with a large and admirable medical staff assisted by numerous and well-trained nurses, and an intelligent zeal to give each patient all the personal freedom his condition will allow. This grand hospital has nearly eight hundred acres of land attached. The inmates are classified and separated. Part, all, or none of the expenses are borne by the patients, as their condition permits. Upon each admission, after proper rest, the whole medical staff is summoned and each independently makes a diagnosis, and all are placed upon record. The dignity and worth of the medical officer is recognized by placing all things under his control, who administers the oaths to his subordinates, grants furloughs, etc., and in his own case after serving a certain time is retired and pensioned. Villas are located here and there over the whole estate for proper classes, and made home-like, and the occupants given possession in a way to secure their interest and care. Their laundry, scullery, dairying, stock raising and extensive farming are all aimed to be performed within themselves as a means of treatment of great value. Mental recreation united with bodily labor is the constant aim, and the records show that about 90 per cent. are on the employment roll. Excursions by the inmates are regularly made, and the expenses of those too poor to pay are borne by the asylum. In the Elster, which flows through the farm, extensive swimming baths are provided, while all that indicate restraint and confinement are removed.

The principal places for treating insane in France are La Salpêtrière, Paris, an immense almshouse which contains about sixty-five hundred people, of whom about six hundred are of unsound mind. It has seventy-four acres of land attached to it. The asylum of St. Anne is mod-

ern and contains nine hundred patients, and those only dependent and suffering from acute attacks are here treated. Clinical teaching is extensively conducted by the Paris faculty of medicine. Charenton is old, was founded in 1642, and was a monastery of the monks of St. Jean de Dieu, who first treated the insane. It holds six hundred and is self-supporting. Here, as at St. Anne, bathing, Turkish baths, douches and packs are largely used as a means of treatment. Clermont Endise is principally noted for carrying out successfully the colonization of the insane. It contains sixteen hundred who are separated into classes, and all are employed who can be induced to work. It has one thousand acres of land, thoroughly cultivated by the inmates, who raise not only all vegetables necessary, but are so successful in horse and cattle raising that many prizes are taken at exhibitions and fairs, which interests and stimulates the patients who rear and exhibit them. Coercion is forbidden, but rewards in money and dainty foods, etc., are given as inducements to labor, and six hours is a day's work. All are controlled by the distinguished alienist Dr. Gustave Labitte. Here, as in many other asylums in Europe, all sewage and offal are utilized.

From the preceding it will be seen the present treatment of the insane in England, Ireland and the Continent is kindness, comfort, physical and mental employment of the pleasiest varieties and adjusted to the tastes, with the greatest liberty and least restraint possible. How does the treatment in America compare with this? Let us see. The revolting history of Europe struggling up through all the grades of semi-savage and barbarous life we have none. Our pioneers came with the most advanced forms of Christian civilization then known and practiced; therefore, our insane were never subjected to dungeon and prison life. Yet they were far from being treated and cared for as to-day. Still we see the seeds of love and humanity germinated in their favor earlier than in any other spot on earth, for forty-two years before the sympathetic and learned Pinel begged and was allowed to unchain the fifty-three from the old Bicêtre Hospital in France, the Friends in Philadelphia gave him the precedent and taught him the lesson, and as Pinel was one of the best educated alienists of his day there is scarcely a shadow of a doubt he was familiar with this great fact. This was, in my opinion, the most remarkable stride from custom, experience and so-called science ever made in the interest of mercy, kindness and sympathy, and is confirmation of the thought before expressed that those only with cultivated spiritual perceptions, or strong natural veneration for the supernatural have ever made the most intelligent, strenuous and successful efforts, and showed the broadest and best judgment in the treatment of the mentally diseased.

From the origin of that sect founded by Geo. Fox to this hour, where is there a body of people so spiritual, so pure, so charitable in practice and so gentle and peace-loving as the Friends? All that is coarse and brutal have no place in their lives. War, slavery and oppression they fight to the death, while they as ardently cultivate peace and gentleness. Spiritual perceptions with them are the realities, and the grossness of literalism finds no place in their chart of life. How natural then that they should first put forth the hand that unlocked the doors and removed the shackles of their weak and benighted brothers, and lead them forth into the freedom and inspiration of God's blessed sunlight. Yes, while the youngest of the mighty nations, we are the oldest by nearly half a century in setting these captives free. In old England the first well authenticated account we have of a home for the insane on a basis of moral and gentle restraint over physical confinement is that of the York Retreat, founded by the Friends in 1792, which is still open both as a retreat and "mercy seat."

When we remember that we are in fact thirty-eight separate nations, each assuming absolute control and treating their mentally infirm as their intelligence and conscience guide them, it is with the keenest patriotic pride we witness such advanced philanthropy. The single aim of all these great commonwealths is to lift speedily the dark cloud of mental depression with strong but gentle hands. Therefore, everything that money and willing hands can secure is theirs: broad acres with lawns, flowers, walks, parks, farming, stock raising, dairying and every form of indoor work, to which are added libraries, music, pictures, beautiful hangings, attractive mottoes and soothing colors, and upon them are erected homes of every size and condition, from the massive and grand looking linear, compact structures designed by the late Dr. Kirkbride, to the two-story wood cottage. The bars are kept from the windows, doors unlocked, mechanical restraint, save in the rarest instances, forever hidden from sight. All the daily and best news and books with cheerfully lighted and seated reading and study rooms are theirs. Amusements, intellectual entertainments of a high order are lavishly provided, and all are treated with that gentle respect so vital as a remedial agent in mental derangements. Some of the States, as New York and Michigan, are dividing them into classes and acute cases kept by themselves, and no case is too chronic or desperate to be called incurable, or placed beyond the best medical skill. The strongest and most gratifying evidence we have of the cultivated tone of our country is seen in the hospital provided by the general government for the insane of our Army and Navy. Its buildings are upon four hundred acres and much more will be asked for and doubtless received and added to it. Lands

for farming, grazing, horticulture, floriculture, lawns, walks, and strolls are attached.

This valuable investment is under the superintendence of Dr. Goddard, an alienist whose written articles and opinions are known and valued by all intelligently informed on insanity. His earnest efforts have pushed this asylum to the forefront of modern treatment. Pleasant apartments for all and work on the farm for those who enjoy it, and also for those who can be induced to engage in dairying, stock raising and floriculture. Their literary tastes are gratified also by ample libraries, reading-rooms, resting places, etc. The most gentle and just treatment is secured to all with liberties and freedom of action that would have stamped its superintendent as wildly insane if permitted a few years ago; and the freedom here enjoyed is still considered by some a reckless flying in the face of hoary-headed but decrepit experience. The various types of brain disease are here treated in a thoroughly scientific manner. The able medical staff in a methodical and painstaking manner watch each type, noting all its objective and subjective symptoms and its termination. If death results the able pathologist commences his researches, and carefully preserves all changes and discoveries. Thus, at this institution, a literature and authority are made that are standard throughout not only America, but the world. Here again the thought pushes to the front, already expressed, that those of the strongest and most vivid spiritual discernment and culture have done by far the greatest work for the betterment of the insane. Grand and ample as is this hospital, with the thousands who have crossed its threshold but to be blessed and improved, its existence was conceived in the heart and head of that unostentatious, simple, zealous Christian woman, Dorothea L. Dix. The life of this woman is a monument of what may be done single handed when one's soul is on fire and burns itself out in earnest love for the helpless. She not only went from one end of our land to the other, visiting all places of all kinds were human beings, from whatever cause, were confined, exhorting and instructing their officials, while she gathered facts on all subjects and of all descriptions; and with these she addressed, pleaded with and besieged city officials, State legislatures and United States Congresses, in session and out of session, until she beheld the entire American system changed for the better, while her eyes and great heart were filled with the tears of joy and thanks as she saw reared according to her dearest wishes thirty asylums. Her labors did not stop here, but crossing the Atlantic the hospitals and prisons of Europe heard her loud knocking at their doors, which persisted until admitted, and they were thoroughly inspected and reported. From her Scotland received the inspiration and

instruction that lifted her insane out of pestilential, dark dungeons and placed them in the homes of light, cleanliness and comfort, and to-day no country excels her in the humane and successful treatment of the sick in mind.

While I cannot stop to speak of the scores of asylums in the various States, all excellent in their way, I am reluctant to pass the Willard of New York. This was constructed for the chronic insane, the sympathies of Dr. Willard having been called into action by the wretched condition of the so-called incurable insane confined in the poorhouses of the various counties. Here the classes are separated, able bodied workers by themselves, feeble-minded and harmless by themselves, etc., and each in comfortable structures upon various parts of a large farm, employment or amusement being provided for each, all under the care of the same administration. Its buildings are not expensive, the plan works admirably, and it should commend itself to every State, as the immense sums of money required to build the Kirkbride style are not necessary. In the treatment no case is considered absolutely hopeless, and a delightful home is here provided for more than two thousand. At Utica, in the same State, the asylum is one of the most admirably conducted in the world. Its superintendents have been a long line of officers who have stood from the first on the outposts of advanced alienists, and for forty-four years they have edited the *Journal of Insanity*, which, for scientific worth in its line, has no peer in America, and is an authority in all nations. Here, as in the government hospitals, all that experience and love of the work suggests is tried, and all pathological changes of the brain and nerves are critically examined and reported by the accomplished pathologist of the staff.

In many respects New York is far in advance of all other States, and one of the most radical is the examination of all persons connected with her asylums, and if successful, placed upon the civil list, where they live and act above all political scheming and huckstering. Nearly each State and Territory has its peculiarity in the care of its insane, yet I must say here that the old foster-mother of social, scientific and educational advancement, Massachusetts, has a grand asylum system, with her separation into classes, and her training school for nurses, all of which mark her advanced position.

Coming now to our own and what is the "great State of Ohio," what do we find? With pride and truth we can say we have six State institutions, a credit alike to us and the nation. Situated in Cleveland, Columbus, Dayton, Athens, Toledo and Carthage. Also several private homes, as the Cincinnati Sanitarium and Oxford Retreat; the former presided over by the scholarly gentleman and distinguished alienist, Dr. Orpheus Evarts. Our Cleveland asylum has

been partially destroyed by fire, but was originally on the Kirkbride or compact linear design, and is now a congregation of grand buildings three and four stories high, and for the past fifteen years in charge of Dr. Jamin Strong, whose kindness, suavity, executive ability and skill mark his continued success, and whose opinions in his specialty upon the witness stand or to the court are law. The record of recoveries is flattering and the low mortality remarkable. A farm of one hundred and sixteen acres is attached. It has sixty attendants, one to each twelve, and its capacity is seven hundred, and always crowded. Seventy additional are employed on the farm, laundry, kitchen, etc. Of my personal knowledge I can say that so home-like and tranquil has this great State retreat proven that many, who have been discharged, when they feel their old affliction coming again upon them urge their friends to return them to it, or voluntarily go alone. Our asylum in Columbus is under the skilful care of Dr. J. W. McMillan. The buildings are four stories, massive and striking in appearance, with a capacity of nine hundred, and to which is attached three hundred and twenty acres, and is both an ornament and credit to our Capital city. Its superintendent considers congregate dining halls and the moving of the infirm to the first story in place of the fourth, where they now are, very necessary. The Athens asylum is very expensively constructed, the buildings being three and four stories in height, and with a capacity of eight hundred, and generously supplied with attendants for all departments, and presided over by Dr. Richardson, whose zeal, experience, foreign travel and study have made him a most successful and efficient officer. To it is attached a farm of one hundred and eighty acres. The Dayton asylum is on the Cleveland plan, all its appointments are substantial, very fine looking and costly. Its superintendent is Dr. Pollock, a thoughtful, careful and successful general practitioner before entering upon his duties, and under whose care order and excellent results are obtained. Its capacity is six hundred, and about two hundred acres are attached divided into lawns, walks, grazing and farming. The asylum at Longview has a capacity of six hundred and eighty-four, with ninety acres of land and the buildings are on the plan classed as old by some, but for durability, cheerfulness, good lighting and fine appearance is hard to excel. The last State asylum to be named is at Toledo. Under the progressive, and I may truly say adventurous Dr. Toby. It is by far the largest hospital in our State, its capacity being 1,170, and present number nearly up to that point. One hundred and seventy-five acres is attached, and more to be asked for. It is on the cottage plan, the buildings being but two stories in height, cheap but comfortable; the freedom

allowed is phenomenal and everything that militates with non-restraint is set far in the background. Excellent reports come from this most modern of all treatments of the insane. Our citizens have never said no when asked for money to build and sustain asylums. We have immense sums now in these institutions, and are almost constantly enlarging them for this ever increasing class.

Are there are yet things left undone in the best interests of the helpless insane? Yes. Let me tell some of them. The first and most important thing is to take from all county poorhouses these unfortunates and so-called incurables that are so generally persecuted by vicious and ignorant political thugs, who often get these positions as reward for party services, and have the State alone take entire charge of them. In my opinion there is not one county in the State that provides proper apartments and treatment for them. On the other hand the brutal crowding and endless confinement is shocking and destructive of all hope of recovery, for they have no occupation, improper treatment and no comforts. Mercy joins justice and conscience in saying, *remove them all*. Second, we must have and shall never cease until we do have all officers and attendants thoroughly examined, and only when a rigid test proves them peculiarly fitted for their positions can they occupy them. Then put them upon the civil list, as in New York and some other States, above political removal, intrigue and continued uncertainty. Third, we want a separation of the acute and chronic, far apart, that each may be treated, environed and employed in the way most conducive to recovery. Fourth, no more immense buildings to be erected where they shall be collected and kept, but colonies, especially for the chronic, be founded and made comfortable in small inexpensive structures. Fifth, in connection with each asylum at least one-half acre of land for each patient, that everything pertaining to rural life may be cultivated. Lastly, we want the medical schools to dignify much more than has ever been done the study of all mental and nervous affections, and so instruct their graduates that they will recognize and treat these diseases in their earliest and most curable stages by having them speedily placed in these special hospitals.

MEDICAL ACHIEVEMENT IN CHINA.—It is said of Dr. Kerr, a medical missionary at Canton, that he has, in the past thirty-six years, treated over 520,000 patients, and has prepared twenty-seven medical and surgical books. He has trained one hundred medical assistants, chiefly Chinese. China now possesses one hundred and four hospitals and dispensaries, at which, in 1889, more than 348,000 patients received treatment.

ORIGINAL ARTICLES.

MATERIALISM VERSUS SENTIMENT IN THE STUDY OF THE CAUSES AND CORRECTION OF CRIME.

Read in the Section of Medical Jurisprudence, at the Forty-first Annual Meeting of the American Medical Association, held at Nashville, Tenn., May, 1890.

BY G. FRANK LYDSTON, M.D.,
OF CHICAGO, ILL.

When, in response to the courteous and complimentary invitation of the distinguished secretary, I promised to write a paper upon the relation of materialism to the vice problem for this Section, I did not realize the difficulty of presenting views of a comprehensive character within the compass of a single paper. Since beginning my task, however, I have found that it will be impossible for me to present anything more than an array of generalities. These generalities, gleaned from an extensive range of thought upon this subject, I trust may at least serve as food for reflection.

Some years ago I published in the *Chicago Medical Journal and Examiner* a contribution entitled, "The Pathological Causes of Vice." This was based upon observations of the criminal class during my service as surgeon at the Blackwell's Island Penitentiary, and in other metropolitan institutions. This article, while well received by the majority of my friends in and out of the profession, invoked the wrath of a few orthodox individuals to such an extent that I was stimulated to further discussion and study of the subject. Fanatical opposition is sometimes an excellent evidence that our work is based upon sound principles.

In announcing myself as a materialist as far as the study of vice is concerned, I trust that my position may not be misinterpreted, for it is certainly not my intention to detract from the importance of the moral law in its relation to the production and repression of vice, or to lessen the efforts of the moralist in his attempts to oppose goodness to badness. It is the function of the materialist to liberalize the existing theories regarding the causation and repression of vice and to reduce the subject to a scientific and, as far as possible, evolutionary basis.

The study of the causes and prevention of vice and crime in their various phases is one of the most important and practical questions of the age. The varying forms of violation of physical, social, statutory, and moral law, which are included under the heads of *vice* and *crime*, are the outcome of certain circumstances of environment and laws of progression, which are, and have ever been present and operable in society; in all social systems, whether of high or low degree of development, and in every grade of civilization. It is obvious therefore that a philosophical study of

vice is a social necessity, quite as much so as is the study of morbid conditions of our physical bodies resulting from aberrations of physiological laws. Indeed, the two studies are more or less interdependent, and therefore demand the interest of the physician as well as the philosopher. In my opinion it is to the physician, and not to the moralist or law-maker, that the society of the future is to look for measures of repression or the better correction and prevention of vice and crime. Our knowledge of the causes and methods of prevention of crime is at the present time decidedly unsatisfactory and crude from a philosophical standpoint, chiefly because the science of statistics is yet in its infancy, and to a great extent because the moralist has acted as an obstructionist and has impeded the progress of those who have undertaken to reduce the question to a purely physio-philosophical basis.

I will at this point advance the proposition that the actions of man are governed entirely by the state of society in which they occur. Crimes are the result of precedent circumstances; they are the pictured and tangible results of occult influences, past, present and to come, *i. e.*, they are the result of an all-pervading, invincible and everlasting law. Criminal acts are not isolated experiences with no necessary antecedents or future repetitions.

The doctrine of free will, (*i. e.* of individual responsibility), is so simple and appeals so strongly to the self-esteem and sentiment of the masses that it is accepted by the majority of individuals with a faith and simplicity that prevails on no other question of corresponding magnitude. How simple and satisfactory it is for us to say that our fellow-man has committed a crime, because forsooth he is less holy than we! This Pharisaical sophistry is but the outcome of human egotism, and as long as it prevails and controls our social, moral and legal efforts at repression, so long will our criminal classes flourish and multiply. Indeed, "he who does not advance goes backward," and our social system is apt to grow worse instead of better.

It is hardly necessary to go into details regarding the superficiality of the prevalent methods of study and repression of crime. It is so apparent that it must strike the most casual observer. Much has been done in the way of moral and physical persuasion, but very little indeed in the direction of philosophical methods of the study and correction of causes. As civilization has advanced and theology has become enlightened in its theory and methods, a corresponding improvement in the moral tone of the social body should be expected. Unfortunately, however, there has been no improvement—as far as statistics serve to testify—which is sufficient to encourage the efforts of the moralist to any great extent. The futility of moral measures, as demonstrated by

past experiences, is explicable only upon the ground that there is something more than free will to account for criminal acts. Free will is operable only in the case of individuals, and moral persuasion affects only the individual and incidentally the circumstances which sway the volition of the criminal. It accomplishes little or nothing in correcting or antagonizing the general law underlying the production of the criminal class. By analogical reasoning the futility of moral means of repression may be readily shown. We will suppose, for example, that a certain portion of the human body is affected by disease dependent to a greater or less extent upon a depraved constitutional condition. Obviously measures of local correction, *i. e.* correction of the local depravity of tissue, although useful to a certain extent, fail of their object unless the general and constitutional influences which tend to enhance the local trouble are recognized and corrected. The individual is but an atom of the social fabric. When he is depraved, logic requires a search for, and if found the correction of the morbid general or constitutional influences pervading social body which bring about perversion of thought and action in the individual. Moral persuasion is but a minor consideration; the law cannot cope with the question, and punishment is futile because these influences operate upon the isolated integer and not upon the law of causation. Admitting that certain criminals are so by reason of structural peculiarities, the inefficacy of preaching is at once explicable.

That criminality is the result of certain causal influences operating by a fixed law has been recognized by several eminent historical and statistical authorities. Buckle and Quetelet have advanced some striking arguments bearing upon the influences modifying the moral conduct of the human race. It would appear that many of the actions of mankind which we are prone to attribute to free will and independent action upon the part of the individual, are really the result of a fixed and immutable law controlling the moral world, almost as definite and arbitrary as the laws controlling the physical world. As compared with this law the independence, *i. e.*, free will of the individual and the local circumstances of environment in operation at the time of the apparently volitional action, are of but little moment, and are but accidents in the chain of events. It has been shown by the statistics of Great Britain and France that there is a constant proportion maintained in the ratio of criminal acts to the number of population in those countries.

Rawson says: "No greater proof can be given of the possibility of arriving at certain constants with regard to crime than the fact that the greatest variation in the proportion of any class of criminals at the same period of life during a pe-

¹ Inquiry into the Statistics of Crime in England and Wales.

riod of three years has not exceeded a half of one per cent."

Quetelet says: ² "In everything which concerns crime the same numbers recur with a constancy which cannot be mistaken. This is the case even with those crimes which seem quite independent of human foresight—such, for instance, as murders, which are generally committed after quarrels arising from circumstances apparently casual. Nevertheless we know from experience that every year there takes place not only the same proportionate number of murders, but that even the very instruments with which they are committed are employed in the same proportion."

Buckle says: ³ "Suicide is merely the protection of the general condition of society; the individual's volition only carries into effect what is the necessary consequence of preceding circumstances. In a given state of society a certain number of persons must put an end to their own lives. This is the general law, and the special question as to who shall commit the crime depends of course upon special laws which however, in their total sections must obey the large social law of which they are all subordinates. The power of the larger law is so irresistible that neither the love of life nor the fear of another world can avail anything toward even checking its operations."

Buckle further shows by statistics that notwithstanding the varying causes of suicide which exist in society, such as political excitement, want, mercantile crises, disappointments in love, depression induced by disease, etc., there has been in London a very constant average of suicides, the average having been during five years 240 per year. The variation in the number was not very great in proportion to the number of population, running from 213 to 266, the latter number being attained in the year 1846, which was distinguished by the great railway panic. At this time the ratio of suicides might naturally be expected to be extremely high, but as a matter of fact, it was less than one-half per cent. higher than the preceding year. Mechanical laws may be disturbed by accidental disturbances, yet they prevail; so it is with the moral law.

As showing how the regularity in the course of events may manifest itself in the most trifling details of every day life one of Buckle's statements is very interesting. It is not infrequent for individuals through carelessness to drop undirected letters in the mail box. Such an oversight might naturally be attributed to individual carelessness, but it is shown by statistics that in London and Paris, due allowance being made for varying circumstances, increased population, etc., that there is practically the same number of undirected letters found in the mail every year.

It is generally supposed that in the matter of matrimony the individual is governed by free will. Statistics prove that there is a constant variation in the proportion of marriages corresponding to the rise or fall of the price of food products. So it may be seen from the foregoing that as far as statistical evidence goes we may well believe that "there is a Divinity that shapes our ends, rough hew them as we may."

Leaving the question of a general law influencing society and determining with unwavering fidelity the occurrence of certain acts which we term criminal or vicious, it is unquestionably true that there are certain special causes in operation. The influence of heredity is so well recognized that any remarks in that connection may be considered trite; it would however be impossible to do the subject justice without an allusion to it. It is not always an easy matter to isolate hereditary influences from others of a special character which operate in the development of vice and criminality, but there are certain typical cases upon record which conclusively prove that hereditary impulses to breaches of social ethics are a very important consideration in the study of the causes and prevention of vice. There is frequently an intimate association between hereditary defects of a physical character and those manifestations of heredity which result in crime. In many instances a special act of criminality can be directly traced to certain hereditary or perhaps congenital physical aberrations. The powerful influence of heredity in the production of vice and crime is not so manifest in this country as in some of the older countries of the world. Its influence is not so dominant among the higher classes, in countries in which a Republican form of government prevails as in those in which an effete monarchial and aristocratic system of control exists. The older and larger the city the more pronounced its viciousness. Thus it is to London we must look for the very refinements of vice and crime. The *expose* of the hideous orgies of Cavendish Square followed very closely upon those sensational murders of women which attracted the attention of the whole world to the great metropolis.

In Dr. Ireland's book, "A Blot on the Brain," we have evidence collated which is sufficient to convince any thinking man that the aristocracy of the Old World is hereditarily rotten to the core. My hearers may perhaps be familiar with his unmerciful handling of the House of the Romanoffs, in which his statements are so eminently true that the sale of the book has been prohibited throughout the Russian domain. Not that the aristocracy *per se* are more liable to viciousness than any other class of people similarly situated. Unbridled license, idleness and the possession of unlimited resources, when taken in connection with the circumstance of consanguinity or in-breed-

² Sur l'Homme, Paris, 1835.

³ History of Civilization in England.

ing, are enough to account for the corruption of the dominant element in European society.

That actual physical aberrations or atypical conformations of structure must bear a certain responsibility for the development of the criminal class is amply shown by the researches of Benedict and Osler. These experimenters have shown quite a constant relation between atypical cerebral development and criminality. The assertion that criminals and a certain class of insane exhibit a defective or aberrant brain development, has been the conclusion of such students of the subject as Corre, Lombroso, Mills, Rousel-Marro, Pavlosky, Varaglin, Tenchini, and Badik. To be sure we must take into consideration the naive declaration of Benedict that certain of these cases were collected as the result of a *a priori* conviction that the criminal is an individual having the same relation to crime, as his next blood kin, the epileptic, and his cousin, the idiot, have to their common encephalo-pathic condition. Hackneyed as the illustration may be there is as yet no better exemplification of the effects of heredity than that embraced in the wonderful tables and statistics of the immortal Richard Dugdale in his history of the Jukes.

Ribot, in his famous work on Heredity, has shown remarkable examples of an inherited predilection not only for crime in general, but of certain forms of crime and vicious impulses.

I perceive that my paper is spinning out to an unwarrantable length, and I will therefore present as briefly as possible those causes which students of this important social problem should always be ready to recognize.

1. The first cause is that occult all-pervading and remorseless law which pervades all social systems. To this law I would apply the old term *predestination*, were it not in my opinion too arbitrary an expression and likely to lay me liable to the impeachment of illiberality. This cause has already been sufficiently expiated upon. There appears to be an occult influence of an epidemic character affecting chiefly the crimes of murder and suicide. This is so trite that I would scarcely mention it but for my desire for completeness of classification. There has recently occurred in rapid succession in numerous large cities in this country a considerable number of cases of wife murder followed by suicide. These are an illustration of a peculiar kind of homicidal mania of an apparently epidemic character which occurs now and then. It is my opinion, and in this I am not alone, that the public press fosters this epidemic influence by its blood-curdling accounts of such cases. It is a question in my mind whether the complaisant manner in which the *minutiae* of robberies and defalcations are recited by the newspapers, has not its influence in producing crime.

2. Hereditary impulse independent of percep-

tible physical aberrations. It is possible that habit, persisted in through many succeeding generations, may result in a faulty power of reasoning, which, although not characterized by variations in physical conformation, may yet be transmitted through countless generations.

3. Defective physique and imperfectly developed intellect, hereditary or congenital.

4. Acquired disease lessening the moral sense and will power. Instances of this kind are familiar to all of us. Vicious or criminal acts performed under the influence of acute delirium or mania and due to various diseases, are frequently met with.

5. Injuries to the brain. This cause of crime and vice is a very familiar one, especially to the alienist and neurologist.

6. Alcoholism. To this cause there are many who, in what I consider illiberality, attribute nearly if not quite all cases of criminality. There is no question but that alcoholism is a potent cause of crime, but there are thousands of cases of criminal acts which are apparently traceable to it, yet in which the influence of alcohol is secondary to physical causes inherent to the individual. There were certain interesting facts brought out by the recent Congress of Alcoholism in Paris, which illustrates the importance of the study of the relation of alcoholism to crime. It was shown, for example, that there was quite a constant relation between the amount of alcohol consumed in various social systems and the amount of crime. It is my impression, however, from a study of the statistics developed by this Congress that the survey of the field of criminality had been rather a narrow one, and that certain collateral elements in the causation of crime had failed to receive their due need of consideration. Some of the studies of the Congress were rather interesting in this connection. For example, it was shown that in Berne, where there are only four saloons per thousand of inhabitants, criminality was more prevalent than in Zurich, where the proportion is 12 to the thousand.

7. Vicious example and surroundings—environment. This involves the question of criminal contagion, which is very important in connection with our own defective methods of correction. The herding together of all grades of crime is one of the most pernicious systems that could be devised. In our own city of Chicago, for example, there is no reformatory for young lads, and they are therefore sent to the Bridewell, where they eventually become contaminated by older criminals. This proceeding is as rational as would be the sending of a case of sore throat to a diphtheria hospital.⁴

8. Defective education and consequent imperfect mental discipline. This is a question on

⁴ A movement is now on foot to establish a reformatory in Chicago.

which the progressive physician and the philanthropic politician, if such *rara avis* exists, should be a unit.

9. (a) Perverted conception and mal-administration of the law. (b) Unjust dispensation of the law, statutory and moral. Illogical interpretation of divine law. This cause is of more importance than is usually assigned to it. What may be termed the inequalities of Justice have been responsible for fully as many cases of confirmed criminality as almost any other cause which could be mentioned.

Bishop Robertson once said: "Justice is a pair of huge iron jaws which open and close with mechanical regularity. Nearly every man at some time in his life comes within the legitimate reach of these jaws. Many escape just at the nick of time because they do not happen to be within reach at the time the jaws are open and closing, while others less guilty perhaps, but also less fortunate, are caught."

A very interesting story is told in this connection of two school boys who were stealing apples together. They were detected and pursued. One was caught, while the other one escaped. The one who was captured was sent to jail and thrown among criminals from whom he acquired a moral contagion which infected his after life. After his release those acts which before his incarceration were merely boyish pranks, assumed a criminal character and he became a confirmed criminal. The boy who escaped remained in school and doubtless kept up his mischievous tricks during his school days. He afterward studied law, became a lawyer, and eventually was elected a judge. Twenty-five years after the apple stealing episode the judge sentenced his former comrade to death for murder.

10. Alleged detective science or man-hunting. The manner in which the ambitious modern would-be detective pursues discharged criminals is an apt illustration of "man's inhumanity to man." How frequently it transpires that a criminal leaves the prison gates with the resolve to lead an honest life; he secures a position but the eye of the law is still upon him, and some human tiger in the guise of a detective speedily warns his employer that he is harboring a jail bird. Discharge follows, and perhaps another place is secured with the same result, and so the relentless pursuit goes on and on until the jail bird finds every avenue closed to him except the road back into the jail. Why have we not a Hugo among us to describe the pursuit and persecution of our own Valjeans? It is unquestionably true that the persecution of criminals by would-be Vidocqs does much to keep up the census of our jails. A want of faith in reformation on the part of those who should hold out a helping hand to the criminal, drives many a man back to crime.

11. Physical, moral, social, and matrimonial

mésalliance. This involves the question of consanguinity. It is questionable whether we as physicians will ever succeed in accomplishing much in the correction of this particular cause. The sanitary marriage is the dream of the idealist. If we shoot at the moon however, we may make a pretty satisfactory target though we fall far short of the mark. Gross physical infirmities and certain pronounced mental defects may at least be taken into consideration in the question of matrimony. Proper selection in marriage means means both physical and mental improvement in the same. The human animal is certainly entitled to some of the benefits to be derived from the science of breeding. Authorities are somewhat divided upon the question of consanguinity, yet there are few who are not willing to admit the necessity of careful and ripe judgment in considering the question of the marriage of blood relations.

12. Aberrations and perversions of a sexual character are occasionally the cause of crime, more frequently perhaps than is generally appreciated. Many cases of murder from alleged jealousy are due to sexual insanity. Rapes and various crimes of a bestial character may be due to inherent perversion or to actual insanity. There are many illustrations of crime committed as a consequence of inherent sexual perversion.

13. The intermarriage of criminals. As much as has been said upon this question, it is doubtful whether the correction of this influence by the State is possible. If the privilege of matrimony be denied to the criminal class, illegitimate relations are apt to be established with an even more deplorable result. Such people are not apt to stand on ceremony, and the correction of this cause is therefore more theoretical than practised.

14. Corruption in politics. Under this head I will embrace political encouragement of ruffianism and protection for criminals. A very sad case recently occurred in Chicago of a prominent lawyer who became insane as a consequence of a blow upon the head inflicted by an alleged respectable citizen during a quarrel of a political character. As a corollary of political corruption we have an imperfect and corrupt police system, the keystone of which is the axiom that it takes a rascal to catch a rascal. This cause of criminality must prevail as long as the credentials of an alderman are the qualities of a deep, hard drinker and a good rough-and-tumble fighter.

15. Niggardly and misapplied charity, with consequent failure to relieve actual want. As is well known, starvation and crime are first cousins.

16. The importation of the criminal refuse of the Old World, and what is worse, individuals with fanatical social, political or religious views. The important question of immigration demands more attention than is usually accorded it. It is really one of the most vital issues of the day. The

instance has been known, and quite recently, that nearly ten thousand immigrants were landed in one day at Castle Garden alone, to say nothing of other ports of entry. Were it established that all of these people are respectable and producing elements in American society, they would certainly be a very valuable addition to our population. There is something striking however, in the fact that, although the foreign-born citizens constitute but one-eighth of the total population of the country they furnish one-third of our criminals, one-third of our paupers, and one-third of our insane. In short, the character of our immigrants is so polluted by the wholesale exportation by the Old World of the insane, criminal and pauper class, that every one thousand immigrants furnishes twenty per cent. more of the inmates for our jails, asylums and alms-houses than the same number of American born. This is a cause which must be grappled with by the statesman and not by the philanthropist. Should politics become honest, or approximately so, there is hope for remedying this evil, but under the present system of political quackery a remedy for this cause is like some of the others I have mentioned, more theoretical than practical.

In this array of generalities and necessarily imperfect classification of causes of vice and criminality, it is obviously impossible for me to entirely cover the field, but if I have succeeded in presenting in an intelligible manner ideas which will serve as an incentive for the study of the subject on the part of my intelligent readers, I shall have accomplished my object. As Dumas once said of mendicity: Criminality is "an organized body, a kind of association of those who have not, against those who have." It is high time that the respectable elements of society should begin the study of the causes and prevention of crime in a philosophical manner. If this be done and the philosopher, preacher, statesman, jurist and physician put their shoulders to the wheel and work in unison, the time may come when the criminal class may not be so pronounced a curse in our social system as it is to-day.

PUERPERAL ALBUMINURIA.

Read in the Section of Obstetrics and Diseases of Women, at the Forty-first Annual Meeting of the American Medical Association, Nashville, Tenn., May, 1890.

BY S. P. DEAHOFE, M.D.,
OF POTSDAM, O.

By albuminuria I mean a condition in which albumen appears in the urine. It may or may not be associated with a decided diffuse nephritis; I say decided, for it is more than likely that if albumen exists for any length of time in the urine, there is more or less nephritis.

I have never been able to distinguish between albumen of Bright's disease and that where the

disease does not exist. Semmola, in the *Archives of Physiology*, states that there is a difference in the appearance of the precipitate; and that the albumen of Bright's disease diffuses more rapidly through animal membranes.

A very important form of albuminuria is that found during pregnancy; most frequently in primiparæ, and frequently associated with other symptoms of Bright's disease. The following is a very interesting case:

Mrs. D., aged 32, primipara. Family history: Father was an epileptic; other than this it was good. The patient's previous health had been moderately good, she was not robust, but rather poorly developed. Married October 23, 1887, became pregnant about December 24, 1887. On April 28, 1888, she first noticed that her feet were swelling. This swelling rapidly increased until May 13, when I was called to see her. Her entire body was œdematous, including hands and face. There was difficulty of breathing, due to œdema of the lungs. Heart was acting fairly well. She complained of headache and nausea, but there were neither vertigo nor any trouble of vision. Bowels were constipated. I ordered the urine saved for twenty-four hours and a specimen brought to my office. Amount passed, 16 ozs.; sp. gr. 1032, albumen in large quantity.

I informed the friends of the gravity of the case and put her upon a skimmed milk diet, and gave her tr. digitalis and bitartrate of potassium to increase the urinary secretion, saline cathartics to act upon the bowels, and vapor baths to act upon the skin. The patient continued to grow worse, and on May 17, the sp. gr. of the urine having reached 1038, albumen increased, the prospects of the case rather gloomy, I called for a consultation. Drs. Baker and Brandon met me next day at 10 A.M., symptoms were still growing worse, amount of urine passed during the previous twenty-four hours, 12 ozs., sp. gr. 1040; urine became absolutely thick upon the addition of nitric acid. The result of the consultation was to continue previous treatment not more than forty-eight hours unless improvement took place; if not, to induce labor.

May 19, condition about the same, except increased headache, and a peculiar heaviness of the tongue was noticed in talking. The lips were now also markedly œdematous.

May 20, 8 A.M. Temperature, which had previously been normal, now rose to 100°. The treatment has been faithfully carried out, but the œdema has increased, the urine remains scanty, sp. gr. 1042, albumen very abundant. I made no quantitative analysis, but upon the addition of nitric acid to the urine in a large test-tube it became so thick that it would not run out of the tube when everted.

May 20, 8 P.M., went to the patient for the purpose of inducing labor but, upon arriving at the

house, the symptoms seemed slightly better and, hoping that an improvement was about to take place, I postponed the operation to watch the further progress of the case.

May 21. Temperature normal, œdema slightly diminished, sp. gr. 1032, albumen about the same, possibly slightly diminished. Treatment was continued.

May 22, 8 A.M., temperature 99.2°, sp. gr. 1030, albumen about the same, treatment continued.

May 23, 9 A.M., temperature normal, sp. gr. 1032, albumen about the same, œdema same. Severe headache, slight nausea, and slight, transient dimness of vision complained of by the patient. Treatment continued, except that the cathartics were withdrawn. 4 P.M., severe headache continues, severe nausea and vomiting with pain in the epigastric region now comes on, cannot retain milk. 9 P.M., headache continues unabated, vomiting ceased, dimness of vision now marked, patient says she sees flashes of light before her eyes. Muscular twitchings are now noticed.

10:20 P.M., convulsions. I arrived in a few minutes. The patient had not yet regained consciousness fully. Gave her $\frac{1}{2}$ gr. of sulphate of morphia hypodermatically, and inhalations of chloroform. Mouth was bleeding from a bite of the tongue during the convulsion. 11 P.M. In the presence of Dr. Brandon I introduced a male elastic catheter into the uterus and let it remain. I found the os low down, soft, and open sufficiently to admit the finger. I stayed with the patient all night. She slept most of the time under the influence of the morphia. Has passed no urine since 1 P.M.

May 24, 9 A.M. Has no pain and expresses herself as feeling quite good. 10 A.M., some bloody discharge from the vagina, but no pains yet. 1:30 P.M., passed about 4 ozs. of urine, the first in twenty-four hours, sweating profusely; occasional pains are now noticed referable to the uterus. Temperature 100.5°, sp. gr. 1034, albumen the same. 8:30 P.M., rests quietly, uterine contractions feeble but increasing. 11 P.M., called and found pains much increased; was delivered of a female foetus at 1:40 A.M. without an unfavorable symptom except the temperature, which remained elevated at 100.5°.

May 25, 8 A.M., temperature 100°, slight headache. 10:30 A.M., sweating freely, headache continues, otherwise feels as well as could be expected. Continued the digitalis, bitartrate of potash, and cathartics. 4:30 P.M., was called on account of patient having difficulty in breathing, and found it due to pulmonary œdema, quite marked upon the right side, evidently due to her lying mostly on that side, the vesicular murmur being almost absent. I changed her position to a sitting posture and then to the left side, with relief of the dyspnoea. Urine is much increased, sp. gr. 1020, albumen reduced more than one-half.

From this time on the patient continued to improve. The cathartics were withdrawn and tr. ferri chloridi was added, also lime water was added to the milk on account of some nausea. Dismissed the case June 1.

I might add here that she was again delivered with forceps of a healthy male child May 24, 1889, having passed through her pregnancy without any of her previous trouble.

The subject of puerperal albuminuria has attracted the attention of obstetricians for many years, and is well known to be associated in ways still imperfectly understood with many important puerperal diseases. In the severer cases a well-marked parenchymatous nephritis exists; but if every case of albuminuria in pregnancy is due to a nephritis, it is probably a form of the disease which may neither lead to severe symptoms nor to chronic disease; however, the absence of severe symptoms or the continuance into the chronic form may often be explained by the most rational of all treatment, viz.: removal of the cause. On the other hand, the appearance of albumen in the urine of a pregnant woman, though not calling for active interference, should be regarded as a danger signal, and put the physician on the lookout for other indications of renal disease.

There are a number of theories as to its causation, such as a poor quality of blood, an altered condition of the blood, which, on account of the call for nutritive supply on the part of the foetus, contains an excess of albuminous material. Any condition producing sudden hyperæmia of the kidneys giving rise to a state analogous to the first stage of Bright's disease, such as sudden exposure to cold and impeded cutaneous action.

PRESSURE OF THE GRAVID UTERUS.

Prof. Edes, of Harvard University, thinks that in many instances it is the result of impeded abdominal circulation, although it is rare that the gravid uterus can press upon the renal veins.

Bartels shows that the renal veins occupy a position which secures them from pressure.

Playfair says: "The obvious fact that in pregnancy the vessels supplying the kidneys are subjected to mechanical pressure from the gravid uterus, etc., suggests that here we may find an explanation of the frequent occurrence of albuminuria; that this is further strengthened by the fact that the albumen rarely appears until after the fifth month."

That this last theory is not correct is shown by the history of the case just reported, in which the albumen appeared prior to the fourth month, at which time the gravid uterus could not certainly have pressed upon the renal veins.

The symptoms of albuminuria of pregnancy are by no means constant. Anasarca is probably the most frequent symptom which attracts the attention of both patient and physician, not only

the swelling of the lower extremities, but the face and upper extremities also.

Any puffiness of the face or hands should give rise to suspicion and lead to an examination of the urine. The anasarca may extend throughout the whole body as it did in the case reported, the lungs not escaping. Headache, dizziness, dimness of vision, spots before the eyes, nausea, sleeplessness, irritability of temper, are often met with, and should cause suspicion and lead to an examination of the urine, which is generally scanty and high-colored, and may contain, in addition to the albumen, epithelial cells, tube casts and blood corpuscles. The most formidable of all is eclampsia.

I believe it may be taken as proved that albuminuria is not necessarily accompanied by eclampsia, although the two are almost invariably combined.

Not only is the mother's life in danger ultimately, but there is a strong predisposition to abortion, due to imperfect nutrition of the fœtus by blood impoverished by the drain of albuminous materials through the kidneys. Tanner mentions four cases out of seven which he attended that aborted, one of them three times in succession.

TREATMENT.

The treatment should consist of such remedies as tend to promote the secretion of the urine and thus relieve, or at least diminish, the congestion of the renal vessels. Saline diuretics, such as the acetate or bitartrate of potash, will best answer this indication. Purgatives which produce watery motions should be administered. Dry cupping over the loins may have a beneficial effect in lessening the renal hyperæmia. The action of the skin should also be promoted by the use of vapor baths. The diet should consist of skimmed milk, with which may be allowed a little whitefish. Tr. of chloride of iron is excellent, and may be combined with tr. of digitalis, which acts as an excellent diuretic.

In obstinate cases, where all these fail, we must consider the advisability of inducing premature labor

IS THIS OPERATION JUSTIFIABLE?

Barker says it should be resorted to only after treatment, thoroughly and perseveringly tried, has been without success.

Hofmeier says it does not increase the risk of eclampsia, and may avert it altogether.

Lusk says as far as his experience goes, the practice of waiting upon Nature has proved uniformly disastrous, while the induction of labor has furnished recoveries.

Braun says he has known but one patient to recover between the fourth and sixth months of pregnancy except where abortion has taken place.

I believe it is perfectly justifiable in all cases attended with symptoms of great gravity; and I

should not hesitate to adopt this resource in cases in which the quantity of albumen is great and progressively increasing, and in which treatment has been of no avail, and especially if attended with such symptoms as severe headache, dizziness and loss of sight.

As it is not likely to be indicated until the child has reached a viable age, although in my case it will be noticed that it was much earlier, and the child's life is in danger from the albuminuria, we are justified in performing the operation for the mother's safety alone.

THE MEDICO-LEGAL ASPECT.

This involves a question of medico-legal importance. Charges of inadequacy of cause for its performance may be made, and the physician should take all precaution to avoid these, and thus save him the unpleasantness of a prosecution for a criminal offense.

Tidy says (Vol. iii, p. 100): "It is manifest that if any question should arise or action at law be commenced against a medical man for inducing abortion, it would be necessary to show: 1, that there was a necessity for the operation, the life of the mother being at stake, and the operation being less to be feared than natural delivery; and 2, that his action was *bona fide*."

Now, it may be difficult for a practitioner to successfully defend himself against a charge of inadequacy of cause for its performance, owing to the increasing number of conditions which justify the induction of premature labor; therefore we urge upon medical men, 1, not to induce premature labor or abortion without the most mature deliberations; 2, not to undertake it until after consultation with a second practitioner; 3, in any case to have the full consent of the husband or guardian, in writing, if possible.

Taylor says (p. 592): "This practice has been condemned as immoral and illegal, but it is impossible to admit that there can be any immorality in performing an operation to give a chance of saving the life of a woman when, by neglecting to perform it, it is almost certain that both herself and the child will perish.

"Any question respecting its illegality cannot be entertained, for the means are administered or applied with the *bona fide* hope of benefiting the female, and not with any criminal design."

When eclampsia supervenes what shall we do? Shall we attend to the convulsions and let the labor take care of itself, as Gooch says? There seems to be a difference of opinion upon the subject, one advising the immediate emptying of the uterine, others who leave the labor entirely alone. Evidently that course which seems least likely to prove a source of irritation to the mother is the one to adopt, and the practitioner must exercise his own judgment as to what course he will pursue. But when convulsions come on during the

earlier months of pregnancy, as they did in my case, there seems, to my mind at least, to be no doubt as to the course to pursue, viz.: to bring on labor with the least possible irritation to the mother. The introduction into the uterus, without rupturing the membranes, of a flexible male catheter, seems to be the best way.

To control the convulsions there are several remedies recommended. If the woman be a strong, healthy one, with marked evidence of great cerebral congestion, and vascular tension, such as a full, bounding pulse and a livid face, venesection is a valuable remedy. Of the sedatives which are useful, chloroform probably stands at the head of the list. Hydrate of chloral, per rectum, or in combination with bromide of potash per os, is highly recommended. That which served me best was hypodermatic injections of morphia in $\frac{1}{2}$ gr. doses, together with inhalations of chloroform intermittently.

THE TREATMENT OF PLACENTA PRÆVIA.

Read by Title in the Section of Obstetrics and Diseases of Women, at the Forty-first Annual Meeting of the American Medical Association, May, 1890.

BY AUGUSTUS P. CLARKE, A.M., M.D.,
OF CAMBRIDGE, MASS.

I am not unaware that much time and attention have been given to the subject of placenta prævia, but the high rate of mortality that has obtained among the mothers and the children, whatever method of treatment employed, is sufficient apology for bringing the subject before this Association. During four years in the Leipzig clinic, Oberman¹ had sixty four cases. The mortality of the mothers was eleven per cent. That of the children fifty three per cent. The treatment employed was Hofmeier's, or as it is sometimes called, the Berlin method. Version combined with external and internal manipulation was employed in cases which were attended with hæmorrhage. The head of the child was brought to the os uteri, and maintained there as a tampon. Massage of the fundus uteri was employed during extraction. Iodoform tampons are advised only in hæmorrhagic cases arising in the earlier stages of pregnancy. The foetal mortality attained as high as 83.4 per cent. when bimanual podalic version was carried out according to the method followed by Behm and others.

Some authorities have thrown out altogether consideration for the child's life, and have brought the pregnancy to a close as soon as it was discovered that placenta prævia existed, and uterogestation had passed the mid-term. There are other authorities not so radical. They advocate the expectant method of treatment. They wait

until hæmorrhage becomes serious before they resort to the induction of premature delivery. Parvin² regards the child viable in the seventh month.

From his experience, hæmorrhage, in the majority of cases, does not come on prior to that time; and protection can be afforded the child, if it can escape the dangers incident to birth.

His most serious consideration is, how can delivery be affected with reasonable degree of safety to the child, without endangering the mother. Parvin offers no newer method, but refers to Zweifel's suggestion for manner of conducting podalic version. The obstetrician for the purpose of making version, should pass one or two fingers anteriorly.

By this means a much further entrance can be made into the uterus, and less violence will be done to the attachments of the placenta. The author here referred to, would conjoin the hydrostatic pressure of Barnes, with the partial detachment of the placental mass, as being the best method of treating placenta prævia after the labor has so far advanced that the vaginal portion has disappeared. This plan, it is claimed is most conducive alike to the safety of the mother and the child. Barnes advises that sufficient dilatation should be obtained, before delivery can safely be accelerated by forceps, by turning or by embryotomy. If turning must be resorted to, the forceps should be used to prevent the delay in the passage of the foetal head, and to relieve the constriction of the only partially dilated cervix. Barnes does not approve of Simpson's method, the entire removal of the placenta before the birth of the child. To hasten labor he would rupture the membrane and separate the portions of the placenta that are adherent within the lower zone. His line of conduct is wholly regulated by the occurrence and the absence of hæmorrhage. Tampons are used, but not relied upon to protect against hæmorrhage. A firm binder is applied over the uterus.

Cases in which the uterus fails to act, dilatation is aided by water bags. Forceps are preferred to version, when the head presents. Hæmorrhage usually ceases after full canalization of the passage, and the placenta is detached from the lower zone. McDonald,³ after the seventh month, would not wait if the hæmorrhage is severe. He first ruptures the membrane, applies a binder over the uterus and gives ergot.

He has experienced great difficulty in using Barnes' hydrostatic dilators. He prefers using one or two fingers, sweeping them round in a circle so as to separate as much of the placenta as is within reach. He exercises lateral pressure on the os uteri to accelerate the labor. If

² Theophilus Parvin, M.D., Philadelphia, Med. News, 1888.

³ Dr. Keith N. McDonald, Edinburgh Med. Jour., also Braithwaite, part 90, p. 272.

¹ Braithwaite's Retrospect, part 98, page 309.

the presentation is not a natural one, he introduces the fingers in the shape of a cone into the os uteri, and retains them there for a while. The uterus is to be steadied, but pressed down until the hand gains admission into the cavity of the uterus. He passes the hand, if necessary, through the placental mass.

Both feet, if in reach, are brought down at once. Of the 4,515 cases delivered in the Rotunda Hospital,⁴ Dublin, during the three years ending November, 1886, there occurred twenty-three cases of placenta prævia. There was a material mortality of four deaths, three of which were complicated with other serious affections. The fœtus was lost in eleven cases. If the presentation was normal, the membranes were ruptured; this caused the presenting part to act as a tampon. Intro-external version was performed. A leg was brought down to act as a plug until expulsion took place through natural efforts, or was aided by artificial means. Against the practice of passing the hand through the placental mass many objections have been urged. Khamsbotham was opposed to this practice. He refers to Deleurye who presented arguments strongly against the practice. In some cases in which it was necessary to let off the liquor amnii, Deleurye recommended that the placenta be pierced by an instrument. The chief objection against the practice of perforating the placenta with the hand, must always be because of the difficulty in the execution. An attempt to penetrate with the hand or the fingers the placenta, is liable to be followed by a displacement of the placental mass. Such displacement might bring on immediate uncontrollable hæmorrhage with a fatal result. It is true, as it was known even to Smellie and to others, that the placenta is sometimes so soft and undeveloped or retrograded, as to be easily penetrated by the fingers, but such a condition cannot be relied upon as existing in the usual cases of placenta prævia. It is an undoubted fact, that the larger vessels permeating the placenta, may sometimes be wounded or lacerated as the open sinuses and vessels are, when the placenta is forcibly detached as was done by Simpson and his followers.

In such cases the immunity of the mother or of the fœtus from danger, can only be ascribed to phenominally occurring uterine contractions, that immediately constrict the vascular tissue to such an extent as to avert the dangers of hæmorrhage incident to the mother, and those of asphyxia to the child. My own experience, based upon careful observation and study, has deepened my conviction that the practice of perforating the placental mass in the great majority of cases of placenta prævia, is not to be commended; nor is my experience favorable to the

practice of the entire removal of the placenta before the birth of the child, as has been so often advocated by high authorities. I believe that such a practice was founded on a mistaken view of the physiology of some of the functions of the parturient organs. In central implantation of the placenta, Barnes⁵ recognized the fact, that there is an enormous ectasia of the vessels. This condition often leads to hyperplasia, the transudation of serum from the vascular channels. The vessels become expanded, the tissues swollen, hard and unyielding. When the implantation is wholly central, the area of growth is more limited than when the seat of the placenta is at the fundus or at the side of the uterus.

Added to this there is often an absence in great measure of the natural stimulus for a speedy accomplishment of labor owing to the undeveloped condition of the child. In the treatment of six consecutive cases of placenta prævia occurring in my own practice, I recognized the fact that the ectasia of the vascular development in the cervix was not uniform.

In the area of growth in almost every case, some portion of the marginal implantation was much more limited than others. After ascertaining the point offering the least resistance, and where the vessels were the smallest, I effected separation of the placental attachment, sufficient to admit the index finger. Careful inspection of the point or points of previous hæmorrhage, often proved quite sufficient to warrant an attempt to make separation of the placental attachment. Firm tamponading to guard against undue hæmorrhage from the open vessels was resorted to. After inserting one or two fingers between the tampons and the detached portion of the placenta, the membranes were sought for. If the cervix was hard and unyielding, no attempt was made to rupture the membrane, until evidence was had that the cervical tissue was soft and yielding, and the lower segment of the uterus contracted at intervals. The administration of ergot was not followed with beneficial results. Kneading or regular massaging the uterus above, contributed greatly to the relaxation of its lower segments. The binder was employed. As the fundal and equatorial zones of the uterus contracted, the lower ones relaxed. On the occurrence of this condition, the tension of the placental vessels was found to be greatly diminished. This gave me full control over the points of hæmorrhage.

In all cases much attention was paid to details. Strict antiseptic precautions were instituted at every step of the proceeding. Until the birth of the child was complete, connection of the placenta, as far as possible, with the cervical tissue was maintained. By the employment of this method of treatment in the six consecutive cases of cen-

⁴ See Dr. Fleming on "The Treatment of Placenta Prævia," *Lancet*, Jan. 15, 1887.

⁵ *Lancet*, 1879; also Braithwaite, part 81, p. 218.

tral implantation of placenta prævia, not a single death of the mother occurred, and only one death among the children. The cause of the death of that foetus, however, was not due to the existence of placenta prævia, but to hydrocephalus in the child.

The mother was phthisical, and the placenta was found to have undergone fatty degeneration. In two of the cases of this series, hæmorrhage occurred at the close of the seventh month; in two, at the close of the eighth month; in one, after the eighth month; in the last, near the close of the ninth month. In another series of eight hundred obstetric cases occurring in my own practice, there were four cases of placenta prævia. In two of the cases hæmorrhage occurred at the seventh month; in the third case, hæmorrhage did not appear until the second week in the eighth month; in the fourth case there was no hæmorrhage until the close of the ninth month.

This last patient was a primipara. The os and cervix were rigid and swollen. The hæmorrhage at first was moderate, but it gradually increased and at length became alarming.

Careful examination revealed that the placental vessels at the left and posterior aspect of the cervix had broken away. Tampons of iodoform wool and gauze were firmly applied.

This controlled the hæmorrhage for the next twenty-four hours, after which the cervix was more yielding. Further resistance was easily overcome by digital and manual dilatation.

The vaginal introitus was irrigated with warm sublimate solution. The iodoform tampons were continued. On the third day labor pains came on; these were encouraged by the application of the binder, and by massage to the fundal and equatorial segments of the uterine tissue. As the labor progressed, hæmorrhage ceased. The placenta was not fully detached until after the child was born, but was carried to the right and supported by an assistant using napkins dipped in a warm solution of bichloride. The child did well and the mother made a good recovery. I have no doubt that had I ruptured the membrane when first called, and attempted podalic version by internal and external method, the child would have been asphyxiated before the rigidity of the os and cervix could have been overcome, even if the subsequent expulsion of the head had been aided by the application of the forceps, as has been sometimes advised. In one case of this series, hæmorrhage occurred after the close of the seventh month; in one, during the first week of the eighth month; in the third, hæmorrhage did not appear until after the second week of the eighth month; in the fourth there was no alarming hæmorrhage until the close of the ninth month. In the first two cases of this last series, the mother survived. The foetus in one was still-born; the cause of its death was congenital ab-

dominal fissure. In the third case both mother and child survived; in the fourth the mother survived as above stated. In reporting these cases, I do not wish to lay claim as yet to any special method of treatment, for I am not unmindful that the outcome of the treatment of another series may be altogether different.

In the presentation of these cases, I can only commend for consideration, the method I adopted, in preference to others more radical in their nature, and which have so often been attended with unhappy results.

For, according to Churchill,⁶ it has been estimated in placenta prævia, that material mortality is as one in three.

Read has estimated as one in four and a half, and Barnes as one in ten and two thirds. Says Fitzpatrick, the dangers from prematurity, asphyxiation and malpresentation are very great. According to the same high authority, Churchill estimates that half the children are lost. In this connection there is a point in the treatment that should be emphasized, and it is this. It often happens that those who are engaged in the practice of obstetrics, and who may become exceedingly expert in detecting the various positions of the foetus and in conducting examinations, and in passing judgment upon methods of treatment, have really no surgical knowledge.

The nature and kind of training they have received, have not fitted them to meet and cope with the emergencies arising from the occurrence of a severe case of placenta prævia.

Knowledge to meet such emergencies can be obtained only by long, tedious and constant practice, and in purely surgical and gynecological cases. As the obstetrician has not, as a rule, the trained hand of the surgeon, the case is frequently hurried to an early close, often at the expense of the mother, and more often at that of the foetus.

SPECIFIC TREATMENT OF TYPHOID FEVER.

Read in the Section of Practice of Medicine, Materia Medica and Physiology at the Forty-first Annual Meeting of the American Medical Association, held in Nashville, Tenn., May 22, 1890.

BY J. H. VAN EMAN, M.D.,

PROFESSOR OF CLINICAL MEDICINE, KANSAS CITY MEDICAL COLLEGE, KANSAS CITY, MO.

While it might seem the subject of the treatment of typhoid fever is well worn, and that but little progress has been made in its treatment during the last decade, it is yet true that much diversity yet obtains as to its therapeutics, and its rational and specific treatment is far in the rear of both its etiology and pathology.

Long before the microscopic discoveries of Koch and other investigators, the thinking members of the profession recognized the fact that

⁶Lancet, April 6, 1889.

there was a specific cause for typhoid fever, and many other diseases, and attempts were made at various times to make such application of drugs that the disease-producing ferment of poison might be either neutralized or destroyed in the blood, and thus cut short a disease which, under other conditions, either lasted until death ended the scene or the fire ceased to burn for want of fuel.

Without any understanding of the necessary environments for the growth and proliferation of the poison, many different lines of treatment were carried out, with the intention of either cutting short the disease, or at least of lessening its severity.

One of the earliest plans of specific treatment was based on the supposition that the excretions of the microbe of typhoid fever was intensely alkaline, and as no living organism can exist for any length of time in its own excretions, large doses of nitrite of ammonium, reinforced by other ammonia salts as certain indications might require, were used. By this plan of treatment the author (a surgeon in the late Confederate Army) claimed the organisms producing typhoid fever were rapidly destroyed, and in a series of two hundred and twenty-five cases he claimed not a single death occurred.

By repeated and continued doses of calomel, German physicians claimed to greatly reduce the death-rate. Of later date the use of the salicylates, and more especially the salicylate of ammonium, have been highly lauded. The sulphites have also been used for the same purpose; also combinations of iodine and carbolic acid, known as the Bartholow treatment.

Many other plans of treatment, having for their object the destruction or neutralization of the typh-poison, have been tried, but time will not permit further notice of them in this paper. The general plans of treatment, however, have been the so-called expectant, *i. e.*, by meeting the dangerous symptoms as they arise, and thus obviate the tendency to death, be it coming from whatever direction it may.

From almost the earliest history of the disease the mineral acids have held a prominent place in the treatment of typhoid fever; not, however, as a poison destroyer, but as a tonic. They were supposed to assist in keeping up the vital forces until the fever had run its course. All these many years, however, the faculty were combating the destructive effects of an unknown something, a *contagium vivum*, whose effects, both pathological and lethal, were thoroughly understood. Of the laws that governed its growth and reproduction, even of the means by which it entered the human organism, almost absolutely nothing is known.

Within the last decade, stimulated by the investigation of Pasteur, of Koch, of Sternberg,

and of hundreds of other active, thinking, working members of the profession, darkness is rapidly being superseded by light, and we are fast recognizing the truth that all our contagious and infectious diseases are caused by a living entity within the body; a germ that has shape, and form, and laws of self-preservation, and reproduction, just as definite and positive as of any living organism. The veriest tyro in medicine is beginning to understand something, at least, of the life-history of bacteria and their agency in the production of diseases.

In the early part of the fall of 1889, following up the conditions under which pathogenic germs can be cultivated and reproduced, my attention was particularly drawn to the fact that all such germs could only be cultivated in an alkaline medium, and with the converse of this truth, as well, that let a culture fluid, perfect in every other respect, be either intentionally or accidentally made even slightly acid, the germ growth was at once arrested, and not only that, but the germs already in existence soon become feeble and then cease to exist.

It struck me like a revelation, that for the long-continued popularity of the acid treatment of typhoid fever I had found a rational hypothesis. More than that, it occurred to me that I had found a plan of treatment that promised to reduce the proliferation of the typh-poison within the body to the minimum, and possibly to entirely arrest it by a therapeutic agent that would have no deleterious effect on the human organism. Other germicides, such as the mercuriates, carbolic acid, etc., will, when introduced into the body in sufficient quantities to destroy the disease germs, destroy the patient as well.

Acting on my theory, I at once began the treatment of my typhoid cases, as soon as I was reasonably certain of my diagnosis, as follows: For the first 36 to 48 hours I gave calomel in five to ten grain doses until I had very thoroughly cleansed out the alimentary canal, for the purpose of either sweeping out or destroying all typh-germs that had not migrated from the intestine. While doing this I sterilized all foods and drinks, thus preventing the ingress of new germs. This being done, I put the patient on half drachm doses of dilute muriatic acid given in syrup and water, every three hours, night and day. Now as to results. In six cases thus treated, all recovered. In all diarrhœa was promptly arrested and never gave any further trouble; in fact, some little attention was required to keep the bowels open. In no case, after the institution of this treatment, did delirium occur. Neither sordes nor dry cracked tongue in any case. In five of the cases the duration of the disease was under twenty-one days. No complication existed, and convalescence was uninterrupted and unusually rapid. In none of the cases did the evening tem-

perature go above 103° after treatment was well commenced. In one case only, which began with an attack of la grippe, was protracted in its course, lasting nearly five weeks and having as a complication hæmorrhage of the bowels, which, while rather profuse, was readily controlled by morphine and ergot per orem.

It is true that six cases are a small number on which to base an opinion or tabulate results, yet the subject seemed to me to be of such vast importance, and the results obtained so marked, that I felt it a duty to bring the subject before the profession, hoping that many others might take up the work and by the next meeting be able to report results.

NOTE ON NASAL HÆMORRHAGE.

Read in the Section of Laryngology and Otology, at the Forty-first Annual Meeting of the American Medical Association, Nashville, Tenn., May, 1890.

BY FRANK HAMILTON POTTER, M.D.,

OF BUFFALO, N. Y.

LECTURER ON DISEASES OF THE NOSE AND THROAT IN THE MEDICAL DEPARTMENT OF NIAGARA UNIVERSITY.

The object of this short note is to call attention to the symptom of bleeding from the nasal passages depending upon or associated with deformities of the septum, especially of its anterior portion. This observation is not new, but will be found in most of the works treating of nasal diseases. We find, however, that as a rule, the writers consider that the hæmorrhage is caused by a slight erosion located at some point of the deformity. For instance, Bosworth¹ says:—"Slight deformities of the septum are probably the cause and source of an epistaxis more frequently than any other lesion met with in the nasal cavity, the apex of the projecting portion becoming the seat of a slight erosion, probably as the result of attrition by the dust-laden current of the inspired air. In this way the walls of the blood-vessels become thin, while at the same time the eroded surface forms a site for the formation of dry crusts." This opinion may be accepted as fairly representing the views of the profession on this point. Yet it does not cover all the cases of epistaxis associated with these deformities. Some severe cases of bleeding occur without any erosion whatever, at least any that careful observation can detect. It is to this class of cases that your attention is directed. In studying these cases we must eliminate as causes of the hæmorrhage, 1, traumatism; 2, constitutional or systemic conditions; 3, vicarious menstruation; and 4, other local morbid conditions. We find simply an extreme thinness of the pituitary mucous membrane, due primarily to the presence of a deformity. There is no erosion. The hæmorrhage is often severe and difficult to control. It is intermittent. It may occur either upon the convex

or concave side of a deflection of the anterior part of the septum, or upon both sides. Sometimes, where there is thickening of the septum without deflection, we have observed hæmorrhage to occur from the same cause. The mucous membrane appears to become at these points extremely thin, and unable to withstand the blood pressure. I know of no pathological investigations of this condition, and speak only from a clinical standpoint. While it may not be strictly accurate to use the term "thin" in this way, it expresses very well the clinical features of these cases.

To illustrate how severe these hæmorrhages may be occasionally, I recall the case of a man aged 46 years, in good health and without constitutional disease, who, from repeated bleedings during about fifteen days, reduced his weight ten pounds, and was found in bed weak and frightened. Fear, of course, is an element to be considered in such a case, the loss of blood not answering entirely for the patient's condition. The treatment of these cases involves the removal of the deformity or the cauterization of the bleeding surface. When the deformity is sufficiently large to cause obstruction to respiration through the nostril, the thickened or deflected portion should be removed, preference being given in this operation to the fine nasal saw. Or where the deformity is sharp and projecting, even if not large enough to cause obstruction, it may be removed in a similar manner. As the wound heals and a new membrane is formed, we will find that the hæmorrhage will disappear. When the above conditions are not present, or when the bleeding takes place from the concave side of a deflection, the surface should be thoroughly cauterized. For this purpose I generally prefer chromic acid fused on the point of a probe. In this way each bleeding point can be touched. Frequently we find that these points are located at the union of the triangular cartilage with the vomer and the perpendicular plate of the ethmoid, and it is well to be especially careful in looking along these sutural lines. It may happen that a single cauterization will not be sufficient. The scab that usually forms after the application of chromic acid will not cling to the parts, or even fail of formation altogether. In such a case it must be reapplied as soon as we find the hæmorrhage recur. Sometimes I have found it necessary to apply it four and five times before success was obtained. Never has it failed when followed up in this manner. Of course the usual after-treatment is to follow, both after the removal of the obstruction and the cauterization, that now pertains to the proper performance of nasal surgery.

This treatment can be followed also when an erosion is present and the cause of the hæmorrhage, but then the indication is so plain that any one would naturally treat it in a proper manner. It is in these rather obscure cases, that could

¹ "Diseases of the Nose and Throat," Vol. I, p. 311.

be easily overlooked, that care must be exercised and treatment promptly determined upon.

The annoyance and even danger of these repeated hæmorrhages, and the difficulty many times in locating the places where they occur, warrants this brief reference to a very simple matter.

MEDICAL PROGRESS.

THE RELATION OF GENITAL DISEASES TO SKIN AFFECTIONS.—DR. FRANK (*Zeitschrift für Heilkunde*) describes a case of chronic urticaria caused by genital disease, which was observed in the gynecological clinic of Prof. Schauta, in Prague. The patient, a sewing woman, 28 years of age, had menstruated since her sixteenth year without difficulty until three years previously. Then her flow was accompanied by headache, an eruption of vesicles upon the back, forehead, cheeks, and extremities; also pain in back and cramps in the abdomen, and a profuse leucorrhœa. The skin symptoms always followed the menstruation promptly, so that in a couple of hours most of the body was covered. The gynecological examination revealed chronic oöphoritis and bilateral salpingitis. On Oct. 16, 1888, both tubes were removed, and eight months later she reported that the menses were not painful and that the skin eruption had entirely disappeared. The explanation of this case lies in regarding urticaria as nervous œdema, and that in the above-mentioned case the relation shown between the genital and skin affection was caused by frequent attacks of pain that increased the sensitiveness of the nerves, especially those governing the vascular supply of the skin.

ANTISEPTIC TREATMENT OF VARIOLA.—M. BIANCHI has described (*Lo Sperimentale*) a treatment that has been attended with excellent results in 96 cases, 22 of which were slight, 39 grave, and 15 very severe. He commences with a full tepid bath of a solution of 1:20 of boric acid; during this bath the patient is covered with an antiseptic soap. During the course of the disease the patient is bathed every four hours with a solution of 1:1000 of corrosive sublimate or the boric acid solution. After these bathings he is anointed with iodoform and vaseline, 1 to 5 parts in the hundred, according to the gravity of the case. All the pustules are opened with an aseptic needle, and their contents evacuated. The patient is then enveloped in aseptic linen that is frequently changed; all objects in the apartment, the floor and walls, are washed every two days with a solution of sublimate 1:200. This treatment diminished notably the duration of the eruption, lessened fever, and prevented se-

vere ulceration and scarring, procuring a relatively favorable condition of the patient and rapid convalescence. It is also of great prophylactic value, as direct contagion will be difficult, and at a distance impossible, because not only the person, but the bed, air, and surroundings of the patient are rendered thoroughly aseptic.

THE INFLUENCE OF DRUGS ON ABSORPTION. The importance of a knowledge of the process of absorption taking place in the intestine cannot be over-rated, and consequently any addition to our information on this subject is to be welcomed. The absorption of drugs by the intestine has been very little investigated, and it is on this point that LEUBUSCHER, of Jena, has made some experiments. The process of absorption must no longer be considered a purely physical one, but a function of living cells, so that any causes which may injuriously affect the life of these cells will also interfere with proper absorption. The cells may be altered by influences acting directly on themselves, or through the blood current, or through means of the nervous system. With regard to direct injury of the cells, Leubuscher experimented by isolating a small coil of intestine in a living animal by means of light ligatures, and then injecting a strong solution of a mineral acid, washing this out with water and introducing a known quantity of grape sugar in solution. Compared with a normal intestine, the quantity of grape sugar absorbed was considerably lessened. In other experiments, the artery supplying the coil was tied, or the vein leaving it, producing in the one instance anæmia and in the other congestion; in both cases, but more especially in the latter, absorption was greatly interfered with. Investigations as regards the third division—namely, the effect of the nervous system—could not be fully carried out. The action of various drugs was then tried. Grape sugar and a solution of iodine in iodide of potassium were used as tests of the power of absorption, and the following drugs were selected: quinine, opium, alcohol, glycerine; also weak solutions of common salt and Carlsbad waters. Coils of intestines were exposed and isolated in two animals. In one the grape sugar or iodine solution alone was injected, and in the other the same mixed with the drug to be tested. The results were afterwards corroborated in animals in whom an artificial intestinal fistula had been secured. Quinine, opium and morphia, even in weak solutions, interfered greatly with absorption. Morphia acted in the same manner when it was introduced into the system by means of hypodermic injections. Alcohol in weak solutions (5 to 2 per cent.) increased absorption, but in larger quantities hindered the process. Glycerine produced no decided effect, weak solutions of common salt increased, and Carlsbad water had no effect on absorption. A few exper-

iments were also tried by estimating the quantity of iodide of potassium passed within a certain time in the urine of patients after a dose of this drug had been administered by the mouth, the iodide being dissolved either in water, alcohol, glycerine, Carlsbad water or milk. With alcoholic solutions the quantity was increased as compared with the watery solutions; with glycerine, this was the same as with water; Carlsbad water also increased it, but milk lessened the quantity. —*Lancet*.

ACTION OF URINE ON TISSUES.—This subject was recently discussed before the Société de Biologie. The older surgeons considered infiltration of urine as a grave accident, particularly in preventing the union or cicatrizing of wounds. This opinion is erroneous in more than one point, as the clinic daily demonstrates the negative. On the other hand experimental researches of Guyon and Buchard have shown that urine alone is aseptic. That it becomes hurtful after alteration, due to the accidental development and multiplication of the pyogenic bacillus which give the urine irritating properties, ramified in certain cases by gangrenous and diffuse phlegmons. In his turn M. Tuffier, in experimenting upon animals, has once more confirmed the views now all but universally admitted. They fully support some recent surgical operations that seem bold to the point of rashness, such as the resection of the vesicle wall for neoplasm, etc. Genito-urinary surgery is, like other branches, dependent largely upon experimental work for its further advancement.

STERILITY IN THE MALE.—CASPER (*Berlin Klin. Wochenschr., Rev. d. Sci. Med.*) has observed the following curious and interesting case: A man of 30 years had been married two years, to a young woman who presented nothing that would account for the barrenness of their marriage. The husband had an inflammation of the urethra, complicated by left epididymitis eight years before, but no evidence of antecedent syphilis. The sexual organs presented a normal conformation, testicles of normal consistence, but on the upper portion of the left epididymis was an induration the size of a bean. The prostate and seminal vesicles were normal. The urethra readily allowed the passage of a No. 22 Charrière. The lymphatics were generally indurated, especially those of the groin. A red, dry ulcer was found on the posterior wall of the pharynx as well as ulceration of the right tonsil. Semen was normal in appearance but contained no spermatozoa. After two weeks of specific treatment, five spermatozoa were observed in the semen, and after an additional two months as many as 20 spermatozoa could be counted in a single field. At this time the wife conceived, and at the

end of less than ten months was delivered of a child presenting all the signs of hereditary syphilis. The mother remained free from all signs of syphilis.

The author closes the article with some observations upon the two forms of masculine sterility; the absence of the spermatic fluid and azoospermia.

PREMATURE LABOR.—At the meeting of the International Medical Congress, in the Section of Gynecology and Obstetrics, the discussion on the Indications and Methods for producing Premature Labor was opened by DR. PARVIN (Philadelphia) in an eloquent address, in which he briefly referred to the fact that out of some thousand cases nearly seven-eighths require premature labor for deformities of the pelvis, and these cases must be decided on the degree of deformity. He then recounted the various diseases in which it might be required for the sake of the mother, such as albuminuria, in which he considered it but seldom necessary, even in cases that went on to eclampsia, quoting Gooch's well-known aphorism; in cardiac diseases also he employed it but exceptionally, but frequently had recourse to it in pneumonious disease, where it gave satisfactory results, more especially in acute lung affections, where dyspnoea was a prominent symptom. In obstinate vomiting as well as in chorea it might occasionally be required, but only after all other means had failed. For the sake of the child it became necessary in cerebral apoplexy, and in some cases of cholera. Professor Macan (Dublin) discussed the ethical side of the question in pelvic narrowing, and dwelt fully on what he called the "proportionate value" of the mother's and child's life. He stated that in Ireland and other Catholic countries the question was to some extent affected by the religious aspect, but that notwithstanding the great improvements in the Cæsarean section and its lessened mortality, the final decision between it and craniotomy rested with the mother. Whatever method was adopted should be carried out with the most rigorous antiseptics. Dr. Dohru, while admitting the great improvement in Cæsarean section, contended that there was still a wide field for premature labor in which it was of the greatest benefit. Dr. Calderini recommended that in the case of a living child premature labor should not be induced when the true conjugate diameter was under seventy-five millimetres.

ABDOMINAL SECTIONS BY PROFESSOR MARTIN.—On Wednesday morning, August 6, DR. MARTIN, of Berlin performed three abdominal sections at his private hospital in the Elsasserstrasse before a company of distinguished foreign operators. Each patient was chloroformed in her ward, then carried upon a couch with wheels to a room where the abdomen was thoroughly washed

with sublimate, the pubis shaved, and the urine drawn off. The visitors, at the request of the operator, entered the operating theatre divested of their coats and waistcoats. The operator and his assistants were in a yet more complete undress uniform. The patient was brought into the theatre, underwent a fresh washing, the juice of a lemon being lastly squeezed over the abdominal integuments. The operator sat between the patient's thighs, the chief assistant—also sitting—was placed to the patient's left. In all three cases the operation was performed with great rapidity, and the abdominal incision was made very long, almost reaching the umbilicus, although in no case was a large tumor present. The wound was also closed quickly by means of stout catgut sutures, not placed closely together. In the second case a suppurating tube was removed from the right side. In the third an intraligamentary ovarian cyst was enucleated. The first operation was of great interest. An interstitial myoma of moderate size was present. The uterus and its appendages were drawn out of the wound, and the vessels of the broad ligament temporarily secured by means of large pressure forceps. Then a vertical incision was made, extending down the back and front of the uterus, passing over the fundus. The myoma was next enucleated. The capsule was treated after Dr. Martin's special method; none of its substance was cut away, but its raw surfaces were united by deep, and its cut edges by superficial, catgut sutures. The forceps being removed, the sutures and appendages were replaced in the pelvis. In none of the cases was flushing or drainage employed. The instruments were immersed in a 2 per cent. solution of carbolic acid. For the washing of the patients and the operator and assistants a 1 in 1,000 solution of sublimate was employed. The spray was not used.

REMOVAL OF A PORTION OF THE LIVER.—M. TERRILLON reported to the Académie de Médecine (*La Semaine Médicale*) the case of a woman who presented herself at the Salpêtrière with a large, painful tumor in the region of the false ribs on the right side. It was determined that this growth sprang from the liver. An exploratory puncture was made at the highest point of the tumor, which gave exit to a few grams of liquid resembling that found in hydatid cysts. Notwithstanding that this slight operation had diminished the size of the tumor, a laparotomy was decided upon. The opening was made in the right side parallel with the false ribs. A portion of the liver, as large as two fists, presented itself, literally stuffed with innumerable small hydatid cysts. It was determined to remove the tumor, but as it was directly continuous with the tissue of the liver, excessive hæmorrhage was feared. To avoid this an elastic ligature was thrown about

the growth, to form an artificial pedicle. The diseased part separated by the elastic ligature was secured to the outer wall of the abdomen. At the end of seven days this portion mortified and separated in the line of the ligature. There remained an ulcer, the base of which was formed by the necrosed liver tissue, separated from the peritoneal cavity by the free adhesions which had formed. After six weeks the ulcer was completely healed, and the patient in excellent health.

INFECTIOUS ORIGIN OF TETANUS.—The view that tetanus is (*Bulletin de la Gazette Médicale*) infectious has long been prevalent in France and other countries. Recently LEYDEN has reported to the Society for Internal Medicine of Berlin, three cases of tetanus in man, one of which was cured. In the three cases the bacillus of Nicolaïer was found in the neighborhood of the "tetanic" wound; inoculations successively upon the mouse, rabbit and dog producing the characteristic disease in each instance. With the first two animals the result was fatal. The interesting conclusions in these cases relate to pathogenesis and treatment. We can believe with Leyden that tetanus is a virulent disease, the symptoms being caused by the contact of the poison with the nervous centres, without the intervention of anatomical lesions that are problematical. For the same reason we can admit that the chances of a cure augment as the disease lengthens, and if the patient survive the sixth day there is a good chance of recovery. The indications for treatment point more strongly to local antisepsis, than in any other microbial or virulent disease.

ACUTE GONORRHOEA.—SCHWIMMER especially recommends the following injection in acute gonorrhœa:

R. Salicylate of mercury, .01 gr.
Water, 100 grs.

The injections to be used three times daily. At the end of three or four days the discharge has, as a rule, become mucons in character, when the remedy is to be discontinued. For chronic cases he recommends the same drug in a strength of 5 centigrams to 100 grams of water.—*L'Union Médicale*.

TREATMENT OF HERPES TONSURANS.—CHARON (*Journal de Médecine de Bruxelles*) claims excellent results in the treatment of this troublesome affection by Reynold's method, that consists essentially in making use of the cataphoric action of the galvanic current. The positive pole, covered with a sponge saturated with a 1 per cent. solution of bichloride of mercury, is placed over the affected portion of the scalp, and the negative pole upon some indifferent point, *i. e.*, sternum or back. The application is continued for fifteen to thirty minutes, and is said to be followed by prompt improvement.

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 68 WABASH AVE.,
CHICAGO, ILLINOIS.

All members of the Association should send their Annual *Dues* to the Treasurer, Richard J. Dungleison, M.D., Lock Box 1274, Philadelphia, Pa.

LONDON OFFICE, 57 AND 59 LUDGATE HILL.

SATURDAY, SEPTEMBER 27, 1890.

JEQUIRITY.

The papers on jequirity and the discussions thereof which were listened to with great interest and profit at the meeting of the American Medical Association held at Nashville, and which have recently appeared in the pages of THE JOURNAL, revive for a moment the lagging interest in the remarkable history of this drug. Many of the remedies which the last decade has brought to light have had a more or less chequered career. Some of them have enjoyed a certain amount of popularity in their day, and have been relegated to a deserved, and sometimes an undeserved oblivion. Others, which brought with them unquestionable elements of success, have stood the test of time, and are come to stay, while others obscurely lived and died between the covers of some bulletin of materia medica. Few remedies, however, have been ushered into the world with better patronage or more *éclat*, and have had such an interesting history as jequirity. With its South American reputation, the Brazilian bean found its way into DR. DE WECKER'S clinic, and from thence, with his indorsement and recommendation, it soon found a place in nearly every clinic throughout the civilized world. A host of experimenters set about to put it to the crucial test, and its virtues were tested in every case where the old remedies had apparently failed, or whenever the irresistible craze for something new tempted the ophthalmologist to experiment with this suddenly famous drug. Hardly had it reached this country when some ugly reports appeared in some of the oph-

thalmological journals, but such was the power of its reputation that trials were continued, and in spite of adverse criticism, its position seemed to be assured. Hardly a clinic could be visited, where some patients were not seen undergoing the torments of a course of jequirity treatment—and the little vial containing the infusion was exultantly pointed out as the cause of the torments and the great specific for trachomatous conjunctivitis and corneal pannus. There were a number of men, however, who watched this revolution in the treatment of pannus with some misgivings as to the ultimate result. They demanded of the remedy not only a greater assurance of success, but also a greater insurance against danger. They could not quite make up their minds to subject a patient to a course of treatment which, during a certain period of its development, placed the inflammation beyond their control. Still, brilliant results were frequently reported. Numerous eyes which had been entirely given up, were restored to usefulness—but it was remarkable how many eyes were given up, and how frequently the classical methods entirely failed. When notes were carefully compared it appeared that in the clinics where jequirity was not used trachomatous patients got along quite as well as in those where the infusion was freely applied; and there was a good deal less anxiety as to results. The outcome of these observations and comparisons, was that very many who were carefully watching the experiments, were led to rely on the less violent methods and to abstain from the use of jequirity.

Time, which brings about so many changes in methods and procedures, has not been idle in this instance. Jequirity is not much used now. The reason why its popularity has so remarkably waned, is not difficult to ascertain. It is necessary to state here that our remarks apply only to the infusion. With the powdered jequirity we have had no experience.

Glancing at the clinical history of the drug, it is evident that there are three great objections to the jequirity treatment. First, the painfulness and severity of the process. Second, the danger of corneal ulcerations. Thirdly, the unreliability of the ultimate result. It is unnecessary to discuss the first statement. Every one who has witnessed a patient with jequiritic ophthalmia, has witnessed a patient in severe pain. The danger to the cornea has been often much underestimated.

It is claimed that the intense inflammation can be controlled and in this manner any tendency to ulceration of the cornea can be checked. Experience teaches, however, that instances frequently occur where the inflammation can not be controlled, and where the result is disastrous. With such a possibility in view, it is difficult to gainsay the verdict dangerous. The statement regarding the unreliability of the ultimate result may be called in question, yet there is an abundance of testimony to its corroboration. Let it not be understood that we would have jequirity exterminated. It has its place, but only as a *dernier ressort*, to be employed when the less heroic methods have entirely failed. The classical methods have been by some much underestimated, and they ever will be if not used with proper discrimination. The promiscuous rubbing on of blue stone, and the persistent brushing the lids with nitrate of silver, without proper attention to the changes which are taking place, particularly in the cornea, must necessarily bring discredit on this method. A little more brains and a little less perfunctory routine work would add greatly to the credit of our clinics and materially decrease the percentage of failures. There is one other consideration which is worthy of mention in this connection on account of its practical bearing, although it has no scientific value. It should be borne in mind, when using a dangerous remedy, that the misfortunes of conscientious and competent physicians are only too liable to contribute to the fortunes of a certain class of lawyers.

The foregoing remarks may seem rather superfluous to the experienced ophthalmologist, but they are certainly opportune for the tyro in ophthalmology. Heroic measures have a potent charm, which often obscures the danger associated with their adoption. Therefore a repetition of the note of warning is not amiss.

EXPERIMENTAL RESEARCHES ON THE PATHOLOGY OF FEVER.

ROUSSY (*Arch. de Physiol.*, xxii, p. 354, 1890) has recently added some original experiments to our knowledge of the febrile process. He has observed several cases of high temperature of brief duration from the use of stale beer, decayed flesh, and drinking stagnant water containing vegetable matter, such as hay, leaves, etc. He refers

the cause of this fever to soluble chemical substances rather than to a specific microorganism. In experiments upon animals he found that intravenous injections of water containing decaying organic matter produced an intense fever after reaching 42° C., and marked gastro-intestinal disturbance, when a like quantity of the same substance introduced into the stomach did not cause fever or other disorders.

The writer especially calls attention to the high fever produced by beer yeast. When rubbed up with distilled water, and after 24 hours filtered, and a cubic centimetre of filtrate injected, hypodermatically, it is followed immediately by severe attacks of fever lasting from twelve to fifteen hours. That this fever is not due to the mechanical effects of the germs was proven by the fact that when a quantity of yeast cells were collected on a filter and dried at a temperature of 120° C., then mixed with distilled water and injected, the temperature rose but a fraction of a degree. That the fever was caused by the product of the living cell was demonstrated by cultivating beer yeast in bouillon, then carefully washing the cells at the bottom of the glass with sterilized water, and allowing them to stand for three days. The injection of this mixture produced the same stormy febrile attacks as that caused by the injection of stale beer.

He was able to separate the peculiar substances causing this fever, by the following method: a considerable quantity of yeast, 2-3 kg., was added to 1-2 liters of water and allowed to stand with occasional agitation for two or three days. After careful filtration, absolute alcohol was added until nothing more was thrown down. The precipitate was collected on a filter, washed, redissolved, and again precipitated. At last a white shining flaky precipitate was obtained, that under the microscope appeared to be made up of three or four substances. Through the different solubility of these substances in water, diluted and pure alcohol, it was possible for Roussy to separate them. Fever was only caused by one, a substance presenting fine granular masses of a light yellow color, which deliquesced, forming a syrupy mass that when dried adhered strongly to the vessel. In a desiccator the precipitate was pure white, resembling porcelain, slightly scaly and easily pulverized. It was readily soluble in

water, slightly in ether, and not at all in alcohol, benzine, chloroform or bisulphide of carbon. Upon the tongue it rapidly melted, at first having a resinous taste, then a biting feeling which rapidly rose to a sense of strangulation.

If one-half milligram of this substance, "Pyretogenin" as it is called by the writer, is injected for each kilogram of the animal's weight there is a rise of temperature beginning one-half to one hour after the injection, and frequently reaching as high as 42° C. It is accompanied by chills, vomiting, diarrhoea, etc. The pulse is small, hard and frequent, and the skin dry. After six or seven hours the animal is again in a normal condition. During the febrile movement there is an increase in urea, carbonic acid and the amount of heat eliminated.

THE EFFECTS OF COFFEE ADDICTION.

The excessive consumption of coffee by the working population, especially the females, of the district of which Essen is the centre is the subject of a paper by DR. F. MENDEL, in the *Berlin klinische Wochenschrift*, showing the principal disorders consequent upon the chronic abuse of that substance. He states that great numbers of the Essen people are in the habit of drinking coffee from morning till night, averaging daily a pound or more for each individual, of the Ceylon berry, which contains about four grams of caffeine to the pound. The author arranges the morbid phenomena observed by him in three groups, which are all remotely or directly referable to the ill effects upon the nervous system of the chronic abuse of caffeine. First, there are nervous troubles, beginning in a feeling of lassitude and indisposition to work, followed by depression of mind, cephalalgia and insomnia. These symptoms disappear more or less promptly when the individual has taken a concentrated infusion of coffee. Second, muscular disorders, as a greater or less diminution of vigorous motion, the impairment being no greater in the coarser domestic labors than in fine handwork, and tremors of the hands, even when at rest. Third, circulatory phenomena, as small, accelerated and irregular pulse, enfeebled apex-beat of heart, palpitation and some precordial distress; coldness of the extremities, appreciated even by the patient; anæmia of the mucous membranes and yellowish white complexion; cardial-

gia, eructations, sense of fullness of or pressure over the stomach. Anorexia is frequent, with nervous dyspepsia. A tendency to acne rosacea has been observed in a certain proportion of cases. The treatment consists in the gradual withdrawal of the coffee and the substitution therefor of milk, which helps to re-enforce the oftentimes scanty dietary; cognac in small doses at the outset of treatment; the patient to have daily cold baths with energetic friction; to spend as much time as possible in the open air. If the character of the daily labor is such as to produce nervous strain, this difficult work should be discontinued temporarily, at least.

EDITORIAL NOTES.

THE CONDEMNED AND THE FACULTY OF MEDICINE.—The last man condemned to death has declined to go to the dissecting room with his head cut off. What is droll in the whole proceeding is that the judges have hastened to comply with the wishes of an assassin, in which action they have been vigorously applauded by the political press. To our mind such a proceeding is scandalous, as paupers in our hospitals are entitled to the same consideration, and ought to have it accorded to them as readily as to a murderer. It is the least the latter can do to render some service to science, when during life they have caused so much trouble. Let the patients in our hospitals, those who can walk, get up and go to the Palais de Justice and there claim a burial of the first class; surely the judges would accord it to them sooner than to the Pranzini and Eyraud. In closing let us add that M. le Ministre has not understood the gravity of this request—it means, without doubt, the ruin of anatomical study, in encouraging such a ridiculous fear of the amphitheatre of l'École de Médecine.—*Le Progrès Médical*.

CHOLERA.—The epidemic is still prevalent in the interior provinces of Spain. It is reported that the full extent of its ravages is not made known to the public, the Government having surveillance of all telegrams which would be calculated to excite apprehension. So far as ill-founded and sensational reports are concerned we deem this action eminently judicious. The disease is reported as steadily advancing along the African coast of the Mediterranean Sea. The Russian

Government is advised of a severe outbreak in the seaports of the North Pacific Ocean, and all vessels coming from Asiatic Russian ports are subjected to the closest scrutiny. Sporadic cases are reported here and there in the United States, and sensational articles are sent broadcast by the press which at any other time would fail to command the least attention.

THE MEDICAL SOCIETY OF THE MISSOURI VALLEY held their third annual session at Council Bluffs, Iowa, September 17 and 18. There was a large attendance. The membership includes many able physicians and surgeons. The following officers were elected: President, Dr. J. M. Richmond, St. Joseph, Mo.; 1st Vice-President, Dr. B. F. Crummer, Omaha, Neb.; 2nd Vice-President, Dr. G. W. Coit, Missouri Valley, Ia.; Secretary, Dr. F. S. Thomas, Council Bluffs, Ia.; Treasurer, Dr. T. B. Lacy, Council Bluffs, Ia. The next meeting will be held at Kansas City, Mo., December 18 and 19.

GOLDEN BELT DISTRICT MEDICAL SOCIETY.—The Fall Meeting of this Society will be held in Abilene, Kan., on the 2nd prox. Dr. P. Daugherty, Junction City, Kan., President, and Dr. F. B. Browne, Salina, Kan., Secretary.

THE PASTEUR INSTITUTE IN CHICAGO.—This institute was opened on July 2. Twenty-four persons have thus far been under treatment. In twelve of the cases it was confidently believed that the dogs which inflicted the wounds were mad. In the other cases doubt is entertained upon that subject. The patients were treated by inoculation, and in every instance without any appreciable ill-effects.

REDUCED RATES.—The fare from Chicago to Louisville for those who propose to attend the annual meeting of the Mississippi Valley Medical Association, which convenes October 8, and the American Rhinological Society which meets in the same city two days earlier, has been placed at one and one-third rates for the round trip. There should be a full representation from the upper Mississippi Valley at these meetings. Abundant provision is made for a large attendance.

MEDICAL MISSIONARIES.—Among the missionaries who sailed from San Francisco September 4, per steamer Oceanic, we find the following: T. R. Jones, M.D.; Mrs. Stella B. Jones, M.D.;

Miss Rachel R. Benn, M.D.; Miss Ida Stevenson, M.D.; all for North China; J. H. M'Cartney, M. D., and wife, for West China; Miss Rosetta Sherwood, M.D., for Korea.

BERLIN MEDICAL CONGRESS.—It is gratifying to learn that the United States was so well represented at the International Congress. Excepting Germany it had the largest number of members, being represented by 659. Germany, excepting Berlin had 1,752, Berlin 1,166, Russia 429, Great Britain 358, Austro-Hungary 262, France 179, Italy 146, Denmark 139, Holland 112, Belgium 62, Switzerland 67, Spain 41, Sweden 108, Norway 57, Roumania 32, Luxembourg 2, Portugal 5, Turkey 12, Greece 5, Bulgaria 5, Servia 2, Monaco 1, Canada 24, Brazil 12, Chili 14, Mexico 7. Other parts of America 30, Egypt and Africa 14, China 2, Japan 22, India 2, Australia 7.

KLEBS-LÖFFLER BACILLUS.—Spronk, Wintgens and v. d. Brink claim to have demonstrated that the Klebs-Löffler bacillus is the essential etiological factor in diphtheria. From pure cultures they have obtained a substance that produces paralysis similar to the post-diphtheritic. —*Nederl. Tijdschr. v. Geneesk.*

A RECENT FRENCH DECISION has reversed the old rule of French jurisprudence that a physician cannot recover for attendance upon the last sickness of an individual. Dr. Benoist, of Saint-Nazaire, recently carried a case of this kind, involving a charge of 236 francs, to a court of last resort and secured a favorable decision.

PROF. ERNST V. BRÜCKE held his last lecture on July 17. The occasion was properly observed by students and colleagues of the eminent physiologist. He is retired from his professorship in consequence of the Austrian law that does not permit a teacher to remain in his position after having reached the age of 70. He had been professor of physiology in Vienna for forty-one years.

THE RIBIERI PRIZE.—The Turin Academy of Medicine announces the subject selected for the competition for the International Ribieri Prize as being "Researches on the Nature and Prophylaxis of the Infectious Diseases of Man." The value of the prize is \$3,600. The competing papers should be written in either the Latin, Italian or French languages.

TOPICS OF THE WEEK.

PROTECTIVE INOCULATION AGAINST TUBERCULOSIS.

Probably the most noteworthy discovery reported at the recent session of the International Medical Congress was Prof. Koch's announcement of a substance that has the power of preventing the growth of the tubercle bacilli, not only in the test-tube, but in the animal organism as well. Guinea-pigs, that are extraordinarily susceptible to tuberculosis, inoculated with this substance, acquire immunity to inoculations of the tubercle bacilli; and in animals affected with general tuberculosis, inoculation with the substance will stop the morbid process without any injury to the organism. The experiments are yet incomplete, and their author very conservatively refrains from drawing any other conclusion than that of the possibility of making the body resistant to the action of pathogenic bacteria.

In this, as in other discoveries that have marked new eras in the progress of science, independent observers have touched the threshold at the same time. Koch's omission to state the character of his substance only allows us to surmise that it is similar in character to that discovered by two French observers, who established the date of their discovery in somewhat the same fashion in vogue among the philosophers of the sixteenth and seventeenth centuries. According to *Le Mercredi Médical* of August 27, Dr. Grancher and Dr. H. Martin deposited a sealed envelope with the Paris Academy of Medicine in November, 1889, containing a description of a method of treatment by which they had arrested for a long time the evolution of experimental tuberculosis in rabbits. The publicity that Prof. Koch gave to the results he had obtained in making guinea-pigs refractory to tuberculosis, or in curing incipient tuberculosis, induced Grancher and Martin to publish their researches on the same subject earlier than they had intended. In all their experiments they had used the rabbit, making the inoculations by intravenous injections, obtaining thus a tuberculosis that was fatal in a short time, that made local treatment impracticable, and that gave rise to definite lesions in the liver, spleen, and lungs. As the tuberculosis thus created was always fatal, there was a solid foundation that permitted of an exact appreciation of the positive or negative results of a method that was intended to confer a refractory condition or to cure after infection.

Inoculations were made, at the same time, in protected rabbits and in test rabbits in a vein of the ear, of the same quantity of a virulent culture of the *Bacillus tuberculosis* diluted with a small quantity of sterilized water. In a series inoculated on December 31, 1889, the test rabbit died on the twenty-third day, while the protected rabbits lived from a hundred and twenty-six to two hundred and twenty-nine days after the inoculation. The necropsies were negative; the spleen was small; and the liver was free from bacilli, though in the circumlobular spaces there were some embryonic cells, constituting a trace of a tuberculous process on the way to recovery.

They attempted to find a graduated virulence as well as a loss of that virulence, and, while not mathematical,

the results were sufficiently constant to be employed after the same fashion that Pasteur used desiccated spinal cords for treating rabies. The most virulent culture is designated as number one, killing a rabbit in five days or less; the cultures numbered two and three are fatal after a variable time, according to the resistance of the animal. Cultures four, five and six are less fatal, while cultures seven, eight, nine, and ten decrease in strength and do not affect rabbits.

A rabbit is inoculated in a vein of the ear with half a Pravaz's syringe of a culture diminished in virulence to number six. In a week culture number three is injected, and this is repeated in nine days; two weeks later culture number two is injected, then, nineteen days later, culture number one. After inoculation with number one the animals usually die, though not so quickly nor with such severe lesions as the test rabbits inoculated at the same time. If the inoculations stop at number two, the rabbits live for months thereafter.

Very justly, these experimenters believe that they have succeeded in giving to rabbits a prolonged resistance against sure and rapid experimental tuberculosis, and also in conferring immunity against that disease, the duration of which remains to be determined. The probable benefit of these discoveries to humanity is so patent that comment is supererogatory.—Editorial, *N. Y. Med. Journal*.

SANITATION IN RELATION TO BUSINESS.

In every community there is, aside from all others, a business interest. Where there is no business, no commercial activity, and no effort to produce something, there can be no prosperity and no happiness. People must live, and in order to do so, must have that on which to subsist. To enjoy more than a simple existence, more must be had to enjoy. None of these things produce themselves, but must be secured by some endeavor. This endeavor will be commensurate with the ability to do and the doing.

A community is the aggregate of individual units—a multiplication of the individual. The aggregate of business prosperity is the sum of individual industry and productiveness. A community can be no more than its individual members. Its character and collective energy is the whole of its individual parts. A race is savage because its members are. An army is strong because its individual soldier is. A ship is durable because of the durability of its component parts. The character of everything depends on that of the parts of which it is composed. So, the business prosperity of a community depends on that of the individuals composing it. But on what does the prosperity of the individual depend? Everything else being equal it depends on his physical ability to render some service, his ability to do something, his health. Consider the individual case. Other things equal, his prosperity depends on his physical capacity for work. Render him physically incapacitated and his personal means for gaining a livelihood cease. Make him strong and healthful, and he has the elements to attain prosperity. What is true of the individual is true of a

collection of individuals, and, hence, the prosperity of a community depends on its healthfulness.

Health has a money value outside of every other consideration, and those interested in the industrial and business progress of a community cannot ignore the important element of health and attain the highest prosperity. Notwithstanding this fact we must confess to a lack of interest in the preservation and promotion of health on the part of that portion of a community generally designated as "our leading business men." These "leading business men" seem not to recognize the importance of health as an element of great value in the business progress of a community. They give that over to municipal machinery, which too often is run by political motors in the interest of party ascendancy. It would seem unreasonably that business men, interested in the means of developing industrial progress, would neglect so important a factor as health, but they do. It probably results from a lack of proper realization of the value of this element, or an ability to see wealth, or the means of producing it, as only tangible objects. To such an extent is this true that we often see our business men opposing schemes for the promotion of the general health on account of their cost, and too often prove themselves unfriendly to health boards, building inspectors, inspectors of plumbing, smoke inspectors and the like offices maintained for the promotion of health. Of so much importance is the factor of health in the general progress of industrial and business interests, that the most cordial co-operation should enlist itself in support of health ordinances and agencies designed for its promotion. This liberal spirit should be so thoroughly and actively operative as to set the bounds of political influence and interference to the extent of establishing independent and unhampered administration of health laws.

The progress of a community depends on the individual units of progressive force. These units in this instance are human beings who can be weakened by insalubrious surroundings, or strengthened by proper sanitary conditions. It is the office of sanitary science to preserve and promote health. It has its agencies through which it operates to this end. It asks at the hands of the State and city, laws and ordinances by which officers may be selected to enforce the observance of hygienic laws. The efficacy of these depends largely on public support and the co-operation of all citizens. The business interests of every community should enlist itself in this cause, and lend its support as a profitable investment. Sickness is not only a cost to be borne, but, by lessening the power of production, it retards business progress. As a business proposition the healthfulness of a community is worthy of the deepest consideration.—*Sanitary News*.

EPIDEMIC VISITATION.

Epidemics do not prevail at all times; therefore special predisposing circumstance or influence must be present and lend its aid to produce widespread visitation. The contagion of measles, scarlet fever, diphtheria, whooping-cough, or small-pox, like that of enteric or typhoid fever, is probably never wholly extinct in any country where these diseases have once prevailed; yet their epi-

demie prevalence only occurs in uncertain cycles or during particular seasons. To determine why epidemics rise and spread in some years so much more generally or widely than in others, is one of the most interesting points in medical physics; but, unfortunately, no satisfactory answer has yet been given to this curious and most interesting question, and, while the phenomenon can not be explained, we must be content in our ignorance to refer it to the influence of what is called by Sydenham and the older physicians, "The medical constitution of the air." Precisely the same uncertainty occurs with the crops; this year luxuriant growth and an abundant harvest; next year a general or partial failure; but the seed, under all modifying or controlling influences of growth and multiplication, remains the same in quality. In other words, the crops may vary as to the quantity or abundance of the harvest, but the specific quality is unchanged under all conditions.

Again, some soils are absolutely sterile for the growth of certain grains. For example, Indian corn does not grow to perfection in Ireland, while wheat, rye, oats and barley in that country come to maturity and yield the husbandman a successful harvest; and the same is true of certain localities concerning the prevalence of enteric or typhoid fever, also diphtheria and scarlet fever.—Dr. James F. Reeves, *Tenn. Health Bulletin*.

THE NATURE OF THE MICROBE.

For a long time there was a dispute as to whether disease germs were animal or vegetable, and the word microbe was adopted as a neutral term. Finally Pasteur compounded a fluid entirely of minerals, furnishing only carbon, hydrogen, oxygen and nitrogen, in form easily obtainable, and it was found that the microbes could subsist on this. As it was found that these disease germs would subsist on either animal, vegetable or mineral matter, wherever they could easily obtain carbon, hydrogen, oxygen and nitrogen, all bacteriologists now class them as vegetable organisms.

CARRIAGE OF INFECTIONS BY PHYSICIANS.

The communication of contagious diseases by physicians is a question which has for some time been agitated in England, the general conclusion being that, although it cannot be denied as a thing possible for a medical man under some circumstances to convey infection from one patient to another, the risk of this taking place is, if ordinary precautions be taken, almost nil. This is thought to be clearly shown by the experience of the London Fever Hospital, where the resident medical officer in the discharge of his duties is constantly passing from the scarlatina department to the departments for measles, typhoid, diphtheria, etc., and yet, as stated, it has never been found that he transfers these contagia, although he would be much more likely to do so than an ordinary practitioner, inasmuch as the poison is necessarily more concentrated in a fever ward than in a room where only one patient is treated; the medical attendant is not, as a rule, brought into sufficiently close and prolonged connection with his patient for his clothes to receive any very large amount of the contagion, and a short exposure in the open air is generally sufficient to disinfect him. For all ordinary purposes, washing the hands in a disinfecting solution and a short exposure to fresh air will sufficiently disinfect a practitioner, though it is advisable that he change his coat and visit his infectious patient last. *N. Y. Tribune*, September 13, 1890.

PRACTICAL NOTES.

ASEPSIS IN VACCINATION.

Dr. Alfred Leach reports, in the *British Medical Journal*, a six years' experience in the anti-septic management of vaccination, of which the following are the principal precautions:

1. The lymph is collected on the day it is used.
2. The instruments, the patient's arm, and the lymph tube, before being opened, are washed in a disinfecting solution.
3. In four places small scarifications and valvular punctures are made with a Graefe's cataract knife that is charged with lymph.
4. When the wounds are perfectly dry they are dusted with bismuth, and a pad of dry lint is applied.
5. After the second day the parts are daily washed with a gentle current of cold water. No sponge is allowed to come in contact with the arm.

Results: He has had only one case of inflamed arm during the six years he has employed this plan of management.

STROPHANIN.

Strophanthus now holds a recognized and valuable place amongst the remedies used in the treatment of cardiac complaints, being perhaps only secondary to digitalis. An interesting article was read at the Medical Congress held in Vienna in April last, by Rothziegel, on the active principle of strophanthus—namely, strophanin. An abstract of the paper is published in the *Centralbl. für Klinische Medizin*, 1890, No. 27. The doses given were 0.0002 to 0.0003 gram, amounting to $1\frac{1}{2}$ to 5 milligrams per diem. In English measure this would amount to about $\frac{1}{3000}$ to $\frac{1}{2000}$ of a grain for a dose. It is best given in capsules, and repeated every two hours. Rothziegel sums up his results thus: 1. The circulation was in most cases greatly improved, the pulse became stronger and more regular, a difference being sometimes noticed in from five to ten minutes after the first administration of the drug, but the full effect upon the pulse was not attained until the second or third day of its use. The improvement occurred later than with digitalis, but if the strophanin were continued, its beneficial effects were more lasting, and persisted for some time after the drug had been discontinued. 2. The dyspnoea, palpitation, and other symptoms occurring in organic disease of the heart were much relieved whilst the patient was taking this drug. As a rule, the dyspnoea disappeared before the palpitation. In cases of so-called "nervous palpitation" strophanin produced some relief, but this was only temporary. 3. The amount of urine secreted was increased, but not until the stro-

phanin had been taken for some considerable period, and, moreover, the quantity passed was not so large as when digitalis or the tincture of strophanthus had been given. The increase in quantity of urine lasted several days after the strophanin had been discontinued, and was apparently due to increased blood-pressure, and not to any direct action on the kidney. No sign of kidney irritation was noticed at any time. 4. Gastric disturbances, even after prolonged use of the drug, were very rare, and even when such phenomena did appear strophanin could be taken in capsules without any discomfort. As a general rule the appetite was increased. The condition of the stools was not altered. There was no diaphoretic action. 5. The nervous system was only influenced indirectly, and that favorably, owing to the improved strength and regularity of the heart's action. 6. An accumulative action was not noticed in the case of strophanin, and the drug may be continued for weeks without any ill effects. 7. Subcutaneous injections ($\frac{1}{2}$ th grain in watery solution), in cases where the heart's action was very weak, produced a rapid and lasting effect on the pulse, and no unpleasant local effects were caused by the puncture. 8. With the tincture of strophanthus, strophanin compared unfavorably. The tincture acted more certainly, quickly, and energetically than the alkaloid; this was especially noticed in its diuretic action. Cases, however, occasionally occurred in which not only the tincture of strophanthus and digitalis, but also the other cardiac tonics, could not be taken, but in which strophanin was well borne, and the latter was found to be a good substitute for the tincture in such cases. Other instances were also noted in which all the cardiac tonics were ineffectual, whilst the administration of strophanin was followed by satisfactory results. 9. The indications for the use of strophanin in valvular disease, with or without affection of the myocardium, are the same as in the use of digitalis—that is to say, when there are indications of heart failure. In acute and chronic Bright's disease strophanin produces diuresis, especially if the heart's action is at all weak.—*Lancet*.

BOROGLYCERINE CREAM.

Dietrich (*Pharm. Centralhalle*) proposes a cream of boroglycerine as follows: Boric acid, 1 part; glycerine, 24 parts; dissolve by the aid of heat; anhydrous lanoline, 5 parts, paraffine ointment, 70 parts, to be melted together. These, when cooled, are to be thoroughly stirred together to a creamy consistence. Coloring matter and perfume may be added, if desired. As a cosmetic application to the face and hands this compound has certain advantages over the ordinary creams or balms.

SOCIETY PROCEEDINGS.

American Orthopædic Association.

*Fourth Annual Meeting, held in Philadelphia,
September 15, 16 and 17, 1890.*

FIRST DAY—MORNING SESSION.

The Association met in the College of Physicians, and was called to order by the President, Dr. De Forest Willard, of Philadelphia, at 10 A.M.

After a short business meeting, the President delivered the

ANNUAL ADDRESS.

In a few well chosen words he welcomed the members of the Association and extended to them the hospitalities of the city—a city which for more than a hundred years has been regarded as the centre of medical education, and as the home of surgeons who have given careful and thorough attention to their professional work.

Dr. Willard found orthopædic surgery in Europe in a far less advanced state than he had anticipated. Orthopædic surgery in America stands far ahead in its surgical aspect, and in the ingenuity of its mechanical contrivances, than in Europe. Such men, however, as MacEwan, Edmund Owen, and Howard Marsh are doing excellent orthopædic work.

DR. E. H. BRADFORD, of Boston, read a paper entitled

TREATMENT OF DEFORMITIES OF SPASTIC PARALYSIS,

in which he said orthopædic surgeons had not done full justice to the surgical treatment of this affection, although it is one which occasions distortion and difficulty in locomotion, which is because the disease has been but little understood. Light has been thrown upon the subject quite recently by neurologists, and it is now recognized and its clinical history understood. The author has not been able to gain permanently satisfactory results by the use of appliances—although in infantile paralysis—sometimes confounded with spastic or cerebral paralysis—appliances are of great assistance. He has not derived any benefit from the use of electricity, and but very little from massage. In affections of the lower extremities from this disorder, he has had satisfactory results from tenotomy and myotomy of the resistant muscles—*i. e.*, tendo Achilles, hamstring muscles, and the adductor muscles. After operation a light appliance should be worn to aid locomotion for a month or so. Permanent benefit may be expected in children free from mental deficiency. His experience was based upon fourteen cases, with ages ranging from 4 to 16. He had had no experience in operating upon adults with this affection.

DR. ARTHUR J. GILLETTE, of St. Paul, contributed a paper and reported a case of

TENOTOMY FOR RELIEF OF DEFORMITY IN SPASTIC PARALYSIS.

The patient was 11½ years of age. The deformity was the right forearm flexed upon the arm. Whenever excited the muscles of the arm became rigid, as did the fingers of the hand of the same arm. The right foot was in the position of talipes equinus, and when the patient attempted to walk and weight was thrown on the foot, it was brought into the position of talipes equino varus.

Dr. Gillette divided the tendo Achilles, which permitted the foot to come into good position. It also relieved the flexion at the knee which was present. He then placed the foot in plaster of Paris and allowed it to remain there for a few weeks, the child playing and walking as much as she desired. When he removed the plaster he applied an ordinary ankle brace with a "stop joint" to prevent the foot from returning to its former position. It is now eight months since the operation, and the child has not had the slightest spasm of the muscles of the foot. The ankle-joint will permit of almost the normal movements, and she walks with but a slight limp.

DR. AP MORGAN VANCE, of Louisville, read a paper entitled

AMPUTATION AS AN ORTHOPÆDIC MEASURE,

in which he stated that the introduction of amputation as an orthopædic measure was something out of the recognized lines, but as orthopædist is expected to relieve patients of crippling and deformity, it is obvious that if amputation in some cases is the best and often the only way this can be done, the operation may become orthopædic. In the past ten years quite a number of cases had come under his care where there was no doubt in his mind that amputation, performed for convenience sake, would have been better than any other treatment. Among those where the knee can be saved will be found a few cases of old infantile paralysis (talipes), and adult cases of congenital talipes, where painful bursæ have developed and life is often unendurable from the pain caused by walking. On the other hand, old subluxated knees with ankylosed patellæ, with flail joints and great shortening, are not uncommon. Several of these cases can be converted from hopeless cripples into useful members of society by a proper amputation and adjustment of a good limb.

Dr. Vance reported four cases illustrative of the good done by amputation performed orthopædically.

FIRST DAY—AFTERNOON SESSION.

DR. HENRY LING TAYLOR, of New York, read a paper entitled

A READY METHOD OF COUNTER TRACTION AT
THE KNEE,

in which he said experience had shown the obstinate and serious nature of many cases of synovitis and arthritis of the knee, and the frequency of grave sequelæ, unless treated with the utmost care and precision. Properly applied counter-extension with fixation and recumbency usually afford prompt and often marvelous relief to the intense suffering in the active stage of the trouble, and at the same time provides conditions favorable to the proper nutrition of the joint, and the subsidence of the inflammatory process. Fixation alone, or simple traction by means of the weight and pulley, however useful in an emergency, give by no means the same results. Dr. Taylor is convinced that the early application of some form of counter-extension is of extreme importance in surgical inflammations of the knee-joint.

DR. F. H. MILLIGAN, of Philadelphia, contributed a paper on the

TREATMENT OF INFANTILE CLUB-FOOT PRELIMINARY TO OPERATION.

He offered some suggestions regarding the treatment to be used in cases of club-foot before proceeding with the operations of tenotomy and osteotomy. Not infrequently we hear of tenotomy, and even of osteotomy, as having been performed on the feet of infants not more than two or three months old. This he considers premature practice.

In private practice and among people possessed of a fair amount of intelligence, the traction principle is by far the preferable method of treating infantile club-foot; but in dispensary practice we meet with a different class. The directions are not faithfully attended to, and the cases show little improvement. For this reason the fixed dressing is preferable for the class of cases that apply for treatment at the dispensary clinic. But neither the fixed dressing nor any other can be depended upon to correct a case of severe club-foot or effect a permanent cure without a final resort to the use of the knife.

DR. BENJAMIN LEE, of Philadelphia, in a paper on

SACRO-ILIAC DISEASE,

reported two cases of this affection, and from them deduced the following corollaries:

1. Disease of the sacro-iliac symphysis induces a characteristic deformity of the spine, of which the features are a lateral displacement of the entire trunk in a direction away from the affected side, comprising the entire length of the spine, and the almost complete absence of rotation.

2. It also induces a peculiar rolling or waddling gait.

3. It is often the cause of inveterate and excruciating sciatica.

It is useless to attempt to remedy the spinal distortion as long as its cause remains unrelieved.

5. The existence of chronic pain in the sciatic nerve not yielding in a reasonable space of time to medication, should always lead the practitioner to make a careful examination of the spine and of the region of the ilio-sacral juncture.

6. This affection is met with more frequently in adult than in child life.

7. Its appropriate treatment consists in splinting the pelvis and thus preventing motion between the opposing surfaces of the symphysis, motion not being its natural function.

8. For the same reason extension can not be expected to produce favorable results in this affection that we obtain from it in arthroidal joints.

9. The disease is often of extremely slow development.

10. Its first symptom is often abdominal pain, whence it may readily be mistaken for peritonitis, ovaritis, cystitis, and the like.

11. This pain is principally referred to the side on which the lesion exists.

12. The existence of severe unilateral abdominal pain, accompanied by little or no febrile action, should lead to the suspicion of the existence of this affection.

13. A mechanic may, by a happy chance, give temporary relief to a patient suffering from this disease, but as he is entirely ignorant of its seat and nature, he is perhaps not the safest person to refer the patient to.

DR. ROYAL WHITMAN, of New York, read a paper on

PERSISTENT ABDUCTION OF THE FOOT

in which he said the successful treatment of any chronic affection demands a personal, persistent attention to details on the part of the surgeon.

The two principal objects of treatment are (1) to overcome the contraction and spasm of the abductors; (2) to strengthen the abductors. This is best accomplished as follows:

The patient being etherized, the affected foot is forcibly extended and adducted—that is, the heel and toe are both turned inward so that the inner border of the foot is bent like a bow, it is then forced inwards under the leg to a position of extreme equino-varus, the operation being attended with audible cracking of adhesions in all the diseased articulations. In this position a well-fitting plaster bandage is applied with the object of persistently overstretching the shortened ligaments and contracted muscles and holding the foot firmly in its new position. The bandage may remain on a variable length of time according to the subsequent pain and the difficulty that has been experienced in the reposition. From one to three weeks is the average time, when it is removed.

SECOND DAY—MORNING AND AFTERNOON SESSIONS.

The two sessions of this day were devoted to the subject of *Rotary Lateral Curvature of the Spine*. The following papers were read, after which there was a general discussion of the subject by the members of the Association:

The Nervous and Muscular Elements in the Causation of Idiopathic Curvature, by Dr. Benjamin Lee, of Philadelphia; *The Muscular Element in the Etiology*, by Dr. Chas. M. Scudder, of Boston; *Etiology*, by Dr. R. W. Lovett, of Boston; *Mechanism of Rotation*, by Dr. A. B. Judson, of New York; *Treatment*, by Drs. E. H. Bradford, of Boston, and Henry Ling Taylor, of New York.

THIRD DAY—MORNING SESSION.

DR. JOHN RIDLON, of New York, read a paper entitled

A REPORT OF SIXTY-TWO CASES OF HIP DISEASE OBSERVED IN THE PRACTICE OF HUGH OWEN THOMAS.

He presented for consideration further facts regarding the use of the Thomas hip splint. Nothing appears to indicate that the principles upon which Mr. Thomas has based his teachings are in any way at fault; though in practice there is still something to be desired.

The average duration of limp before treatment was commenced in 62 cases was a little over ten months. The average duration of treatment was not computed, as only a few cases were cured and as many had been under treatment but a short time. Of 58 cases that had been under treatment for a longer or shorter time, 24 had shortening; 24 had adduction, 5 had abduction, 3 inward rotation, and 2 had outward rotation. In the cases where abduction coexisted with the shortening, the abduction was an advantage as it compensated in a measure for the shortening.

DR. JAMES K. YOUNG, of Philadelphia (by invitation), contributed a paper on

DISEASES OF THE EYE ASSOCIATED WITH SPINAL CARIES,

in which he said the diseases of the eye associated with caries of the spine are from necessity of the same pathological nature—strumous or tubercular. The occurrence of ophthalmic affections in certain cases of spinal caries has frequently been observed, and the direct association has been frequently noted.

Diseases of the eye associated with caries of the vertebræ are scrofulous or tubercular, the difference being principally in degree.

Scrofulosis may be considered the constitutional predisposition to caseation; tuberculosis the same condition infected with bacilli of tuberculosis.

Both the lesions of the eye and the caries of the vertebræ yield readily to a constitutional and local treatment.

DR. SAMUEL KETCH, of New York, in a paper entitled

POSTERIOR RACHITIC CURVATURE OF THE SPINE, said, that of the deformities of the spine whose underlying cause is found in the condition known as rachitis, the ones most commonly seen in practice are the *lateral* and *posterior*.

The etiology and pathology of posterior rachitic curvature of the spine are essentially those of rickets in general, the deformity being simply one of the local manifestations of a general diathesis. Dr. Ketch believes the causation is largely mechanical, and furthered by such movements as tend to throw the weight of the body on the weakened vertebræ and their appendages. A large number of cases show a limitation of the curve to the dorso-lumbar spine, a very favorite position for the occurrence of Pott's disease.

In the treatment of young children, from one to two years old, he never advises the use of mechanical supports, the tissues being so unstable that any pressure is apt to be badly tolerated. In this class the constant recumbent position, with fresh air and sun-baths together with internal treatment and close attention to the diet are usually sufficient.

THIRD DAY—AFTERNOON SESSION.

At this session the following papers were read:

Lateral Deviation of the Spinal Column in Pott's Disease, by Dr. R. W. Lovett, of Boston; *Relief of Paraplegia*, by Dr. A. J. Steele, of St. Louis; *Prognosis of Pressure Paralysis*, by Dr. T. Halsted Myers, of New York.

OFFICERS FOR 1891.

President—Dr. A. B. Judson, New York.

First Vice-President—Dr. Ap. Morgan Vance, Louisville, Ky.

Second Vice-President—Dr. George W. Ryan, Cincinnati, Ohio.

Secretary—Dr. John Ridlon, New York.

Next place of meeting, Washington, D. C., in connection with the Congress of American Physicians and Surgeons.

LOCAL ANÆSTHESIA BY MEANS OF CARBONIC ACID.—According to Voituriez, the anæsthetic effects of carbonic acid, described by Brown-Séquard, can be obtained in an extremely simple manner by means of the ordinary siphons containing mineral water charged with the gas. The anæsthesia is obtained by projecting at a distance the contents of two or three siphons of seltzer water, limiting the application to the part to be operated upon. The insensibility to pain lasts about five minutes and then slowly disappears. The method is chiefly applicable to the limbs, as about the head and trunk the irrigation is somewhat inconvenient.—*London Medical Recorder*.

ASSOCIATION NEWS.

American Medical Association.—Report of the Librarian.

Mr. President:—I have the honor to present herewith the Catalogue of Additions made to the Library of the Association from June 15, 1889, to May 15, 1890. During this period 123 distinct titles have been added, exclusive of Transactions of Societies, Reports of Boards of Health, Periodicals, etc., not previously received and catalogued.

The number of volumes added during the past year is 241, and the Library consists at present of about 8,000 volumes, representing 3,100 titles.

It is respectfully suggested, that the subscription to the *Index Medicus* for 1890 be continued, and the sum of \$10 be appropriated to that end. Respectfully submitted,

C. H. A. KLEINSCHMIDT, M.D., Librarian.

3045 N. S., Washington, D. C., May 15, 1890.

CATALOGUE OF ADDITIONS TO THE LIBRARY OF THE AMERICAN MEDICAL ASSOCIATION, BY DONATIONS, EXCHANGES AND SUBSCRIPTIONS, FROM JUNE 15, 1889, TO MAY 15, 1890.

Adams, S. S., The Relation of Dentition to Diseases of the Alimentary Tract.

Algandona, M. S., Prophylaxia de la Siphilis.

NECROLOGY.

Silas H. Douglas, M.D.

At a meeting of the Department of Medicine and Surgery of the University of Michigan, held on the 4th of September, 1890, the following minute was adopted, with direction that it be entered in the records of the faculty.

Silas Hamilton Douglas, one of the founders of this department of the university, and for twenty-eight years a member of this faculty, died in Ann Arbor, August 26, 1890, at the age of 74 years. He was one of a very few strong men of steady purpose, who opened a way for medical education in this State, and from the first determined that broader foundations should be laid for the support of medical learning. Elected as professor of chemistry in this university on August 5, 1846, he was soon active in those movements which obtained the adoption, by the Board of Regents, of a plan for the organization of a department of medicine, presented by Dr. Zina Pitcher and others, January 17, 1848. His interest in medicine was direct and personal; he had entered upon practice as a physician before he became a college teacher, and in the beginning of the medical school he held for a time the chair of materia medica in addition to that of chemistry. Dr. Douglas was one of the original members of this body who have served, each in turn, for a considerable period, as the dean of the faculty. Of these but one remains with us, now our honored presiding officer, a witness of the growth of medical education, rising evenly and surely upon the foundations laid by these fathers.

Early in the building of the foundations Prof. Douglas set out to provide for the laboratory method of study, then nearly unknown in medical schools, yet a method which has become characteristic of the finest training of the time. When Dr. Douglas had labored in the university for ten years, on May 8, 1856, the Board of Regents made provision for the erection of a building under his charge to serve as a chemical laboratory. Of this it is stated in President Tappan's annual report of the following year, that it was "one of the most complete and efficient in our country." To this and its development Prof. Douglas gave the best years of his life. It was due to the indomitable courage and unyielding perseverance strongly knit in his sturdy nature, that laboratories of science gained an early and vigorous growth in this institution. And it was through his interest in medical education that medical students received the best of laboratory opportunities. A staunch defender of the interests of the department of medicine and surgery, he was confident of its future strength and service. To him and his early associates in medical education a great debt of gratitude is due. We remember his services with thanksgiving, and write his name with honor.

To his family and his relatives we desire to extend our sympathies, and we invoke for them the consolations of the religious faith which he sustained.

CORYDON L. FORD, M.D., Dean.

University of Michigan, Department of Medicine and Surgery, September 4, 1890.

MISCELLANY.

LETTERS RECEIVED.

B. Westermann & Co., Dr. J. B. Ingals, New York City; Rev. John F. Stanton, New Albany, Ind.; Dr. B. M. J. Conlin, Alexandria, S. Dak.; Dr. R. S. Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from September 13, 1890, to September 19, 1890.

By direction of the Acting Secretary of War, the following changes in the stations and duties of officers of the Medical Department are ordered:

Major Charles L. Heizmann, Surgeon, is relieved from duty at San Antonio, Tex., and will report in person to the commanding officer at Ft. Clark, Tex., for duty at that station, to relieve Capt. Edward B. Moseley, Asst. Surgeon, who, upon being relieved by Major Heizmann, will report in person to the commanding officer at San Antonio, Tex., for duty. Par. 23, S. O. 211, A. G. O., Washington, September 9, 1890.

By direction of the Acting Secretary of War, Major Joseph K. Corson, Surgeon, is relieved from duty at Ft. Sherman, Idaho, and will report in person to the commanding officer, Washington Bks., D. C., for duty at that station. Par. 4, S. O. 412, A. G. O., September 10, 1890.

By direction of the Acting Secretary of War, a board of medical officers, to consist of Col. Edward P. Vollum, Surgeon; Major George M. Sternberg, Surgeon; Major Albert Hartsuff, Surgeon; Capt. William E. Hopkins, Asst. Surgeon, is constituted, to meet in New York City on October 15, 1890, or as soon thereafter as practicable, for the examination of candidates for admission into the Medical Corps of the Army. Par. 8, S. O. 213, A. G. O., Washington, September 11, 1890.

Capt. Frank J. Ives, Asst. Surgeon, is granted leave of absence for three months, commencing about October 1, 1890, provided one of the Acting Asst. Surgeons serving in the Dept. of the Missouri can be assigned to duty in his stead, at Ft. Sill, Oklahoma Ter., during that time. By direction of the Acting Secretary of War. Par. 26, S. O. 213, A. G. O., Washington, September 11, 1890.

Capt. John J. Cochran, Asst. Surgeon, now on duty at Ft. Adams, R. I., will proceed to Mount Vernon Bks., Ala., and report in person to the commanding officer of that post for temporary duty, and on completion of the duty contemplated, he will return to his proper station. By direction of the Acting Secretary of War. Par. 2, S. O. 214, A. G. O., Washington, September 12, 1890.

Major Henry McElderry, Surgeon, leave of absence for seven days heretofore granted by the Superintendent of the U. S. Military Academy, is extended to November 10, 1890, on account of sickness. By direction of the Acting Secretary of War. Par. 5, S. O. 214, A. G. O., Washington, September 12, 1890.

First Lieut. William N. Suter, Asst. Surgeon, leave of absence granted in S. O. 149, June 26, 1890, from this office, is extended fourteen days. By direction of the Acting Secretary of War. Par. 6, S. O. 214, A. G. O., Washington, September 12, 1890.

Capt. William G. Spencer, Asst. Surgeon, will, upon the abandonment of Ft. Bridges, Wyo. (his present station), report in person to the commanding officer of Ft. Omaha, Neb., for duty at that station, relieving First Lieut. Alfred E. Bradley, Asst. Surgeon. Lieut. Bradley, on being relieved by Capt. Spencer, will report in person to the commanding General, Dept. of the Platte, for duty as attending Surgeon at the headquarters of that Dept. Par. 16, S. O. 214, A. G. O., Washington, September 12, 1890.

Official List of Changes in the Medical Corps of the U. S. Navy for the Week Ending September 20, 1890.

P. A. Surgeon F. W. Olcott, ordered to the U. S. S. "Alert."

ADDRESSES.

THE DOCTORATE ADDRESS,

*Delivered to the Graduating Class of the Kentucky School of Medicine,
June 19, 1890.*

BY GOVERNOR J. PROCTOR KNOTT,
OF KENTUCKY.

After a humorous exordium which at once put him completely *en rapport* with his audience, Governor Knott said:

Pardon me, however, if I call your attention at the very threshold to the duties and responsibilities of the profession to which you have consecrated your talents, your energies and your lives. No other calling known among men demands a more absolute self-negation than the one you have chosen. No other vocation—not even the sacred ministrations of religion itself—requires a more constant exercise of the higher faculties of the human mind, or a more earnest devotion of the purer and nobler attributes of the human soul.

The physician who is thoroughly imbued with the true spirit of the Hippocratic oath not only dedicates his life to the service of his fellowman, but abjures everything that can impair his usefulness, degrade his profession, or debase the dignity of his manhood. Wherever the plaintive voice of human suffering calls—whether from the palace or the hovel, the sumptuous abode of luxurious ease, or the infernal wards of the loathsome lazaretto—regardless of every consideration of his own security or comfort, unmindful of the tempest that may rage around him, or of the insidious virus of contagion that may steal into the citadel of his life with the very air he breathes, he must go. While the life or death of his stricken patient may hang upon his tenderness and skill, he is the anxious sufferer's lodestar of hope, the repository of his confidence, the custodian of his honor, his friend and adviser in his last dark hour, and the comforter of the loved ones who may gather in impotent anguish about his dying couch.

If there is one of your number who has failed to realize, in all their awful solemnity, the tremendous obligations inseparable from such duties and responsibilities, or who has not resolved that so far as God hath given him the capacity, he

will emulate the virtues and rival the skill of the most accomplished of his compeers or the proudest of his predecessors, I would tell him now, in all sincerity and candor, that he has made a grave mistake in his calling—the noble profession of medicine is not for him.

I congratulate myself in the belief, however, that none of you are so ignoble in your aspirations as to be content with the mean promise of the old Spanish proverb "that in a village where every one else is blind the one-eyed man is king." On the contrary, I feel confident that I voice the unanimous sentiment of your class when I say that one who could be degraded enough to take advantage of the unsuspecting credulity of his fellowman, and ignorantly tamper with his life or his health, with no higher motive than the gratification of a sordid, unholy lust for gain, trusting to the kind offices of the undertaker to hide the evidences of his murderous charlatanism out of sight, it would be the basest flattery to call a scoundrel. I am satisfied that there is not one of you who is not inspired by the noble ambition to become, not only the peer of the proudest of your chosen profession, but *princeps inter pares*.

You should remember, however, that such a position among the truly great does not "come by nature," as honest Dogberry supposed to be the case with reading and writing. If you would occupy it you must win it for yourselves. If you would wear the laurel, you must bear the heat and dust of the arena. You can never scale the perilous pinnacle of professional distinction by standing idly at its base and gazing listlessly at the coveted diadem that glitters upon its summit. You must climb the dizzy height with slow and painful toil, and you had better realize that fact at once.

Let me conjure you, therefore, to set about it now. Eschew, this hour and for life, whatever may tend to impair your faculties or impede your progress. Concentrate all the energy of your nature upon the achievement of that one grand object and enter upon it with an invincible confidence in yourselves. Do not mistake me, I pray you. I do not mean the ridiculous self-conceit of the contemptible coxcomb of the profession, who imagines, because he has his diploma, that his number six hat covers all the medical science

that has been developed since the birth of Chiron the Centaur. When I counsel confidence in yourselves, I mean courage—a brave, manly, unconquerable reliance upon your own exertions; an abiding consciousness that whatever man *has* done, man may do again; the cheerful conviction that Hercules helps those who help themselves. You may do this and still incur no risk of being dazzled by your admiration of your own intellectual endowments. Extraordinary as the natural abilities of some of the more brilliant of your profession may appear to you, the mental disparity between them and yourselves is by no means so great as you may possibly suppose. Axtell or Sunol may be able to go a mile, or ten miles, perhaps, much quicker than a common plug, but the plug will make it in his own time if he keeps on plugging.

Remember, that he who is capable of thoroughly mastering the five fundamental rules of arithmetic may, in time, by patient and persistent effort, solve with facility and pleasure the most abstruse proposition in the highest range of mathematics, and make himself as familiar with the sublime machinery of the sidereal universe as with the simplest piece of mechanism fabricated by human hands. What he may lack in natural aptitude he may supply by well-directed energy and patient perseverance. Fix your eye steadily upon the bright goal of your ambition and constantly press toward it

“———Like the Pontic Sea,
Whose icy current and compulsive course
Ne'er feels *retiring* ebb, but keeps due on
To the Propontic and the Hellespont.”

I am aware that when you look over the long catalogue of illustrious names that adorn the annals of your profession, and consider the wonderful contributions they have made to the sciences of medicine and surgery, you are apt to think that your predecessors have left you nothing to do but to practice what they have been taught, or, at best, to glean a well-reaped field where there is no glory to be won and no garlands to be woven. Yet, there was never a graver mistake. Your profession with all its marvelous development in learning and all its astonishing exhibitions of skill, has but rarely approached the domain of scientific truth and anchored in some of its smaller inlets. The occasional adventurer who has gone ashore has only picked up a few trifling pebbles that lay scattered along the beach. The territory remaining to be explored is as illimitable as the universe itself.

The saying is trite, indeed, that of all the great departments of human knowledge, medicine is that in which the accomplished results are most obviously tentative and imperfect; the one in which the range of unrealized possibilities is most varied and extensive, and the one from which the most astonishing and beneficent returns might

be expected if the same patient and intelligent investigation were directed to it that has been employed during the current century in mechanical invention and material development. Let me exhort you, then, to learn, above all things, “to labor and to wait.” The world was not finished in a day; the mountain range, whose snow-clad summit is kissed by the earliest gleam of the morning sun, was not the growth of an hour, but the slow product of myriads of ages. The history of human progress is crowded with illustrations of the fact that we are constantly in contact with principles and conditions which have remained unobserved since creation's dawn, waiting for some patient, inquisitive thinker to recognize and develop them—great terminal truths which may become the prolific sources of incalculable benefits to our race; and for aught we know, the one who will be crowned, by the common acclaim of coming ages, as the greatest of all the discoverers in medical science the world has ever known, from the age of the Asclepiadæ to the present hour, may be sitting at this moment in your midst.

Have you ever traced the tremendous consequences which have frequently resulted from an accidental thought or the most trivial and aimless experiment? Over twenty-five hundred years ago, Thales of Miletos observed that, by rubbing a bit of amber, it was made to attract light objects with which it was brought in contact. Thousands gazed in stupid wonder upon the mysterious phenomenon. It was noticed three hundred years afterward, by Theophrastus, and four hundred years later, by Pliny; yet none of them ever dreamed that, in the subtle agency which they supposed barely capable of lifting a feather, there lurked the strength of a sleeping giant, more marvelous in the magnitude and versatility of its powers than all the fabled genii of the East. But a little less than a century ago, by the most trifling of all possible accidents, the attention of one of your own profession was directed to the same occult force under different and totally unsuspected conditions. His observations upon the accidental discovery he had made inaugurated a series of intelligent experiments, and, to-day, electricity is the ready servant of man in all his manifold necessities. Tractable as the homing dove, it carries his messages around the world with the speed of thought. It is the unerring instrument of the enlightened scientist in his most subtle investigations, the indispensable implement of the ingenious artisan in his most delicate handicraft, and one of the most effective agencies of the skillful physician in relieving the sufferings of his fellow-beings. It propels our machinery with the power of a thousand horses, and mocks the effulgence of the noonday sun with the dazzling splendor of its light. And yet how little we know of the real nature or the ultimate possibilities of that wonderful agency which

would, perhaps, have remained dormant for ages yet to come but for the initial observations of Galvani!

If I have dwelt at undue length upon this familiar illustration, selected at random from a multitude that might be adduced, I have done so to impress upon your minds, not only the pregnant truth that the wide field of useful labor you have selected teems with rich rewards for your intelligent toil, but the paramount importance of constantly cultivating correct habits of observation and thought. Aristotle was right when he said that "incredulity is the source of all wisdom." You should think for yourselves—closely, carefully, patiently and independently upon everything that may come under your notice, that may be at all cognate to your profession, and never be satisfied that you know enough about anything as long as anything about it remains unknown. Take nothing for granted that may seem inconsistent with correct reason or established facts, simply because some one of acknowledged authority may have said it, and reject nothing as unworthy of your investigation on account of its apparent insignificance, or because it does seem to square precisely with the preconceived theories of the faculty.

Had Jenner been less observant, or less inquisitive, or too bigoted, or too indolent for investigation, he would probably have been content to prescribe some simple salve for the pustule on the milkmaid's hand, and thousands would be dying to-day of small-pox who enjoy an absolute immunity from that dangerous and disgusting disease. Whether the old Jesuit fathers taught the doctrine that "the proof of the pudding is in chewing the bag" I do not know; but, if the doctor who accompanied one of their early missions to Peru had not adopted the custom prevalent among the aborigines of chewing the bark in order to ascertain the nature of the tree, it is probable that the discovery of quinine, the *sine qua non* of his more modern professional brethren, would have been postponed for centuries.

In the first year of the present century, Sir Humphrey Davis suggested the employment of nitrous oxide as an anæsthetic in surgery; but as the suggestion came from a layman it was passed unheeded, if not with silent disdain, by the great lights of your profession. Eighteen years later, Michael Faraday called attention to the anæsthetic effects of sulphuric ether, but it was regarded merely as a matter for curious experiment in the lecture-room, but of no practical consequence. Nearly forty years ago, an obscure but inquisitive countryman happened to be present when one of his neighbors was bitten by a rattlesnake. He not only observed the almost instantaneous effect of the poison, but examined the fang, and finding it to be a finely pointed tube through which the virus had been injected into the cir-

culcation of the victim, it occurred to him at once that the effects of an anodyne administered in a similar manner would be equally prompt. He carried the murderous tooth to an intelligent physician, explained its operation, and begged to have an instrument made by which morphine and other medicines might be similarly applied for the relief of human suffering. The doctor smiled at his rustic simplicity, but now he would consider himself everlastingly disgraced if he should be caught without a hypodermic syringe and a little vial of morphine and atropia in his vest pocket.

I mention these facts not only to illustrate the importance of your paying attention to little things, but to warn you not to reject an apparently reasonable suggestion without proper investigation, no matter from what source it may come. The leading principles taught by "the great father of medicine" himself were those of rational empiricism. He neither attempted nor pretended to form his theories from a *a priori* reasoning, but made a careful study of the phenomena of nature, and from them deduced such conclusions as those phenomena seemed to justify.

The celebrated Cornelius Celsus, the contemporary, if not an associate, of Horace and Ovid, although a follower of Hippocrates and Asclepiades, was not a blind adherent of any sect. He did not hesitate to dissent from the views of his illustrious prototypes where he thought they were in error, and accepted with equal impartiality whatever he found to commend, whether in the teachings of the Empirics, the Dogmatics, the Methodics or the Eclectics; and the immortal Claudius Galenus himself, the most distinguished and the most esteemed of all the ancient apostles of medical science, while strenuously maintaining the superiority of theory over mere empiricism, blended in his own school the empirical knowledge he had derived from the teachings of Satyrus, Stratonicus and Eschriion. In short, the man who makes himself truly great in any calling is the one who has sense enough to know a good thing when he sees it, and decision of character enough to make it useful whenever he may find it.

Whatever you may accomplish, however, in your professional career, you should make up your minds not to be surprised to find yourselves deprived of much of the credit that may be justly due you. In your profession, as in all others—

"Full many a flower is born to blush unseen,
And waste its sweetness on the desert air;"

While, on the other hand, full many a name shines upon the envied page of history with a borrowed light to which it is not entitled, and which its owner himself would not pretend to claim.

Both of these ideas are illustrated, to some extent, in the present fate of the celebrated William Harvey. If that illustrious man could return to the earth to-night, he would probably be astounded

to find himself regarded by millions of people, including a large majority of even the more intelligent classes, as the first discoverer of the mere movement of the blood in the human body, a fact familiar to thousands from the earliest antiquity. He was not even the first to suggest the idea of its circulation, which, it is said, was, at least remotely, conjectured by the immortal Stagirite himself, and still more distinctly by Mondino, Berenger and others of more modern times. Whether it was observed by the great Vesalius or not, we have no means of knowing, but it is certain that the leading outlines, not only of the pulmonary but the larger circulation, were taught by his friend and successor, the ill-fated Michael Servetus, more than fifty years before Harvey was born; and still more clearly by others, especially by Harvey's preceptor in anatomy—Fabricius—who pointed out to his pupil the valves in the veins of the extremities, and set his inquisitive mind to investigating their office. If he could stand where I stand and speak to you as I do tonight, he would tell you that he only did what some of you may yet do with respect to some other important but unsettled question in your profession. That he was not willing to sit down, content with what others had ascertained, but that he gathered up all the facts already known, improved upon the knowledge of his predecessors, and, by a series of patient, intelligent and carefully conducted experiments, elaborated an already existing theory, and demonstrated its truth to the exclusion of a doubt.

I have alluded to the example of this famous physician, however, more especially to emphasize the important truth that, without a certain degree of dissatisfaction with the existing condition of professional learning, coupled with a passionate disposition for honest, earnest, independent and intelligent inquiry, anything like progress in medical science is an impossibility. It is universally admitted that among all the brilliant names that illustrate the earlier annals, if not the entire history of your profession, that of Galen stands pre-eminent. Yet, it would have been far better for the human family, perhaps, if Galen had never been born.

The blind, abject, almost idolatrous deference of his successors to his teachings, with all their crudities and absurdities, postponed everything like genuine progress in scientific medicine for centuries. They regarded his writings as the ultimate authority from which there could be no appeal, and rejected with disdainful scorn whatever appeared to be inconsistent with his *dicta*. In their vain attempts to reconcile the theories of their master with the phenomena of nature, they had but little time to interrogate herself, and still less inclination to pursue the study of medical science in those fields in which it can be followed with any assurance of success. Eschewing

everything like originality of thought or independence of inquiry, they went on for more than five hundred years, stifling intelligent investigation and killing their patients according to the most approved methods of Galenian science.

I would warn you, however, that if it should be your fortunate lot to make any great discovery or improvement in the practice of your chosen art, or any very remarkable contribution to medical science, you should be prepared for a general howl of dissent from the less profound and more pretentious of your professional brethren, until it shall have received the approbation of their acknowledged leaders. I am not fully prepared to believe that the man who first suggested the practicability of carrying corn in both ends of the bag when going to mill, instead of the old practice of putting a rock in one end to balance the corn in the other, was actually mobbed by his indignant neighbors as a dangerous revolutionist; but I suppose it is really true that Galileo barely escaped a sound roasting for expressing the opinion that the earth moved around the sun, and not the sun around the earth. It is a fact, at any rate, that the disturber of ancient prejudices, or long-accepted opinions, generally raises a storm about his head, and nowhere has that truth been more frequently or more strikingly illustrated than in the history of the medical profession.

When Galen, at the solicitation of many of the most distinguished philosophers and men of rank, commenced a course of lectures in the imperial city upon the anatomy of the human system, the novelty of his teachings and the bold contempt with which he assailed the long-accepted fallacies of his predecessors raised such a tempest of indignant criticism among his professional rivals, that he was not only compelled to abandon the rostrum, but to get out of Rome. And when Vesalius, in the sixteenth century, defied the authority of Galen, which was still considered supreme, and destroyed by actual demonstration the credit of nearly all the learning to which the earlier masters had pretended; when he swept away the long-venerated rubbish of ancient error and laid the immutable foundation upon which the splendid fabric of modern medical science has been reared, he brought upon himself a perfect deluge of virulent reproach from even the most distinguished of his professional contemporaries. And you will perhaps be surprised to learn that among the foremost of his detractors was the celebrated Fallopius, concerning whom, I have no doubt, you have heard a good deal from your diffident but distinguished Dean, unless his lectures have been too much abridged by his characteristic taciturnity.

When Harvey first published to the world his beautiful demonstration of the true theory of the circulation of the blood, it is said that there was not a single physician over forty years of age, either in

Great Britain or on the continent, who coincided with his views. On the contrary his practice fell away from him, and he was for years the object of the extremest obloquy and abuse. Nor was it until after his experiments had been repeated, and his observations endorsed by many of the most eminent anatomists and physiologists of the period, that his theory was accepted by the far more numerous class of his brethren, who were profound in nothing but their ignorance of scientific truth, and their conceit of their own professional culture and ability.

And so when Dr. Ephraim McDowell published his modest account of his first ovariectomy, some eight years after it was performed, it was denounced as a falsehood, and its author held up by the leading medical and surgical writers of the day as a liar and imposter; and it was not until ten years after that the learned editor of London *Medico-Chirurgical Review*, who had been one of his most malignant satirists, had the grace to thank God that he had lived to ask pardon of the great pioneer surgeon of Kentucky for the injustice he had done him.

It is an ill wind, however, that blows nobody any good; and it is probable that the world is indebted to the intolerance of the medical profession during the fifteenth and sixteenth centuries toward any improvement or innovation in their own peculiar department of learning, for the initial step in the wonderful development of astronomical science which has taken place since that period. About the year 1500, a German physician, becoming disgusted with the bigoted deference to the doctrines of the earlier masters, which seemed to render an advancement in the philosophy or practice of his profession an impossibility, abandoned it and devoted himself to the study of mathematics. He soon detected the absurdities of the Ptolemaic hypothesis concerning our system of planets, and revived the theory of Pythagoras, that the sun was the center of a series of spheres, including our earth, which revolved around it, and also upon their respective axes. For thirty years he labored on the demonstration of that sublime truth, and, tonight, the name of Nicholas Copernicus, the great prototype of Kepler, Galileo, Newton, Herschel and Leverrier, remains written upon the star-decked vault of heaven in characters of ineffable glory, to be hymned by the spheres as long as they shall continue in their wondrous pathway through the skies.

I hope I have made myself clearly understood, urging upon you the importance of thinking and investigating for yourselves. Mark me: I would, by no means, advise you to tamper with the health or trifle with the lives of your patients by reckless or questionable experiments; far from it, indeed. You had infinitely better confine yourselves to catnip, cumfrey and elecampane for the

sake of your own consciences as well as for their safety. I simply mean that, while you should act prudently, you should act independently; that you should not regard everything you see in the text-books as absolutely infallible, nor reject anything because it may not be backed by the *ipse dixit* of some recognized authority in the profession.

John of Salisbury, one of the most celebrated scholars and among the wittiest writers of the twelfth century, has left as a sketch, in his *Polycraticon*, of the average medical graduate of his period, which I beg leave to read to you, in order that you may see the immense difference between them and some of the newly-fledged physicians of the present enlightened day. He says:

"They return from college full of flimsy theories to practice what they have learned. Galen and Hippocrates are continually in their mouths. They speak aphorisms on every subject, and make their hearers stare at their long, unknown and high-sounding words. The good people believe that they can do anything because they pretend to all things. They have but two maxims, which they never violate—never mind the poor; never refuse money from the rich."

We find an occasional survivor of this species even in our own age, and if there is one of you who has made up his mind to prostitute his sublime profession solely for the sordid purpose of accumulating lucre, he will be certain to take his place among them, and you will soon find him resorting to all the artifices of the knavish quack in order to magnify his own importance and to multiply his chances for "gathering gainful pillage."

On a county court day, when the streets are full of country folk, he will rush out of his office, fling his pill-bags across his saddle, mount his horse and gallop off on a suppositious call, as though life or death depended on his speed; and, after an hour or two, he will come galloping back again, run into his office, rush out again and scurry away in the opposite direction. He will be a prompt attendant at the most popular church in town, where he will sit "as demure as a harlot at a christening" until some impecunious emissary, whom he has hired for a trifling consideration to do so, hurries in with a most anxious expression on his countenance and calls him out just as the service has reached its most solemn point.

If he should happen to perform some trifling operation in minor surgery, he will have it paraded in the local newspaper as one of the most astonishing feats of the scalpel since the days of Antyllus or Heliodorus; but if he should venture beyond his depth, and cut off the wrong leg, or have his victim die under the knife, he will contrive to have as little said about it as possible, and satisfy the community that the patient's death was only a question of time anyway.

While constantly parading exaggerated accounts of his own superior learning and skill, he will lose no opportunity to injure his absent rival by insidiously depreciating his merits or openly misrepresenting him behind his back. If he should be called to a patient in the absence of the family physician, he will not fail to pronounce the medicine which the doctor has left a deadly poison, and then prescribe the same thing under another name. If a consulting physician should say, in the presence of the patient, that he might safely rely upon the "*vis medicatrix naturæ*," he will whisper to some officious friend of the sick person standing by: "That will kill him quicker than strychnine." In speaking with one of the unlettered multitude about his practice, he will never use a term his hearer will be likely to understand, if he can think of a technical synonym of "learned length and thundering sound." He will never prescribe such a thing as common poultice, but will recommend a cataplasm of certain ingredients. He will not even suggest a wash of ordinary salt and water; it must be a saturated solution of sodium chloride. As I have already said, however, I am happy in the conviction that none of the gifted and aspiring young men whom I have the honor to address to-night will ever condescend to the low artifices or be content with the degraded level of the vulgar sham, the mere pretender.

Mr. Sergeant Balentyne, the celebrated English barrister, on being asked what was the highest qualification for a Lord Chief-Justice, replied that "a Lord Chief-Justice should, in the first place, be a gentleman, and then, if he should know a little law it would be so much the better." And so I would say, while it may be necessary in the practice of your profession that you should know something about medical science, it is absolutely indispensable that you should be gentlemen! By this I do not mean that you should simply cultivate the graces and practice the ordinary amenities of courteous intercourse common to polite society, but that you should at all times, and under all circumstances, illustrate the heaven-inspired virtues of honest, earnest, noble Christian men. That you should spurn with indignant scorn the low, mean vices of envy, malice and evil speaking, and never suffer yourselves to be betrayed into anything that can degrade your manhood or cast the slightest stain upon the bright escutcheon of your honorable profession. Above all things let your demeanor toward professional brethren be candid, manly and just, and your deportment to your patients kind, considerate and conscientious.

I feel that I owe you an apology for having detained you so long, but while I bid you the heartiest God speed in your chosen career, I trust you will permit me to hope, that if you shall at some time in the great unexplored future that

lies before you recall a single word I have spoken, by which you have been comforted or encouraged in the attainment of the success to which you aspire, you will not regret the courteous attention you have given me, and for which I tender you my profoundest thanks.

ORIGINAL ARTICLES.

STRICTURE OF THE URETHRA IN WOMEN.

Read in the Section of Obstetrics and Gynecology, at the Forty-first Annual Meeting of the American Medical Association, at Nashville, Tenn., May, 1890.

BY ELY VAN DE WARKER, M.D.,
OF SYRACUSE, N. Y.
FELLOW AMERICAN GYNECOLOGICAL SOCIETY.

In this paper I limit the term stricture of the urethra to organic contractions in the lumen of the canal not caused by traumatism, incidental to her sex or the result of destructive or malignant disease. In a surgical sense, it is the same condition that we define by this term in the male.

I find it necessary to thus limit the disease, because the affection is supposed to be rarely found in women, that all manner of causes have to be enumerated in order to explain its presence. In the two most recent and elaborate monographs upon the subject, that by Fissiaux¹ and by Herman,² all manner of accidental conditions are invoked to explain the condition. When the causes of urethral stricture in women are reduced to two, specific urethritis and traumatism principally (Fissiaux), it will be clear to any one who studies it independently and free from the unfortunate bias of the authors, that this method simply perpetuates the prevailing error concerning it.

There are certain reasons why organic contractions of the anterior urethra in women should be expected, as the outcome of her functional life. If we examine the external genitals in women of various ages, some of the most marked changes will be presented by the picture of the urinary meatus and the urethral prominence. What in the virgin is small and compact becomes enlarged in the middle-aged married woman, so that it projects forward between the nymphæ and forms a large, rounded mass bulging downward into the vestibule. The urinary fissure has become irregular, with overlying flaps of the external mucous membrane, one-lobed, bi-lobed, or tri-lobed, in every variety of form. These changes may and do exist without any functional deviation from the normal.

These alterations are evolutionary in character, and are shared in by the other external genitalæ. The gland of the clitoris has become greatly en-

¹ *Annales de Gynecologie*, January and March, 1879.

² *Transactions of the London Obstetrical Society*, 1887, p. 27.

larged over the virgin form and its prepuce elongated; the nymphæ have increased many times in breadth and thickness, and projects beyond the commissure of the pudendum, and the myrtiform bodies occlude the vestibule. That the functional activity which is the source of this evolution may easily pass beyond the normal, is proven by the frequency that stricture of the urethra, or condyloma, angioma, caruncle, and irritations are found.

In the sexual act the urinary meatus and prominence are as much exposed to friction and contact as the urethral opening in the male. These organs in one sex have no exposure to morbid causes, that are not equally shared by the other, aside from gestation and pregnancy, which speaking mathematically, is a plus condition as against women. The practical outcome of this is that the woman who has not, at some period of active functional life, suffered from urinary distress, is very rarely met with; and further, I will boldly assert that every man who faithfully follows my method of urethral exploration will confirm, that urethral strictures, or contractions, sufficient to cause symptoms, are as frequently found in women as in men. I express this opinion in no spirit of arrogance or undue self-assertion, but I shall expect every man who offers an opinion to the contrary, other than what may be said hastily in debate, to do so only after he has applied to the study of this subject the modern and approved methods of urethral exploration. He must abandon his authorities and their textbooks, which have nourished a most absurd error, and study this matter for himself from the general surgery standpoint. In the event that there may be some among you who have not examined the literature of the subject, but who may wish to know what gynecological authors have to say about it, I can well afford to give the brief space that this requires.

Skene, in his fifth edition, does not mention the subject. Emmet says that it is rare except as the result of violence. Among older English writers, Churchill says: "My own experience does not qualify me to speak as to the frequency of organic stricture of the female; it can not be very common, or I should have met with it. But I have met with two cases which I suppose to be spasmodic stricture;" and which cases he relates, and which were evidently cases of hysterical retention. West, McClintock, Sir C. M. Clark, Barnes, Baker, Brown, Tait, do not mention the subject. Graily Hewitt says it is rare compared to the other sex, and dismisses it in six lines. The later French authorities do not give it any mention so far as I have examined. The elaborate and painstaking German authors ignore the matter. Even Winckel, in a special treatise on the Urinary Organs of Women, in the "Handbuch des Frauen Krankheiten," gives it no con-

sideration worthy of the name. Coming to more modern times in English literature, we find Hart and Barbour, Mundé, Gordelle, Brown, pay it no attention. In the ambitious monograph of Herman already referred to, and which aims to be scientific, the matter is very inadequately treated, and in a manner which proves that the author neglected to apply to his investigations the methods of modern urethral surgery; while the paper of Fissiaux, so far as it advances our knowledge of the subject, might as well have been written a generation past. In the "American System of Gynecology," our own Baker starts out with the remarkable statement that stricture of sufficient degree to give rise to urinary symptoms is rarely met with. It is very evident from this that I have a fair field all to myself, as negative evidence never yet proved anything. The mysterious part of the matter is how such a mass of negative evidence was ever able to group itself about a subject so easy of demonstration as this. The mystery is cleared up when we come to examine Skene's book on the "Diseases of the Bladder and Urethra in Women."

Dr. Skene gives more importance to the lesion than any other systematic writer, by admitting that it occurs often enough to demand attention. "The form of stricture that will most frequently come under your consideration," he says, "will be a contraction of the meatus urinarius, produced in many cases by too liberal use of caustics in the treatment of abnormal growths at the lower end of the urethra, or from vulvitis." It is in relation to the method of examination directed by Skene, who simply follows in the footsteps of his predecessors in a sort of traditional way, wherein lies the error. He directs that the passage be explored with a sound, using one so large that it will not pass the stricture, thus locating it, and then using a sound that will pass through it, the extent of the obstruction may be known. If a surgeon writing upon male stricture were to direct such a method of exploring the passage, here would be very few strictures of large calibre, as Otis calls them, that we would ever know much about.

It is by methods such as just described that the period of error has been prolonged. Now, there was a time within the memory of many of us when it may have been said that, in an exact and scientific way, we knew very little about stricture of the male urethra; and yet, concerning this, careful instruction had been given for generations. There came, however, with the use of instruments of precision, a period of more exact examination, which not only gave a more perfect, but a far wider range of knowledge. In this way an abnormal state was all but discovered and its outcome given its due value, for previous to this period, strictures of large calibre were, if known, given no practical importance. Previous

to this period the general surgeon gave about the same instructions concerning exploration of the male urethra that Dr. Skene has given for that of the female. It cannot be disputed that, so far as stricture in women is known and treated, it stands to day where the surgery of the male urethra did a generation ago. I date the knowledge of strictures in the male of large and small calibre, their number, location and extent, their consistency and dilatability, together with the calibre of the passage yet in a normal condition, to the invention and general use of the exploratory bulb, and urethrometer. Previously they were simply able to say that a urethra was strictured, provided the contraction was small enough. If we trust in urethral exploration in women to the sound, we simply learn that we have to deal with a narrowed passage, and we overlook strictures of large calibre entirely; whereas if we explore with the bulbs we learn not only all the sound can reveal, but also the extent, number and location of the constricted points, their firmness and dilatability, and the differential diameter of each.

Some attention has been given to the question, What is the normal size, or lumen, of the female urethra? I do not understand how a solution of this question can throw any more light upon its strictures, than a knowledge of the average diameter of the vagina would aid us to an understanding of atresia of that passage. The question is, not the diameter of the passage, but, is it free from disease; are there no contracting bands or inflammatory deposits that diminish its size, be they large or small? In the male urethra, Otis has tried to make an average of this kind of practical importance as a guide to the depth of an internal urethrotomy in a given size of the pendent organ, but I believe few surgeons cut according to Otis's table now. Those that I have seen do it, generally incised more extensively than was necessary, especially at the meatus. The accessibility and exceeding dilatibility of the female urethra precludes the necessity of internal urethrotomy, and there is even less need here than in the male to establish a law of average. It is interesting, and may have its usefulness, to know something about the average normal. Dr. Herman, in the article referred to, makes an attempt in this direction. He employs an instrument that cannot be taken as a comparative standard like those made upon the French scale, which are not arbitrary numbers, but express millimeters in circumference. For this purpose he uses Hegar's dilators, which he describes as "cylindrical rods pointed like the small end of an egg," which must be conically pointed sounds. Even in the use of these imperfect instruments he used so much force, that on several occasions he "produced slight lacerations of the mucous membrane."

TABULATION OF DR. HERMAN'S MEASUREMENTS.

Hegar's Dilators.	Equivalent in English scale.	Equivalent in French scale.	No. of persons examined.
No. 7	12	22	55
" 8	14	25	11
" 9	17	29	21
" 10	18	30	15
" 11	Not given.	Unknown.	6
" 12	"	"	1

The conclusion is that in most cases the healthy female urethra will admit a No. 17 catheter, and nearly all cases a No. 14. In the above table the equivalent in the English scale is approximated upon the American, and I assume that there is no material difference. It is very evident, I believe, that beginning in the above table with Hegar's dilator No. 9, the observer used a dilating degree of force, as the fact of bleeding mucous membrane proves. Had he used a urethrometer or the exploring bulbs, the error of using too much force would have been avoided and his measurements would have had scientific value. This author makes gonorrhœa a very frequent cause, a fact that was overlooked by Winckel. He also regards the urethro-vaginal cellular tissue the homologue of the prostate gland in the male, from the fact that in aged women this septum is thickened and indurated, and this causes narrowing of the urethra. It is difficult to follow Dr. Herman to such a conclusion, and I believe that the majority of observers will dissent from such a comparison. If it were necessary to imagine such a homology, function and situation would suggest the vulvo-vaginal glands. I believe, on the contrary, that the urethral narrowing in aged women is due to the senile involution to be observed in all the genito-urinary apparatus of the sex.

In my own observations to test the calibre of the normal urethra, I noticed the liability to error from the extreme dilatibility of the passage when in a healthy condition, an error more difficult to guard against in using the urethrometer than the bulbs. In the following table the measurements were made by the careful introduction of the bulbs, using no force that could put the tissues upon the stretch.

No. of cases.	French scale—millimeters in circumference at meatus.
20	23
18	24
24	25
9	26
18	27
16	28

This does not express the size of the urethra, but rather that of the meatus, at which point there is a slight narrowing. Beyond this point the measurements were taken by the urethrometer, and the increase in the calibre was represented by 1 to 3 mm.; but if the screw of the instrument was slowly turned, thus applying the dilating force gently, one or two divisions of the

scale could be added to the above without any discomfort to the woman. For this reason measurements must always lack the exactness that insures scientific value, except for those made at the meatus. Bulbs larger than 29 F. I found would not pass the meatus without dilating force, except in cases in which appearances indicated a morbid condition of the part. In my measurements, every case in which blood followed the bulb or urethrometer, was rejected as being in a morbid condition, or as having an excess of force used in the manipulation. There is not a case represented in my table, that the measurement would exclude the idea of stricture, or contracting bands, that is, the stricture of large calibre. This at least has been my experience, but this morbid condition is indicated by urinary symptoms more or less constant, or recurring at long intervals.

Several of the writers who give the subject any attention at all, appear to derive their standard of comparison from stricture in the male. To a certain extent no comparison is possible. Except as the result of traumatism, the impervious urethra or exceeding nervous stricture is not met with in women, but are often met with in men. In connection with an exceedingly crude method of examination, it is this standard of comparison which has so generally led gynecological writers astray on this subject. Further, a narrowing in men that will cause but a slight diminution in the current of urine, never retention, and but rarely dysuria, will produce all these symptoms in women. I believe this to be the true distinction to be made between the sexes in the symptoms of stricture. Women are exposed to all the etiological conditions that men are, plus a few others incidental to their sex, but these in no way contribute to what may be regarded as sexual difference in symptoms. From whatever cause, retention, incontinence, dysuria and strangury are symptoms much more frequently met with in women than in men, and in consequence slighter pathological changes will cause more active disturbance in the former. If strictures of large calibre in men have the pathological importance that such an accurate observer as Dr. F. H. Otis assigns to them, strictures of a like character have more serious import in women. What Civiale, in 1850, says of male stricture, "that the slightest obstruction in the urethra is able to produce the gravest symptoms," is true with enhanced force in women.

It is not necessary to reason any further from analogy. There is an established method of practice that will bear out the truth of my argument. A long established treatment of dysuria in women has been forcible dilatation of the urethra, an operation usually made with the finger of the operator. I have so treated these cases of painful urination many times; sometimes with success,

and other times with failure. It was difficult to explain the contradiction in results. I have now learned that when I have succeeded in curing my patient I had to deal with a stricture of large calibre—in other words, I had treated a stricture by what in the surgery of the male urethra, is termed divulsion. Since I have begun habitually to examine the urethra with the exploring bulbs in all cases with urinary symptoms, I have never made the operation of forcible dilatation except I wished to examine the cavity of the bladder with the finger. In doing this operation in dysuria I have frequently felt the narrow constricting bands, but without really understanding their nature until I had studied the condition of the passage after the manner of Otis. It is possible to detect stricture of this size with the sound, as resistance is at every point alike, and from the size of the sound that you are able to pass, it does not appear that any stricture is possible. Free as was the opening of the urinary passage, the widely dilatible constricting bands were sufficient to keep up a constant fret of the mucous membrane. I have found these obstructions in urethras that would admit a 28 to 30 F. sound with but very little force, and followed by only a few drops of blood. In exploring, it is well to remember that it is always more easy, as well as less painful to the patient, to introduce a large sound than it is a large bulb. This constant condition of urethral irritation in this group of cases constitutes, I believe, a sexual trait in the different reaction of strictures of this character in the sexes. That which causes frequent and painful micturition in women and greatly disposes to spasmodic retention, will, as a rule, be intractable catarrh in men when situated in the penile passage.

It is remarkable how sensitive the bulbs are in detecting and locating stricture of wide lumen. Sometimes the constrictions are arranged in groups, and a No. 24 or 27 F. bulb will slip along in a series of jerks that offer but little resistance to the hand; but more usually one or two obstructions are found from the middle to the outer half of the passage. The lumen of the normal female urethra is not the same throughout its length. It is contracted toward the meatus, expanded in the middle portion, and contracts again toward the bladder, as may be demonstrated by the urethrometer. One must not, therefore, allow error to occur from the introduction of too large a bulb, which would move with more freedom at one portion of the urethra than another. With one that moves with but little force, the sensation of meeting one of these obstructing bands is so characteristic that there is but little danger of error. They differ in one important particular from obstructions of the same diameter in the male. In women they occupy but a small space longitudinally of the passage, while in the male half an inch to an

inch is sometimes involved. All the symptoms evoked by strictures more contracted are observed in those I have been describing. I know of no differential symptoms by which to distinguish the different degrees of contraction. The gravity of the symptoms does not appear to depend upon the extent to which the lumen of the passage is encroached upon, but rather upon the degree of the irritation existing.

Symptoms of functional disturbance due to stricture have their periods of exacerbation and intermission, so that the patient will give a history of frequent and painful micturition, with intervals of relief of a duration of days, and even weeks. Oftentimes the patient rises in the morning in a comfortable condition, with a renewal of the urinary symptoms toward the latter part of the day, especially if she has been much upon her feet, the disturbance lasting well into the night. The power of control is sometimes impaired, the patient being obliged to promptly respond to the inclination, otherwise there will be an involuntary escape of urine.

The form of stricture that I have most frequently met with, and one that produces the most acute symptoms, is the annular stricture of the meatus. It is a firm ring situated at the verge of the opening, and ranges in calibre from 13 to 20 F. They offer quite a solid resistance to the exploring bulb, which has sometimes to be pressed against the ring for a moment before it yields, and what is even more characteristic, presents about an equal resistance to its withdrawal. Some are of large calibre. I have noted one of 23 F. in which the urinary symptoms were very urgent, and which totally disappeared on the passage of sounds with very slight dilating force. The resistance offered to the withdrawal of the bulbous sound both in the annular stricture at the opening and in the obstructions further up the canal, is one of the most characteristic sensations to the touch presented by these delicate instruments. The treatment of these strictures at the meatus is quite painful, and cocaine ought to be used. In a very few instances I have divided the obstruction upward, but this plan gave no special advantage except in relieving the painful stretch at each passage of the sound.

Very small strictures near the meatus, but not involving the opening—the analogue of what we so frequently meet with in men—I believe are quite rare. In women such an obstruction nearly always involves the meatus. I recall one such case in which the meatus received with difficulty a No. 19 F. bulb and a firmer contraction half an inch beyond. The subject was sixty-two years of age, the mother of several children, and had suffered several years from difficult and painful micturition. In this case I divided the strictures, as dilatation was painful even under cocaine. From the thickened and inverted prepuce, the

hypertrophied right nymphæ with its hardened and corrugated surface, and the general pigmentation of both nymphæ, I suspected long continued masturbation. A long time after the patient confessed that such was the case. This was interesting, as the urethra of this woman presented about the same condition met with in men who have long been subject to this vice.

Persistent retention due to the mechanical obstruction as a symptom, I have not often met with. I believe I would rather express myself to substitute retarded flow for retention. In one case in which a 16 F. bulb passed the meatus with difficulty, the flow of urine was very slow in starting, and the bladder was slowly emptied with a small reluctant stream. In this instance, before any exploration or stretching, the obstruction offered an opening not to exceed 12 F. to the flow of urine. This woman had had gonorrhœa about ten years previous to my treatment. If one looks for symptoms of mechanical obstruction in stricture of women, I fear it would be very misleading. Therein lies one of the obstacles to the general recognition of this condition in women. As a sex, she is continually subject to urethral and bladder symptoms, but without other indications of stricture, that the condition nearly always meets with some other explanation. What in man would inevitably lead to a urethral exploration, even on the part of a very ordinary surgeon, is never made in women, except in cases of exceptional severity.

Another condition sometimes met with at the meatus is what has been called eversion of the mucous membrane of the passage. It is very troublesome and difficult to cure. This is, in my opinion, simply a form of stricture. Cases so treated have made prompt recoveries. Its prototype in the male is the fusiform stricture of the meatus of Otis. This author states that it is rare in the male, and he applies the term congenital to it. In this sex the condition is not revealed except as the result of exploration. In women, however, it is not rare to meet with a rolling out of the mucous lining which presents at the meatus as a red irritable margin. When a full size bulbous sound is introduced, the protruded mucous membrane is pushed before it, and the resistance to its introduction ceases when the bulb is pushed through the ring. On withdrawing the sound, its point is caught by the ring of mucous membrane which is pulled out to its full extent, thus offering considerable resistance to the withdrawal of the bulb.

The point which I wish to impress is that this is essentially a stricture. Those of you who have treated the condition know how disposed it is to return even after the margin is pared or cauterized away. I believe that it is explained by the existence of an annular stricture at the meatus and a subsequent dilatation of the urethra be-

hind it. Of course, I do not allege that this may not occur from dilatation of the urethra without stricture; but the diagnostic use of the bulbous explorers demonstrating the obstruction at the meatus, puts the pathology beyond doubt. With or without excision of prolapsed mucous margin, permanent cure may be attained by gradual dilatation with the sounds. Two cases of this condition, both in middle-aged women, were cured by relieving the stricture at the meatus, with cure of severe urinary symptoms. In old women, in whom it is more frequently found in connection with annular stricture of the meatus, its cure is practically impossible without cure of the stricture.

I do not propose to take up your time with the detail of illustrative cases. The proof of the matter is so simple to everyone who will provide himself with a set of exploring bulbs, and habitually employ them in every case that presents with urinary symptoms, that I do not believe I can make my case stronger with the history of cases, as I urge all to test the accuracy of my statement. In the treatment of stricture the bulbs are of course not used. I make use of graduated steel sounds, the same that I used when in general surgical practice to treat male stricture. The action is two-fold—to dilate gradually and to cause the absorption of the constricting exudate, and that latter end is not attained by sudden and forcible dilatation. The treatment made two or three times a week, extends over a considerable length of time; but the relief given to the patient early in the treatment is very satisfactory. A dilatation of the urethra is no more important than the absorption caused by the passage of the sounds, it implies a more or less prolonged treatment.

The use of electricity as a treatment I have not had any experience with. Fissiaux states it has given good results at his hands, but I have found the use of graduated sounds so satisfactory that I have not been tempted into new ways. I believe that electrolysis so-called, in the sensitive female urethra to be a very painful method, and would not promise any more speedy or permanent results than dilatation.

In conclusion I again urge the employment of the exploring bulbs in all cases of dysuria, with the conviction that those who will faithfully follow my methods, earnestly seeking for the truth, will find ample verification of what I claim concerning the frequency of stricture in women, and the important part it plays in the disabilities of women.

THE UNIVERSITY OF BASEL, the only university in Switzerland that has excluded women students, has just decided to admit them to the medical department.

SOME OF THE VAGARIES OF THE GRIPPE.

Read in the Section of Practice of Medicine, Materia Medica and Physiology, at the Forty-first Annual Meeting of the American Medical Association, at Nashville, Tenn., May, 1890.

BY C. F. ULRICH, A.M., M.D.,
OF WHEELING, W. VA.

The influenza, or "grippe," as it is generally called, Protean in its forms and chameleon-like in its aspects, has made a flying trip through our country, and left its multiform impression upon our population. This strange disease enjoys as many titles as a European nobleman: influenza, because it exercises such a decided influence upon all the tissues and functions of the human body; *la grippe*, because, when it once takes hold, it rarely lets go its grip; *rheuma epidemicum*, because, under its dire influence, the universal nose and throat becomes a perennial fountain; *cephalalgia contagiosa*, because of the infernally Plutonian headache it induces; *fallette*, because, when attacked by it, we are driven almost to madness; *coquette*, because it plays with our feelings as a cat does with a mouse or a young lady with her devoted admirers; *petit courier*, because it runs from organ to organ, suffering none to escape, until we almost wish ourselves dead, to escape the torments of the dreadful disease. We might go on multiplying epithets *ad infinitum*, that have been applied to this polymorphous disease; but let this suffice as an introduction to a brief and unvarnished account of the strange antics of this Harlequin of diseases.

It is not my intention to attempt a scientific analysis of this strange visitor among us, which doubtless has been, or will be done during this meeting, by minds much better fitted for the task than your humble writer; desiring only to give a brief sketch of the unwelcome visitor as it appeared in our midst. I cannot give statistics, having none at my command that are reliable; I cannot enter into a scientific discussion of its etiology, because I have not fathomed it; its symptomatology, because that would include a description of all known diseases; its diagnosis, because it resembles all other diseases in some of its forms; its prognosis, because it is as uncertain as the winds. Neither can I say much of its treatment, because, though called upon to treat several hundred cases, I have not succeeded in establishing any fixed principle of treatment, but have simply proceeded in a tentative manner, treating the symptoms as they arose. Therefore, knowing nothing of its causes, though without doubt the bacillus will sooner or later be discovered; but little of its treatment, having only proceeded empirically in the management of the cases that have come under my observation, I have thought it best to speak of the whims and vagaries the disease has been guilty of as seen in the valley of

the Ohio, and more especially in Wheeling and the immediate vicinity.

When it was first announced that the influenza or grippe was upon us, many of the physicians treated the idea with scorn. They said it was nothing more than a catarrhal affection of the mucous membrane, due to the peculiar changeableness of the weather, for you all remember that last winter, in the strict sense of the word, was no winter at all, the weather resembling that of spring more than anything else. Whenever, in December, 1889, a physician pronounced a case "influenza," it was said of him that he was taking advantage of the prevailing panic, to cover up his ignorance, or save himself the trouble of investigating, by pronouncing the case "grippe." Many said: "Oh, they are only frightened by the reports from Europe, and imagine that the terrible disease ravaging that Continent is upon us; while we have really nothing but a series of bad colds from the vicissitudes of the weather." But soon a change came o'er the spirit of their dream. Persons who were seized by the fell destroyer, whether physicians or laymen, confessed their error, and admitted that there was such a disease, and that it was unlike anything they had ever felt before. Having experienced its horrors myself, I can speak feelingly upon the subject. Imagine that you have an iron band placed like a hoop around your brain; that this band has a peculiar screw-like attachment by which it can be tightened. Then suppose that some malignant hand has hold of that screw, and is turning it with fiendish joy until your agony is almost past endurance. This is the first onset of the grippe, from which it doubtless derives its name. Let no one tell me that it is merely a catarrhal affection of the mucous membrane! Those whose brain has been held as in a vice by its relentless grip, know better. There is something more; there is undoubtedly an inflammatory affection of the meninges of the brain and medulla oblongata, acting upon those organs very much as a bone felon does upon the nerves of the finger. This is the initial symptom of almost every case of grippe. But what follows is as various as the catalogue of diseases. This monster has the wonderful faculty of penetrating every weak spot in the human body, rooting up old and almost forgotten complaints, bringing them again to the light of day. Almost every ill that human flesh is heir to is sought out and reproduced by this dire disease. Persons who have been afflicted with catarrhal trouble (and who is there that has not?) have nose and throat turned into a flowing fountain, and cough until they choke in the endeavor to throw off the bronchial accumulations of mucus. One who has been affected in times past with gastric catarrh or intestinal trouble, as soon as the dreadful grippe lays hold on him, is at once seized with pains and cramps in the stomach, retches and vomits, unable to retain

the food which his appetite has induced him to take; or is attacked with colicky pains and perhaps diarrhœa. Has one been formerly afflicted with rheumatism and supposed himself entirely relieved of it; with the first onset of the grippe all his long forgotten pains are on him again, and his rheumatism is again in full possession of his body.

I will mention one case as an example. A friend of mine who, eight years ago, had gone through an attack of rheumatic fever continuing thirteen weeks, but had not been troubled by the malady since, sent for me one day, and I found her stretched in a helpless condition on the bed, unable to move a limb and suffering all the horrors of rheumatism. On questioning her closely, I found that her attack began with that furious pain in the head which characterizes the grippe. Treating her with that fact in view, I succeeded in relieving her in a few days.

A member of my own family had had typhoid fever three years ago and, as frequently occurs, was affected each succeeding year with threatening symptoms which never materialized. But during the prevalence of the grippe, she was attacked by the relentless monster; immediately the typhoid condition was developed and she went through all the stages of the typhoid fever, with, however, decided modifications of the symptoms.

One peculiar case occurred in my practice during the epidemic. A woman had gone through a course of primary and secondary syphilis; but supposed herself entirely cured, having seen nothing for a number of years. During the winter just past she was seized with the grippe, and the old eruption made its appearance again, being especially malignant on the mucous tissue of the mouth, tongue and fauces. I do not make this a typical case, it being the only one of the kind seen by me; but it goes to corroborate the inference drawn from the others.

Women who had suffered from disturbances of the menstrual function and supposed themselves entirely cured of the trouble, upon being attacked by the grippe, experienced a return of the old symptoms and found themselves as bad as ever. Such troubles as nasal and pharyngeal catarrh, gastritis, enteritis, cystitis, etc., being reproduced by an attack of the grippe might be explained by the old theory that it is essentially an affection of the mucous membrane, and that those organs which had gone through such diseases before, being thereby rendered more sensitive and susceptible of inflammation, were the first to feel the weight of the attack. But how shall we explain the rekindling of other diseases: typhoid fever, rheumatism, neuralgia and the host of other diseases that are reawakened after a Rip Van Winkle sleep of many years? What occult power exists in this mysterious agent that is able to resuscitate the dormant powers of a disease that was supposed

to have been long since buried beyond the possibility of resurrection? It certainly is something more than a mere affection of the mucous membrane. There is an occult mystery in the vital processes of health and disease, of growth and decay, that we are as yet unable to fathom, investigate as we may. We know, or think we know, that all the functions of the body originate in and are regulated by the cerebro-spinal and ganglionic system of nerves.

Now, any disease that has such far-reaching influence as to simulate almost every known malady, or to rekindle it when its fires have been extinguished so long as to be almost forgotten by the sufferer, must have its seat in the fountain of all vital action—the brain and the nervous system. It is a well known principle that all moving bodies travel in the path of the least resistance. When the cloud bursts and the rain falls in irresistible torrents on the mountain tops and the water rushes with mighty force down the steep sides, it always selects the beaten paths and gullies made by former rains, where its course is the easiest, meeting with but little resistance. The same principle holds good in disease as in everything else. When the brain, the great electric battery of the human body, becomes diseased and sends its unhealthy currents along the telegraphic wires known as the great network of nerves that permeate every organ of the body, the same rule will be observed, and the diseased conditions will be conducted to the places that have been previously affected. When we take this fact into consideration we can easily account for the otherwise mysterious and inexplicable phenomenon of such a variety of diseases, and such a multiplicity of symptoms all springing out of the grippe. It is true, when we have arrived at this solution, we are still in the dark and not much wiser than before; for we do not know the nature of the enemy that is attacking us, and have not ascertained his vulnerable point. Nevertheless, we have succeeded in locating the trouble and have discovered to what point our main attack must be directed.

We must fight the enemy in his stronghold and, if we succeed in conquering him there, everything will be safe. But if we fail in that, the separate diseases that spring out of this source must be combated, and a serious contest, with doubtful result, is to be expected. The modern antipyretics—antipyrin, antifebrin, phenacetin, to reduce the exalted temperature and control the cerebral excitement; aconitine to retard the great rush of blood which overwhelms the brain—these have been, in my hands, powerful engines for good in the first onset of the disease. For the mucous inflammation which follows and sometimes accompanies this first stage, I have found the hydrastis canadensis, in the form of the colorless fluid extract, of most wonderful efficacy. If, however, we fail in destroying the root of the

evil, it behooves us to make a long fight and beat the enemy out of all his hiding-places, which sometimes tries our skill and patience to the utmost limits. Our treatment must then be the same as though we were dealing with the idiopathic diseases. But I will not venture to say more concerning the treatment; nor do I insist upon the absolute correctness of my theory regarding the nature of the disease.

I merely throw out these few suggestions as the result of my observation of about 300 cases that have come under my treatment since the 1st of January, hoping that my crude ideas will set some of our brain-workers to thinking and cause them to develop ideas that will enable us not only to combat this dreadful disease, in case it should visit us again, but also help us to explain many morbid phenomena that as yet are as a sealed book to our comprehension. It has often been said that afflictions are blessings in disguise, and we who have been afflicted, have scoffed at this and called it the ravings of a cranky preacher. But when such an epidemic as we have just passed through, and with the sequelæ of which we are still battling, induces us to investigate and look deeper into the causes of things than we have done heretofore, the benefit to future generations is not to be calculated.

EAR COMPLICATION FROM CHRONIC CATARRHAL INFLAMMATION OF NOSE AND THROAT.

Read in the Section of Laryngology and Otology, at the Forty-first Annual Meeting of the American Medical Association, at Nashville, Tenn., May, 1890.

BY W. I. EDWARDS, M.D.,
OF NASHVILLE, TENN.

In the short space of twenty minutes allowed to us to read a paper of any importance, we can merely give a few hints or outlines of the intention of our subject, and therefore cannot do justice to the subject or to ourselves, so I will only give a partial and brief notice to the anatomy of parts involved, and to treatment.

In thinking over the various troubles that may arise from catarrh of nose and throat, I find none attended with more pain than non-suppurative inflammation of middle ear. This form may call for prompt and immediate action from the very nature of its severity, and in order to discuss it intelligently we will have to look at the anatomy of the parts involved, as well as the diagnosis, prognosis and treatment.

First, we will look at the nose, and we find both cavities lined with a mucous membrane. This membrane also lines the pharynx, larynx, and Eustachian tubes.

Now we have traced the same membrane from the nose to throat and inner ear. And it is from

the continuity of this membrane that we have ear trouble from catarrh of the nose and throat, which may go on for years with but little trouble, but it is only a question of time when it may prove very serious to the sense of smell, taste or hearing, and the party may at any time contract a new cold of the chronic form, which may give excruciating pain in the ears, and then summons the family physician, who drops a few drops of laudanum and sweet oil into the ear, and tells the patient that it does not amount to much, that it is only earache,—of which they are fully aware, for it is an almost intolerable pain, and often prostrates the most robust men. They, too, often allow the disease to go on and not only rupture the drum, but involve the mastoid cells, which may necessitate trephining; while a careful diagnosis might have defined a different course of treatment and prevented breaking down of the drum, necessitating impairment of hearing, if not total loss; besides the very great pain, and the following discharge, which may prove very annoying.

We also find in chronic catarrh, hypertrophic rhinitis, which involves the mucous membrane and turbinated bones. These bones and tissues become so much involved that it is difficult for the patient to breathe through his nose; often one side will close for a few moments and then open, and the other side close; or we may have hypertrophy of one side and atrophy of the other.

When we have a hypertrophied condition of the nose, we may also have the same condition of the Eustachian tube, causing tinnitus aurium, and impairment of hearing. But the most distressing condition to the patient is the annoyance of the ringing noise in the ears, which often causes loss of sleep and even impairs the mind. And again, we may have, from an abraded surface of the mucous membrane from scabs forming, a polypus formed that may close one side of the nose, or may have one or more on both sides, cutting off all air from the Eustachian tubes, and from pressure, inflammation, and the want of the physiological action of air, we may have pain, tympanitis and impairment of hearing, and all of these to a very distressing condition. I will report a few cases:

Case 1.—Mr. G., aged 50, had been suffering from catarrh for forty years. On examination I found fibromata, or fibrous polypi, in both sides of the nose, protruding from anterior orifice of nose, and extending back and filling the nose, distorting the face; nose looked more like a frog than a nose; tumors extended down the throat; these had been removed three or four times with forceps and cold snare, in the space of thirteen years. His health was broken down, impairment of hearing, with pain in ears, with occasional discharge. I gave tonics, built the patient up as well as possible for his condition, and then re-

moved polypi with galvano-cautery; polypi was so large could not use wire loops, and had to use a cautery knife to remove a part before using loops. Patient being very weak, made two sittings; had but little lost; kept up the tonics, used local treatment, consisting of thoroughly cleansing the parts with biborate and bicarbonate of soda, aqua, carbolic acid in warm camphor water, then spraying the nose with pinus canadensis, carbolic acid and fluid vaseline. Patient made a rapid recovery of health, discharge from ears ceased, all pain relieved, and his hearing restored.

Case 2.—Mr. L., age 62, had been troubled with catarrh for most all his life, and had suffered with severe earache, and loss of hearing in one ear, with distressing ringing noise. I found exostosis of turbinated bones of one side, and echondromata or cartilaginous tumor of the other. Removed this with the galvanic cautery snare without loss of blood, and removed the exostosis of the other side with dental skill, and smoothed the surface with forceps and galvanic cautery knife. Used the same after-treatment of this case as the other reported. Patient made a good recovery of hearing, relieved of tinnitus aurium, and was relieved of the catarrh.

Case 3.—Mr. C., age 71, had been suffering from catarrh for fifty years, attended with all the annoyance of difficult breathing through the nose, scabs forming, spitting, ringing in the ears, and at last was attended with violent pain in the ear, side of face, and head. I was called out of the city to see him; found patient prostrated with high fever, and almost intolerable pain, with five physicians attending him, watching and expecting him to die. Patient had lost power of speech and not able to raise his head. I found temporal and mastoid bone very much involved. I diagnosed pus in mastoid cells, with rapid absorption of pus to brain. I advised trephining; was opposed by some of the physicians, for the reason that they thought he would die in a few hours, and might die while operating; however, the family left it to me. I operated at once and removed a large quantity of pus. Patient slept well that night, was able to sit up in bed next morning to eat his breakfast, and was able to come to Nashville for regular treatment for his catarrh in ten days.

Case 4.—Miss F., age 18. I was called in consultation with her family physician, who had been treating her for a week for earache; found the young lady prostrated with pain in her head and ears, had high fever, could neither eat nor sleep. I diagnosed catarrh of inner ear, with pus in the mastoid cells. I found a hole in drum of ear, but no discharge. History: She had catarrh of nose and throat, and about one year before this attack she had a severe spell of earache, followed by a discharge, which only lasted for a few days. I advised operating on the mastoid

bone at once; physician opposed it. I told them it would have to be done, and the sooner the better, and when they wanted me to let me know. On the next day I was called for to do the work. I operated by cutting down on the bone with a free incision, and probed through the periosteum into the cellular bone, and removed a large amount of thick pus. I syringed the cavity thoroughly with a warm solution of carbolized camphor water, and put in a tent. Patient slept well that night; removed tent twice a day for a week, at which time she was able to come to my office for further treatment of the catarrh of the nose and throat.

Case 5.—Miss F., age 15. Had catarrh of the nose for three years; could not breathe through the nose at all; could only hear watch when pressed to ear, with very distressing ringing in the ears. I found sessile fibrous polypi, which had been removed one year before. I could not reach the base of these tumors through the small contracted orifice, and decided to do Rouge's operation. I gave ether, and dissected the upper lip and nose proper from their points of attachment on the superior maxillary bones, then drew the detached portion upwards, then the anterior nasal cavities were fully exposed, and tumors easily reached. Removed them with galvano-cautery with loss of but little blood, adjusted the nose and lip, which were held in place with firm bandage placed on upper lip, and extending around the head. It healed rapidly and the patient recovered with all the necessary after-treatment. Hearing restored to normal condition, and no disfiguration of face or nose, which is a very great consideration to young ladies. And the doctor who would dare disfigure one of those lovely creatures, just to save time and trouble to himself, is not worthy of the title which we all have the honor to bear. For our calling is second to none in its noble and life persevering efforts to restore the sick, heal the afflicted, and point them to the great High Physician of all, whose ever-watchful eye is on doctor and patient alike, and to whom we all have to give a strict account of our deeds, good and bad.

623½ Church Street.

SOME THOUGHTS ON INEBRIETY.

Read in the Section of Medical Jurisprudence, at the Forty-first Annual Meeting of the American Medical Association, Nashville, Tenn., May, 1890.

BY J. F. AXTELLE, M.D.,
OF HARTFORD, CONN.

Fred C., æt. 37, came to this city from Nova Scotia twelve years ago, a bright, manly young fellow, and secured a situation as salesman in one of our leading dry-goods houses. He was liked by all who had dealings with him, and was advanced from time to time by his employers. Soon

he got to going out evenings, would drink with a friend when asked, but did not care for it otherwise. This went on for about two years; then he found that when he drank once he wanted more, and would keep it up for two or three days, be sick for a week, and would drink no more for six months. When on some special occasion he would again take a drink, he would then keep it up as before.

About this time he became engaged to be married, but the parents of the young lady objected, having heard of his habits, but finally consented if he would not drink for a year; he accepted the situation and won his bride, but on the night of his wedding got drunk, and kept so for two weeks. From this on for two or three years he would average four sprees a year. About this time he lost his situation. He went to Boston, but became so bad that his wife had to leave him, and came home. He was again thrown out of employment, came back to Hartford, went to work for his old employer, but could not keep sober a month. He soon went through quite a little property which was left him by his father, could not support his family, and his wife's parents had to take her and her child to their home.

About a year ago the wife obtained a divorce for non-support and intemperance, and he then made an unsuccessful attempt to commit suicide by taking laudanum.

Last week I signed papers to have him sent to an insane asylum, and while signing the paper, the thought came to me, why could it not have been signed ten years ago? Has a man the right to be a drunkard? If we admit that he has not, we are ready to proceed with the remedy; but all will not admit this position. They cry out liberty, individual liberty, and the right of the individual to do as he pleases will be forever their watchword. Has the individual such a right? Has he the right to disgrace his family, and to impoverish his wife and children? Has he the right to have children to inherit his weakness?

Instances might be selected of men without family or ties of any kind, and the position taken, that no one is hurt but themselves, but how is there to be any security that they will not ultimately commit some crime, or at least become cares to the public as lunatics or paupers? It seems to me that the unincumbered individual has no right so to live as to damage society and become a burden to the public. It is sheer madness to claim the right of the individual who has a family to drink to excess.

Drunkenness, inebriety, dipsomania, or whatever scientific term we may be pleased to give to the habit of excessive drinking of alcoholics, will be considered and regarded as a disease, as we regard insanity, and the individual so afflicted will be treated and cared for as though he were actually insane.

In many, if not all, public and private asylums, there can be found men and women who are insane in no sense except one habit, and who are treated as insane, yet no one seems to object to it, and the law winks at it. This fact alone shows the drift of unconscious public sentiment, and shows that society does regard such persons as practically insane.

It would perhaps astonish the criminal lawyers to know that a large part, perhaps a third, of the inmates of our asylums for insane, know right from wrong as clearly on most subjects as the best of us; but the trouble is to keep from doing the wrong.

Why should not the man with an ungovernable habit, which will lead him and all that are dear to him to sure destruction, be regarded as powerless to act for himself, just as the suicidal maniacs? Have his children or his friends no rights? Has his wife no legal or moral status? Shall he go on procreating unfortunates like himself, to in time, perhaps, fill poor-houses, jails and asylums?

The strong arm of a benign and merciful law should stop him, should declare him unsound, and place him in confinement, before he has destroyed his property and himself.

CURIOSITIES OF HOMŒOPATHIC PHARMACY.

Read before the Medical Society of the District of Columbia,
April 23, 1890.

BY ROBERT REYBURN, M.D.,

PROFESSOR OF PHYSIOLOGY AND CLINICAL SURGERY, MEDICAL DEPARTMENT OF HOWARD UNIVERSITY, WASHINGTON, D. C.

Having recently obtained a copy of the circular and price list, issued by a dealer in higher potencies residing in New York City, I desire to impart to the members of this Society and the profession, some of the information therein contained. This document is a printed pamphlet of thirty-two pages, and is entitled "Catalogue of Morbific Products, Nosodes, and other Remedies in High Potencies." These remedies are for sale at No. 13 W. 38th St., New York City. By Samuel Swan, M.D.

Glancing over the catalogue, on page 16, we were struck by one article of the materia medica, kept for sale and called "luna, or moonlight." How in the world is this obtained, and what are its properties? Astronomers have long disputed as to whether the rays of the moon possessed any heating power, but why need they any longer be in doubt, when they may be bought by the vial full, and seen and tasted by ordinary mortals?

On page 20, we find three species of *pediculi* (or lice) on the list of remedies to be dispensed, namely: *pediculis pubis*, *pediculis capitis* and *pediculis corporis*. These minute animals we only expect to find on uncleanly persons, and the idea of

swallowing them, or a preparation made from them, no matter how dilute, is rather startling to the uninitiated. The *pediculis corporis*, by-the-way, has a note in brackets after it, stating that this special lot came from Boston. The inquiry then arises in our minds, Why is this? Are the Boston *pediculis* more voracious, or of larger size than those of other cities? What is the cause of their superiority? Unfortunately, the vendor of these delectable preparations does not condescend to inform us upon these points, so we are compelled to remain in ignorance.

On page 1 we find on the list the name "*acarus scabies*" translated "lice insect." As the *acarus* mentioned is the one found in the disease known as the itch (in common parlance), and is not the *pediculis*, there seems to be a (H) itch in the Latin; but trifles like this need never daunt the swallower of preparations like these.

But, thank Heaven, there is on the first page one familiar remedy, viz.: "*adeps anserina*" (goose grease). How well do we remember the vile odor of this substance when applied externally to the neck in our youthful days. To paraphrase Hamlet, "The offense was rank and smelt to Heaven." Never did we imagine we should see it prepared in "High Potencies" and given in granules.

On page 15, "*lachryma filia*" are defined as "Tears from a young girl in great grief and suffering." In ancient Rome small crystal or glass flasks have been found called "lachrymalia," which are said to have contained the tears of the mourners. Were these "*lachryma filia*" obtained from such sources, or are they the tears of some modern damsel, mourning, perhaps, like Miss Flora McFlimsey, because she had nothing to wear, or in utter desperation from the lack of a spring bonnet, or it may be crossed in hopeless love?

The explanation of "*flavus irides*" on page 11, is "yellow ray of the spectrum." Here is bottled sunshine with a vengeance! Photographers have long desired to fix the fleeting rays of the sun, and make their pictures glow with the colors of nature, and here we have them prepared and fit for internal medication. Would that we knew the secret of this preparation! One thing is certain, if we *must* swallow globules, it would be much pleasanter to think of swallowing bottled sunshine, than a preparation of *pediculis corporis*, even though they were labelled as coming from the city of Boston.

On page 6 we find, "*carbunculus* on neck of swan very severe." We are not told whether the carbuncle was very severe upon the swan, or whether the pus obtained from it has been very severe upon the unlucky patient who takes it—perhaps both statements may be true.

"*Fel gryllus Americana*" (page 11), or "Brazilian cricket," is said to be beneficial for "sup-

pression of urine with or without pain," and this important fact is also stated, that "a boy who had chills and fever swallowed a live cricket and never had a chill afterwards."

On the first page several dainties are provided for lovers of preparations of the high potencies. One is "*adenia*," or "glands from a person suffering with Hodgkin's disease;" a little further on is the "Ailanthus bug," an insect found on the odorous though unfragrant Ailanthus tree. On the same page "*Albumenurea*" is defined as "renal albumen," or in other words, the putrid and disgusting products of the decomposition of the human body, as found in diseased urine.

On page 2, "*anthracin*" is said to be "pus from a carbuncle." On page 4 are two delightful compounds: one is from the *Blatta Americana* or "American cockroach," and the second is a more distinguished member of the same family, namely: "*Blatta Orientalis*" or "East Indian cockroach." Farther down the same page is "*Buboin Syphilitica*" or "pus from syphilitic buboes." On page 5 are a number of preparations of calcaria from different parts of the body, as "*calcaria renalis*," or "stone of the kidney," and "*calcaria*" from the lungs and bladder. On page 6 we have three preparations made from the different varieties of catarrh to choose from, viz.: catarrh of the intestines, catarrh of the bladder, and catarrh of the nose. In this case you certainly "pays your money and takes your choice."

Page 7 gives us a little ray of hope that we may not be called upon to swallow any more such vile compounds, for there we find "*cerulia irides*" defined as "blue ray of the spectrum," but as if to dash our newly found hopes to the ground, immediately beneath is given a preparation made from the "chancre of syphilis."

Page 8 gives a remedy for constipation in newly born infants, viz.: colostrum, found in their intestines previous to and after birth. Page 9 gives preparations of two varieties of poisonous snakes, viz.: *crotalus horridus* (rattlesnake) and *crotalus cascavella*. On the same page is "*crusta lactea*," commonly called "milk crust," and found on the heads of sickly or uncleanly babies. Farther down on the same page are preparations of diabetes mellitus, and also of the serum found in cases of dropsy.

Pages 10 and 11 give preparations entitled "*electricitas*" or electricity, and "*galvanismus*" or galvanism. It has been said of our countryman, Franklin, that he brought down the lightning from Heaven for the service of man, but our homœopathic brethren can do more than that, they can make it edible and drinkable for ordinary mortals.

But time fails me, and I can only enumerate a few of the choice morsels obtainable in the high potencies: "*hippозinine*," a preparation from the glanders; "*lyssin*" from hydrophobic patients;

"*osteo necrosis*" from necrosed or dead bone; pus from abscess of rectum, and caries of heel, pus from septic abscess.

Page 22 gives us "*rubrum irides*," or red ray of the spectrum, and thus completing the list of rays of light, used in the manufacture of their globules. On page 23 we find four varieties of cancer served up to us, viz.: of the breast, uterus, bowel and face.

Page 25 seems to show that Dr. Brown-Sé-ward's so-called elixir has been anticipated, for we there find two preparations, one "*testiculo galinae*," or testicle of the fowl, and "*testiculo muliebris sinistra*," from the left ovary of a woman.

Many other preparations might be given, but I will conclude by giving an extract from the note after page 30. Dr. Swan says that the plan of sending grafts has been adopted, viz.: "If a graft is put into a vial filled with unmedicated pellets, and corked, the whole mass will be medicated in half an hour." Farther down on the same page he says: "When a vial of medicine is nearly emptied, fill it with unmedicated pellets and you will not have to purchase the remedy a second time."

THE CLINIC.

A CLINICAL LECTURE.

Delivered at St. Luke's Hospital, March 26, 1890.

BY HENRY T. BYFORD, M.D.,
OF CHICAGO.

Gentlemen:—As this is the last time I shall meet you here, I shall naturally have more to say and less to do than usual. The amount of practical work to be done during the season, and the limited number of clinic hours at my disposal, twelve in number, allow of little time for talk.

ABSCESS DISCHARGING INTO PERITONEAL CAVITY.

The case now upon the table is exceedingly interesting, for the patient may be said to bear a charmed life. No cat, thrown from a shot tower, ever lauded on its feet more triumphantly than does this woman after passing through the extremest perils of the knife. She has been twice within the shadow of the valley of death, yet a high temperature never came to her, nor has a good appetite ever gone from her.

Three months ago my colleague drained a peritoneal cyst situated in the lower abdomen. The cyst wall promptly sloughed off and gave rise to the most foul-smelling, septic and troublesome discharge imaginable. The abscess walls were made up of intestines matted together and had not, after three months, ceased pouring out large quantities of pus. But for the patient's prodigious digestive powers, she would undoubtedly

have, ere this, been forced to obey the summons that awaits all men. Three weeks ago I attempted, with the advice of my colleague, to establish better drainage, in order that the tax upon the patient's system, and coincidentally upon the commissary department of the hospital, might be lessened.

You will remember that upon enlarging the opening, and attempting to make a counter-opening in the left iliac region, the abscess wall parted asunder, and with its residuum of pus and abundance of granulation débris entered the open peritoneal cavity. Not having expected to invade the sacred precinct of that cavity, I had taken no unusual antiseptic precautions either with regard to the patient, the room, the assistants or myself. All hands, sponges, instruments and vessels had been smeared with the pus. There was, however, nothing left but to go ahead and treat the peritoneum on the same principles as an open abscess in any other part of the body. Consequently I cleansed my hands, called for hot water from the faucet (as sterilized water was not prepared), and washed out the peritoneal cavity most thoroughly. A large perforated rubber tube was then passed from the opening in the iliac region at the left border of the suppurating surfaces, through an opening made in the recto-uterine pouch into the vagina and out at the vulva. The pus-secreting area above was packed with an abundance of iodoform gauze extending slightly beyond it all around. Dry aseptic dressing over both ends of the rubber tube and over the iodoform packing completed the operation.

The patient was sitting up with the bed-rest eating a hearty dinner on the seventh day. Today there is nothing left of the abscess but a narrow sinus extending just under the abdominal wall from the median line incision two and one-half inches toward the anterior iliac spine. I have attached a very small rubber tube to the large one, and now draw it through to leave in place of the large one. As there is practically no discharge I will remove this one in a few days, and send the patient home, where a change of scene and diet will complete the cure.

ENUCLEATION OF OVARIAN AND TUBAL ABSCESES, MICKULICZ DRAINAGE.

The iodoform tampon, or Mickulicz drainage, is one of the most valuable of the later improvements in the technique of peritoneal surgery. What could have been more brilliant than the action of the gauze in this case, or the almost parallel case operated upon before you, two weeks ago. In the latter case, after enucleating diseased appendages, including two large abscesses, you will remember that the oozing from the intestinal walls, broad ligaments, posterior surfaces and bottom of the pelvis on both sides threatened, if not promptly checked, to destroy our already exhaust-

ed patient. I made a sack of iodoform gauze to fit the interior of the pelvis and packed it with gauze, whose magical touch immediately transformed the discharge of blood into serum, and the condition of the patient from one of considerable alarm to comparative unsolicitude. The gauze was removed little by little each day, in order to allow the intestines time to fill in the evacuated space. The last gauze was taken out on the eleventh day without any unusual bad symptom having occurred. At present there is an opening two-thirds of an inch deep, one half wide and one inch long, which has not yet shown the least disposition to suppurate, and whose walls are as clean as a freshly cut surface.

THE HEALING OF OPEN WOUNDS WITHOUT SUPPURATION.

The secret of healing a wound without suppuration is really known to but few, although the principle is known to all. The principle involved in the method I use is that germs cannot develop without moisture, and the whole secret consists in keeping the wound dry. But "there's the rub," as Shakespeare would have elegantly expressed it. Nearly all surgeons use powders and medicines and completely fail. An antiseptic powder does not keep large raw surfaces dry, and, under the influence of moisture, decomposes, becomes inert and actually promotes suppuration, for it buries itself in crevices and folds, from which, with its adherent septic material, it cannot be dislodged without being washed with that moisture for which the imbedded germs are confidently waiting.

The way I do is to pack the cavity loosely with sterilized gauze if it be large, or with sterilized absorbent cotton if small, and use a dry aseptic dressing over all. Neither iodoform nor any other powder should come between the packing and the dry gauze over it, for powder interferes with efficient capillary drainage and the all essential drying sterilizing process. The packing should, in extraperitoneal wounds, be changed two to four times daily, according as the discharge is serous or purulent, until the packing is no longer wet through, then once a day, then once in two days until the dried surfaces have contracted. As long as the discharge is purulent or abundant I wash the cutaneous edges with alcohol at each dressing to keep the skin clean. The cavity is merely dried out thoroughly with absorbent cotton or gauze, and neither medicine nor moisture allowed in it. In hospital wards where serous cavities are frequently opened, this method is invaluable, since it enables us almost to do away with suppuration and its dangers.

TRUE PELVIC ABSCESS.

The case of the patient now being anæsthetized is the historical, old fashioned, antiquated, but by no means extinct variety of pelvic abscess, in

which the entire connective tissue of the pelvis is involved. It originated in an acute attack of some kind several months ago, and was evacuated a few weeks afterward through the vagina. Its origin may have been from infection through the uterus and Fallopian tube, a hæmatoma, or from an ulcerating abscess of the tube or ovary discharging into the connective tissue. Infection may in some instances come from inflammation or ulceration of the rectum.

Upon vaginal exploration I discover a hole smaller than a pin's head through which pus may be squeezed. It is, as you can see, half way between the vaginal entrance and the cervix, on the recto-vaginal septum. With sharp-pointed scissors I make an opening large enough to admit a probe into the abscess. I now slit up the whole sinus along the probe making an opening large enough to admit two fingers. By digital examination I find almost the entire pelvic connective tissue excavated, although abundantly fringed and columned with soft granulation tissue, so as to interfere somewhat with the free evacuation of the pus. The rectum passes through the cavity so that the pockets on either side almost meet under it on its sacral aspect. Had it opened into the rectum I think it would have discharged itself more completely and have done better than it has done by this high vaginal opening, although I am, in this opinion, at variance with the majority of teachers. I am now breaking down this irregular and unhealthy granulation tissue with my fingers, and washing out the abscess with a solution of mercuric bichloride in water, 1-2000. I will now stitch this rubber drainage tube, whose end reaches to the sacrum beside the rectum, to the vaginal edges. As it will take a long time for the cavity to contract, it will be necessary later, either to dilate the vaginal opening again, or introduce a self-retaining drainage tube after the orifice has contracted and hardened enough to hold it. For ordinary irrigations I prefer a two per cent. carbolic solution as being safer and more stimulating than a mercuric solution. For washing out abscesses opening into the rectum, plain water is preferable on account of the dangerous absorbant power of the bowel.

RÉSUMÉ.

Gentlemen, this concludes my portion of this course of clinical lectures. In these eleven clinics in this amphitheater, we have had six peritoneal sections, a laceration of the perineum extending high up into the rectum cured by Tait's method of operation, an Alexander's operation, an amputation of the cervix, and the usual number of lacerations of cervix and perineum, uterine curettings, etc. Among the peritoneal sections we have not had a bad symptom; nor a case of suppuration among the plastic operations except in the drainage tube hole of the Alexander oper-

ation. A lesson to be learned is that it is not the atmosphere nor remote surroundings that need occupy our attention, but rather the field of the operation. Strict cleanliness as to all that comes in contact with the patient, whether it be an instrument or finger, an article of clothing, a sponge or what not, will do more to insure good results than all else. With it poor operators even may obtain good results, without it even good operators must have humiliating experiences.

MEDICAL PROGRESS.

BLISTERING BY HYPNOTIC SUGGESTION.—In the *Bolnitchnaia Gazeta Bolkina*, Nos. 26, 27 and 28, 1890, p. 650, DR. IAKOV V. RYBALKIN, of St. Petersburg, publishes his remarkable experiments, which confirm the statements made by Presalmins (1840), Focachon, Beaunis, Delbœuf, Forel, Jendrassik, and Krafft-Ebing that cutaneous blisters can be easily raised by hypnotic suggestion. The author's experiments were performed in the presence of a number of the medical officers of the Mariïnskaia Infirmary, the subject being a strongly-made and well-nourished house-painter aged 16, suffering from typical hysteria magna and extremely sensitive to hypnotising procedures and post-hypnotic suggestions. On February 21, at 8.45 P.M., the patient was thrown into a deep hypnotic sleep, and then told that, after awakening, he was to shiver from cold and to approach a stove in the room in order to warm himself; when doing so he was to touch the stove with his right forearm and to contract a severe burn ("pain, redness, heat, bladder,") about the middle of the inner surface of the part. The suggestions were repeated thrice, after which the lad was ordered to awake. He obeyed all the suggestions in the strictest possible manner, and even loudly screamed from pain as soon as the suggested area came in contact with the stove (which was quite cold). On immediately inspecting the part a slight palish swelling, surrounded by a reddish zone, which proved to be painful on touch or pressure, was found exactly at the suggested point. The limb was at once bandaged, and the lad sent to bed (in the room). He could not fall asleep, however, being tormented by an acute "rending" pain caused by the "accident." On removing the bandage at 11 P.M., a considerable swelling with papular erythema was found, the adjacent zone, 4 or 5 centimeters wide, being exceedingly tender. The limb was again securely bandaged, and re-examined at 10 A.M. on the next morning, when there were found two slightly yellowish semitranslucent blisters as large as a nut and a pea respectively, and around them a group of smaller vesicles (each of the size of a

pin's head). On another examination at 3 P.M. (eighteen hours after the "accident"), all the individual blisters proved to have coalesced into one large bladder. Two hours later the blister burst. The after course presented nothing different from an ordinary case of burn.—*British Medical Journal*.

TREATMENT OF ACUTE GONORRHOEA WITH THE CONSTANT CURRENT.—After Apostoli and Laquerrière had published the effect of the constant current upon microorganisms, PROCHOWNIK (*Münchener Med. Wochenschrift*) undertook a similar work and reached a like result, *i. e.*, that the positive pole of a galvanic current possessed distinct anti-mycotic properties. From this he inferred that the application of the positive pole might be useful in certain forms of uterine and cervical catarrh, as well as gonorrhœa. Of this latter class four cases are described in which the application was followed by prompt improvement. The first case was that of a woman infected by her husband on the 2nd of September. Eleven days later she came under the author's care, with typical gonorrhœal inflammation of the cervix and urethra, but only moderate involvement of the vagina. Numerous bacteria were found in the secretions, but they all contained gonococci, and a pure culture of the latter was obtained from the secretion of the cervix. The discharges were thick and of a greenish color. From September 18 until Oct. 5 the battery was employed six times by means of copper sound in the uterus with a current strength of from 80 to 100 milliampères. After the third application the secretion of the cervix was free from gonococci, and after the sixth was free from all germs and remained so for one year, during which time they were occasionally looked for. The cervical secretion after six weeks was clear and has remained so up to the present.

A second case was that of a woman who had been delivered six weeks before the infection. The urethra and vulva were severely inflamed but the vagina remained comparatively free. The disease extended to the subinvolved uterus which discharged thin bloody pus. The patient was treated in the same way as the first case and after seven applications the discharges were free from germs. Shortly after her recovery she again conceived and was delivered of a healthy child.

A third case, that of a young woman, 16½ years of age, with a very narrow vagina. She was at first treated for a severe colpitis; when this was relieved, the positive pole was applied in the uterus. After ten treatments the gonococci had completely disappeared from the discharges. The patient remained under observation for six months, but without any return of the disease.

A fourth case, similar to the second, was treated with equally brilliant results.

The author comes to the conclusion that the

cervix is the most important place for the development of the gonococci, and from this nidus they extend themselves along the mucous membrane of the uterus to the tubes and from there to the cellular tissue of the pelvis. The urethra may be left to take care of itself, as the germs soon disappear, or it may be treated with the current, though the author says that a strength of 30 or 40 milliampères is not tolerated except when cocaine is used. When the vagina is involved it should be irrigated with a solution of sublimate or chloride of zinc, followed by the use of clear water.

SUCCESSFUL REMOVAL OF HYDATID TUMOR OF THE BRAIN.—In the *Australasian Medical Journal* for July, 1890, DR. GRAHAM and MR. GRUBBE record a case recently under their care in which a hydatid tumor was removed from between the dura mater and pia mater of the brain. The patient was a lad sixteen years of age, who suffered from severe headache, nausea, vertigo, double optic neuritis with atrophy, loss of memory, mental dulness, and paresis of the right arm and leg. A tumor involving the left motor area was diagnosed, and Mr. Grubbe trephined over it. He found the bone very thin, not more than ¼ in. thick, and on opening the thickened dura mater a single simple hydatid cyst was seen, and easily extracted. The pia mater was intact. The cyst measured 4 in. in diameter, and held 19 oz. of fluid. The patient recovered. After six weeks he was able to get up and walk, his memory returned, and in all respects he was well except for his blindness. Such a case as this was extremely favorable for surgical treatment, as its situation greatly facilitated exact diagnosis, and its removal was unattended with any injury to the brain itself. It is believed to be the first recorded case of the kind. Dr. Davies Thomas records three cases of recovery from cerebral hydatids, in one of which the cysts were passed through the nose and mouth; in two others they were removed through incisions in the scalp after the tumors had perforated the cranium.—*Lancet*.

HEMORRHAGE FROM THE CLITORIS DURING LABOR.—MENSINGA (*Internationale Klin. Rundschau*, July 29, 1890) reports an interesting case of this kind. A woman 36 years of age had seven or eight children, and in the most of her labors had employed no physician. The pains in the last labor were very severe and rapid, so that the head was soon on the perinæum, when they ceased and a severe hæmorrhage set in, this continuing for some time. Mensinga was sent for. He completed the labor easily with forceps, without any apparent laceration of the soft parts. The hæmorrhage still continued, notwithstanding that the uterus was fairly well contracted. A closer examination revealed a small rent in the

region of the clitoris from which a fine stream of blood constantly poured. The author refers to the case of Berthod (*Gazette Médicale, Nr. 33*) in which a fatal hæmorrhage took place from rupture of a varix of the clitoris by a fall upon the arm of a bench. He discusses the possibility of the sudden distension of the vulva causing the rupture of a similar varix in this case.

AMERICAN THERAPEUTICS OF DIPHTHERIA.—PROF. A. JACOBI, M.D., in this paper, presented at the Berlin Congress, traced the history of various epidemics extending from 1659, when Samuel Danforth lost "four children by bladders in the windpipe," down to the time (1868) when he furnished a list of 203 cases, by which it became known that the contagion was very active and affected every kind of wound. The present condition of the therapeutics of the disease in North America was marked by the extra attention devoted to prophylaxis both in literature and in practice. The sanitary arrangements made in New York City for combating epidemics of the disease were admirable, the cases being carefully isolated. Practitioners endeavored to preserve the general health of their patients by the use of cold water, and the catarrh of the mucous membranes of the nose and throat were combated with salt water, boracic acid, nitrate of silver, excision of hypertrophied tonsils, etc. Chlorate of potassium was employed to preserve intact or to restore the mucous membrane of the oral cavity, tincture of the chloride of iron for its anti-fermentative and astringent effect, in frequent doses, so that a child of a year takes from three to four grams daily, in twenty or forty doses. The local treatment of diphtheritic wounds or surfaces (circumcised prepuce, vagina) was mostly by tincture of iodine, iodoform in powder or ointments, or solutions of bichloride of mercury, 1 in 1000 or 3000. An extensive list of other drugs was given. Gargles were considered adjuvants when no violence was used in their administration, but nasal injections were gradually taking their place, seeing that they reach the most affected part of the larynx much better and are much better tolerated. Nasal diphtheria would not get well without some warm, mild injection. Conjunctival diphtheria he treated with ice and strong solutions of boracic acid. Referring to the medical treatment of diphtheria, he was of opinion that it was impossible to give too much brandy in this disease, and stated that from 50 to 1000 grams might be given daily with advantage. Alcohol ought to be given early, and a certain quantity in all cases, seeing that heart failure comes unexpectedly, and then stimulation comes generally too late. It was therefore a good practice to give cardiac tonics in time. Strychnine was indispensable in diphtheritic paralysis. The author spoke of the effects of mercury on this disease, and then alluded to the operative treat-

ment by intubation, which had supplanted tracheotomy because of the rapidity, bloodlessness, and equal efficiency with which it can be performed. Its results in the hands of its discoverer, O'Dwyer, were as good as those in tracheotomy. Every case was managed according to its individual indications; isolation was enforced, fluid food given, moderate stimulation resorted to, absolute rest enjoined, even the nasal injections are made in a recumbent or semi-recumbent posture, and complications watched and treated.—*Lancet*.

THE CHANCES OF TERTIARY SYPHILIS.—FOURNIER, before the Congress for Dermatology and Syphilography, held in Paris in August, 1889 (*Annual de Dermatol. et. Syph.*), gave his experience in 2,600 cases of syphilis, extending over the past twenty-nine years. The question at what time are tertiary symptoms most likely to appear, was answered by 2,395 cases in the following way: 1. The frequency of tertiary syphilis increases from the first to the third year after infection, reaching the highest point in the third year. 2. The number rapidly falls from the fourth to the eleventh year. In the next decade the number falls more slowly. From the twenty-first to the thirtieth year, tertiary symptoms are seldom, while after thirty years they are very rare indeed.

The relative frequency with which different organs are attacked was in 3,429 cases, as follows: Tertiary syphilide, 787; subcutaneous gumma, 128; tertiary genital forms, 157. The tongue was affected in 152, gums 179, pharynx 71, other mucous membranes 30, bones 336, nose 173, joints 14, tendons (gumma) 3, muscles 12, digestive tract 4, rectum 5, pharynx and trachea 23, lungs and heart 2, aorta 6, liver 9, kidneys 9, testicles 145, eyes 69.

The nervous system was affected with extraordinary frequency, 1,075 cases, nearly one-third of the entire number. The following were the chief forms: Brain syphilis 461, cerebro-spinal symptoms 11, monoplegia 3, medullary syphilis 77, tabes 355, tabes (cerebro-spinal) 45, muscle atrophy 19, general paralysis 32, insanity 9, eye paralysis 57, facial hemiplegia 13, unclassified 11.

ETIOLOGY OF PANOPHTHALMITIS AFTER INJURY FROM A FOREIGN BODY.—POPLAWSKA (*Fortschr. d. Med.*) examined twelve eyes that were enucleated for this cause. The vitreous body showed the most important changes. It presented a marked infiltration of small cells, especially in the neighborhood of the foreign body, and also a fibrinous exudate. In this exudate germs were found consisting of bacilli, in the form of strings, nests and masses either free or, as in two cases, enclosed in white blood cells. From the absence of bacilli in the anterior chamber, he was justified in assuming that the bacilli were introduced with the foreign body and then

caused suppuration. Cultures could not be made, owing to the fact that the specimens were preserved in alcohol.

SOMNAL.—The new hypnotic, somnal, has been tested by DR. FRANK WOODBURY, who, in a recent number of the *Dietetic Gazette*, states as his conclusions that instead of depressing the system as chloral does, it slightly stimulates the gastric mucous membrane, relieves nausea and pain, improves the appetite, increases the secretion (probably), and does not cause constipation. The circulation, respiration and temperature are not notably depressed after its administration. It acts, he says, very much like chloral, but is more pleasant to take and not so depressing in its effects upon the nervous system and the circulation.

BROMINE AS A DISINFECTANT.—Bromine as a disinfectant is said to be coming to the front. It is an inexpensive by-product of the manufacture of salt, selling at 70 cents a pound, and in solutions containing one part in weight to about eight hundred of water, it may be used freely without affecting anything which it may touch. A few gallons used daily will remove all ammoniacal odors from stables, or a few quarts will thoroughly deodorize the entire plumbing system of an ordinary house. The undiluted bromine is strongly corrosive, and if it touches the skin causes a painful burn.—*The Pacific Record*.

THE MODE OF ACTION OF PATHOGENIC BACTERIA.—Although the "germ theory of disease" is now generally accepted, and the microorganisms themselves have been demonstrated and cultivated, little is yet known about their mode of producing diseases in their hosts. Various theories have been advanced, but no definite result has been obtained until quite recently. ROUX and YERSIN were the first to make any discoveries; they experimented with the diphtheritic bacillus of Löffler. They found that in cultures of this organism a "poison" existed, soluble in water, which possessed the same properties, when injected into animals, as the pure culture itself, producing acute nephritis, fatty degeneration of the liver, inflammatory oedema at the site of inoculation, and paralysis of the hinder extremities. The poison acted slowly, the local symptoms only appearing after several days. They obtained the poison by filtration of the broth cultures through a Chamberland (porcelain) filter and evaporating the filtrate in a vacuum. They also found this poison is far more abundant in old cultures than in recent ones; that it is precipitated by alcohol, and that it is destroyed at 100° C., and its virulence weakened at a temperature of 58° C. Brieger and C. Frankel have confirmed these experiments and extended them in many ways. They likewise selected Löffler's bacillus

for investigation. For the exhibition of the specific poison they cultivated it on ordinary peptone broth, or in broth which had been mixed with from 4 to 5 per cent. of glycerine and 10 per cent. of serum obtained from ox blood. The culture was filtered through a Chamberland filter, the filtrate evaporated to one-third of its original bulk in a vacuum at a temperature of 30° C. and was then treated with ten times the quantity of absolute alcohol with a few drops of concentrated acetic acid. The mixture was allowed to stand for twelve hours surrounded by ice and then filtered, the precipitate being dissolved in water and again filtered. The filtrate was then evaporated to dryness in a vacuum, and a light amorphous mass, snow white in color, remained. This substance gave the reaction of a proteid, allied to serum albumen. It was insoluble in alcohol, and precipitated by strong mineral acids, ferrocyanide of potassium, and acetic acid. It also gave the biuret reaction, the red coloration with Millon's reagent, the xantho-proteid reaction, and turned the polarized ray to the left. This substance was extremely poisonous, and when injected into animals produced the same symptoms as the culture. Brieger and Frankel found a second proteid in the filtrate, allied to the first in its chemical composition, but not poisonous. The above observations are a great advance in our knowledge of bacteriology, but even more valuable work has been done by DR. SIDNEY MARTIN for the Local Government Board, the results of which he read before the Royal Society on May 22 of this year. Dr. Martin chose the anthrax bacillus for his investigations. He cultivated it on pure alkali-albumen, filtered this through Chamberland's filter, and proved by means of the microscope and further cultivation experiments that the filtrate contained no bacilli or spores. He obtained two poisonous proteids—albumoses—which produced in mice local oedema, and in larger doses slow death in stupor and coma. But here, however, he went further than the German observers; he found also an alkaloid, similar in action to the anthrax albumoses, but much more powerful. The chief chemical characteristic of the purified albumoses, according to Dr. Martin, is their strong alkalinity in solution; as the alkaloid is a strong base and alkaline, he suggests that the alkalinity of the albumoses is due to the alkaloid being in a nascent condition in the albumose molecule. The alkaloids form crystalline salts in the forms of needles and prisms with mineral and oxalic acids. The importance of these observations cannot be too strongly commented on; they are the first of what will probably be a long series of experiments, and will greatly advance our knowledge of microorganisms, and happily lead to improved methods of treatment.—*Lancet*.

SATURDAY, OCTOBER 4, 1890.

PHTHISIS AND TUBERCULOSIS.

DRS. HENEAGE GIBBES, Professor of Pathology in the University of Michigan, and E. L. SHURLY, Professor of Clinical Medicine in the Detroit College of Medicine, have published a series of papers in the *American Journal of the Medical Sciences*, reviving again, in an altered form, the old question of the identity of phthisis pulmonalis and tuberculosis, which many of our readers have probably been fondly hoping was forever set at rest by the discoveries of KOCH. The experimental and pathological studies which the papers embody, would seem to have been conducted with great care, and, whatever may be thought of the conclusions reached by the authors, some of the facts, as stated by them, need either to be contradicted or explained before the relations of the various diseases commonly classed as tubercular to each other and to the tubercle bacillus can be said to be clearly made out.

Dr. Gibbes, who approaches the subject from the pathological side, claims that phthisis and tuberculosis are absolutely distinct processes, which not only never pass into each other, but, so far as his observation extends, never occur in the same subject. According to him, tubercle consists, histologically, of giant-cells, contained in a reticular stroma. In phthisis, the primary lesion is a broncho-pneumonia, the alveoli and bronchi being filled with small cells, and fibrin, without any giant-cells. Both morbid products may undergo cheesy degeneration, followed by liquefaction and formation of cavities, most frequently in

the apices of the lungs. Both may occur disseminated in small nodules—so-called miliary tuberculosis—indistinguishable to the naked eye, but always entirely distinct in their microscopical appearance.

Believing, as Dr. Gibbes does, in the absolute distinctness of the two processes, it is natural that he should doubt the dependence of both on a common cause—the bacillus of Koch. He claims to find important differences in its distribution in the lesions of the two diseases. In phthisis it is uniformly present at all stages, and is found in cavities in enormous numbers. In tubercle, on the contrary, it is never found until caseation has taken place, and may be absent even after the formation of cavities. He is very emphatic and positive in regard to its absence in the early stages of miliary tubercle, having examined an immense number of specimens, stained after the most approved methods, with the most powerful microscopes, without finding a single bacillus. As the author is an acknowledged authority on the staining of bacteria, it would not seem that his statements could be dismissed on the ground of defective observation, in the absence of reliable statements to the contrary by equally competent observers.

It is claimed by Koch and his followers that a disease, identical in all respects with human tuberculosis, can be produced in animals by inoculating them with a pure culture of the tubercle bacillus, from which all of the original tuberculous matter has been eliminated. On this point Dr. Gibbes first calls in question the accuracy of Koch's experiments, on what seems to us the rather slight ground that his accounts of them do not prove that he took all the precautions which he himself declares to be necessary to avoid the possibility of including some of the original matter. It would certainly have been much more satisfactory if Dr. Gibbes had satisfied himself and informed us, from actual experiment, exactly what the effect of inoculation with a pure culture is. He then goes on to deny the identity of the lesions of artificial tuberculosis with those found in the human subject in either of the diseases under consideration. The nodules found in the lungs and other organs of the subjects of such experiments consist, he says, of collections of round cells, bearing no resemblance to either true reticular tubercle or the broncho-pneumonic lesion of phthisis. They undergo cheesy degeneration,

and bacilli are then found in them at that stage, but are invariably absent in the earliest stage of the disease.

He questions the identity of the bacillus found in bovine tuberculosis with that occurring in the human subject, both on account of its smaller size and because the lesions produced by inoculating rabbits are in some respects dissimilar, bearing more resemblance to those of tuberculosis in the human subject than those resulting from inoculation with human tuberculous matter. He also gives the results of examination of a variety of animals—mammalia, birds and reptiles, dying with what was considered tubercular disease, which we omit as of no special importance in their bearing on the question at issue.

The clinical side of the subject is treated in a separate article by Dr. Shurly, and also in the concluding paper of the series which appears under the names of both collaborators. It can not be said that he adds very much to our previous knowledge. He agrees with Dr. Gibbes as to the non-identity of phthisis and pulmonary tuberculosis, and says that "the careful observer" will be able to distinguish between them, but, although he describes acute, sub-acute and chronic phthisis, he fails either to describe tuberculosis or to indicate by what criteria it is to be distinguished from phthisis. As neither author informs us where we can find the lacking information, it is to be feared that even careful observers may not know what they should look for. As they take the ground that the distinction is an important one in regard to prognosis, phthisis being a curable disease in its earlier stages, while tuberculosis is incurable from the start, it is to be hoped that this deficiency may be supplied when they publish the results of researches which they say they are making in regard to heredity and contagion in these diseases.

Assuming the correctness of these observations, what conclusions may be properly drawn from them in regard to the relations of the bacillus of Koch to the various processes which have been considered tubercular, and in connection with which it is found? Prof. Gibbes does not assert that the bacillus is not the cause of any of the diseases with which it is associated, although he makes his opinion plain that it is not the cause of all of them. In order to answer this question intelligently it may be well to call to mind some

of the facts which may be considered established. One of these is, that the inoculation either of tuberculous matter or of a pure cultivation of the bacillus is capable of producing in the lower animals, a disease, characterized by the development of nodules, in the lungs and elsewhere, which present a certain resemblance to miliary tubercles, and contain, sooner or later, the characteristic bacillus, which disease is capable of being propagated to other animals by inoculation. The criticisms of Prof. Gibbes cannot be considered to invalidate the positive results of numerous observers to this effect. Prof. Koch reports, in his address before the Berlin Congress, that bacilli which he has had under cultivation for nine years are unchanged except for a slight diminution of virulence. That any of the original matter used for inoculation would, under such conditions, preserve its virulence so long seems, to say the least, very improbable.

The important points raised by Prof. Gibbes in opposition to the theory that the bacillus is the cause of the various diseases that are called tuberculous, are, first, that the lesions are histologically distinct, and, secondly, that the bacillus is absent from the lesions of some of them in their earlier stages.

If we are to accept his histological distinctions as valid, we must believe that inoculation of matter from the lesions of either of two distinct diseases—phthisis and tuberculosis—will produce a third infectious disease, distinct from both. If we accept the results of other observers, we must conclude that the same effect may also be produced by inoculations with the bacillus alone. This would be something as if the inoculation of matter from either measles or small-pox should invariably produce scarlatina. It would seem at least equally probable that the same morbid agent might produce somewhat different reactions under varying circumstances.

In regard to the alleged absence of the bacillus from the early lesions of tuberculosis, this peculiarity appears, according to Prof. Gibbes, to be shared by the disease produced by inoculation. Whatever may be the reason for his failure to find it in the one case may explain its absence in the other.

It would seem, then, that in order to refute the view of Koch and his followers as to the etiology of the tuberculous and phthisical processes, it is

incumbent on Prof. Gibbes to prove that the inoculation of the tubercle bacillus, by itself, is not capable of producing the effects alleged. If its introduction, in minute quantities, into guinea pigs, rabbits, dogs and other animals is capable of setting up in them a fatal infectious disease, it would be strange if its presence, in great abundance, in the human system, should be innocuous.

To question the conclusions drawn by Dr. Gibbes from the facts which he reports is not by any means to depreciate the interest and possible importance of the facts themselves. They seem to offer an inviting field for further study. It may be that the microorganisms in the two forms of disease which he distinguishes are not identical, notwithstanding their apparent similarity. But probably the framing of hypotheses to account for the facts would be better left to the investigators themselves.

PROTRUSION OF THE CERVIX UTERI A CAUSE OF DELAYED LABOR.

Cases of labor, in which there is a prolongation of the anterior lip of cervix pushed downward before the presenting part, are sufficiently frequent and are easily managed. Exceptional cases, however, occur from time to time wherein the accident is a most undesirable cause of protracted labor. The tissues may be so firm, at the external os, that the cervical walls containing the presenting head will be stretched to an exceedingly thin covering and be caused to protrude between the thighs of the patient.

DR. JAENTZER describes such a case in the *Archives de Tocologie*, for May, where a midwife was in attendance. The delayed labor caused the calling in of this physician on a statement that the expansion of the os uteri was complete and that the head of the child was presenting, but that no neck could be felt, by digital examination, on the child above the head, and no uterine cervix. On ocular examination, he found a tumor as large as the head, reddish in color and containing an orifice about $\frac{1}{2}$ an inch in diameter, protruding from the vulva. The occiput of the child, thinly covered by the layer of distended cervical tissue, was presented to the left side of the mother; rotation had not taken place. Anæsthetics were administered and the tense tissues

at the external os were incised and the opening enlarged, by digital manipulation, and the membranes ruptured. The child was dead; it was delivered by traction with little difficulty, the midwife making counter-pressure on the retracted tissues. The cervix was readily restored to position, and the patient, under antiseptic precautions, made a good recovery. It could not be found, by subsequent inquiry, that there was any history of prolapse of the cervix during pregnancy, or of any inflammatory process, causative of the complication in question; its cause remains unknown. It has sometimes happened that women, with a history of specific infection, and with an inflammatory rigidity of the uterine mouth and neck, have had their labors retarded from this cause. But under profound anæsthesia and the use of dilators the obstructing tissues can usually be forced to recede and the labor terminated with or without the use of forceps. DUHRSEN has advised the use of multiple incisions in the cervix in delayed labor due to the rigidity of inflammatory processes, and holds it to be a process nearly devoid of danger, if the incisions be made in many places and not extensively in any one of them, and if antiseptic measures be thoroughly carried out. By this procedure, it is thought that the life of the child may not infrequently be saved, when otherwise it would be lost through the delay incident to other methods of relief.

EX PEDE HERCULEM.

While for the most part it is wise for professional and technical journals to refrain from any controversy with the lay press, there is occasionally such a flagrant invasion of the scientific field, that it would not be wise to pass it by in silence. We refer especially to an editorial in the *Chicago Herald*, a journal devoted to the exploiting of politics, anent "Insanity of Insane Experts." In this article we find the following: "Doctors who make a specialty of insanity are known to become either morbid upon the subject or actually mad." We challenge this statement as one emanating from the inner consciousness of the writer, as nowhere is it supported or affirmed in the literature of medicine. KRAFFT-EBING, BUCKNILL, TUKE, SPITZKA, SAVAGE, MEYNERT and CHARCOT are either morbid or actually mad according to this enlightened "expert!"

That attendants upon the insane are more likely to become insane than those outside of asylums, is admitted, but that this is explained solely by association with the insane will hardly be believed when we reflect that the asylum attendant is frequently overworked, for long hours, and that the occupation is peculiarly trying and full of anxiety. Attendants spend the greater portion of their time within doors and they are disinclined to active exercise when opportunity offers. While these, mostly physical conditions, play the chief rôle in the production of insanity among attendants upon the insane, we are not disposed to deny that association alone may be an important factor, particularly among the mentally weak and imperfectly educated. This idea of mental contagion is embodied by French writers in the *folie à deux*. That this sort of contagion renders all students of psychiatry morbid or mad we are disposed to deny, especially as there are no facts or statistics to support such a conclusion.

The statement that "the number of persons sent to insane asylums and in them made insane, is undoubtedly increased by the want of precision in tests of insanity, and the dependence of ignorant and timid jury-men upon the pretensions and affirmations of experts." If it is true that in erecting palatial hospitals for the insane, we have constructed nothing but factories for lunatics, the sooner they are closed the better. But we think this statement, like the others, must have arisen from the depths of the editor's brain. We must ask for the facts, and if he can produce a single authentic case in the State of Illinois, where a sane person has been sent to an asylum and there made insane, we will admit the truth of the proposition.

By a careful perusal of the editorial we are forced to the conclusion that the writer has himself dabbled in psychiatry, and that he has been infected with the "subtle and insidious intellectual malaria in the atmosphere of insanity." In the future we would advise the writer to avoid this subject;—avoid it, as he would a pestilence!

"WESTERN HEALING" IN CHINA.

The above is an expression used in Chinese cities by those practitioners who desire to have it known that they are learned in foreign medical methods. When a native doctor puts on his

sign-board the words, "western healing," he relies upon this announcement as a means of attracting patients; he appeals to a sentiment which he knows is already widely diffused—so widely, in fact, that it now offers the best method of securing lucrative practice. Such sign-boards are not infrequent and may be found even in the country districts remote from the provincial cities. This fact is more significant when contrasted with some of the incidents in the early history of "western healing" in Canton, as recorded in the earliest reports of medical missionary work in that city. When the first important case of surgery was presented at the Canton hospital, it was necessary to amputate the man's arm with a view to saving his life. This necessity was explained fully to the man and he refused firmly to permit the surgeon to do the operation. It was only by the gift of fifty dollars given the patient by MR. JARDINE, who was a surgeon by profession and who was to act as assistant to DR. PARKER, the operator, that the man's life was saved. From this point, about half a century ago, the work has grown, by dint of tireless industry, skill and judgment, to the present day; now not a year passes by without the founding of one or more new hospitals in some part of the Flowery Kingdom. The latest movement, recently inaugurated in the United States, is one having for its object the building of the first asylum for the insane which China will possess. This, like the first "western healing" hospital, will have its location at Canton.

EDITORIAL NOTES.

MILK AND ELECTRICITY.—An Italian scientist, Tolomei, has made a study of the souring of milk by thunder-storms, and concludes that this rather annoying phenomena of the dairy and household is explicable on the ground of the production of ozone during such storms. It may not act directly upon the milk to sour it, he thinks, for he prefers not to ignore, or discard, the prevailing opinion that the change is due to the presence of the bacterium-ferment and is allied to other fermentations. He assumes that in the presence of ozone, when it comes into contact with the upper surface of the milk—in the form of a layer superimposed on it, without agitation—the bacterium finds its most favorable

conditions of propagation. Some experiments made by Tolomei go to show that ozone, when electrically generated without detonation, effects the souring of milk more rapidly than when its liberation is abrupt and accompanied with report.

SOUVENIR OF THE BERLIN CONGRESS.—We note that the *British Medical Journal*, for August 23, contains a double-page illustrated sheet giving process-portraits of eight of the leaders of the German-speaking medical profession who took part in the recent International Congress. We see there the faces of Virchow, Koch, Leyden, Von Bergmann, Leibreich and Gerhardt, of Berlin, Billroth of Vienna, and Esmarch of Kiel. These reproduced photographs are not of the finest order of engraved work, yet the faces therein portrayed are sufficiently clear and individual to serve as a remembrance of the occasion and of some of Germany's representative teachers. As it may not be generally known that the *British Medical Journal* has its regularly appointed agent in the United States, we take the occasion here to add that the publishing house of the Blakistons, 1012 Walnut street, Philadelphia, is its representative in this country.

MEDICAL COLLEGES—A COMPARISON OF THEIR REQUIREMENTS.—The *Times and Register* of September 20, contains a valuable article, with tabulated statements of the requirements on the part of medical students by our various colleges, precedent to graduation. It will be found valuable not only for purposes of comparison, but will serve as a basis for determining the average of medical requirements in this country.

AMERICAN RHINOLOGICAL ASSOCIATION.—The eighth annual meeting of this Association will be held at the Gault House, Louisville, Ky., October 6, 7 and 8, 1890. The profession is cordially invited to attend the meetings of the Association. The President, Dr. Arthur G. Hobbs, of Atlanta, Ga., will deliver the opening address. The following named railroads have granted rates of one and one-third: Louisville & Nashville, Queen & Crescent, Louisville Southern, Newport News & Mississippi Valley Co., and the Ohio & Mississippi. These tickets are good for the week, and will include the Mississippi Valley Medical Association, which meets Wednesday, Thursday and Friday of the same week. Be sure and take a certificate from each and every ticket agent from

whom you purchase a ticket on your way to Louisville. Present this to the Secretary for countersign, when you will be entitled to return at one-third fare.

THE CANADIAN MEDICAL ASSOCIATION.—At the annual meeting of this association, held in Toronto on September 9, 10, and 11, the following officers were elected for the coming year: President, Dr. T. G. Roddick, of Montreal; General Secretary, Dr. Birkett, of Montreal; Treasurer, Dr. W. H. B. Aikins, of Toronto; Vice-Presidents, Ontario, Dr. A. H. Wright, of Toronto; Quebec, Dr. S. P. Lachapelle, of Montreal; New Brunswick, Dr. S. H. Coburn, of Fredericton; Nova Scotia, Dr. John Stewart, of Pictou; Manitoba, Dr. D. Young, of Selkirk; British Columbia, Dr. E. A. Prager, of Nanaimo; Prince Edward Island, Dr. Taylor, of Charlottetown; Northwest Territories, Dr. E. A. Kennedy, of MacLeod. The next meeting will be held in Montreal.

NEW YORK POLYCLINIC.—The catalogue of the New York Polyclinic shows an attendance for the session of 1889-90 of 422. The Faculty have resolved to exclude all but graduates of regular medical colleges from matriculating at this school. Practitioners who are graduates of a regular medical college, or who have attended one or more courses of lectures at such college, and have a legal permit to practice, will be admitted.

VIRGINIA STATE MEDICAL SOCIETY.—At the meeting of the Virginia State Medical Society, held recently at Rockbridge Alum Springs, the election of officers resulted in the choice of Dr. W. W. Parker, of Richmond, for President, Dr. John W. Dillard, of Lynchburg, Dr. Jacob Michaux, of Richmond, and Dr. H. M. Patterson, of Staunton, First, Second and Third Vice-Presidents, respectively; Dr. Landon B. Edwards, of Richmond, Recording Secretary; Dr. John F. Winn, of Richmond, Corresponding Secretary; and Dr. R. T. Style, of Hollins, Treasurer.

SURGICAL DRESSING FOR SOLDIERS.—The Government of India has sanctioned the issue of a packet of first field dressing, in lieu of a bandage, to every officer and soldier proceeding on active service, irrespective of whether the operations are undertaken against a European power or not.

TOPICS OF THE WEEK.

THE ANTIQUITY OF THE HUMAN RACE.

In the Anthropological Section of the British Medical Association at the recent meeting in Leeds, the President of the Section, in the course of a very able address, referred to the subject, and his remarks are reported by a correspondent of the *Lancet* as follows: He said: "One of the most vital questions was: What is the antiquity of the human race—or rather, what is the antiquity of the earliest objects hitherto found which can with safety be assigned to the handiwork of man? This question is susceptible of being entirely separated from any speculations as to the genetic descent of mankind; and even were it satisfactorily answered to-day, new facts might to-morrow come to light that would again throw the question entirely open. On any view of probabilities, it is in the highest degree unlikely that we shall ever discover the exact cradle of our race, or be able to point to any object as the first product of the energy and intelligence of man. It may, however, be hoped that from time to time fresh discoveries may be made of objects of human art, under such circumstances and conditions as may enable us to infer with certainty that at some given point in the world's history mankind existed, and in sufficient numbers for the relics that attest this existence to show a correspondence among themselves, even when discovered at remote distances from each other. Of late years how little have we heard of any scruples in accepting as a recognized geological fact that, both on the continent of Europe and in these islands, which were then more closely connected with that continent, man existed during what is known as the quaternary period, and was a contemporary of the mammoth and hairy rhinoceros, and of other animals, several of which are either entirely or locally extinct. The principal instances on which the believer in tertiary man relies may be classified under three heads: (1) The presumed discovery of parts of the human skeleton; (2) that of animal bones said to have been cut and worked by the hand of man; and (3) that of flints thought to be artificially fashioned. On the whole, therefore, he thought that the present verdict as to tertiary man must be in the form of "not proven." As to the origin and home of the Aryan family, the last twenty years had seen important changes; but, after all, they were speculations merely. In concluding, the speaker said: "There are, indeed, now but few parts of the world the inhabitants of which have not, through the enterprise of travelers, been brought more or less completely within our knowledge. Even the centre of the dark African continent promises to become as well known as the interior of South America, and to the distinguished traveler who has lately returned among us anthropologists as well as geographers owe their warmest thanks. It is not a little remarkable to find so large a tract of country still inhabited by the same diminutive race of human beings that occupied it at the dawn of European history, and whose existence was dimly recognized by Homer and Herodotus. The story related by the latter about the young men of

the Nasamones who made an expedition into the interior of Libya, and were there taken captive by a race of dwarfs, received curious corroboration from modern travelers. Herodotus may, indeed, slightly err when he reports that the color of these pigmies was black, and when he regards the river on which their principal town was situated as the Nile. Stanley, however, who states that there are two varieties of these pigmies, utterly dissimilar in complexion, conformation of the head, and facial characteristics, was not the first to rediscover this ancient race. At the end of the sixteenth century Andrew Battel, our countryman, who, having been taken captive by the Portuguese, spent many years in the Congo district, gave an account of the Matimbas, a pigmy nation of the height of boys of twelve years old; and in later times Dr. Wolff and others have recorded the existence of the same or similar races in Central Africa."

WORKING HOURS FOR WORKING MEN.

At the recent meeting of the Brighton Sanitation Congress Dr. W. B. Richardson delivered an address upon this subject, to which the *Lancet* makes the following reference:

"He much regretted that at such congresses the working classes could not take an active part throughout with other members, and that they could not have a working man presiding over one of the Sections. But whatever might be the case in the future, this was not at present possible. Work, he proceeded to urge, was every man's portion, and was valuable, not only as a fact, but as an idea provocative of good results even from the humblest worker. Work was hard or difficult according to the will of the worker, and in this respect there was a great deal of difference in the relations of employers with workmen. As regarded any limitation that should be put on work, he said from a sanitary and health point of view eight hours was a good standard, not absolute, because the pressure of work varied, but as a fair average. What was wanted in order to get at that standard was not so much change in the relations between employer and employed as a change in the public mind, the public at large being most exacting in their demands, and making hard workers keep long hours really for no useful purpose whatever. It would be a good point to begin with if the hours of buying and selling could be reduced. Three classes of work were of especial moment: where with bodily exertion the intensest watchfulness was demanded—as, for example, in the case of the railway engine-driver; where it was one continued grind and monotony, as in the case of postmen; and where the work was excessively hard—as in pile-driving. There were occupations in which the body was in a bent position while at work, in which cases the period of eight hours for work was the maximum, and was often too long. Objection might be made to these arguments that man was not a mere machine, but had a mind. But this only made the toil the harder, for the mind was at work all the time. Another objection was that some luxuries, like indulgence in alcoholic drinks, might promote decay more rapidly than the hardest work, and that the

men who had no occasion to work injured themselves by physical labors and pleasures quite as much as those who had to work for their bread. There must also be a better system of recreation during week days, in which music must play a large part—music which could be provided in great extent by the working classes themselves. For health's sake and life's sake, for the health and life of the nation as well as of the individual parts of it, the periods of labor require a great deal of lightening. An example bearing to millions of minds a meaning as beautiful as it was forcible required to be set. The yoke might be made easy, the burden light, before the healthy working heart could beat out, to the full length of days, the healthy body and the healthy mind. Selfishness and want of common sense had to be removed, and it was for associations like the Sanitary Institute to make those reforming ideas known far and wide, and so lead to what they so much desired—the best cultivation of the garden of the world.'

ETHER DRINKING.

As our readers are doubtless aware, ether is used largely as an intoxicant in various parts of the North of Ireland, and the practice is stated to have arisen during the teetotal movement so successfully carried on by Father Mathew. Those who had taken the pledge against alcohol not wishing to break it, found that by using ether they could still indulge in the habit of intoxication. The ether can be obtained at almost any hour. It is rapid in its action, and the effect disappears shortly; but the chief attraction is in the small quantity (about a tablespoonful or less), and the cheapness of the drug. Methylated ether being the cheapest form, is the kind generally used, and as its cost is about one penny an ounce, its consumption is very great.—*Brit. Med. Jour.*

STATE MEDICINE.

In private life the office of the physician is to subdue or mitigate illness, as far as possible, so that his patients may be able to devote themselves to their work or pleasures. To this end, in addition to his combat with actually developed disease, his advice is freely tendered respecting personal hygiene—habits of diet, of dress, occupation, exposure, etc.

Toward the aggregated people, as massed into States, the medical profession as a body occupies a correlative position.

It is our duty, as a class, to indicate to the governing powers the best devised means of protecting the citizens of the Republic against preventable bodily ills. Medicine is, consequently, to a far greater extent than is officially or popularly recognized, of economic importance to the Government.

However costly be its work, surely public hygiene saves more to the State than is actually expended. Countless lives are preserved, the waste of disease minimized, and material production or exchange in a relative ratio is increased. This point, capable of much elaboration, should be constantly brought to the attention of legislators. Scarcely anything can be more important

to the community than the preservation of its present and future effective force. The commander is idolized who in time gains a glorious victory at the sacrifice of comparatively few men. Peace hath its victories no less than war, we are told, and this work of State medicine, under whatsoever name it be carried on, is surely one of the chiefest.

This country of ours, so vast in domain, with so many diversities of climate, such an extensive coast line, such a mobile population, flooded constantly by a stream of immigration from all parts of the Old World, peculiarly exposed to the importation of virulent infectious, stands in special need of public prophylaxis.

It is gratifying, therefore, to know that of late years earnest study and strenuous effort have been devoted to the solution of problems relative to public health. A number of able papers upon sanitation were presented to the recent meeting of the American Medical Association.—Dr. John V. Shoemaker, *Tenn. Health Bulletin.*

A SUBSTITUTE FOR TOBACCO.

Many different vegetable substances used as stimulating beverages in widely distant parts of the world have been shown to contain caffeine as their active principle. Only one substitute for tobacco has, however, yet been discovered. This is the leaves of the *duboisia Hopwoodii*, a shrub growing in Australia, the leaves of which are chewed by the blacks in the same way and for the same purpose as tobacco is chewed. The leaves contain an alkaloid piturine, which is said by certain chemists to be identical with nicotine, but more probably is only closely allied to it. Messrs. Langley and Dickinson have recently shown that the actions of nicotine and piturine are in every respect identical.

THE HEART-BEAT AFTER DEATH.

A few days ago a criminal was executed at Epinal, France. Immediately after the execution, which was effected very rapidly, the corpse was given over to Dr. Gley, Professeur Agrégé at the Paris Medical Faculty. The heart beats were observed during six minutes after death. Dr. Gley was able to study auricular and ventricular contraction, which he observed to be independent of each other. Dr. Hallett examined the dead body of another criminal executed at Montreuil, and detected the heart beats a quarter of an hour after death.

CURING CONSUMPTION BY INOCULATION.

Whatever may be the results of Dr. Koch's experiments, about to be made, of curing consumption by inoculation, they are sure to lead to considerable disagreement among doctors; and, though success should crown his efforts, it is safe to predict that years will be required to introduce the process. In the meantime we may expect a renewal of the discussions that attend every proposed system of inoculation for any purpose. The importance of finding a cure for consumption will, however, excite general interest in the experiments to be made.—*Times and Register.*

PRACTICAL NOTES.

TREATMENT OF A "COLD" BY SALICYLATE OF SODA.

The *Memphis Med. Jour.* says of this remedy: Salicylate of sodium in free doses give as satisfactory results in the treatment of "bad colds" as it does in cutting short tonsillitis. Sodii salicylatis, ʒss; syr. auranti cort., ʒss; aquæ menth. piper., ad. ʒiv. M. Sig. A dessertspoonful every three or four hours. A dose every three hours until a free specific influence of the salicylate—tinnitus aurium—is observed—will so far control the symptoms that the aching of the brow, eyes, nose, etc., will cease. The sneezing and "running from the nose" will also abate and will disappear in a few days, not leaving, as is usual under other treatment, a cough, from the extension of the inflammation to the bronchial tubes.

BOILED WATER.

If there is the least suspicion that the water-supply is polluted, get the small quantity to be used for drinking purposes from some source entirely above suspicion. If this is impracticable, boil all water for drinking, and to remove the insipid taste of boiled water, filter it. Even infected water used in cooking, and in making tea or coffee, is undoubtedly entirely safe, providing it has actually been boiled.—*Sanitary Inspector.*

ANTISEPTOL.

The following method of preparing antiseptol, the trivial name given by M. Yvon to cinchonine iodo-sulphate, is given by the *Pharmaceutical Journal*: Dissolve 25 grams of cinchonine sulphate in two litres of water, and precipitate this with a solution of 20 grams of potassium iodide and 10 grams of iodine in a litre of water. The light voluminous kermes brown precipitate that is produced is described as being inodorous, insoluble in water, soluble in alcohol and in chloroform, and as containing 50 per cent. of iodine. It is said to be an efficient substitute for iodoform.

CORROSIVE SUBLIMATE SOLUTIONS.

We have occasion so frequently to recommend the use of a solution of corrosive sublimate to destroy the germs of disease, that it seems well to give some instructions for its preparation. To make a standard solution, from which the weaker solutions may be made, take four ounces of corrosive sublimate and one pound of sulphate of copper, and dissolve them in one gallon of water.

To make a solution of 1 to 500, add 8 ounces of the above to 1 gallon of water. To make a solution of 1 to 1000, add 4 ounces of the above to 1 gallon of water. To make a solution of 1 to 2000,

add 2 ounces of the above to 1 gallon of water. Remember that these solutions, while most effective in the destruction of disease germs, are, at the same time, highly poisonous.—*Annals of Hygiene.*

PRESCRIPTION OF PEPSIN WITH ANTACID.

Dr. I. N. Love, of St. Louis, offers the following prescription as a pleasant antacid in the summer disturbances of children, where there is a history of several days' looseness of the bowels or frequent evacuations:

Listerine,
Glycerine,
Brandy (best),
Syrup of tolu, of each two drachms.
Essence of pepsin (Fairchild's), one ounce.

In this combination Dr. Love does not find that the alkaline constituents of the listerine interferes with the action of the pepsin; the clinical results have been satisfactory, although the dictum of the chemist would lead one to expect an impaired activity.—*Dietetic Gazette.*

TREATMENT OF VARIOLA.

Dr. Gawalowski reports excellent success in the treatment of variola with baths of permanganate of potassium. The salt is added until the water is of a rose red color. By this method the temperature is lowered, the pustules disappear, and recovery takes place rapidly.—*Revue de Therap. Med. Chir.*

PRESCRIPTION FOR BRONCHITIS.

Tincture of hyoscyamus,
Compound spirit of ether,
Syrup of tolu,
Syrup of wild cherry,
Water, equal parts of each.
The dose of this is a teaspoonful.

—Dr. E. J. Janeway, *Southern Med. Record.*

AMENORRHOEA.

Prof. Parvin, in cases of amenorrhœa in young girls, especially if anæmic, recommends the following pill very highly:

R. Ferri sulphat. exsic.,
Terebinthinæ albæ, ʒā gr. j.
Pulv. aloës, gr. ʒj.
Use such a pill t. d.

TREATMENT FOR SLEEPLESSNESS AND DELIRIUM.

In a case of sleeplessness of typhoid fever, Prof. Da Costa described urethran, grs. xx, to be repeated once. In a case of delirium in a man who had pneumonia he used paraldehyde ʒj with an equal quantity of oil of sweet almonds. If it will do good, three doses are sufficient.—*College and Clinical Record.*

FOREIGN CORRESPONDENCE.

LETTER FROM LONDON.

(FROM OUR REGULAR CORRESPONDENT.)

Curious Statistics of Longevity—Relative Mortality amongst European Troops—The Effects of Influenza on Hurts and Surgical Accidents and Wounds—Ladies of Title and Foreign Princesses among the Ranks of Trained Nurses—The "Asclepiad" on Fasting—Sulphate of Copper as a Disinfectant—Annual Report of the Inspector of Retreats—A New Spray to produce Local Anæsthesia—Medical Aid for Indian Women—The Inconveniences of Fashions in Medicines.

Some curious statistics of longevity have just been published by the German Government. It appears that in 1888 there were ninety-one persons in Prussia who were over a hundred years old, and between 1864 and 1888 upwards of seven thousand persons of over a hundred died, and of these one hundred and fifty-five were more than one hundred and nine.

Some details have just been published on the relative mortality amongst European troops during time of peace. As one might suppose, the Spanish troops give the highest standard of mortality, and that not because the soldiers are weakly so much as the sanitary arrangements are inadequate or neglected. The deaths represent 13 in a thousand. Russia comes next, but the interval is large. The mortality is about 9 in the thousand. Then follows the Italians with 7.74. So far the series is almost as a shrewd observer might guess it would be. What follows is more perplexing and more interesting. Austrian, French, English, Belgian and German; that is the order. In round numbers the deaths of Austrian soldiers are in the thousand 7, of French 6, of English a little over 5, of Belgian a little over 4, and of Germans a little under 4. This is a great triumph for the Germans, the more so as the largeness of their army ensures a certain reliability in their statistics. One other detail is given. The ravages of consumption are enormously greater in the case of the British army than of any other nationality. In this case the French are the most favored.

Attention is drawn to the effect of influenza on hurts and surgical accidents and wounds. It also affects weak eyes. The want of recuperative force in persons undergoing surgical operations who were attacked with influenza has been most marked. The flesh did not heal, and this was also the case in patients who had had influenza but who were convalescent when operated upon.

One of the medical papers takes occasion to comment upon the strongly fashionable favor which nursing is now enjoying, and points to the

fact that English ladies of title and foreign princesses and countesses are now found among the ranks of trained nurses. It may be supposed that ladies of this position who take it up as a profession do so out of honest devotion to the work, even where the calling is adopted for bread winning it is not without considerable advantages. The fear is that it will become overcrowded, as indeed it begins appreciably to be. In what other female profession is there so well conceived a pension fund as that of the nurses?

Referring to the recent fasting ordeals in England and America the *Asclepiad* is of opinion that it may now be assumed that a forty or forty-two days fast with continuance of life is well within the order of natural phenomena, and that the human body has a possible power of endurance from ten to eleven days beyond what has recently been attempted, the extreme limit being fifty-three to fifty-five days. It follows that the technical opinion on fasting given in coroner's courts and in courts of justice, as well as the opinion that will have to be written in technical and standard works of medical jurisprudence, must in future be considerably modified. Another lesson is the long time life can be sustained by water alone. The writer of the article further notes the curious fact that where the disposition to starve goes with the starving the powers of endurance are immensely prolonged.

The Spanish authorities, as also the French and the Austrians, are insisting upon the exclusive employment of sulphate of copper for the disinfection of evacuations (vomits and fæcal matter) and of linen, etc., in the sick room. It has also to be used for washing the face and hands of persons in contact with choleraic patients. In most cases this disinfectant is being given away gratis by the administration to those applying for it. In the report on disinfectants recently prepared at the instance of the Hygienic Institute and Medical Direction of Buda Pesth, based upon exhaustive researches, the use of sulphate of copper is urged as the best of all disinfectants—better than carbolic acid in any form and incomparably better than sublimate and all the more recently introduced disinfectants. Laxivated ashes are commended as a disinfectant, especially for privies, as also lime wash. Both are pronounced inferior to copper sulphate.

The Home Office has just issued the tenth annual report of the Inspector of Retreats with respect to six retreats licensed under the Inebriates Acts, 1879 and 1888. It is said that but for the somewhat formidable attestation before the magistrates the majority of those now entering the homes as private patients would be willing to avail themselves of the provisions of the Acts. The licensee of one retreat writes: "The number of applications received for admissions has been very high, amounting often to 12 and 14 a week,

but alas, only a tithe of the cases are received, owing to the impossibility of securing the consent of the patients to being placed under restraint, and I fear that until some alteration is made in the law the usefulness of these retreats will be very much restricted." Likely patients are very sensitive and increased willingness among them to take advantage of the benefits of these homes is ascribed to the removal in the altered title of the Act of the obnoxious epithet "habitual drunkard." It is complained that patients show a strong tendency to enter a home for an insufficient period. Hence come disheartening breakdowns, not immediately, as a rule, but upon the first cause, from extra excitement—a marriage or a death, a pecuniary loss or a gain, a holiday or extra worry alike may serve to prove that the recuperative work has been but half done. Plenty of open air exercise, with the maintenance of a cheerful spirit in the home are especially commended as important factors in the curative treatment of inebriety.

Local anæsthesia is produced at one of the leading hospitals by means of a spray composed of ten parts of chloroform, fifteen parts of ether and one part of menthol. After one minute's application of this compound spray, complete anæsthesia of the skin and neighboring tissues is produced and will persist from two to six minutes. This suffices for some minor operations, such as opening an abscess of the cervical glands, incising a deep-seated whitlow or excising an epithelioma of the nose, etc.

The efforts made in providing medical aid for Indian women are bearing good fruit. The Dufferin Fund now employs thirty qualified lady doctors and has 230 ladies under training as nurses. So far it reckons that its benefits have reached some 200,000 poor native women, but as Lady Dufferin herself asks, what is this among so many? Taking, however, into consideration the different Medical and Lenana Missions, the total sum of good accomplished in this direction make up a very considerable whole. It is a rule strictly observed by the Dufferin Fund that all those whom it employs shall be fully trained and highly qualified, and by insisting upon this condition it is securing the best medical services which women are capable of rendering.

In his presidential address at the Pharmaceutical Annual Conference at Leeds, the President dwelt upon the inconveniences of fashions in medicines. The great change in our materia medica that has taken place during the last 30 years has on the whole been beneficial, but the president nevertheless deplored the unfortunate habit of running after new remedies. It is a startling token of the spread of the public faith in patent medicines that the government stamp duty on these nostrums has risen since 1860 from £43,000 to £220,000 per annum, or nearly fivefold. Alto-

gether the English public are calculated to spend about 1¼ millions sterling every year on these articles alone.

G. O. M.

DOMESTIC CORRESPONDENCE.

The New York State Examination Act.

To the Editor:—In view of Dr. Carroll's letter in *THE JOURNAL* of September 13, 1890, it would seem proper for me to add a final word, which I promise shall be the last.

As I did not, in my letter of August 30, attempt to defend the Act in question, but did point out the misrepresentations of Dr. Carroll in regard to the Medical Society of the State of New York, which any one unprejudiced could readily see was the sole purpose of my communication, it is difficult to understand how he can say that I misapprehend "both the intention of my [his] criticism and the act which he defends." When a man of presumed information asserts that there was a time in its history when but "two [members] per annum out of the many 'eligibles' could be elected" in the Society in question, there would appear to be very little reason to expect any gain from further discussion with him on that point. As the question of "code" is foreign to the object in view, I beg to decline a discussion of that subject also; particularly as there are other more important questions that engage the attention of the medical profession just at present.

WILLIAM WARREN POTTER.

284 Franklin Street, Buffalo, Sept. 20, 1890.

NEW INSTRUMENTS.

MODIFICATION OF LEWIS' URETHRAL APPLICATOR.

BY G. FRANK LYDSTON, M.D.,

OF CHICAGO, ILL.

Dr. Bransford Lewis, of St. Louis, Mo., recently published, in *THE JOURNAL*, a very ingenious applicator for the purpose of applying dense, oily liquids to the urethra. The instrument consisted of a round box with a tight-fitting cover, and a rubber tube for introduction into the urethra. The cover is provided with a thread which tightly fits a female screw with which the inner surface of the box is provided. The ointment that is to be applied is placed in the box, the tube is introduced into the urethra and the cover screwed in until the required quantity of the medicament has been forced into the canal.

As the soft rubber tube is rather unmanageable

ble, I have devised a modification of the instrument, in which a hard rubber endoscopic tube is utilized instead of the soft tube. Another detachable tube, slightly curved near the point, is used for the cervix uteri.

I can endorse this apparatus as an efficient means of medicating the urethra and cervix in chronic inflammatory affections. I do not, however, recommend its use in acute affections of these parts.

NECROLOGY.

Death of Sir Edwin Chadwick.

Few men have deserved better of their country than the veteran sanitarian, whose death at the advanced age of 91, we have to record. His investigations of the sanitary condition of London, dating back to 1847, were the official starting point of a reorganization of the Health Department, and laid the public legislative basis of the first of a series of sanitary reforms which have been of inestimable value during the last half century in the saving of life and diminution of sickness and disablement. His subsequent services to the cause of army health reform and his continuous devotion to great and small questions of public and personal sanitation, placed him

quite in the first rank of non-medical sanitary reformers. It has always been the great failing of this class of valuable public men, while assimilating the facts and conclusions placed at their disposal by great investigators such as Grainger, Snow, Farr, Rumsey, Parkes, and Simon, to assume to themselves a much larger share of merit in the building up of the edifice of public sanitation than, under any searching investigation, properly belonged to them. No one, however, will more cheerfully admit, or indeed, enforce than ourselves—speaking on behalf of medical men—the immense claims of Sir Edwin Chadwick to public gratitude, and the great services which he rendered by the application which he made of the medical knowledge placed at his disposal, and of the principles which the great sanitary reformers to whom we refer laid down for his guidance, and of the public whom he addressed. It has been aptly observed that had he, as a military man, succeeded in destroying one-hundredth part of the lives which he was prominent in assisting to save, his statue would have been erected long since in more than one of the great cities of the empire, and he would have been loaded with honors and titles. As it is, it was not until he attained the age of 90 that he received the honor of knighthood. Through a long series of years he languished in the shade of official displeasure and retirement, and it was only his indomitable energy, untiring industry, and capacity for clear statement and the summary of voluminous detail which enabled him frequently to arrest public attention to his amateur utterances on subjects on which he ought to have been enabled to speak with official weight. His career was one of unchecked labor and unalloyed usefulness, and his memory will remain for many long years as that of one of the greatest and least rewarded benefactors of the people of this kingdom. It will be interesting to see what, if any, public recognition is made—now that he has passed away—of so distinguished a career and such vast services.—*Brit. Med. Journal.*

William Kitchen Parker, M.D.

Dr. William Kitchen Parker, for many years professor in comparative anatomy at the Royal College of Surgeons, England, died in July last at Cardiff, aged 67 years. He was one of the most eminent morphological anatomists of his day and the author of many valuable works, among which may be mentioned his "Morphology of the Skull," "The Shoulder Girdle" and "Mammalian Descent." For many years the Royal Society appropriated annually a large share of its research funds to publish and illustrate his monographs and papers. During much of the time that he was most active in original research and in the publication of his valuable

works, he was also engaged in general practice to get a living. A few years ago, the government granted him a small pension, on which he retired and devoted his whole time to the anatomical studies he loved so well. He was an enthusiast, a vigorous and indomitable scientist, and pre-eminent for his care in giving credit to his fellow-workers who were enabled to add anything to the sum of knowledge in the fields in which he worked.

BOOK REVIEWS.

TRANSACTIONS OF THE NEW YORK STATE MEDICAL ASSOCIATION FOR THE YEAR 1889. Volume VI, Edited for the Association by EDWARD K. DUNHAM, M.D., of New York City, and published by the Republican Press Association, Concord, N. H., and J. H. Vail & Co., New York. 1890.

The sixth volume of Transactions of the Association has just come to hand. The Committee on Publication consisted of Drs. Alfred L. Carroll, of New York County, Chairman; Glover C. Arnold, of New York County; William B. Eager, of Orange County; J. W. S. Gouley, New York County; John H. Hinton, of New York County; John G. Truax, of New York County; and E. D. Ferguson, of Rensselaer County.

The volume of 450 pages is published in a style creditable to the publishers, and bears evidence of the most painstaking labor on the part of the Editor, Dr. Edward K. Dunham.

The sixth annual meeting convened at Hotel Brunswick, New York City, September 25, 26 and 27, 1889. President, Wm. T. Lusk, M.D., of New York, officiating, and the Report of the Committee of Arrangements presented by its Chairman, Dr. John G. Truax, was accepted and adopted.

The President's Address upon "Tubal Pregnancy," with illustrations, is an admirable paper, and worthy of most careful perusal. It was very ably discussed by Drs. Goodell, of Pennsylvania, Henry O. Marcy, of Massachusetts, and by Janvrin and Henry F. Risch, of New York County. The second special subject considered was that of "The Treatment of Hernia." The leading paper upon this subject was presented by Dr. Joseph D. Bryant, of New York City. Among other important papers presented was that on "Alcoholic Insanity," by T. D. Crothers, of Connecticut. "Fads Old and New" receive their just deserts from Dr. Didama, of Syracuse, N. Y. "The Temporary Transfixion Ligature" was the subject of a carefully prepared paper by Dr. Thomas H. Manly, of New York City. "Shadow-Lines of Insanity" is the title of an interesting article by Dr. John Shrady. Under the heads of leading questions,

the subject of hernia receives a very extended and exhaustive discussion from a number of prominent surgeons. The general address upon Medicine was presented by Dr. E. K. Dunham, of New York City, his subject being the "Bacteriological Tests of Drinking-Water."

Dr. Henry O. Marcy has an article upon "The Cure of Hæmorrhoids and the Use of Buried Animal Sutures." "Ataxic Paraplegia" is discussed by Dr. Darwin Colvin, of Wayne County, and Dr. Charles Edmund Bull has an able paper upon "Extraction of Cataract without Iridectomy."

The third general subject upon the programme is that of "The New Hypnotics." The leading paper under this head was presented by Dr. Wm. H. Flint, of New York, in which he considers the value and uses of sulphonal, amylen hydrate, hydrobromate of hyosine, paraldehyde and urethran; his object being "to give a summary of the therapeutic applications, the contraindications, the toxicology, the modes of administration, and in some cases the physiological action of these newer hypnotics." Dr. Wm. H. Robb, of Montgomery County, presents a valuable paper upon "Pelvic Cellulitis." "The Treatment of Acute Peritonitis by Laparotomy" is discussed by Dr. John Cronyn, of Erie County, and by others. An article upon "Diphtheria," by Dr. E. F. Marsh, of Oswego County, was read by title—giving its history, etiology, symptoms and treatment.

Our limits preclude the presentation of a full list of the papers presented or of the discussions that accompany them. The volume will be found to be a valuable accession to any library, and reflects great credit upon the work of the Association.

The Report of the Librarian, Dr. J. W. S. Gouley, states that the library of the Association now numbers 8,000 volumes, and is now placed in the same building with the Mott Memorial Library. The total fellowship of the Association, as reported at the annual meeting for 1889, was 732, and represented by five District Branches, including the entire State of New York. The growth of this organization in the brief period of six years is the best guarantee possible of its permanent success.

FAMILIAR FORMS OF NERVOUS DISEASE. By M. ALLEN STARR, M.D., PH.D. With Illustrations, Diagrams and Charts. 8vo, pp. 339. New York: William Wood & Co. 1890.

The object of this handy volume is to make known to practitioners the recent marked advances in neurological medicine, particularly in the direction of the localization of brain and spinal cord lesions with special reference to diagnosis and medical and surgical treatment. It is in no sense a text-book or systematic treatise on

diseases of the nervous system but, as set forth by the author, a systematic digest of the work in the Nervous Clinic of the New York College of Physicians and Surgeons.

The first seven chapters give a brief but very clear outline of the present knowledge of cortical function and localization, while chapter six, on aphasia and the cortical areas governing language, is particularly clear and valuable. The explicit directions for the thorough examination of patients presenting difficulties of speech from cerebral causes are worthy great attention. Chapters ten and eleven are devoted to a discussion of the localization of spinal cord disease. Chapter fourteen, on multiple neuritis, is a reproduction of the author's valuable article on this interesting and important topic in "Wood's Reference Handbook of the Medical Sciences." Chapter twenty, by Frederick Peterson, on ordinary forms of insanity, presents the subject attractively and instructively, but of necessity in the briefest manner. The importance of the early diagnosis of general paresis, upon which he dwells, is timely. His preference for private over public institutions for the treatment of acute cases, however, will be questioned in many quarters. Electro-therapeutics are treated with scant courtesy, and the static form of electricity is pithily classed with "other mild forms of counter-irritation," and aside from its mental effect relegated to the limbo of things useless.

Typographically and otherwise the book is a credit to the publishers. The cuts are clear and of material value to the context. The style is lucid and free from pedantry. It is heartily commended as furnishing the practitioner in condensed form what is latest, best and most practical in the treatment of the diseases discussed.

THE ANATOMY OF THE CENTRAL NERVOUS ORGANS IN HEALTH AND IN DISEASE. By DR. HEINRICH OBERSTEINER, Professor at the University of Vienna. Translated, with annotations and additions, by ALEX. HILL, M.D., M.R.C.S., etc. With 198 Illustrations. Pp. 432. Philadelphia: P. Blakiston, Son & Co.

A careful reading of this extremely valuable addition to the literature of anatomy, and in particular to its most complicated part, commands admiration for the thoroughness, painstaking and indefatigable labor of the author who, from a mass of material formerly scattered in periodicals, has collected, carefully weighed and herein systematically presented the best that is known on the subject. He has been very fortunate, moreover, in his translator, who has given us a book in English, and not the jargon which so frequently characterizes translations from other languages, and especially from the German. An obscure or involved sentence is sought for in vain, and a wholesome use of Saxon is very refreshing on

a subject usually buried under a pedantic nomenclature.

The work in no wise takes the place of textbooks on descriptive anatomy, a knowledge of which it presupposes, but is prepared for the advanced student, practitioner and specialist. A notable feature of the book is its American-like wealth of illustration. The cuts are not only original but extremely well executed, and the plan of showing the exact appearance of sections and their schematic outline in association is productive of happy results. Were the parts named in full instead of indicated by initials they would leave nothing to be desired.

The opening section gives in a brief, practical way the various methods of examination, and is followed by skilfully arranged chapters on Morphology, Histology, Arrangement, Topography, Course and Connection of Nerve-fibres, etc. A plentiful and judicious use of face type is made, to indicate topics and sub-heads. Occasional interpolated paragraphs by the translator, himself an authority on the subject, add material value and clearness to the text. Owing to its advanced and technical character the book may meet with a limited demand, but no one who gives attention to the advances made in this branch of medical knowledge will be without it.

A TEXT-BOOK OF MENTAL DISEASES, WITH SPECIAL REFERENCE TO THE PATHOLOGICAL ASPECTS OF INSANITY. By W. BEVAN LEWIS, L.R.C.P., M.R.C.S. (Eng.), Medical Director West Riding Asylum; Lecturer on Mental Diseases at the Yorkshire College. With Illustrations in the Text, Charts, and Eighteen Lithographed Plates. Pp. xxii, 552. Philadelphia: P. Blakiston, Son & Co. 1890.

In this interesting volume the author has aimed at a full presentation of the anatomical and pathological aspects of his subject, believing that former text-books on mental diseases have been disproportionately occupied with the clinical side of insanity. The work is divided into three parts. Part I deals with the anatomy of the cord, medulla, mesencephalon, thalamencephalon, prosencephalon, the encephalon as a whole, the cerebral cortex and cortical lamination. Part II, the clinical section, discusses the states of depression, states of exaltation, fulminating psychoses, mental enfeeblement, recurrent insanity, epileptic insanity, general paralysis of the insane, alcoholic insanity, insanity at the periods of puberty and adolescence, at the puerperal and climacteric periods, and senile insanity. Part III, the pathological section, takes up the subjects of morbid conditions of the cranial bones, investing membranes, brain substance, histological elements of cortex, forms of tissue degradation, and the pathological anatomy of general paralysis, of epilepsy and of chronic alcoholism.

The anatomical and pathological sections are handsomely illustrated by numerous lithographic plates. The clinical section contains numerous tables and charts of statistics and many clinical reports of illustrative cases. The author's statistics are based upon an analysis of 4,000 cases of insanity treated at the West Riding Asylum.

TRANSACTIONS OF THE AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS, 1889. Vol. II. Edited by DR. WILLIAM WARREN POTTER, Secretary, Buffalo, N. Y.

This, as its title indicates, is the Transactions of the second meeting of this Association. The Association is one which is bound to make itself felt in the lines of scientific obstetrics and gynecology. Its first two meetings have been pronounced successes. The present beautiful volume of Transactions contains papers read and discussed covering the whole range of obstetrics and gynecology, by the following well known men: Rollin L. Banta, Buffalo; David Barrow, Lexington; J. Henry Carsten, Detroit; William J. Conklin, Dayton; William S. Gardner, Baltimore; Rufus B. Hall, Cincinnati; Hampton C. Hill, Saco, Me.; Joseph Hoffman, Philadelphia; Lewis S. McMurtry, Danville; E. E. Montgomery, Philadelphia; William H. Myers, Fort Wayne; William Warren Potter, Buffalo; Joseph Price, Philadelphia; Charles A. L. Reed, Cincinnati; Geo. Rohé, Baltimore; Byron Stanton, Cincinnati; William W. Seymour, Troy, N. Y.; William H. Taylor, Cincinnati; A. Vander Veer, Albany; William H. Wathen, Louisville; Wm. H. Wenning, Cincinnati; Xavier O. Werder, Pittsburgh.

THE NEUROSES OF THE GENITO-URINARY SYSTEM IN THE MALE; WITH STERILITY AND IMPOTENCE. By DR. R. ULTZMANN, Professor of Genito-Urinary Diseases in the University of Vienna. Translated by GARDNER W. ALLEN, M.D., Surgeon in the Genito-Urinary Department, Boston Dispensary. Philadelphia and London: F. A. Davis, 1889.

We have in this little work the translation by Dr. Allen, of two monographs written by Prof. Ultzmann, of the University of Vienna, upon two important subjects. If additional light can be thrown upon them, its value will be quickly appreciated by those who have found them difficult of diagnosis, and often intractable in management. The neurosis of the genito-urinary organs are very fully considered. Reflex influences receive especial attention. The diagnosis, prognosis and treatment of these affections will be found instructive to students and helpful in practice. The second monograph deals with sterility and impotence in the male. It is a valuable article. The volume is one of the "Ready Reference Series."

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from September 20, 1890, to September 26, 1890.

Major Johnson V. D. Middleton, Surgeon, is relieved from duty at David's Island, New York, and will report in person to the commanding officer, Ft. Columbus, New York City, for duty at that station, relieving Major Joseph R. Gibson, Surgeon, and reporting by letter to the commanding General, Div. of the Atlantic. Major Gibson, on being relieved by Major Middleton, will report in person to the commanding officer, David's Island, New York, for duty at that station, and by letter to the Superintendent of the recruiting service. Par. 1, S. O. 219, A. G. O., Washington, September 18, 1890.

Capt. Aaron H. Appel, Asst. Surgeon U. S. A., leave of absence for seven days granted by the commanding officer, Ft. D. A. Russell, is extended twenty-three days. Par. 3, S. O. 70, Dept. of the Platte, September 17, 1890.

Capt. C. B. Ewing, Asst. Surgeon, is granted leave of absence for one month, to take effect the 1st prox. Par. 5, S. O. 131, Dept. of the Missouri, September 22, 1890.

Under the provisions of General Order 43, c. s., Hdqrs. of the Army, Adjutant General's Office, the post of Little Rock Bks., Ark., will be abandoned, to take effect not later than October 1, 1890. Capt. Paul R. Brown, Asst. Surgeon, will accompany Company E to Ft. Supply, Indian Ter., and there take station until further orders. G. O. 15, Hdqrs. Dept. of the Missouri, St. Louis, Mo., Aug. 11, 1890.

Major J. P. Kimball, Surgeon, in view of the early abandonment of Ft. Elliott, Tex., to which post he is at present assigned for station, is relieved from duty at that post, and will, upon the expiration of his present sick leave of absence, proceed to Ft. Supply, Ind. Ter., and report to the commanding officer for duty. Par. 2, S. O. 132, Dept. of the Missouri, September 24, 1890.

ORIGINAL ARTICLES.

THE SURGICAL TREATMENT OF CROUP.

Read in the Section of Laryngology and Otology, at the Fort-first Annual Meeting of the American Medical Association, Nashville, Tenn., May, 1890.

BY F. E. WAXHAM, M.D.,

PROFESSOR OF LARYNGOLOGY AND RHINOLOGY IN THE COLLEGE OF PHYSICIANS AND SURGEONS OF CHICAGO; PROFESSOR OF LARYNGOLOGY AND RHINOLOGY IN THE POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL OF CHICAGO.

When medical treatment has been thoroughly tested and it is evident that the patient must die from asphyxia unless relieved, then we must meet the emergency by surgical measures.

A nice question of judgment often arises as to the proper time for interfering surgically. When shall we abandon all hope of saving the patient by medical means, and when shall we know that the child will perish unless given prompt relief? In answer to these queries I would say that when the voice becomes whispering, when the cough becomes suppressed, when in addition the dyspnoea becomes urgent, and the loud stridor heard both on inspiration and expiration, and when there is marked recession at the base of the sternum and above the clavicles—when all these symptoms are present and continuous, and not relieved by the use of emetics, it is certainly time to operate.

I do not advise and do not practice early operations. Operations performed early, with the first symptoms of laryngeal invasion, should not be sanctioned, as many will recover under medical treatment. Operative measures, on the other hand, should not be postponed until the patient becomes moribund, for while many will recover even under these circumstances, yet their chances for recovery are far less than when the operation is performed earlier.

We should endeavor to strike a happy medium between the two extremes and bear in mind the indications for surgical interference. Having determined that an operation is imperative, the next question to decide is the choice of operation. Shall we choose the time-honored operation of tracheotomy or the more recent operation of intubation of the larynx?

The latter operation requires far more skill and delicacy of *technique*, and is an operation limited

to those especially qualified. In the hands of those so qualified it gives results that cannot be attained by the older operation. It is an operation that I would unhesitatingly recommend in preference to tracheotomy at all ages, under all conditions, and under all circumstances. In support of this statement I would fully record two hundred and eighty-five cases with one hundred recoveries, or 35 per cent. These cases have ranged from 5 months to 20 years in age, and from mild diphtheritic forms to the most malignant. All have been operated upon in private practice, and the majority of them in poor and destitute families where tracheotomy would scarcely have been undertaken. If any one claims the superiority of tracheotomy over intubation under these circumstances I would challenge them to record their cases. Tracheotomy in hospital practice, where patients can have every care and attention, or when performed upon selected cases and upon the older patients, will give fair results; but when performed as intubation is, upon young babies, upon bad diphtheritic cases at all ages and among all classes, the results will be disheartening.

My first 150 cases were duly recorded in THE JOURNAL; the remaining cases coming under my care I desire to record at the present time.

It is often said that intubation is performed early and unnecessarily, and that if tracheotomy were performed under the same circumstances the results would be equally brilliant. This is a mistaken idea and I desire to refute it. By the record of these cases it will be seen that nearly all were in the practice of other physicians and I have been called as a last resort, after all other measures had been exhausted, and when it became evident that the patient must die unless relieved. Not infrequently the operation is so long delayed that the patient is dead upon my arrival, and too frequently they are found unconscious, pulseless and comatose. A few of these cases have been so remarkable as to be worthy of special mention.

Case 181.—This patient was not only greatly exhausted from the disease, but also by previous attempts at intubation which had been unsuccessful. Upon arriving, the patient was found unconscious, pulseless at the wrist and upon the very verge of suffocation. A tube was quickly

introduced and artificial respiration performed. The child soon revived, wore the tube four days and made a perfect recovery.

Case 191 was another that was pulseless and unconscious and required artificial respiration, but is living and well to-day. Drs. Kippax, Guerin and Jacques were present at the operation and will verify this report.

Case 226.—Upon arriving I was informed by Dr. Case, the attending physician, that it was *too late*, the boy was dying. The sphincters had relaxed, the eyes were rolled upward, he was livid, unconscious and pulseless, and within five minutes undoubtedly would have been dead. With the remark that we would give him a chance for life, a tube was quickly introduced and artificial respiration performed. He fully revived and wore the tube three days, when it was ejected. The dyspnoea returned and it became necessary to reintroduce it. In four days it was removed and the child made a perfect recovery.

Case 254.—This was a case in which the constitutional symptoms were very severe and the diphtheritic membrane not only covered the whole pharynx but also invaded the larynx, trachea and bronchial tubes. Upon introducing the tube, membrane was pushed down in front of it. It was immediately withdrawn, when a long strip of membrane was ejected. The tube was reintroduced. Two days later there was evidence of membrane below the tube; it was removed and a membranous cast of the trachea ejected. On the seventh day after the operation the patient was able to do without the tube. The respiration, although easy, was rapid on account of the extension of the membrane to the bronchial tubes. The child was very much prostrated from the very beginning of the disease, and the heart's action was feeble and rapid; she was tided along, however, from day to day with an abundance of nourishment, stimulants, digitalis, strychnia and ammonia. Gangrene occurred in the toes of both feet, they becoming cold and black. Gangrenous spots were also seen upon the legs between the knees and the feet. Although the respiration became natural the circulation became more rapid and feeble, and the child died ten days after the tube was removed.

Case 252.—In this case the pharyngeal symptoms were mild, no membrane being visible in the pharynx, but the child was dying from suffocation due to laryngeal obstruction. The tube was introduced, giving prompt relief. Two days later it was evident that membrane was present below the tube, and when it was removed a partial cast of the trachea was expelled. As the respiration was still greatly impeded, the tube was reintroduced. Two days after this it again became evident that there was partially detached membrane below the tube. It was also evident that membrane had extended into the finer bron-

chi. The tube was removed and this membranous cast was ejected, which you will observe is a cast of the whole trachea and the two larger bronchial tubes. The patient was now able to breathe comfortably, and made a perfect recovery.

Case 257.—This patient was a baby only 15 months of age, a child of the poorest of Italians. The small room occupied was so filthy and crowded that tracheotomy never would have been considered for a moment. The baby was dying of suffocation when the operation was performed. The tube was coughed out on the second day and it became necessary to reintroduce it. On the fourth day it was removed and the child recovered.

Case 259.—This patient was a little girl 6 years old. The surroundings were even more wretched than in the previous case. The furniture of the room consisted of two old chairs, a rickety table, a small round stove and a sporting bull-dog. Everything was filthy in the extreme. The child was found to be suffering from a semi-malignant form of diphtheria. The nasal cavities were invaded, the pharynx covered with diphtheritic membrane, while the difficult respiration indicated that the larynx was invaded. The odor from the decomposing membrane in the throat was most offensive. The throat had been torn, bruised and lacerated by previous unsuccessful attempts at intubation, and the child's condition seemed most deplorable—so much so that one of the physicians present stated, with some vehemence, that if this patient recovered there was a *God in heaven and antiseptic surgery a delusion*. A tube was quickly introduced, which was coughed out on the fourth day, and perfect recovery followed. This case seemed miraculous to all who witnessed it.

These cases are only a few out of many of the same character, but sufficient, I hope, to prove to you that the operation is not performed early, unnecessarily or upon selected cases.

In Regard to After-Treatment.—The same line of treatment that has been instituted before the operation should be continued just as faithfully afterwards. In case the pharyngeal symptoms are severe and the nasal cavities invaded, antiseptic washes and frequent doses of iron are indicated. Where the pharyngeal symptoms are mild and the disease manifested principally in the larynx, with a tendency to extension downward, the bichloride of mercury should be vigorously employed. During the past two years, in those cases where the treatment has been noted, the following results have been obtained: In ninety-nine cases where the bichloride of mercury was administered there were fifty recoveries, or 50.5 per cent. In twenty-six cases where it was not administered there were nine recoveries, or 34.61 per cent.

Care of Patient.—The success attending the treatment of croup by intubation will depend, first, upon the delicacy and skill with which the operation is performed; and second, upon the care

SUMMARY.

One hundred and fifty cases previously reported, with forty-one recoveries, or 27.33 per cent.
 Present report of one hundred and thirty-five cases, with fifty-nine recoveries, or 43.70 per cent.
 Total, 285 cases, with 100 recoveries, or 35 per cent.
 The ages have been as follows:

Under 1 year,	10 cases with	3 recoveries, or	30 per cent.
Between 1 and 2 years,	37	" 9	24.32 "
" 2 and 3 years,	46	" 10	21.76 "
" 3 and 4 years,	47	" 17	36.17 "
" 4 and 5 years,	59	" 23	38.98 "
" 5 and 6 years,	27	" 14	51.85 "
" 6 and 7 years,	18	" 7	38.88 "
" 7 and 8 years,	20	" 9	45.00 "
" 8 and 9 years,	7	" 4	57.14 "
" 9 and 10 years,	6	" 3	50.00 "
" 10 and 11 years,	3	" 1	33.33 "
At 12 years,	2	" 0	00.00 "
At 13 years,	1	" 0	00.00 "
At 14 years,	1	" 0	00.00 "
At 20 years,	1	" 0	00.00 "

285 cases, 100 recoveries, or 35.00 per cent.
 There were ten cases under the age of one year; of these, one was five months old, one six months, four were nine months, two ten months, and two eleven months of age. Among those to recover after the operation were two nine months old and one of ten months.

There were 93 cases under three years of age, with 22 recoveries, or 23.65 per cent.

There were 193 cases over the age of three years, with 78 recoveries, or 40.62 per cent.

and judgment exercised in the subsequent management of the case. One of the greatest dangers following intubation is from detachment of membrane below the tube. When the tube is introduced, if membrane is pushed down in front of it and there is evident obstruction, it should be

removed at once. The expulsive cough that follows will expel the membrane. One must exercise the greatest judgment in the selection of the proper tube. A tightly fitting tube that could not be expelled when membrane became detached below it, has been the cause of many a death. There are always indications of membrane below the tube, and one should be constantly on the alert and anticipate the dangers that constantly threaten. A peculiar hoarseness to the cough, and sometimes a flapping sound as the membrane is forced up against the bottom of the tube, are indications that should never be unheeded. Under these circumstances the tube should at once be removed, and the expulsive cough following will in the great majority of cases expel the membrane. Some advocate performing intubation first and tracheotomy later if necessary. This will rarely be required if these indications are duly appreciated and properly met. In this manner complete casts of the whole trachea, and often of the larger bronchi, can be secured just as effectively as by a tracheotomy, and with much less danger to the patient.

We cannot consider the surgical treatment of croup without reference to tracheotomy. It is an operation that will always have a place in the

treatment of this disease. Intubation is an operation requiring so much delicacy and skill that its employment will be limited to those specially favored. Those who have not had special training or who are not unusually dextrous should never attempt intubation, but should resort to the older operation.

While there are some who have but little faith in tracheotomy and who question its utility, yet statistics prove conclusively its value as a life-saving operation. Recoveries from tracheotomy amount to about 26 per cent. In 1886 it was my pleasure to collect reports of 306 cases operated upon in Chicago with 58 recoveries, or 18.95 per cent. Agnew¹ (1878) reports 11,696 cases with recoveries amounting to 26.25 per cent.

Monti¹ (1884, Vienna) 12,736 cases with 26.8 per cent. of recoveries. Lovett¹ and Monroe, 21,853 cases performed in various parts of the world, with 28 per cent., while Mastin¹ has collected reports of 862 cases operated upon in the United States with recoveries amounting to 26 per cent.

It must be admitted, however, that individual operators often present a much larger percentage of recoveries. On the other hand, some meet with almost uniform failure, and their cases are never reported. Thus it has come to my knowledge that one operator has performed tracheotomy one hundred times with but one recovery, another fifty times with two recoveries, another twenty with one, another fourteen with none, and another eight with none, making a total of 212 cases with but four recoveries, or 1.88 per cent.

In operating the slow method is to be preferred when there is sufficient time; the tissues being carefully dissected and blood-vessels avoided or ligated. After the trachea has been opened all loosened membrane should be removed before the tracheotomy tube is inserted. The wound should be frequently dressed with antiseptics, and a pad of antiseptic gauze constantly worn over the tracheotomy tube. Feathers and brushes should not be introduced into the trachea, as is too frequently done. As little irritation should be produced as possible, and for the purpose of dissolving the sticky secretions that collect in the trachea and for exciting coughing by which to cause their expulsion, a warm alkaline solution should be employed instead, either by an atomizer or by pouring it directly into the tube. In case membrane is present below the tube, papyotin, tripsin or a saturated solution of pepsin may be employed for the purpose of dissolving it. The tube should be removed and cleansed as required, and it should be remembered that unremitting care and attention is the price of success.

SOFT-HANDED SONS OF TOIL.—This is the classification of our craftsmen according to Dr. Holmes.

¹ *Cyclopædia of Diseases of Children*, Vol. ii.

REPORT OF A CASE OF LEFT LATERAL, HOMONYMOUS HEMIANOPSIA WITH A WOUND IN THE OCCIPITO PARIETAL REGION.

Read in the Section of Ophthalmology at the Forty-first Annual Meeting of the American Medical Association, at Nashville, Tenn., May, 1890.

BY ROBERT TILLEY, M.D.,
OF CHICAGO, ILL.

Cases of well-defined lateral homonymous hemianopsia must ever, in the nature of things, be rare; and such phenomena arising from a wound and uncomplicated with other symptoms, must, if possible, be still rarer. Of course, the impossibility in this case of demonstrating the actual abnormal state of the involved part of the brain detracts from its interest; but there are several questions which arise in connection with such a case which may be profitably passed in review. I will first report the case:

W. S., male, 21 years of age, came to the clinic at St. Luke's Hospital, Chicago; he had previously been to another institution in the city, but, as he was complaining of a noise in the ears, he was referred to the ear department and no observation seems to have been made of the eyes. He still complained of a noise in the head on the left side, but he complained also of the loss of the left half of vision of the left eye. He assured me that the right eye was "all right." I was examining, when I first saw him, the patients before some students of the Chicago Medical College, and after making a rough finger test of the field of vision of the left eye, and finding his statement relative to the loss of the left half of the left eye correct, I accepted his statement relative to the right eye, and discussed with the students the possible conditions which might bring about such a phenomenon; at the same time remarking that it seemed impossible for any pathological condition of the optic nerve or chiasm to produce such a clear cut vertical hemianopsia of one eye. The fundus was examined and nothing abnormal was found; no optic neuritis, no detachment, no atrophy, no choroiditis. The pupil was a little larger than its fellow on the right. No definite conclusion was reached that day as to the cause of the difficulty. On examining him next day with the perimeter, the observation was extended to the right eye and the patient was astonished to find that his right eye was affected in an exactly similar way. Whilst previously traces of syphilitic infection were vigorously sought for without result, attention was now immediately directed to the posterior part of the head. The following history was then obtained, in part from the patient and in part from his mother: at the close of January, or the early part of February, he was, when the worse for liquor, struck on the back of the head with a tin pail; he walked about a block to his home after receiving the

blow and when within a few steps of the door was found senseless several hours after the blow was inflicted. The mother reports that he was not fully conscious till nine or ten days after the injury; that the doctor called in said that the injury on the head was a scalp wound but that the skull might be injured beneath. No sutures were used for the wound.

There was no paralysis of any kind, no difficulty of speech, nothing abnormal noticed about sensations. The one thing that the mother noticed was that while in bed he seemed to reach out for things as though he could not see; after he was up he was constantly mistaking his way by going into one room when he intended to go into another. Questioned relative to the size of the left pupil, the mother and patient report that they have for several years previously noticed that the left pupil was at times larger than the right and that he had experienced and spoken of the noise in the left side of the head several years prior to the wound on the head.

Examination of the eyes showed the external appearance normal in every respect, except that the left pupil was larger than the right, movements of eyeball normal, pupillary reflexes normal, the left pupil a little sluggish, convergence normal. Accommodation good and binocular vision, as shown by stereoscope, good. V. R. E. $\frac{5}{8}$, 0.5 easily, L. E. $\frac{1}{2}$, 0.5 but has to focus a little nearer, he does not, however, accept minus lenses. He can read readily without inconvenience.

Ophthalmic examination.—The only abnormal condition in the fundus was a slight choroidal crescent in the infero-external segment of the O. D. more marked in the left than in the right eye. There was no optic neuritis in either eye. I looked on several occasions for this on account of the effort made by Drs. Edmonds and Lawford to explain the existence of optic neuritis in the various cerebral affections.¹

V. F.—The observations were made with a small shaded electric lamp in a dark room for the sensation of light, with the finger, and for the color red with the perimeter. The clearness and accuracy with which he recognized in the region to be indicated both the finger and the red object, and the total lack of evidence that he had any conception of its presence before that point, showed that the case was one of a well defined homonymous hemianopsia, the line of vision being practically vertical except in the immediate region of the point of fixation. The exhibition to you of the actual chart taken with a Steven's registering perimeter, will give you a more accurate idea of the field than any words can. It is illustrated by the diagram Fig 1. You see that the line is nearly vertical except about the fix-

tion point, where it extends gradually to about five degrees to the left of the median line. Several charts were taken at different intervals but they varied very slightly, the variations being rather in the periphery than in the central line.

Left eye. Right eye.
RECOGNITION OF RED.

To demonstrate the action of the iris a light was brought into the dark part of the field of vision, a dark card was placed vertically in front of the eye, so as to cover as accurately as possible the half of the pupil through which the left half of the retina received its light, and a small electric lamp suddenly illuminated, and the irides were always seen to contract on the appearance of the light. It was thus apparently demonstrated that the existing lesion was situated not in the optic tract but in the cortical region; and, as it involved the left half of the field of vision, the lesion should be found in the right cerebral hemisphere. The external wound on the head was located four inches and a half forward from the occipital protuberance, and the center of the wound was five-eighths of an inch to the right of the median line. The demonstrations were made in the presence of Dr. J. E. Owens, Senior Surgeon of St. Luke's Hospital, the internes, and some students. The patient was also seen by Drs. S. J. Jones and Moyer, and the whole examination was repeated in the presence of Dr. Church, of Chicago, Sunday, May 10. There existed no other manifest lesion. No difficulty in walking, no hyperæsthesia or anæsthesia. The only record of temperature that I have is 97.4° on March 27, and I regret that I have not repeated the observation.

At the latter part of March the question of operative measures for relief was suggested to the patient and his mother. After reflection he said: "I can now attend to my work, I can dance and play baseball—preferably at first base—and I will be satisfied with that."

I should add that although there was no syphilitic history, I kept him for a few weeks under mercurial treatment, and to my astonishment the previous existing difference in the pupils disappeared, so that I have not been able to observe it for about three weeks. There is, however, no difference in the general field of vision. The noise on the left side of the head referred to in the ears, is not so troublesome to him. There was nothing visible in the ear that would seem

¹ See Transactions Ophthalmological Society, Great Britain and Ireland, Vol. vii, 1887.

to account for the existence of the noise; and it must not be forgotten that it existed before the wound and before the hemianopsia.

The patient claims to have been previously troubled with a tape worm. I simply mention this in order to put before you all the possible factors which may enter into the phenomenon. It is not impossible that the difficulty may be caused by the presence of a cysticercus located in the right cuneus. As the hemianopsia came on, however, suddenly, it is very improbable. It must, however, be remembered that the patient was not himself aware of the presence of the difficulty in the right eye until it was demonstrated to him.

The question arises here: Is the phenomenon associated with the external wound found on the head? There is nothing suspicious about the wound itself. The scalp is freely movable over the bone. There is no tenderness on pressure or when percussed. The region of the wound is a little—say about half an inch—anterior to the commencement of the occipital lobe; it is located a little—five-eighths of an inch—to the right, favoring the theory of an injury to the right rather than the left cuneus, which is just what we should expect to establish the theory. That the lesion is not in the optic tract is probably proven by the pupillary reflex when the light is thrown upon the pupil from the blind half of the field of vision with the functional half protected with a dark card.

Supposing it to be proven, as far as any case can be proven under the circumstances, that the lesion is in the accepted cortical area for vision—the cuneus—is it caused by a depression of the inner plate of the skull or by an extravasation of blood? What is the best advice to give relative to operative measures? In expressing your judgment on this point, as I trust you will, let me ask you not to forget the relation of the longitudinal sinus to the cuneus and the possibility of getting along in life fairly well, especially when the loss of vision is on the left side. As the patient said, he could follow his work, play baseball and dance.

If it was thought wise to recommend an operation, the question of the time that had elapsed since the accident would necessarily cut some figure; but how much? In a consultation with Dr. J. E. Owens about two months after the receipt of wound an operation was recommended, in the expectation that the difficulty arose from a depression in the inner plate of the skull in the region of the cuneus, and that its elevation would result in a restoration of the lost vision.

With your indulgence, I will supplement this contribution with a few notes taken from a case in some respects very similar—in some respects very different—but the final result being as nearly alike as it is possible for two cases to be. The case that I refer to was published before the cortical centers had received such attention as they

now have, and the exact location of the injury is not as clearly indicated as it would be in any report of to-day. It was published in the *Irish Hospital Gazette*, Dublin, 1873:

Case of Compound Depressed Fracture of the Skull with Considerable Loss of Brain Substance and Extensive Laceration of the Longitudinal Sinus—Recovery—with Observations. By J. Stannus Hughes, M.D., F.R.C.S.I.

Feb. 5, J. O'B., 35 years. Struck on the back of the head with a heavy iron coal box whilst at work in the hold of a ship. On removing the hair an extensive depressed fracture of the skull implicating portions of the occipital and parietal bones was revealed. Patient was in a state of complete insensibility, but on the removal of the piece of depressed bone an alarming hæmorrhage from the longitudinal sinus set in; on which the patient, without assistance, sat up on the operating table and asked in a loud voice and in a rational manner, "What has happened? Who did it? Is my mother here?"

The several pieces of bone removed were as large as the palm of the hand. Patient recovered completely, as far as the external wound was concerned. But the interesting part is in the examination of the field of vision later.

Ophthalmic Examination by H. R. Swanzy.—The ophthalmic examination reveals no abnormality of any kind in either fundus oculi. The optic nerves, so far as they can be seen, are perfectly healthy. His central vision is nearly normal.

What he does suffer from is a lateral hemianopsia. The defect occupying the right hand side of the field of vision of each eye and dividing the field precisely in the perpendicular meridian, the fixation spot, however, having escaped.

This, of course, indicates some disturbance in the course or at the origin of the left optic tract. What the nature of that lesion may be I am not prepared to say; perhaps a disorganization of the nervous tissues due to an extravasation of blood, perhaps direct injury. Probably you yourself will be able to form the best conjecture on this point, being acquainted with the case from the commencement.

The report of A. H. Jacob and F. Wilson coincided with the above.

DR. JACKSON: I have within a few months, seen a case of hemiambyopia, with the divisions between the ambyopic portions of the field, as in Dr. Tilley's case. Within the ambyopic field a segment smaller than a quadrant, with indefinite outlines, which was absolutely blind. The reactions of the pupils were quite normal. The condition followed a gunshot wound of the occipital region of the opposite side.

DR. DE SCHWEINITZ described two cases of lateral hemianopsia, the result of gun-shot wound of the head; in one there had been chromatopsia. He thought the presence of cortical hemianopsia, without other symptoms, and in the absence of Wernicke's pupil symptom, practically located the lesion in the cuneus, and referred to the works of Temer, Monk and Seguin. The question of trephining should be decided by the amount of disadvantage and discomfort the patient experienced as well as the amount of good that would result. The intimate relation of a large, venous sinus to the trephine wound did not in itself con-

traindicate the operation, because it had been demonstrated that hæmorrhage from wounds, even of the lateral sinus, could be controlled with remarkable facility by packing.

A PLEA FOR THE GENERAL ADOPTION OF THE AXIS-TRACTION FORCEPS.

Read in the Section of Obstetrics and Diseases of Women at the Forty-first Annual Meeting of the American Medical Association, at Nashville, Tenn., May, 1890.

BY JOSEPH HOFFMAN, M.D.,
OF PHILADELPHIA.

In presenting any question concerning the forceps I am well aware that I am treading upon hackneyed ground. Without preface I shall hasten to the statement of my argument for the adoption of the axis-traction forceps. First of all, the use of the forceps is to be considered as an *obstetric procedure*, which before employment, is to be fully justified, both in the interests of the mother and of the child, entirely apart from the convenience or prejudice of the operator. The forceps are to be applied, neither because the mother demands them nor because they are a time-saving convenience for the obstetrician. Their use is strictly a logical one, and must be differentiated from every fallacy of apparent justification. The question has been asked, Can there be a too frequent use of the obstetric forceps? On the other hand, we hear continually of the "abuse" of the instrument. Now, if a part of the practicing obstetricians are in doubt as to whether they shall not use the forceps on every occasion where there is delay or other seeming cause, and if another portion give them only an occasional place in their application, the position of the two must be entirely different. If their application is for obstetric good and not for convenience, which must be conceded, they must save either mother or child, or both, from troubles or dangers she would otherwise undergo. Given a normal pelvis and a normal head and presentation, with normal application of forces, the labor has for its accidental factor the dilatation of its maternal soft parts. Now, if such dilatation, both perineal and cervical, is tardy, it is evident that an early application of the forceps must be accompanied with consequent injury to the maternal structures, while the injury to the child must, or should be small, under skillful application of the instrument. If now, on the other hand, there is free relaxation of all the soft parts and a deviated presentation, or a slight disproportion between the diameters of the foetal head and those of the pelvis, which uterine contraction and external manipulation have been unable to overcome, thereby prostrating the mother and interfering with the foetal circulation, the use of the obstetric forceps comes under consideration as a preservative measure,

and is directly advantageous, as it can be applied without force or forcible effects upon both mother and child. It is at this point that the general misconception of the use and intention of the forceps arises. Probably it is a teaching fault as well as a learning fault. Once let it be considered that the foetus in the pelvis is a foreign body like the aching tooth in the jaw, and we have the obstetric forceps and the old tooth-key, similar instruments of torture, both having force as the foundation of the ends they would attain. This idea, unfortunately, even if not confessed, is that followed out by too many obstetricians and obstetrical teachers, whose lectures must indorse, as a resultant of their ideas, pressure forceps, blades useful for leverage, and the like. It makes the forceps a lever or a tongs, with which to pull or pry by force, and loses sight of the principle that it must be for harmless application, the supplement of existing forces—to be used in their lines if they are normal, to restore them if abnormal, and to conserve or reinforce them if they are weak, and to substitute them if under certain conditions they are absent. Once accept and apply these principles and the abuse of the forceps ceases, even in cases where otherwise their application would be questionable. So far as the foetal head is concerned, in what light must the ordinary obstetrical forceps be considered? From a mechanical standpoint we must see that it works at a manifest disadvantage. Its adaptation to the foetal head is maintained, no matter what the resistance opposed by the maternal structures, by a maximum pressure at the extremity of the long arm of the lever composing the handles. If the resistance is small, the pressure is not less, but only shorter, owing to the speedy escape of the head, and expends itself to the disadvantage of the mother, in damage to the perineal floor. If this force is not applied the instruments slip, and damage both the foetal head and the maternal structures. If the resistance is great, the compressing force must be necessarily great to overcome it, while the contusing force upon the maternal structures is proportionate to the resultant of the force expended in the axis of the pelvis and that lost against the pubic bones. In the use of the ordinary forceps this ratio must exist; it is a mechanical necessity and must be overcome, if at all, by mechanical principal efficient according as they approach mechanical exactitude. With this approach to mechanics we must lose sight of all idea of violent force, of which much may be lost and compensated for by additional force. Considered from the standpoint of the foetus the force expended against the pubis is lost; considered from a maternal standpoint the force becomes harmful in its pressure effects, just as also the additional force by direct pressure upon the foetal head is harmful. It therefore appears that considered mechanically the ordinary obstetrical forceps is a

defective instrument, permitting neither the satisfactory utilization of the force applied, nor its regulation so as to conform with the principles previously suggested. Now, as the pelvic axis is the line in which all forces must act in order to be effective, it follows that the greater the deviation from a normally formed pelvis, the greater must be the resistance to any force acting outside of or at variance with this axis, and that in cases of pelvic malformation the violence must be correspondingly greater, both to maternal and foetal structures.

The problem is accordingly presented as follows: Given a resistance we must apply a force which shall work along the axis of the pelvis, and at the same time minimize lost energy and maximize the energy exerted in the axis of the pelvis and which alone is efficient in the expulsion or delivery of the foetal head. The more nearly this problem is solved the more direct will be the traction, the less will be the force required, and the more natural will be the artificial delivery, or, as has been suggested above, the two will supplement each other. To fulfil the above indications numerous modifications of the common forceps have been invented, among which are those of Hermann, Hubert, Hartmann, Morales, and I think we may justly say, finally culminating in those of Tarnier. These have been essentially modified by Poulet and others. The latest German idea, that of Breus, I regret not to be able to present. It is ably advocated by Winckel, though too much to the exclusion of Tarnier's forceps.

The conformity of the pelvis is such that when occupied by the foetal head, the problem to bring an ovoid body through a circular canal with a curved axis is presented. Now to accomplish this it is evident that the force should be applied to the centre of the head or foetal ball, and should act in the centre of the cylindrical passage, the vagina, and at the same time varying in reference to the position of the application of the force as the head descends in the pelvic curve.

The ordinary objection urged against the Tarnier forceps is the danger of rupturing the perineum by the traction apparatus. This is entirely theoretical, as the rods are to be kept parallel with the forceps handle, and when this is done they practically fall within the blades, and can do no damage that would not occur without them. With both Tarnier's forceps and Poulet's modification they of the blunders yet common with many practitioners cannot be perpetrated. I refer more particularly to the so-called pendulum or lever motion of the forceps, and to the rotatory motion advocated by Osiander. These manipulations, while practicable in the ruder arts, have no place in obstetrics, and can result only disastrously to the maternal tissues. It will also be seen that the direction taken by the head as it engages, must be in the path of the least resistance,

inasmuch as the traction exerted does not guide, but only applies a force that is directed by the handle, which indicates lateral variations in the descent upon the perineum. These lateral deviations are the foundation of the excuse for the pendulum movements, which are only experimental manœuvres to determine in what direction the head will move most easily.

A brief epitome of the specific positions in which axis-traction is especially advisable is all that can be set down here. First of all, in high operations in which it is desirable to make traction in the pelvic axis and not against the brim, a careful analysis of cases will show that the axis-traction principle offers better results, so far as the mortality of the child and the effects on the maternal structures are concerned, than pressure forceps.

As was before remarked, in deformed pelvis the results must be even more notable. In occipito-posterior positions any tendency of the head to rotate is not interfered with, but is allowed to take place freely. In my hands I have noticed a complete revolution of the blades and, of course, of the head in their grasp. In other occipito-posterior positions, in which the perineum usually suffers severe laceration, the lifting effect of these forceps—which, while bringing the head downward and outward, nevertheless raises it toward the pubes—is peculiar, and cannot be imitated by any other procedure. That of Osiander, while essentially the same in its intent, cannot be compared in its accomplishment.

In the low operation, in which the short forceps are commonly applied, the same effect can be justly claimed. The short forceps, as such, in my estimation, have no place in obstetrics; I have no doubt that of all instruments they inflict the most damage to both mother and child. If, when the head is on the floor of the pelvis there is any need for the application of forceps, the axis-traction principle is the one that fulfils all the indications, expediting labor and at the same time saving the perineum by lifting, not dragging the head through.

The final argument for the general adoption of the axis-traction principle is, that by it the force is applied at the centre of or near the centre of the fenestration, and that hence the leverage effect which must be exerted upon the structures within the grasp of the blades, must cause less direct violence.

ARISTOL.—Aristol, the new substitute for iodoform, is reported by various observers to prove efficacious in many cases where iodoform has been successful. It is said to be non-poisonous and has the very decided advantage of being without odor.

REPORT OF A CASE OF TRANSPLANTATION WITHOUT A PEDICLE FOR CICATRICIAL ECTROPION, BLEPHAROPLASTY? BY WOLF'S METHOD.

Read in the Section of Ophthalmology at the Forty-first Annual Meeting of the American Medical Association, held at Nashville, Tenn., May, 1890.

BY J. MORRISON RAY, M.D.,

SURGEON TO THE EYE AND EAR DEPARTMENT, STS. MARY AND ELIZABETH AND LOUISVILLE CITY HOSPITAL; CLINICAL LECTURER ON EYE, EAR AND THROAT, UNIVERSITY OF LOUISVILLE (SPRING COURSE).

The increasing number of successful flap operations without a pedicle, induces me to report a case and to urge its more general adoption in cases of extensive cicatricial ectropion.

Geo. Davis, negro, æt. 32, came under observation at the Louisville City Hospital. Six months previously he was blown up by the premature explosion of a blast. The skin of the right side of the face and head was extensively destroyed. The angle of the mouth, ala of the nose, and the forehead were involved in dense cicatricial tissue. The lower lid was entirely destroyed. The upper lid was everted and firmly fixed to the supra-orbital margin. The free border of the lid was well preserved and contained normal cilia; the eyeball was free from injury, but showed conjunctivitis and superficial corneal erosions from exposure. From the amount of cicatrix on the face, a gliding or pedicle flap seemed impossible. The method of Wolf was therefore decided upon. Chloroform was given; the conjunctiva and cul-de-sac were flooded with a warm bichloride of mercury solution, 1-6,000, and the surrounding parts thoroughly cleansed with soap and water and the bichloride solution. The upper lid was dissected from its attachment to the brow. The cicatricial bands were freely divided and the lid margin brought well down, and by four stitches attached to the stump of the lower lid.

This left a surface 2 inches long by $1\frac{1}{4}$ in width to be filled by transplantation. One small artery bled freely and required twisting. The surface thus exposed was left and the arm prepared. A space measuring 3 inches long by $1\frac{3}{4}$ in width was mapped out on the left arm to the inner edge of the biceps, as near as possible the shape of the gap to be filled. The field of operation was rubbed well with ether, then with soap and water, and flooded with the warmed bichloride solution. The skin was dissected up by means of a pair of iridectomy scissors, care being taken to get the flap free of all subcutaneous connection and fatty tissue. The flap was surrounded by warmed bichloride gauze. By the time the skin was well loosened up, the oozing from the lid wound had stopped and the surface appeared dry and glazed. The flap was quickly freed, placed on warmed gauze and rapidly transferred to the lid. It fitted

well save at one place, where the flap overlapped; a small strip was here cut off by scissors.

No stitches were inserted, but the flap was pressed well down in contact with the cut surface, and the parts covered with moistened gold-beaters' skin. The parts about were smeared with iodoform ointment; over these several layers of iodoform gauze; then a small bit of absorbent cotton, and firmly bandaged. The other eye, which was not injured, was left free.

While the flap was being adjusted in position, my friend Dr. Vance dissected up the edges of the wound in the arm, and brought them as nearly as possible together by a continuous suture, but the piece removed was so large, that complete coaptation was impossible. This wound was also dressed with iodoform gauze and a bandage. The next day the patient was sitting up.

The dressings were not disturbed until the fifth day, at which time all save the gold-beaters' skin was removed. Through this, the transplanted piece looked healthy, and there was no secretion. Iodoform gauze and a light bandage were reapplied and changed daily until the ninth day. At this time the stitches which bound the lid down were cut loose, and the gold-beaters' skin removed.

The flap was firmly united throughout, and on pricking with a pin, sensation seemed to be present. It was now dressed with iodoform ointment and a light bandage.

On the twelfth day, the epidermis began to loosen around the edges of the transplanted skin. On the fourteenth day he was exhibited to the Medico-Chirurgical Society of Louisville, and beyond the desquamation which extended around the edges about $\frac{1}{8}$ of an inch in width, the flap looked well. In a few days this came away, leaving a granulating surface surrounding a central portion on which the epidermis was still adherent.

Contraction began at the end of three weeks, and in a short time the surface had contracted to one-third the size of the original surface. Three months and a half after the operation he was last seen, at which time he presented a central portion of healthy integument 1 inch long by $\frac{3}{4}$ of an inch wide, surrounded with a narrow whitish band which corresponded with the portion for which the epidermis had desquamated. The lid was freely movable and the cornea easily covered.

Flaps as large as this have rarely been successfully transplanted, but it is our belief if care in its adaptation and perfect cleanliness in the work be carried out, it will, in the majority of cases, be successful, and deserving of merit as a plastic procedure. From a study of this case and others recorded, the following conclusions seem justified:

1. If perfect antiseptic and aseptic measures be instituted, large flaps of skin may be successfully transplanted.

2. The flap must be quickly dissected by scis-

sors, free of all connective and fatty tissue, and rapidly transferred to the surface to be filled.

3. Before the flap is placed on the denuded surface, all hæmorrhage must be well stopped.

4. Perfect immobility of the lid must be obtained by stitching its free edge to the lower, or to the cheek, and care taken to have the flap in exact apposition, no air bubbles being allowed under it.

5. Stitches are not required to hold the flap in position, since suppuration at the stitch holds may be a source of infection, and the parts can be held in perfect apposition by gold-beaters' skin or non-contractile collodion.

6. The size of a transplanted piece must be one-third larger than the surface to be filled, since the skin contracts after being dissected loose.

7. The lid must be brought as far down as possible, since the contraction that follows the healing process will lessen the transplanted surface to one-third its original size.

8. The dressings should be left undisturbed for five or six days, in order that firm adhesion may be formed between the surface and the transplanted skin.

9. The surface to be filled must be a freshly denuded one, for if it be a granulating surface, the secretions will lift up the flap, and sloughing follow.

DR. HOTZ, of Chicago: The final result of the transplantation of Wolf's flaps is seldom satisfactory; its shrinkage makes the lower lid turn down again; its thickness makes the upper too heavy. Prof. Thiersch's method is better suited for the upper lid and also good for the lower lid. He takes large flaps of epidermis including the Malpighian layers, shaved off from the arm with a razor. These grafts take much better than Wolf's flaps; they make a thin, light coat like the original skin of the upper lid, so that it can be opened and closed in the most natural manner.

ALCOHOLIC HEREDITY IN DISEASES OF CHILDREN.

Read in the Section of Diseases of Children at the Forty-first Annual Meeting of the American Medical Association, at Nashville, Tenn., May, 1890.

BY T. D. CROTHERS, M.D.,
OF HARTFORD, CONN.

A. B. came under my care for home treatment for periodic inebriety. He has used wine on the table at meals for twenty years; for ten years past he had drunk in paroxysms. His wife used wine on the table also, and during pregnancy and lactation had used both beer and wine freely. He had two children, one a girl of eight years, the other a boy five years old, both invalids, and had been under constant medical care from infancy, the general diagnosis being scrofula and general

anæmia; and both were of pale and delicate appearance, extremely excitable and nervous.

They had continuous irritation of the stomach, from an unrestricted diet of all kinds of foods and drinks, except wine and beer; were very passionate at the slightest opposition to their wishes, and after a period of rage would be greatly exhausted and have a distinct fever for a day or more. The girl had attacks of emotional religiosity, in which she manifested great sorrow and melancholy at her sins, and asked the prayers of all persons she came in contact with; at other times she was precociously bright, and irritable at any opposition to her wishes.

The family physician had no faith in heredity, and treated these various conditions as so many symptoms of threatened organic disorders which his skill and remedies prevented from gaining farther. Both had suffered from rubeola and scarlatina, and were supposed to have never fully recovered. Bronchitis, enteritis, gastritis, neuritis, and various heart diseases, were constantly threatening, and as constantly averted. Finally, death of the physician brought a new man who recognized the alcoholic heredity of these cases, and ordered them to the country where the diet was restricted, and enforced exercise outdoors, and frequent bathing when it could be carried out.

These children had marked nerve and brain instability, with low vitality, and were neurotics, which would of necessity develop insanity, inebriety, or any other form of nerve and brain degeneration; and the rational treatment should have recognized this condition, and given special attention to the diet and surroundings, and the avoidance of all existing causes that would stimulate the brain and nervous system.

A physician wrote me that he had given tincture cinchona to a neurotic child of one year of age, for slight fever which resembled malaria. In a short time the child would cry for the medicine, and only would be satisfied for a little time after it was given; on one occasion it took at once a two-ounce mixture of this drug. He changed to other tonics, but found that nothing would satisfy the child but tinctures. The child was found to have an alcoholic mother, who died soon after its birth, and the alcohol in the tinctures aroused an organic memory which had been inherited.

In private practice, some years ago, I treated a little boy for over five years, for the most confusing and varied disorders and diseases that it was possible to have; he recovered from one disorder only to be prostrated with another. None of them were well defined or clear, and much difference of opinion prevailed among the numerous medical men who were called in consultation. At puberty this boy became a pronounced dipsomaniac, suddenly, and without any special temptation. Years after he came under my care, and

was a chronic case. From a study of his history it was ascertained that his father was an inebriate, and died before he was born. Here was an alcoholic heredity, which had escaped notice; and where the alcoholic neurotic symptoms were not understood.

I think we may confidently expect of the practice of medicine, that in the near future such cases will be treated so successfully that the alcoholic or insane predisposition will be warded off. I have heard of numerous instances of children from infancy upward to puberty, upon which alcohol in any form and in small quantities acted as a hypnotic; in some cases no other medicine could be tolerated, and in some alcoholic heredity was present, and in others it was not clear.

In the study of the early history of inebriates, a great variety of diseases common to childhood appear, and seem to have been more intense than in other children. Such cases seem to have suffered more severely than others from nutrient disorders, shocks, and traumatism; they are freighted with some heredity or predisposition to particular forms of degeneration; the organism has received a certain bias, from which it cannot escape. Alcohol, of all other drugs, seems most potent to impress cell growth and function.

No fact is more firmly established than that alcoholic ancestors will transmit to their children a defective brain and nerve power. The form and shape of this defect and its manifestations will vary widely.

In many cases it may not be prominent until after the higher peripheral brain has reached a certain development, especially in the growth of the emotional and inhibitory centers. In others this defect is seen in infancy, in an abnormal hyperæsthesia of the senses, and nutrient disturbances. Some children manifest irritation at all sounds, and all changes of light and surroundings, by continuous crying; the skin or alimentary canal is also very sensitive, and various skin disorders and nutrient troubles follow. Low powers of vitality and slow, irregular growth are common. This condition may continue for years, then gradually disappear, and only re-appear at puberty, or later, in some distinct form of degeneration. Sometimes a marked neurasthenia and anæmia appear in early life and continue up to puberty, then break out into some disease, or develop some hereditary malady.

Another class of children are noted, who come from alcoholic ancestors, by their precocious development of brain and nerve force. They exhibit powers of brain receptivity and instability that is called genius, which give way early to some disease or form of nerve degeneration from various causes. Inebriety, insanity, or both, are very common sequels. Alcohol or opium in any form is almost always a grateful remedy, and is demanded in many instances by the patient. The

use of bitters that contain large quantities of spirits is also very popular, and an unconscious organic memory is awakened that rarely dies out.

In some children this craving for spirits is manifest very early. A case of this kind was brought to my notice by Dr. Smith, of New York, where an infant of two months old could only be quieted by a few drops of spirits. Its taste was so pronounced that it would stop nursing at the sight of the person who gave the spirits, and cry until it was gratified. Fortunately, such instances are not common; but the abnormal tastes of children, and their extreme sensitiveness or obtuseness to sensory impressions, and low powers of vitality and recuperation, are often clear symptoms of an alcoholic impression from ancestors.

This alcoholic heredity will be seen in children that manifest extremes of activity, particularly where there is a tendency to the sudden liberation of nerve energies, as in violent passion (grief or joy) or work, play, or study, which is followed by extreme prostration. The child is said to be sullen, morose, or melancholy, then suddenly manifests the other extremes, indicating a great instability of brain cells and functional control. Its life seems to be threatened with fevers, prostrations, and inanitions, accompanied with mental irritations and wandering neuralgias that tax severely the skill of the physician. These conditions may follow other heredities, but they always point to a degree of nerve and brain degeneration or retarded development, and defective co-ordination, that must be recognized in the treatment.

In all cases where alcoholic ancestors, even back to the second generation, can be traced, there are certain predispositions which must be considered in the treatment.

First. A tendency to exhaustion from feeble vitality, and low power of restoration. Tonics and nutriments that have a direct stimulant action on the brain should not be used, such as alcohol and opium, and meat broths. These remedies have a tendency to still further exhaust the vital forces, paralyzing the nerve centers and increasing the carbonaceous matters of the system.

Second. An instability of cell and nerve function, and strong predisposition to develop into some particular form of degeneration, which is practically an exhaustion of the higher brain centers with craving for relief. All stimulants and remedies which act on the brain centers increase the existing degeneration.

Third. There is a special affinity for all nerve stimulants by those higher brain centers. Their use constantly interferes with the natural development of brain energy from food. Thus, alcohol, tea, coffee, and other substances have a peculiar delusive effect.

From these facts it will be obvious that the diseases of children of alcoholic parentage are far more complex, and require greater care. In ad-

dition to whatever disease they suffer from, there is always neuræsthenia and defective control of the brain centers, which may come into prominence at any moment, from causes both known and unknown. This hereditary bias and neurotic instability enters into all cases.

The general principles which should govern in the treatment may be grouped as follows: 1. No form of alcohols are safe, and narcotics of all kinds should be used with great care. 2. The diet should not include meats of any kind, because of their stimulating character; while meats contain much food force, they act as stimulants to a brain already over-stimulated and exhausted, and increase the peril of nervous disease. The pathological tendency of all these cases is to become alcohol-takers and meat-eaters, hence the diet should always be non-stimulating and farinaceous, and should be carried out with military regularity. 3. The hygienic treatment is also of the greatest importance; every means and measure which can build up a system, and avoid brain and nerve stimulation, is required. 4. Cases of this character should be guarded against every possible extreme, both in the surroundings and physical conditions that are under the control of the physician. The tendency of all energy and nerve force is to pass off in explosions, which should be counteracted; the diseases they suffer from show this tendency to concentrate and become intensified in certain directions, also to manifest distinct exacerbations. Finally, the fact of an alcoholic heredity in disease of children that we are called upon to treat, gives a wider therapeutical range of possibilities, both in direct and preventive medicine.

Recent studies of alcohol cases show that over seventy per cent. are directly inherited. If this is confirmed by later studies, the treatment of inebriety will in the future begin in infancy, and the higher science and art of medicine will win its greatest triumphs along the line of prevention.

SURGERY OF THE SUPERIOR LARYNGEAL NERVE IN SPASMODIC DISEASE OF THE LARYNX.

Read in the Section of Laryngology and Otology at the Forty-first Annual Meeting of the American Medical Association, Nashville, Tenn., May, 1890.

BY J. P. CREVELING, M.D.,
OF AUBURN, N. Y.

The operation of which I am about to speak is one, as far as I know, new in surgery of the larynx, and one of sufficient severity to preclude its performance except in very rare cases where all other means afford no relief, and when the disease is sufficiently severe, as to render the life of the patient so uncomfortable that any procedure, however grave, if it presents even a prospective chance for relief, becomes justifiable and proper.

It will be seen later on that the merit of the operation is based on the result of two cases only, one of which was seriously complicated. It will also be seen that in the first instance the manifestation of the laryngeal disturbance was not confined to that organ alone but reflected to the lungs, producing asthmatic breathing, not very severe, but enough to give annoyance and excite apprehension.

It was not for this disease, however, that advice was sought, but for one of a much more serious nature; one for which no less severe measures could be adopted. It was in this case that I first noticed the result in the larynx of dividing the superior laryngeal nerve. I did not observe the extreme liability of food to pass into the larynx that I had feared, and therefore was less timid to attempt a similar operation for a purely laryngeal trouble of a less formidable character.

In brief I will give the history of the two cases:

Case 1.—M. C., a female, aged 30, consulted me in September, 1888, for a large irregular tumor situated in the base of the posterior triangle of the right side of the neck, and difficult or asthmatic breathing. The tumor extended down under the muscles toward the median line and rested against the trachea. Examination with the laryngoscope disclosed a tumified and engorged condition of the laryngeal mucous membrane, extending into the pharynx. The epiglottis alone remained normal.

I attributed the throat disease, as well as the asthmatic attacks, to pressure of the tumor, and proceeded to operate without unnecessary delay. The base of the growth proved to be large and nodular, pressing firmly against the trachea and adherent to the carotid capsule. It was quite easily detached from the trachea but it was necessary to remove an inch or more of the capsule of the artery. After the removal was completed the wound was closed, which healed kindly, but neither the breathing nor the laryngeal condition were benefited. She declined throat treatment and all other remedies calculated to relieve the disturbed respiration, because she had anticipated a cure with the removal of the tumor.

In about six months she again presented herself with a growth in the posterior part of the upper triangle of the right side of the neck, and one in the upper half of the anterior triangle of the left side also, extending from the angle of the inferior maxillary down along the side of the thyroid cartilage. In extirpating this last mentioned one it became necessary to divide the superior laryngeal nerve. After recovering consciousness it was observed that she was extremely hoarse, and deglutition somewhat embarrassed, but the difficult breathing had been overcome. From this time on she had no more trouble in that direction. It took a long while for the hoarseness to entirely pass away, and in fact the for-

mer strength of voice was never regained. The first opportunity for making an examination of the larynx was some eight months after the operation, when it was found the vocal apparatus of the left side was feeble and responded with less vigor than the right. This was about the only difference noticed in the two sides.

From the facts stated it is evident the tumors were not the cause of either the throat or asthmatic disturbance, as neither was relieved after the first operation although the growth pressed both the pneumogastric and trachea, and both conditions existed before the second growth appeared.

Case 2 does not present the complications of the one just cited, but is a typical case with the following history:

M. G., female, age 17, applied to me for treatment in January, 1890, stating that for some months past she had had "some trouble with her throat which caused her at intervals to make loud and unnatural noises, accompanied by a jerking of the muscles of the neck and motion of the head. The paroxysms occurred quite suddenly, without warning, and with sufficient frequency to prevent her leaving home without great discomfort from attracting the notice of those near her; that she was becoming nervous and irritable from the continued annoyance, and that she must have some relief at whatever cost." There was no uniformity of tone in the perverted voice: it varied from a high pitch to a low bass or guttural sound. In conversation the voice was thick and rough and some syllables not sounded. Prolonged speaking increased the hoarseness, produced discomfort in the throat and rendered the attacks more frequent.

The disease had been diagnosed as a nerve disorder by all who had treated her, so that she had taken the whole catalogue of tonics, antispasmodics, sedatives, stimulants and electricity, with no benefit.

An examination of the throat disclosed a chronic laryngitis involving the whole tube but more marked on the left side, to which side the left arytenoid body was firmly drawn, resting against the wall of the larynx.

On attempting to sound the vowels the summit of the arytenoid seemed to roll upward and outward, instead of inward to meet its fellow of the opposite side at the median line. No examination could be made during the paroxysm.

The parts were thoroughly cocaineized, but while the mucous membrane became pale, and sensibility was reduced to a minimum, it had little or no influence in preventing or modifying the attack. Local treatment was tried for a time but it gave only a negative result. Having in mind the case above mentioned, I concluded to cut down and search out the laryngeal nerve and make gentle traction on it with a view to overcome the spasmodic tendency.

An incision was therefore made just anterior to the carotid pulsation. The dissection was slow, as it will be remembered the superior laryngeal nerve is given off from the pneumogastric high up in the neck above the bifurcation of the artery, and that it passes downward and forward obliquely behind both the internal and external carotid as well as the superior laryngeal artery; and that the nerve divides into an external and upper branch above the bifurcation of the artery.

The nerve was at length found and put upon the stretch by passing a hook behind and lifting it from its bed. It was then traced from the carotid sheath to the point of division. The wound was closed. As soon as she recovered from the chloroform it was noticed that she was equally as hoarse as the preceding case, but that the throat spasm had entirely disappeared. She gradually regained her former voice. As far as known there has been no return of the disease.

From the result in the above two cases it may be inferred:

1. That the superior laryngeal nerve has an important bearing in spasmodic disease of the larynx.
2. That irritation of its terminal fibres as well as of the body of the nerve, may produce spasm of the larynx.
3. That a disturbance of this nerve may be reflected to other parts supplied by the pneumogastric and *vice versa*.
4. That division of the superior laryngeal may not be followed by serious results in the larynx.
5. That proper tension applied to the shaft of the nerve may modify its influence or action on the parts to which it is distributed.
6. That under certain circumstances it may be advisable to stretch or divide the nerve.
7. That the operation should not be performed except to relieve some extreme condition not amenable to other treatment.

ON THE MEDICAL TREATMENT OF DIPHTHERIA.

Read in the Section of Laryngology and Otology at the Forty-first Annual Meeting of the American Medical Association, Nashville, Tenn., May, 1890.

BY WM. H. DALY, M.D.,
OF PITTSBURGH, PA.

Much has been taught of late years, yet little of practical value learned, of the more successful medical treatment of diphtheria. This fact is witnessed by the continued high death-rate. And yet it is still to the medical and not the surgical treatment that the patient must hopefully look for salvation, since, at best, the surgical aspect of intubation and tracheotomy, though valuable aids in the easement of patients, are employed as a last resort in cases that have become desperate and imminently dangerous to life.

I have no intention of attempting to tell you anything new as to the medical treatment of diphtheria, but you will pardon me if I undertake to draw your attention again to a well-trying plan of treatment which I had the honor of bringing to the notice of the profession in a paper entitled "The Simplest and Most Efficient Treatment of Diphtheria," which I read before the Congress of the American Laryngological Association in Philadelphia in 1886. The treatment may be new to your experience as it was recommended and is still uniformly *practiced* by me with more satisfactory results than by any other plan. I say the strict plan may be new to your experience as medical men, since circumstances are so apt to modify, and personal judgment is prone to change any plan from the lines recommended.

Now is it not better to bring again to your notice, after four years further trial, a really *good plan* of treatment, than to undertake to tell you of something that is new and at best only a candidate for that bountiful hospitality which the profession is now extending to everything new and novel, and has done so for the past ten years. We really flourish in an era when novelty, no matter how absurd, can get a lodging place and the best accommodations and willing disciples to propagate a worship of it whether it be pumping gas into the recti of the phthisical patients à la Bergeon, or the injection of an emulsion of the testes of the barnyard fowl into the tissues of the prematurely aged or decrepit.

A novelty is our idol for the day, a medical fad is a trick to lure our poor human frailty, not that we like to deceive but that we are so easily deceived.

Since the article before alluded to, there has been no end of modifications of the plan of treatment there inculcated, each with its advocates, all or nearly all of the methods containing a mercurial. Many of them I have tried, being of a progressive turn, but I have invariably had reason after trial to think better of the results obtained with the calomel treatment pure and simple. I hope no gentleman will hold me to account for not mentioning this or that remedy for the medical treatment of diphtheria, as I am not encyclopedic in my character as a therapist in this disease, and do not intend to wander far from the pure calomel treatment until some other plan is so well established by others as to assure me better results than I now get, and that you can get if you will follow the plan as I have, and not handicap the treatment with all sorts of other drugs, local and constitutional. I am not an enthusiast by any means, inasmuch as the success from any plan of treatment I have tried has never been sufficient to make one feel proud of medicine, but of all I know and have tried this is the best; try it, try it as directed, and don't modify it with any of the one hundred and one things

that are newer, that theoretically seem as though they ought to be good.

It is admitted on all sides in our profession, that calomel is a most active germicide, and were it soluble in water, would soon displace the bichloride of mercury in surgery, but in diphtheria there is an advantage in being able to give this medicine in powder in large doses in that we get the local germicidal action as well as the constitutional effect, and I am sure that if our remedy is early administered that many of the threatening complications may be prevented. In the personal letters I have received from my colleagues since my first paper concerning this treatment, they tell me some of their patients die suddenly, during apparent convalescence, after all the membrane has disappeared, and they appear to die from heart paralysis or from heart clot.

We all know that the calomel pulse is a slow pulse, and also that the poison of diphtheria is one of great depression of vitality, therefore, in view of the possibility of this accident occurring, it is an important point to keep the patient in a strictly recumbent posture until convalescence is well established and far advanced, and this, in practice, is difficult to inculcate with parents and nurse.

Now, what is the method clinically? We will say, to a child three or four years old, suffering from diphtheria (early recognition and opportunity are, as a matter of course, of the utmost importance with this as with any other plan) give of pure, untritured or unmixed with sugar, calomel, in two or five grain doses every one, two or three hours, either dry on the tongue and washed down with a little ice water, or, better, given floated on a little ice water in a teaspoon. This is repeated at intervals until free catharsis follows; the stools are to be carefully observed, and when they assume the appearance of having floating in them gelatinous masses of dark, rather brightish green bile, giving them an appearance resembling chopped spinach, or the water-polyps seen in watering troughs, then the intervals of the dose can be lengthened so as to keep up this condition of catharsis to the extent of one to three stools each day. It is not well to diminish the dose, but simply to lengthen the interval, as there is less liability by this means to produce ptyalism. This is an important point and ought to be remembered. It has been a matter of much surprise to me that there is so little depression caused by the exhibition of these large and frequently repeated doses of calomel in diphtheria, and that ptyalism is so infrequent, especially so if the careful observation is made to keep up catharsis, or rather that fluid condition of the contents of the alimentary canal where the osmotic action is toward them from the blood-vessels, and not *vice versa*. Under this condition of treatment the membrane exfoliates and reforms, if at all, with less and less readiness; the fever abates; the prostra-

tion is slowly replaced by brightness and a disposition to activity, which latter should, of course, be prohibited, lest heart paralysis or syncope should suddenly supervene and cause a sudden fatal termination to the otherwise favorably progressing case. One may exhibit two to five doses of the chlorate of potassium intermediately but this I have not found necessary. I have adhered to the calomel in large and frequently repeated doses, with rather light but nutritious fluid diet, and have found it the most efficient of any treatment; and withal so simple for the nurse and so merciful to the patient. The latter is no small factor in the method, when we compare the dreadful struggles of the little sufferer at the sight of the commonly used—shall I not say abusively used—throat brush and bottle, and all the other implements of the more elaborate treatment to this simpler one of getting the child to open his mouth to drop a powder in, followed by a readily accepted spoonful of ice water. There is needed no argument to show which is the most desirable practically; and I can assure you that this needs but a faithful trial to show you the greater efficiency of this over all other plans of treatment in results.

But there are some rules which I beg you will follow faithfully. These are: 1, Give calomel in its purity. 2, Give it in large doses. 3, Give it frequently. 4, Give it until you have the free and characteristic catharsis. 5, Give light, nutritious diet. 6, Give little or no other medicine. 7, Keep your patient recumbent until convalescence is far advanced.

If these simple rules are followed and common sense is allowed to take the place of common prejudice, you will save more of your diphtheria patients by this than by any other method known to modern medicine.

THE EFFECTS OF DRY ATMOSPHERE ON CHRONIC INFLAMMATION OF THE LARYNX AND NARES.

Read before the meeting of the American Climatological Association held in Denver, September 21 to 5, 1893.

BY E. FLETCHER INGALS, A.M., M.D.,

PROFESSOR OF LARYNGOLOGY, RUSH MEDICAL COLLEGE; PROFESSOR OF DISEASES OF THE THROAT AND CHEST, WOMAN'S MEDICAL COLLEGE, ETC.

In this paper it is my object to invite your attention to a subject upon which unfortunately we have little precise information, hoping thereby to elicit a discussion in which the observation of others may help to remove the deficiencies which I am obliged to confess. The views which I shall here express are based on the study of a large number of cases, but I shall make no attempt to present the histories of these cases in substantiation. Most of my patients live in low altitudes, many of which are damp; though I fre-

quently see patients who live in a high and dry atmosphere.

In trying to analyze these cases I have been unable to decide satisfactorily what particular phases of the disease are benefited and what injured by the dry atmosphere. In the majority, I presume at least four-fifths, dryness of the atmosphere seems beneficial, but in some it is certainly injurious. At first sight it would seem that cases in which there is excessive secretion would be benefited by residence in a dry atmosphere, whereas those suffering from the opposite condition would be injured, but numerous cases attest that this does not follow in all instances: for example, in simple chronic rhinitis with excessive discharge, we find a given number of patients improved by removal from the shores of large bodies of water inland, but a limited number of cases with the same disease will be benefited by moving from inland districts to the damp climate of the sea shore, or the borders of our great lakes. We find now and then a patient greatly improved by going to a high altitude with a dry atmosphere, but usually catarrhal cases are injured by this change.

The more we see of these diseases, the more we are impressed with the fact that catarrhal inflammations are found alike in the damp, chilly atmosphere of the sea shore, or upon the arid plains of Arizona, in the most favored localities of our southern States, and in the delightful atmosphere of Colorado, though not to the same degree in each section.

We may assume that the inflammatory affections of the nares and larynx are essentially of the same character, and that therefore they will be influenced in a like manner, though in different degrees, by various climatic conditions.

These affections we will therefore class together as catarrhal excepting in those instances where we use a qualifying phrase, as for example, tubercular laryngitis.

Usually these catarrhal affections are less frequent in warm climates, therefore, a warm, equable atmosphere would seem best adapted for their prevention or cure. However, in equable climates the air is loaded with moisture, a condition which undoubtedly favors the development and maintenance of certain forms of catarrhal inflammation, yet the opposite condition of dryness also has its disadvantages, for it favors the formation of dust and allows the air to be laden with various irritating substances which might be absent in the damper atmosphere. As certain palpable substances in the atmosphere cause asthma, so in some cases similar substances will excite chronic inflammation of the mucous membrane of the upper air passages. The damp, and often chilly atmosphere of the Atlantic sea shore, and the sudden changes along the borders of our great lakes are peculiarly favorable to the devel-

opment of this disease. Nevertheless, a considerable number of the cases that come to those of us who practice in these localities have originated inland. We frequently find that a person having developed the disease in any given locality will be relieved of it by a change to some other locality, though the latter may be either dryer or more moist than the original residence. I know many that are afflicted with the disease upon the shores of Lake Michigan, who, upon going but a few miles into the country are at once relieved. I have known those who could not live with comfort on the sea shore to have but little difficulty upon the shores of our lakes. I have seen those who have attributed their whole trouble to the sudden and severe atmospheric changes on the borders of our great lakes to become much worse by residence in an equable climate. For example, a patient suffering from a moderate degree of hypertrophic rhinitis went from Chicago to Southern California in hopes of obtaining relief, but there he was unable to breathe through the nose at all, and he was compelled to return to Chicago.

With these conflicting facts before us, how can we determine what climate to recommend to our catarrhal patients? We have observed that as a rule they do best in a comparatively dry climate not more than one or two thousand feet above the level of the sea, but there are many exceptions to this. Occasional cases are greatly benefited by a sojourn in high altitudes, and I hope to hear from the physicians of this locality what particular phases of the disease improve in Colorado.

By ascertaining in individual patients the season of the year, and the kind of days when they feel most comfortable, we may often be able to judge of the most suitable climate for them. Yet it frequently happens with these cases, as with asthmatics, that the climate must be tried by each patient for himself in order to determine what atmospheric condition is best suited to his disease.

Before sending such cases from home we should try faithfully the methods of treatment which have been found most beneficial by expert laryngologists. If these do not succeed we should recommend a dry or moist climate, according to the kind of weather in which the patient feels best—at an altitude of not more than one or two thousand feet above the sea, or even less than this. High altitudes should be tried only incidentally, as they are not apt to prove beneficial.

My observation, which embraces several thousand patients, leads me to the following conclusions:

A dry atmosphere at a comparatively low altitude will generally be found beneficial in the following diseases:

In rhinitis intumescens, which is characterized by intermittent swelling of the tubernated tissues

with obstruction of one or both nares, and the consequent discharges into the throat.

In simple chronic rhinitis, with or without excessive secretions; providing there is but little irritation of the mucous membrane.

In atrophic rhinitis with excessive muco-purulent discharge, with but little tendency to drying.

In such cases of hyperæsthetic rhinitis as improve during the dryer portions of the year. However, most cases of hyperæsthetic rhinitis will be more benefitted by an equable climate even though the atmosphere be loaded with moisture.

A high and dry atmosphere is usually prejudicial in rhinitis intumescens and in atrophic and hypertrophic rhinitis, and indeed in all catarrhal affections occurring in patients of nervous temperament. These injurious effects may be ascribed partly to the dryness of the atmosphere, partly to the irritating dust often found in high altitudes, and partly to the effects of the rare atmosphere upon the nervous system which undoubtedly has much to do with the etiology of catarrh.

A high and dry atmosphere may be expected to prove beneficial in cases where there is excessive secretion with little or no nervous irritability; in some cases due to syphilis, and in exceptional cases of atrophic rhinitis with excessive secretion.

In inflammatory affections of the *larynx* we may expect benefit at a low altitude with a dry atmosphere; in simple chronic laryngitis, and in some cases of tubercular laryngitis. In the latter, however, I prefer an altitude of from 1,500 to 2,500 feet, and there is no objection to the atmosphere being impregnated with the odors of pine and fir which the laity consider of so much importance; but I doubt whether these are of any benefit.

In cases of laryngitis with deficient secretion, or excessive irritability of the mucous membrane, the moist atmosphere of equable climates is generally preferable.

A high and dry atmosphere is usually injurious to persons suffering from chronic laryngitis, but it is beneficial in exceptional cases. My observation, however, does not enable me to decide what cases will be improved by this condition. But it seems probable that benefit would be derived in certain cases of simple laryngitis in phlegmatic patients; in some cases due to syphilis in which the mucous membrane requires stimulation, and in exceptional cases of tubercular laryngitis, in which the beneficial effects of the atmosphere upon the constitutional disease more than counterbalance its deleterious influence upon the local affection. The latter are most likely to be found in patients in whom the mucous membrane of the larynx is not very sensitive. In laryngo-pulmonary tuberculosis patients usually do best at an altitude of from 1,500 to 2,500 feet, in a warm and dry atmosphere, but it is often difficult to

determine what is best for them because of the beneficial effects of high altitudes on tuberculosis of the lungs and their baneful effects on the same disease affecting the larynx.

The injurious effects of such an atmosphere on the larynx are often attributed to the dust which it contains, but the explanation is unsatisfactory, for in persons who are continually inhaling much more dust, in planing mills or machine shops, the injurious effects are oftener manifested on the lungs than the larynx.

It seems probable that the action of this atmosphere on the mucous membrane of the upper air passages is not very dissimilar to that of the wind and sun upon the skin unused to exposure.

Owing to its dryness it causes rapid desiccation and destruction of the superficial epithelial cells with consequent irritation of the subjacent tissues, which in addition to the increased flow of blood to the part, resulting from diminished air pressure, necessarily increase the inflammatory action.

70 State Street.

THE CLINIC.

A CASE OF EXOPHTHALMIC GOITRE.

A Clinical Lecture delivered at the Hospital of the University of Pennsylvania.

BY JAMES TYSON, M.D.,
PROFESSOR OF CLINICAL MEDICINE.

Our patient, a woman, aged 44, was born in Ireland, and is a servant by occupation. Her family history has no bearing on the present disease. Up to three years ago she had good health; at this time she became ill with rheumatism and was confined to her bed for a month. She recalls her knee as being badly swollen. At this time, too, she noticed for the first time a lump growing upon the front of her neck, first in the median line. With this she experienced a choking sensation, especially when she swallowed; but occasionally at night, when lying down, she noticed the same disagreeable symptom. At first the swelling increased slowly, but for the last year it has grown rapidly. As early almost as she noted the swelling she observed that her eyes began to protrude. Her weight at the outset was 160 pounds; it is now but 84, a loss of 76 pounds. The swelling is now on both sides of the neck and nearly symmetrical. The hand placed on it it detects not only a pulsation, but a thrill, more noticeable on the left side of the tumor. The eyes are also equally protruded, and show a large amount of the white. This produces the staring effect which you all notice; she can, however, still cover both eyeballs with her closed eyelids. These two most conspicuous symptoms, the goitre and exophthalmos, give the name to the disease of "exophthalmic goitre." But it is also

called "Grave's disease," and "Basedow's disease," from two observers who early described it. Another symptom noticeable with the thrill in the patient is the frequent pulse, which is also essential. At this time it is 122.

As to the exophthalmos, in addition to the varying degree there is also this less constant feature, first pointed out by von Graefe, and known as the Graefe symptom, viz.: a want of coördination in the motion of the upper eyelid and that of the eye. In health, when the eye is raised or cast down, the upper lid follows it. This does not occur when the Graefe symptom is present. This symptom is said to be diagnostic, and even to occur early in the disease; but it is not constant, and is not present in the case before us. The acceleration of pulse is rightly called essential, because it is always present. It is seldom less than 100, but rarely exceeds 140. In certain cases, however, it is said to have reached 200. Equally constant is dilatation of the blood-vessels, although not always as conspicuous as in this case. There is no corresponding rise of temperature. The three essential symptoms may therefore be said to be goitre, exophthalmos and frequent pulse. In order of appearance, the goitre is generally first noticed; the exophthalmos is next, while the palpitation may not be noticed for some time. The disease generally develops slowly, and these three distinctive symptoms may appear nearly simultaneously. The goitre in itself is in no way peculiar. It is usually of moderate size, not reaching the dimensions of the uncomplicated goitre. The tumor is largely contributed to by the vascularity of the part; although there is also an overgrowth of the glandular tissue of the thyroid gland. Other symptoms also exist. Hypertrophy of the left ventricle is one of these, but it is also absent in our own case. The heart's boundaries do not extend abnormally, although its beat is strong and forcible. The normal rhythm is also preserved; but arrhythmia occasionally occurs. A cardiac murmur is sometimes present; there is here evident mitral systolic murmur, heard less distinctly at the base. These murmurs are often hæmic, for these patients being often anæmic, furnish the conditions of the hæmic murmur. Another frequent symptom is the presence of what is termed "nervousness;" the patient is restless, quick, irritable. This may also show itself in the shape of tremor, either of a part or of the whole body; thus the legs or arms may be affected, or even more limited muscle areas. Sweating, sometimes unilateral, should be named as an occasional symptom.

Exophthalmic goitre is more common in women than in men, according to Trousseau, as 50 to 8. I do not remember having seen a case in a man. It is also more common in the young adult and middle-aged. This woman, who has been ailing for three years, was 41 before she

showed symptoms of this disease; she is the oldest patient with this disease that I have seen.

The relation of the symptoms to each other is difficult to determine. Indeed, there seems to be none, for they are rather the result of a common cause. What this cause is, is not known with certainty; but its nervous nature is generally conceded. Of the three great nervous masses, the brain, the spinal cord, and the sympathetic system, the latter seems the more likely centre of disturbance. Whether the change is one of paralysis or irritation is difficult to decide; each view serves to explain a number of points in the symptomatology of the disease. I am inclined to regard it as a vaso-motor paralysis. The dilatation of the blood-vessels of the thyroid gland and the exophthalmos are equally well accounted for from this standpoint. The eyes are protruded because the blood-vessels posterior to them are dilated and push them forward. The sweating which sometimes occurs is also thus easily explained. The increase in the frequency of the pulse would not be explained by paralysis, but by irritation of the sympathetic system. Such irritation would cause the heart to beat more rapidly; it would not, however, explain the exophthalmos.

As to prognosis, sooner or later most cases improve and some get well. Exophthalmic goitre is rarely fatal in itself; the opportunity for autopsies generally occurs when the patients die from other diseases. Occasionally the condition remains permanent, but in time the majority of cases get well, or at least improve vastly. I have a case under observation; a young woman who, ten years ago, had exophthalmic goitre, who is now well except that her eyes are slightly more prominent than is strictly natural; strangers would not notice it at all.

Whatever irritates or in any way produces a serious impression on the nervous system may cause exophthalmic goitre, such as shocks, trials, anxieties, sudden reverses of fortune; but we cannot ascribe any definite cause to the trouble. Here we are as much in the dark as elsewhere in the study of the disease. However, it is to be remembered that rheumatism is to be included among the causes, and our patient, who has had much rheumatism, may owe her trouble to it.

The treatment is directed to the symptoms mainly. The remedies most used are the bromides and digitalis; digitalis to slow and steady the pulse; the bromides for two reasons: first, as nervous sedatives; and secondly, for their reputed action in producing anæmia of the nerve-centres. In some cases, where there is no cardiac lesion and the pulse is good and strong, aconite with the bromides is of service. Ergot, for its power of contracting the calibre of blood-vessels, is also a rational remedy. This woman has been on carbonate of iron, ergot and digitalis. There is

a difference of opinion as to the propriety of administering iron. I believe the decision should be based on the condition of the patient and the presence or absence of anæmia. By German writers, galvanism of the sympathetic is claimed to be of service. The English physicians have not been so fortunate in its use. Theoretically it should be of service, and we will try it along with the other measures. A constant current of from five to eight cells is used; the negative pole is placed on the fifth cervical vertebra, the positive pole along the sternum. Up to the present our patient has improved under carbonate of iron, two grains at a dose, digitalis and ergot each one-half grain.

MEDICAL PROGRESS.

BACTERIOLOGICAL STUDIES IN SCARLATINAL ANGINA.—WURTZ and BURGESS (*Arch. de Med. Exp.*, May, 1890) have recently made some observations in this line that are of some practical importance. A few cases of scarlatina, in the Trousseau Hospital, were transferred to the pavilion for diphtheritics because of early development of false membrane in the throat. The bacteriological examination in all these cases revealed the streptococcus pyogenes, in a pure state, or associated with other microbes of suppuration. In none of the cases with early developing membrane did the authors find the bacillus of Klebs-Löffler. In two cases of angina with late developing membrane the specific bacillus was found to be present. One of these children that early presented the streptococcus pyogenes was undoubtedly secondarily infected in the pavilion for diphtheritics, to which it had been transferred.

The authors come to the conclusion, that the precocious angina of scarlatina is not, in the great majority of instances, of a diphtheritic nature, notwithstanding the gravity of the symptoms. It is important to differentiate these conditions and not send these patients among the diphtheritic, where they may contract a much more formidable disease.

CONDITION OF THE HEART AFTER DEATH.—The old statement that in death from respiratory failure the right ventricle was filled with blood and the left empty, while in death from heart failure the left ventricle is filled, has recently been questioned, and STRASSMANN (*Vierteljahrsschrift für ger. Medicin*) has added a series of experiments to the literature of the subject. Dogs were killed with prussic acid, blows, stopping the trachea, strychnine and hæmorrhage. The heart was examined immediately after death, and in cases of primary heart failure (also when death was caused by a blow), the left side of the heart

contained more blood than the right. In death from acute asphyxia the reverse was found. It is important that in no case, in any form of death, was the heart found in systole on immediate examination. The right and left ventricle were in diastole, soft and filled with blood, even in cases of strychnia poisoning.

In the later examinations, twenty-four hours after death, the conditions were greatly changed. When *rigor mortis* sets in the left ventricle empties itself and strongly contracts, even in cases where death was caused by heart failure, and at first the ventricle was soft and overfilled. These phenomena are present in the right side of the heart to a less degree, owing to the weaker musculature.

In those cases where *rigor mortis* is present and the ventricle soft and overfilled, the author thinks there is degeneration of the heart muscle. This condition was noted in two of the animals used for experiment: One was suffering from some infectious disease and the other died from prolonged chloroform narcosis.

From the experiments of this writer we are justified in receding from the position of the older authorities that the condition of the heart as found *post-mortem* is an index of its condition at the time of death. It is doubtful if the older observations of death from respiratory failure or heart failure are of any value, as the condition of the ventricle seems to depend upon the time that has elapsed since death.

CANNABIS INDICA IN GASTRIC DISORDERS.—A very useful contribution to our knowledge on the treatment of the various varieties of indigestion is published in the *Deutsche Medicinische Wochenschrift* of August 14 and 21 of this year, by Dr. G. SÉE, who, as stated in our Paris correspondent's letter of last week, has dealt with the same topic before the Academy of Medicine. After a full discussion of the forms of indigestion that are recognized, and the use of cannabis indica in their treatment, Dr. Sée arrives at the following conclusions: 1. The most convenient form in which to employ the drug is the extract, in doses of about $\frac{3}{4}$ gr. daily, divided into three portions. Above this dose the drug is apt to produce unpleasant effects. (The French extract is stronger than the English.) 2. The drug was chiefly tried on the non-organic affections of the stomach. These were divided into two groups. The first included cases in which the gastric juice was altered in composition, especially if there was an excess of hydrochloric acid. The second group consisted only of cases of gastro-intestinal neuroses, in which there was no change in the digestive juices. 3. All these affections—dyspepsias and neuroses—were characterized by five sets of symptoms, occurring in various proportions. (a) Pain, local or radiating, arising spontaneously or

after food. The variations in appetite belong to this group. (b) Atony of the stomach, with or without dilatation, is almost always present. Vomiting is more frequent in the neurotic cases. (c) Flatulence and eructation occur in most cases; in the neuroses the gas consists chiefly of air which has been swallowed; gases formed by decomposition arise from lactic or acetic acid fermentation, and not from excess of hydrochloric acid. These gases are the cause of the painful symptom known as "heartburn." (d) The gastric digestion of flesh food and albuminoids is little affected when hydrochloric acid only is in excess, but it is deficient when too much lactic or acetic acid is present, and completely in abeyance when there is deficiency of acid. In the neurotic cases gastric digestion is normal. Constipation is the rule in most cases. (e) In this last group are placed the varied symptoms—giddiness, migraine, palpitation, agoraphobia, etc. 4. Cannabis indica gives relief from pain and increases the appetite in all cases, no matter on what causes the pain and loss of appetite may depend. If, however, too much hydrochloric acid be excreted, it is better to aid the action of the drug by large doses of bicarbonate of soda, given about four hours after food. Cannabis indica has no beneficial action on the atonic state of the stomach, but it relieves vomiting and cramp of the stomach. The drug has no direct influence in checking flatulence, but it aids the expulsion of the gas and diminishes heartburn. The digestion of food is improved, if the failure depends upon neuro-paralytic conditions, or is rendered painful by an excess of acid, but no improvement is produced if the disorder is caused by a want of acid. As regards the other symptoms—giddiness, sleeplessness, palpitation, and the like—some relief is generally experienced by the use of this drug, but no alteration for the better is noticed in the hypochondriacal, hysterical, or neurasthenic conditions. In short, cannabis indica may be said to be a true sedative to the stomach, without causing any of the inconveniences experienced after the administration of opium, chloral, or the bromides. It should be combined with the use of alkalis in large doses and with mild aperients.—*Lancet*.

PERIODICAL PARALYSIS OF THE FACIAL AND ABDUCENS.—Periodically recurring paralysis is an exceedingly rare affection, and one that is most difficult of explanation. It is not long since Moyer and Hinde reported a typical case of periodical oculo-motor paralysis, and now we have an account of a similar paralysis, in other motor nerves, from the pen of NIEDEN (*Centralblatt f. prakt. Augenhkde.*). The patient, a woman 36 years of age, of good health, free from syphilis, and who had borne seven healthy children, was taken in January, 1884, with a severe pain in the back of the head and spasm of the right side of

the face. Suddenly the left half of the face became paralyzed, which after a time disappeared. Fourteen days later it returned, but yielded after four weeks' treatment with electricity and iodides. In April, after severe headache, the external rectus became paralyzed, and eight days later difficulty in speaking and chewing developed. When protruded the tongue turned to the left. Sensibility of the tongue, and taste normal. The paralysis of the sixth nerve and tongue disappeared after six weeks. In June, 1887, again after confinement, paralysis of the right facial nerve took place, preceded for some weeks by severe headache. This attack disappeared in four weeks. In February, 1889, after severe headache, paralysis of the right adducens, and light left-sided facial paralysis. Recovery in eight weeks. In May, 1890, complete right facial paralysis. This last attack was, like the others, preceded by pain that ceased as soon as the paralysis developed.

The author remarks that in this rare case it is probable that changes are present in the nuclei of the facial and abducens, though the nature of such change is purely speculative.

DIURETIC ACTION OF MILK SUGAR.—Milk and buttermilk have long been recognized as excellent remedies in treatment of diseases of the kidney. It is not long since Sée announced the diuretic properties of milk sugar and recommended its use in dropsy dependent upon heart lesion. His observations were soon confirmed by Dujardin-Beaumetz. We have recently had additional confirmation from the pen of DR. ZAWODSKI (*Deutsche Med. Ztg.*) who employed this treatment in a severe case of dropsy with excellent results. Unlike Sée and Beaumetz, he made no change in the diet of the patient and allowed him to take fluids. The dose also was lessened to 12 to 18 grams a day given with a considerable quantity of milk, that contained at least 50 grams of milk sugar.

The author thinks that this substance is to occupy a prominent place among the diuretics, as it is easily administered, agreeable in taste and of low cost.

REMOVAL OF BREAST DURING HYPNOTIC SLEEP.—DR. SCHMELTZ, of Nice, has recently (*Gazette Médicale de Strasbourg*, July 1) recorded a case in which he removed a sarcomatous breast during anæsthesia caused by hypnotism. The patient was a girl, aged 20, who was easily thrown into the hypnotic state. The operation was performed in the presence of Drs. Lauza and Barriera, and the entire organ, together with the aponeurosis of the pectoralis major was removed by the oval incision. Five drainage tubes were inserted and the wound was closed with thirty-two-metallic sutures. The operation lasted an hour. The patient remained absolutely insensi-

ble, in a condition of the deepest anæsthesia, such as is only seen after large doses of chloroform. Dr. Schmeltz says: "I operated very slowly and quite at my ease; the patient even tried to encourage me by her words; she seemed very gay, and laughed loudly from time to time as if to show that she felt no pain. In order to make the operation easier for me, she turned herself about so as to place herself in the most favorable position, keeping her right arm stretched out so that no assistant was required to keep it steady." She was kept under observation the rest of the day, and having been told not to feel pain and to have a good night, she obeyed these instructions in the most docile manner. The wound was completely healed on the fifteenth day. The only symptom worth mentioning, which Dr. Schmeltz observed in the patient during the operation, was great pallor of the countenance, without any dilatation of the pupil or weakening of the pulse. The tumor weighed 2 kilograms.—*Brit. Med. Journal.*

RELATIVE VALUE OF DIFFERENT METHODS OF TREATING UTERINE MYOMA.—M. R. PICHERIN (*Gaz. des Hôpitaux*) has recently made a careful study of the different methods of treating uterine myoma. He classes castration as among the palliative remedies, while he considers it quite as dangerous as the radical hysterectomy. The principal objection to the removal of the ovaries in these cases is that in all cases it does not bring on the menopause, it does not constantly reduce the size of the tumor, that it is a dangerous and often difficult operation, with a mortality of nearly 14 per cent. In conclusion he says, that the great operators are not agreed upon the indications for oöphorectomy, and he therefore comes to the conclusion that hysterectomy, as it is quite as safe, should be preferred in the majority of instances. The writer speaks warmly of the electrical and medicinal treatment of fibroids, and says that the radical operation should only be thought of after these have been faithfully tried.

GASTRO-HYSTROPEXY.—M. POZZI performs hysterorrhaphy after certain modifications introduced by himself. The uterus having been exposed and brought forward till it touches the abdominal wound, a continuous silk suture is passed through the posterior sheath of the rectus close to its cut edge on the left side, the peritoneum, and the uterus in the middle line, and hence to the peritoneum and sheath of the rectus on the right side of the wound. The uterus is transfixed three times in this manner, the needle passing a short distance under the serous coat, further in the uppermost than the lower points of the transfixion. The suture is finally tied and cut short. The more superficial layers of the abdominal wound are sutured separately. M.

Pozzi described two cases of retroflexed uterus bound down by adhesion where this operation was performed, in the *Annales de Gynécologie* for June, 1890. The first case was a complete success. Alexander's operation had already been attempted without giving relief. In the second there was suppuration of the lower part of the wound, which the operator attributed to the fact that the silk suture had not been sufficiently boiled. The uterus in each case remained firmly fixed to the parietes. M. Pozzi prefers the continuous sunken suture to the interrupted suture passed outside the integuments, and removed on or about the fifteenth day after operation, as practised by Leopold, who considers that a relatively loose adhesion is sufficient.

THE BACILLUS OF PURULENT URINE.—Some experiments have been made in the laboratory of Prof. Strauss, in Paris, by DR. KROGIUS, on the puriform urine of ten patients suffering from chronic stricture, with catarrh of the bladder and pyelo-nephritis. In one of these cases a bacillus was found of rather polymorphous appearance, resembling a small mobile pencil with rounded ends. The bacillus was from 1.8μ to 3.6μ in length, with a breadth equal to one-third of its length. When cultivated the length became considerable, but it developed no spores. It was easily dyed by aniline, but with equal facility decolorized by Gram's method, and it liquefied gelatine. At a high temperature it developed most peculiar colonies. They were distinguished by a strong characteristic odor resembling that of purulent urine. The development of ammonia was very marked. The bacillus very quickly decomposes urea into carbonate of ammonia and water. When newly cultivated and injected in doses of $\frac{1}{2}$ cubic centimetre into the subcutaneous connective tissue, veins, or peritoneum of rabbits, it often caused death in two hours, and never took more than two days to act fatally. Older bacilli are still more poisonous. The puncture shows first œdema and redness, and then the epidermis becomes gangrenous, with an ammoniacal odor. The animals themselves are, in a few hours after the injection, in a state of high fever, prostrated, and suffering from profuse diarrhœa, and ultimately coma comes on, during which they sometimes die in convulsions. The bacillus is called by the author "liquefaciens septicus."—*Lancet*.

A NEW OPERATION FOR CANCER OF THE RECTUM.—DR. AXEL IVERSON, of Copenhagen, presented a communication on this subject to the Tenth International Medical Congress, as follows: One can never know with certainty whether the disease is limited to the rectum or whether the neighboring glands are also involved, and it is difficult to settle the question as to whether an

operation is indicated. Colotomy will relieve for a certain time, and often, indeed, for a long time, the symptoms dependent upon the co-prostasis, but it does not help the pain nor reduce the fœtid secretion. The want of a more radical operation for the relief of this terrible disease is therefore still urgently felt. It is known that cancer of the rectum often remains stationary for a long period, and the author had made autopsies on 47 long-standing cases, in 21 of which there had been no metastasis. This fact gives hope of success from a radical operation. In judging of the latter we need not consider the direct mortality so much as the tendency to a return of the disease. The author then presented statistics of 247 cases of operation for rectal cancer performed in the Scandinavian countries, which showed only a very small number of patients who had survived the operation for several years without having had a local relapse. The results of extirpation were slightly better, as regards prolongation of life, than those of colotomy, but they were little or no better in respect to relief from pain. The author then spoke of the different methods at present in favor, showing wherein they were defective. He thought too great an effort had been made to preserve continuance of fœces, and the operations therefore had not been radical enough. The surgeon should not hope for too much—the essential thing is to make the operation a radical one. A partial operation should be undertaken only when the disease is strictly limited to the anus. In every other case, if one is to operate at all, it is necessary to perform total extirpation of the rectum, making a permanent artificial anus in the sacral region. Unless this is done, it will be impossible to remove all the glands which are liable to be infected. The extirpation of the tissues surrounding the intestine is also necessary, as here are often located the "seedling" cancers. The operation is performed as follows: After a preliminary Kraske operation, with or without resection of the sacrum, oval incisions are made surrounding the anus, and then the rectum is dissected out from below upward, care having been taken to tie a ligature around the anus in order to prevent escape of the contents of the gut. All the pre-sacral connective and adipose tissue is then removed. Next the peritoneum is opened and the intestine drawn down. Now the intestine and the parietal layer of the peritoneum are stitched.—*Medical Record*.

BACILLUS OF WARTS.—A bacillus has been found in the "prickle layer" of common warts by DR. KUEHNEMANN (*Monats. für Prakt. Derm.*) It is described as very slender and delicate, occurring both in and between the cells. This fact would account for many curious phenomena which have been noted in regard to these tumors.

SATURDAY, OCTOBER 11, 1890.

ABSORPTION BY THE SKIN.

It has been repeatedly held that the sound skin will absorb substances in watery solution, and again it has been denied. The teaching of our standard text-books for the past dozen years has been that of PARISOT, who said that the skin was unable to absorb any substances from watery solutions, and that this was due to the fat nominally present in the epidermis and pores of the skin. According to RÖHRIG all substances which act upon and corrode the skin, are capable of absorption. This fact was later confirmed by RITTER and PFEIFFER, who found that salicylic acid was rapidly absorbed when brought in contact with the skin, and other substances brought in contact with a part previously treated with salicylic acid, rapidly entered the circulation. The experiments of these writers would seem to be conclusive as to the impossibility of substances passing through the sound skin. In only one instance out of five did they succeed in detecting iodide of potassium in the urine when a salve containing 10 per centum of that drug had been rubbed into the extensor surfaces of the arm and leg. In the instance where it was absorbed, it had been in contact with the part for four days, and the rancid fat had probably disorganized and softened the epidermis.

Recently, other writers have busied themselves with this vexed question, notably KOPFF, who plunged a portion of the body in a solution of sublimate with potassium iodide, and recovered these substances from the urine. M. STAS ex-

perimented in a similar way with arseniate of potassium, with negative results.

A late number of the *Gazette Médicale de Liege* contains an abstract of the experiments of DR. KILLER, who sought to solve the problem by estimating the amount of chlorine excreted in a given time upon a fixed diet. The first experiments were with full warm baths containing 6 per cent. of sodium chloride. The results were as follows:

Before the baths (3 days)	1.605.
During " " (7 ")	2.108.
After " " (2 ")	1.431.

A second series of ordinary baths (not salt) gave:

Before the baths (2 days)	1.750.
During " " (3 ")	1.177.
After " " (2 ")	2.291.

A third series with salt showed practically no change in the amount of chlorine excreted by the kidneys before, during, or after the baths. As the author says, even the favorable second series does not prove cutaneous absorption, as the baths may have modified elimination of sodium chloride by the tissues. To avoid this source of error he chose the iodide of sodium, a salt not normally present in the body. Of eighteen trials with this substance, eight were negative, and in two of the positive cases one was where the arm plunged into the solution contained a small blister, and in the other, a full bath; it is possible that absorption may have taken place through the natural orifices.

In conclusion we can say that recent experiments only go to confirm the views of older writers, that absorption of substances in watery solution is practically impossible with a sound epidermis. Substances that corrode or soften the epidermis will aid absorption, and the prolonged application of water will macerate the epidermis and in that way admit substances to the circulation.

THE AMERICAN MEDICAL ASSOCIATION IN RELATION TO ORIGINAL SCIENTIFIC RESEARCH.

In the editorial columns of THE JOURNAL of June 14 we referred to the necessity of the creation of a special Section to consider papers presenting the results of original investigation, or of the adoption of some means to encourage such work. The special advantages that THE JOURNAL possesses for the dissemination of the results

of original work are so manifest, when compared with the limited circulation of the reports of hospitals, laboratories, or special societies, that any discussion of that feature of the question is supererogatory. And in an editorial article in *THE JOURNAL*, of August 2, we presented the desirability of more intimate relations between the work of State Medical Societies and that of the American Medical Association, and we may consider this subject as a means to attain such an end. In a leading article in the *New York Medical Journal* of August 16, on "The Relation of American Medical Societies to Scientific Research," the point is made that aside from an occasional scholarship at some university, or the various prizes that are offered for the "best essay, etc." any of our physicians that may desire to undertake some special investigation are compelled to purchase their own chemical or physiological apparatus as well as the material necessary to pursue the investigation. It is urged that the desideratum is means with which the requisite appurtenances may be purchased for competent investigators that can ill afford both time and money; and the suggestion is made that the numerous American medical societies imitate the British Medical Association and allot certain sums of money to qualified physicians to purchase what may be needed to make some special investigations.

It may be information to some of our readers that the British Medical Association, according to their *Journal* of July 26, in 1889 allotted twenty-five hundred dollars, in sums of from fifty to two hundred and fifty dollars, to members in various portions of Great Britain for expenses necessary in making original research.

At present the finances of the American Medical Association do not justify such a diversion of its funds; though the highest aim of our organization must necessarily tend to the realization of measures to encourage and foster original research. But a number of the State Medical Societies have an accumulated fund that could be used, under the direction of a judiciously selected committee, for such purposes. If, instead of the large annual volumes of *Transactions* published at considerable expense to the Society, the latter would confine its publication to the *Official Transactions*, referring such papers as a publication committee recommends to *THE JOURNAL*, the working

expenses of the State Societies would be diminished, consequently more money could be utilized for the purpose we are considering, and a more intimate relation would be established between the State Associations and the American Medical Association.

Such a plan would involve no diminution of the autonomy of a State Society; it would permit many qualified physicians undertaking experimental research who are now deterred by the attendant expense of these investigations; it would give the scientific papers of the State Associations an audience that volumes of *Transactions* do not reach; and well conceived original work would redound not only to the benefit of humanity but to the credit of the investigator, the State Association, and the reputation of American medical science.

A SOUTH AMERICAN QUARANTINE.

The establishment at the mouth of the Rio de la Plata, in Uruguay, used in part as a quarantine station, is a strange combination of hotel, prison, military camp and seaside resort. It is situated on the Flores island, the sovereignty of which is vested in the Republic above named. In the summer months, everything that comes from the neighborhood of Rio de Janeiro is under the ban, on account of the dread of yellow fever, and every person from that port is detained until ten days shall have elapsed from the time of sailing. A single boat-load may comprise from 300 to 600 visitors. Although the accommodations at this Grand Quarantine Hotel are poor the people who journey that way must stop there until the specified time has expired. There are all classes of passengers, as first class, immigrants, traders, officials and the like. When the crowd arrives at the hotel, it is sorted out and packed away, entirely at the mercy of the management, since it is the only place on the island where shelter can be had. A permanent garrison is maintained, and it includes a commandant, surgeon, State's secretary, postmaster, lighthouse keeper and telegraphists. Every morning, during pleasant weather, a tugboat comes over to the hotel from Montevideo, with the mails and provisions. When a "norther" prevails, the tugboat does not come, and inasmuch as the storm may continue as long as five days, the stock of supply may fall to near-

ly the starvation point. As one visitor writes: "Think of stopping at the largest hotel in the world and not being able to get more than one or two meals a day, with bananas for one of the meals. This was during a storm that lasted five days, and there were fully a thousand guests on the island at that time." Protests addressed to the officials are unavailing—they are a little autocracy all by themselves—and patience for those few days is the best and only remedy for the disagreeable situation.

EDITORIAL NOTES.

RECOGNITIONS OF MERIT.—Rush Medical College is fortunate in bringing to its Chair of Physiology the services already so valuable and so full of promise in the future as are those of Dr. Harold N. Moyer. Dr. J. A. Lydston will be a valuable accession to the Faculty of the Chicago College of Physicians and Surgeons as Professor of Chemistry.

SPERMINE.—Dr. Pohl, of St. Petersburg, writes to *Le Mercredi Medical* that he believes that the crystals found in the seminal fluid, as described by Schreider, are the phosphate of an organic base called spermine, which is identical with ethyleneimine, according to Laderberg, and Obel. Pohl has extracted spermine from the testicles of young rabbits, and has used it experimentally. He has observed that it decreases the action of the heart, while it increases the general energy and stimulates the nervous and genital systems. He thinks it probable that castoreum and musk owe their nervine properties to the spermine which they contain. The crystals of the phosphate of spermine have been named the Charcot-Neumann crystals. Ethyleneimine is an artificial product which is isomeric with spermine. Possibly, also, some of Brown-Séguard's results may find their explanation in the hypodermic injection of this leucomaine, spermine, or some other similar substance, which can, in the future, be isolated and definitely described.

THE HYGIENIC ARREST OF LEPROSY.—Dr. Sandreczky, of Jerusalem, has described his treatment of a case of leprosy, which has been under observation four years and which he thinks may fairly be said to be "cured." After two years of treatment the progress of the malady appeared to be stayed; there has been no relapse and all signs

of the disease have disappeared excepting the atrophy of the hands which, of course, is permanent. The case, as given in *Monatshefte für praktische Dermatologie*, was that of a child whose family history was free from leprosy. The treatment was directed principally upon lines of general hygienic management, such as open air exercise, massage, bathing, iron and quinine; the baths were varied with green soap, sulphur, iron or salt, the water being very hot, and free perspiration being promoted by means of proper coverings over the body after each bath. The tubercles were treated by chrysarobin, green soap or iodine, without any manifest benefit.

A POLICLINIQUE AT PARIS.—An institution has been opened at Paris, which bears a close resemblance to the post-graduate schools of the United States. It is located at No. 28 rue Mazarin, as a dispensary and teaching institution, under the title of the Polyclinique de Paris, and is designed to become a centre for practical medical teaching.

THE proceedings of the recent Berlin Congress, which include more than 200 addresses and discussions, will be published in full in a large work, which will appear in separate parts. It is expected that the first part will be ready in the course of the autumn.

A BILL making vaccination optional in Holland has been introduced into the legislative chambers by the Dutch Government. The Minister of the Interior is said to be a member of the Anti-vaccination League, but it is not thought at all likely that the proposal will be adopted by the States-General.

CLINICAL TEACHING AT MOSCOW.—Extensive additions have recently been made to the buildings used for the purposes of clinical teaching at Moscow, and the medical faculty of that University is now of the best equipped in Russia. The Imperial Treasury provided funds for the erection of a University Clinic, and private munificence furnished the means of building clinics for mental diseases and gynecology, and for the instruction of midwives. All these will be officially opened at the beginning of the scholastic year, and a new clinical hospital will also be opened in January, 1891. The total superficial area of the new clinics is 20,000 square feet. In addition

to these new buildings, a children's hospital is in course of erection close to the University Clinic, and will be opened this autumn.

CHOLERA.—Cholera has broken out at Massowah, and the deaths there number fifty daily. The outbreak is stated to be among native tribes under Italian protection. The troops and European residents are free from the disease. A sanitary commission is on its way to Massowah with medicine and disinfectants. Cholera appeared at Aleppo on September 12. In the beginning of September cholera decreased in Spain, but recently there has been an increase in the cities of Toledo and Valencia, and the epidemic has reappeared in villages of the provinces of Albacete, Alicante, Castellon, Tarragona and Toledo, where it had subsided. The city of Valencia still has a high rate of mortality.

MICHIGAN BOARD OF CORRECTIONS AND CHARITIES.—At a recent meeting the Board passed the following resolution:

Resolved, That this Board advise the Boards of Control of the Asylums, Prisons, Reformatories, the State Public School, and Industrial School for Girls, the Institution for the Deaf and the Blind, to appoint a consulting medical staff consisting of a surgeon, ophthalmologist, aurist, neurologist and gynecologist, in connection with each institution, excepting those to which males only are admitted, where a gynecologist will not be needed. That these officers be known as consulting surgeons, aurists, etc., in the records of the institutions; that they be paid only for visits to the institutions, and that those visits be subject to the call of the superintendents, wardens, or other chief officers, or the Board having the institution in charge.

THE late Sir Munguldass Nuthoobhoy, C.S.I., of Bombay, by his will directs his executors to build, on land adjoining the sanatorium which he founded, a bungalow, to be used as a dispensary, for which purpose he bequeaths 10,000 rupees, and for its maintenance 30,000 rupees. To provide a Hindoo licentiate as a medical officer he gives 30,000 rupees, and for the maintenance of the sanatorium 10,000 rupees.

A HEAVY SUIT FOR DAMAGES.—A libel suit for \$200,000 has been entered by William Radam against the *Druggists' Circular* of New York. Radam is the manufacturer of a much advertised microbe-killer, and his alleged damages are for the largest amount, so far as heard from, that has ever been asked in a suit of this nature. The allegations of the complaint show that the business of the said Radam has been damaged by an ar-

ticle published in the *Circular* in September, 1889, which gave the result of an analysis of the "killer," said to have been made by Dr. R. C. Eccles, of Brooklyn, who is one of the recently elected members of the Committee of Revision of the Pharmacopœia. Dr. Eccles stated in that article, that an identical preparation could be made by the following formula:

Oil of vitriol, impure, 4 drachms,
Muriatic acid, impure, 1 "
Red wine, about 1 ounce,
Well or spring water, 1 gallon.

This mixture can be made at a cost of less than five cents per gallon, while a gallon of the original fluid was usually sold at three dollars. It was further alleged that, while muriatic and sulphuric acids, the principal ingredients of the nostrum, could be properly prescribed, by professional advice, as medicines, yet when taken without due caution and counsel tended to become a hurtful poison; and that the theories of the said Radam, as to the cause and treatment of diseases, were asserted to be entirely erroneous. Colonel Robert G. Ingersoll, the renowned lawyer and lecturer, has undertaken the cause of the plaintiff. The proprietors of the *Circular* have expressed the desire that any physicians, who have observed unfavorable results from the use of the "killer," or other facts, interesting under the circumstances, will communicate with them. They claim that their publication of Dr. Eccles' analysis was without malice, and for the furtherance of the health and welfare of the general public, as against a nostrum dangerous alike in design and practical results.

On August 2 the King of Italy signed decrees relative to the organization of "municipal laboratories of hygienic vigilance" throughout Italy for the examination of foods, beverages, etc. These laboratories must comprise at least two departments—namely: a "medico-micrographic" and a chemical one. They are to be under the direct control of the Minister of the Interior.

THE next quarterly meeting of the newly-formed Association of Massachusetts Boards of Health will be held in Worcester October 15. The subject for discussion will be sewage and its treatment. Dr. L. P. Kinnicut will read a paper on that subject, which will be followed by discussion. Upon invitation of City Engineer Allen the members of the Association will pay a visit of inspection to the new sewage purification works at Quinsigamond. It is expected that several sewage experts from Boston and other cities will join the inspecting party.

TOPICS OF THE WEEK.

THE "POLYCLINICO" AT ROME.

British medicine has more than its share of interest in this great work, which, when completed, will be an event of European importance. Not only will the grand façade of its surgical department present as its chief ornament the likeness in bas-relief of the English surgeon who discovered the antiseptic treatment, but the whole building, or rather groups of buildings, will bear the impress in almost every detail of British example and British influence. As already shown, the "Policlinico" is due to the inspiration of the leading physician and consultant of Italy, the statesman, scholar, and man of letters, Dr. Guido Baccelli. Thanks to his prudence, energy, and weight in official circles it is steadily advancing to completion, when the monetary crisis of Rome is causing the suspension of other architectural undertakings only less important. The site on which it stands, the south-east of the city, between the Porta S. Lorenzo and the Porta Pia, skirts on its urban side the Prætorian Camp, whence it stretches out toward the Sabine hills over a space of 160,000 square metres, circumscribed by ample approaches thirty metres wide. The architect bears an honored name in his profession, Giulio Podesti, and has more than fulfilled the expectations he inspired. Under him, again, works Signor Cerebelli as builder, with a "technical office" at his command; while the supreme direction is entrusted to a "commissione governativa," composed of the distinguished surgeon Durante and the equally distinguished physician Bastianelli, with Dr. Baccelli at their head. As one enters by the main approach to the "Policlinico" he is confronted by the "palazzo dell' amministrazione," from which on the ground floor and first floor branch off four great galleries, communicating with all the buildings of which the institution is composed. These consist of three compartments. To the right of the "palazzo dell' amministrazione" is the "comparto medico;" to the left, the "comparto chirurgico;" and at the south-east corner the compartment for infectious and contagious maladies, the laundry, and the "anatomico-pathological institute," with the "camera mortuaria" attached. At the back of the "palazzo dell' amministrazione" are the bath-rooms, the kitchen and the chapel. Every compartment is composed of several clinics, which lie along the principal frontage. To the right, the medical, divided into propædentic, neuro-pathological, medical properly so-called, syphilitic, and pædiatric, to which is annexed a hospital for patients. This hospital, divided into twenty-two pavilions, accommodates easily 295 patients. The "comparto chirurgico" to the left is distributed into the following clinics: the propædentic, the aural (otiatric), the surgical proper, and the ophthalmic; while the "ostetrica-ginecologica" occupies the other corner corresponding to that dedicated to infectious and contagious diseases. This compartment also has a hospital attached accommodating 210 beds for teaching purposes. These clinics accommodate 141 of both sexes; the "comparto chirurgico," as a whole, having 351 beds, and the obstetric

institution 60; so that the entire policlinique provides for 878 patients. The space unoccupied by the buildings is divided by footpaths intersecting parterres, gardens, and fountains. Special operations of transport—as of patients, linen, cadavera—are effected through the immense galleries which place the several buildings in communication. Finally, the "Policlinico" will be provided with every appliance known to the best-appointed hospitals and schools of Great Britain and America, for ventilation, heating, and in the matter of lifts and conveyances for the patients. Dr. Baccelli, with an economic skill not always displayed in such vast undertakings, has succeeded in keeping the outlay, at least so far, within the estimates; which serves to explain the fact that the "Policlinico," which he fondly designates "il mio pomo d'Adamo" (the apple of his eye), as within measurable distance of being *un fait accompli* when other architectural enterprises in Rome are in suspension, if not deferred to the Greek Calends for want of funds.—*The Lancet*.

MODERN EMPIRICISM.

There seems to be a growing danger, which should be recognized and guarded against by students and practitioners of medicine, that physico-chemical research, with the expert inductive reasoning requisite for the application of such research to therapeutics, may result, in consequence of the technical nature of such reasoning, in practice without reasoning; that the rationalism of the few may tend to a form of empiricism in the many.

Few practitioners have opportunities of verifying otherwise than empirically the effects of a new remedy which they "try" on the authority of the physiologist or chemist; hence it follows that in the employment of the newer remedies, there is not now the same familiarity of the workman with his tools which existed fifty years ago in the days of apprenticeship, when an intimate knowledge of the remedies usually employed did not require special training and skill in the higher departments of physiology and chemistry, and when the student was able to master in his course of study the nature and properties of the drugs which were to serve him as the tools of his craft.

This seems to be an inevitable effect of progress in every art, the practice of which is based on advancing science; but it has come to the practice of medicine later than to others.

The popular and commercial names which have to be used for some of the newer drugs, instead of the cumbersome scientific combinations of syllables which indicate their constitution—such as antipyrin, antifebrin, urethæ, hypnone, somual, salol, thallin, etc.—must not be allowed to veil from the practitioner the real nature and constitution of such bodies; and, although it is impossible for the majority to do otherwise than use these remedies somewhat blindly on authority, the attempt must be made to understand the physiological and chemical principles on which the molecular constituents of such remedies are built up, and their efforts combined or neutralized in the many forms of the therapeutical agents now produced synthetically in the laboratory of the physiological chemist.—*Cor., Brit. Medical Journal*.

PROHIBITION OF HYPNOTIC PERFORMANCES IN RUSSIA.

The Russian Medical Department has just issued the following circular (*Vestnik Obshtchestvennoi Higieny, Sudebnoi i Prakticheskoi Meditsiny*, August, 1890, p. 12):—"In consideration (1) that public exhibitions of hypnotism cause considerable injury to the health of subjects experimented upon as well as of spectators witnessing the experiments, the performances being apt to give rise to the development in hypnotized persons of various hysterical, nervous, and even mental affections, which may sometimes amount to a genuine epidemic of hypnotic mania; (2) that such public hypnotic entertainments offer to evil-minded subjects a good opportunity for studying methods of hypnotizing, and for subsequently practising them for various immoral or criminal purposes; (3) that generally such hypnotic performances, being not accompanied by any rational explanation, can breed in the public only erroneous notions, and even implant superstitions, while post-hypnotic suggestions can constitute a source of disturbance of order and the peace of the community by hypnotized persons, and even of committing criminal deeds by the same, the Medical Council has resolved: (1) That henceforward any public *séances* of hypnotism and magnetism are strictly prohibited; and (2) that the application of hypnotism for medical purposes can be permitted solely to medical practitioners, under the condition that the operation is to be practised invariably in the presence of other medical men." It is scarcely necessary to add that the leading Russian medical journals welcome the circular, the necessity of the measure having been unanimously advocated by them year by year.

ANTHROPOLOGY IN GERMANY.

The Congress just held at Münster affords ample proof of the progress Germany is making in anthropological research. Two hundred members were present, and, as usual, Professor Virchow was the most conspicuous and the most honored of the number. The President (Professor Waldeyer) in opening the proceedings, reviewed the history of the German Anthropological Society since its origin at Innsbruck in 1869, and among its achievements he signalized the splendid prehistoric map and the catalogue of prehistoric treasure-trove now approaching completion. At Virchow's instance, comprehensive researches have been made on the racial characteristics of Germany, and from the color of the hair, the skin, and the eyes, it has been ascertained that a blonde and a brown Germanic people dwell side by side in a sort of interlinear fashion. A very interesting memoir on the anthropological features of Westphalia as they emerge from prehistoric investigation, was followed by Virchow's short addresses on the occurrence of bronze ornaments in the Caucasus, on the application of antimony as a cosmetic, on von Schliemann's excavations, and on the cradle of the peoples in Interior Asia. An elaborate paper by Waldeyer came next, on the perennially interesting theme of the antiquity of mankind, including the points of resemblance between it and the higher grades of animals, as well as the importance of climatic influ-

ence, coupled with that of civilization, on the human skull-formation. The last day's sitting was a very animated one, mainly on account of the discussion evoked by a paper giving anthropometrical results based on the measurement of 2,100 English students. The growth of the bodily powers, it seems, proceeds steadily up to the twenty-fourth year, after which it begins, at first almost imperceptibly, to decline. This limit, however, can by no means be assigned to the intellectual powers, which go on increasing till a much later life-period. Another paper of peculiar interest to army surgeons was read by General-Secretary Ranke, on the corporeal measurements of the Bavarian recruits and the physical deductions to be drawn from these. The final contribution, that of Dr. Finke, on the "History of Westphalia, from the Earliest Times up to the Introduction of Christianity," was in some respects the most elaborate and striking of all, though the interest appeared at first to be of a purely local character. It was the work of a most accomplished anthropologist, and showed among its rich antiquarian, sociological, and artistic details what a field of important and stimulating knowledge lies in the immediate neighborhood of every true man of science. The customary banquets and excursions varied the work of the Congress most agreeably, and Virchow, in a genial toast at one of the former, proclaimed that in the interests of science the Münster Academy should be promoted into a fully equipped University. One most significant and gratifying feature of the gathering was the large number of medical men who took part in the proceedings.—*Lancet*.

THE EFFECT OF ENVIRONMENT.

The Rev. W. H. Dallenger, F.R.S., in his address delivered before the Bristol Naturalists' Society, pointed out that in the case of larger animals it was well known that changes in the environment produced change in the organism, but on account of the slowness of succession of the different generations, it was impossible for any one observer to follow up these changes to any extent. In the case of microorganisms, however, the succession of the generations takes place with such rapidity, that it becomes possible to produce well-marked change in the organism by the gradual increments of variation in the environment. In the case of one microorganism, he had been able in some eight years so to change it that it could live and multiply at a temperature of 157° F., although its optimum temperature at the beginning of the experiment was 65° F., and the upper limit at which it could live 100° F.

THE SANITARY CONDITION OF LIVERPOOL.

The position of Liverpool as one of the most frequented ports in the United Kingdom renders it peculiarly liable to the introduction of infectious diseases from abroad, and it suffered severely during the cholera visitations of 1832, 1849, and 1866. It places the system of sanitary inspection of the port in a favorable light, that since the outbreak in 1866 only two cases suspected to be cholera have occurred; and the experience of the last twenty-four years gives good ground to believe that cholera in the South of Europe will not spread to that city.

PRACTICAL NOTES.

POMADE FOR PRURIGO.

R—Boric acid.
White wax ̄ā 10 parts.
Parafine, 20 parts.
Olive oil, 60 parts.

—Kaposi.

POMADE FOR FISSURE OF THE ANUS.

Boric acid, 3 parts.
Chlorohydrate cocaine, 1 part.
Lanoline, 30 parts.

To be used after thorough cauterization of the parts with silver nitrate.—*L'Union Médicale.*

TREATMENT OF GONORRHOEAL ARTHRITIS.

R—Camphor 100 grains.
Extract of opium 75 grains.
Alcohol 1 drachm.
Extract of belladonna 75 grains.

This is to be made into a cataplasm and applied over the part from ten to twelve hours, the joint being made immobile by proper dressings.

IRON, GLYCERIN AND CHLORATE OF POTASSIUM MIXTURE.

Tincture of chloride of iron 30 mins.
Chlorate of potassium 1 dr.
Glycerin $\frac{1}{2}$ oz.
Water, sufficient to make 4 ozs.

Dose for adults, a teaspoonful every two hours; children, 20 drops to half a teaspoonful, according to their age.

A NEW METHOD OF PRODUCING LOCAL ANÆSTHESIA.

Dr. Voituriez recommends in the *Moniteur Thérapeutique* a method of producing local anæsthesia which certainly possesses the merit of simplicity. It is based upon the "well-known anæsthetic properties of carbonic oxide," and consists in pouring on the place to be anæsthetized the contents of two or three bottles of seltzer water, preferably by means of the syphon, which releases the water in a strong stream. The anæsthesia lasts five minutes and then gradually disappears. It is difficult to see how the "well-known anæsthetic properties" of the oxide are exerted by external application. The effect, if any, is probably mechanical.—*Druggist's Circular.*

A SIMPLIFIED TEST FOR SUGAR.

Prof. Nothnagel has communicated to a meeting of the Medical Association at Vienna a paper received from Dr. Becker, of Cairo, on a simplified test for sugar, which depends upon the fact that the paper used for the manufacture of visiting cards contains a larger quantity of potash to

make it heavier and fuller. When this paper is brushed over with a concentrated solution of sulphate of copper and then dried, the salt is crystallized on the surface. If the urine containing sugar is then added by means of a bit of wood and allowed to dry by the action of the air, or by holding it over an Argand burner (without browning the sulphate of copper), the latter is liquefied by the water contained in the small crystals, and the alkaline paper immediately produces the sugar-browning reaction. The more sugar the urine contains, the darker the color produced. The author considers the test highly sensitive.—*Lancet.*

REMEDIES FOR NASAL CATARRH.

Prof. Leffert's solution for nasal catarrh is as follows:

R—Acidi carbolici, ʒj.
Sodii boratis, ʒj.
Sodii bicarbonitis, ʒj.
Glycerini, ʒj.
Aque rosæ, ʒj.
Aque, ad. Oj. ℥ʒ

Sig.—Use as a spray.

Of catarrh snuffs the following are praised:

For scrofulous rhinitis:

Sulphophenate of zinc, 20 centigrams.
Tannate of zinc, 2 grams.
Pulverized tobacco, 10 grams.
Salicylate of bismuth, 4 grams.
Iodol, 3 grams. ℥ʒ

For chronic catarrhal rhinitis:

Pulverized alum, 2 grams.
Borax, 2 grams.
Menthol, 20 centigrams.
Tannate of zinc, 3 grams.
Tannate of bismuth, 3 grams.
Lycopodium, 8 grams. ℥ʒ

—*Pharmaceutical Era.*

HOW TO DETECT THE MORPHINE HABIT.

An efficient means of detecting the morphine habit is by adding a few drops of perchloride of iron to the patient's urine. A characteristic blue tinge results if he is a morphine user.—*N. Y. Med. Times.*

TO CLEAN HYPODERMIC SYRINGES.

Syringes, the canals of which have become obstructed, so that a fine wire cannot be drawn through, may, according to the *Deutsche Medicinische Wochenschrift*, be cleaned by holding them for a moment over a flame, the foreign substances being by this means rapidly destroyed and driven off. If a wire has been rusted into the needle it should be dipped in oil before holding over the flame. To remove the rust from the interior of the canula it is well to pass oil through the canula, then heating it; then rinse it out with alcohol. The needle may then be used.

LETTER FROM PARIS.

(FROM OUR REGULAR CORRESPONDENT.)

Atropine and Morphine to Combat the Noxious Effects of Chloroform—Interstitial Injections of Solution of the Bichloride of Mercury in the Treatment of Tumors—Treatment of Hæmorrhage due to Fibromata by preparations of Ergot of Rye and Hydrastis Canadensis.

Dr. Dastre has, for some time, undertaken experiments with a view of combating in the dog the noxious effects of chloroform, by the association of atropine and of morphine, and Dr. Aubert, of Lyons, was the first to endeavor to ascertain on man the advantages of this method. In a note by Dr. Reynier on the subject, which he read at a recent meeting of the Société de Chirurgie, he stated that he has employed this method in a certain number of cases in his service at the Hospital Tenon, and he has had one death, which he believes should be attributed to the association of these three elements. It was the case of a young girl of sixteen years of age whom he had recently operated on for a tuberculous osteitis of the cuboid bone. Half an hour before the operation, he had injected under the skin half a Pravaz syringeful of a solution containing per syringe 1 centigram of morphine and half a milligram of atropine. The chloroformization was easy. The operation lasted only ten minutes, during which time about 30 grams of the most of chloroform was absorbed. The patient, without awakening, opened her eyes, and the surgeon had left the ward when a message was sent to him to say that she had ceased to breathe. On his return he found her white, livid, still breathing feebly, with the pupils strongly dilated. In a few seconds the respiratory movements were definitely arrested and the pulse ceased to beat. Three hours of artificial respiration was employed, during which, on two or three occasions, the beats of the heart were perceived, but the patient was not restored to life. The autopsy was practiced by Prof. Verneuil, which revealed nothing particular, except anæmia of the bulb. Dr. Reynier concludes that in this case bulbar paralysis was produced by chloroform, and what is to be remarked is, that this paralysis had come on so late, ten minutes at least after the administration of the last drop of chloroform. It may be remarked that in patients anæsthetized by this method, the waking takes place tardily, the atropine and morphine are poisons of slow elimination, and the elimination of chloroform is equally retarded. Dr. Reynier had undertaken, with reference to this subject, a series of experiments, the result of which was that atropine stopped the beats of the heart more quickly, and that, if it renders the

accidents at the commencement less imminent, it exposes more to accidents at the end and renders them more dangerous. According to Dr. Terrier, who, on his side, had made some researches on this method, he observed that the anæsthesia varied according to the subjects. In man, notwithstanding the injection, the period of excitement exists, the wakening is very brusque. In women the agitation does not take place. It is wanting four times out of five. He also had one death in a young woman on whom he had performed nephrectomy. Death took place ten minutes after the cessation of chloroform. Dr. Schwartz observed that by administering chloroform in small doses, as practiced by Dr. Labbé, one never meets with the accidents that are sought to be avoided by the atropo-morphiuc method.

Dr. Poucel, Hospital Surgeon at Marseilles, recommends interstitial injections of solutions of the bichloride of mercury in the treatment of tumors in appearance cancerous. He says he has obtained several cures by this method, and he speaks of tumors of cancerous appearance, as in subjects affected with hereditary syphilis, one sometimes sees tumors develop which for the most part bear the clinical characters of cancer. However, in these cases the iodide of potassium is the principal part of the treatment. It dissolves pseudo cancers of syphilitic origin and remains without effect against true cancer. He states that therapeutically appears to establish that which histology still discusses, viz.: that these tumors of cancerous appearance, and perhaps all tumors, are produced by a microbe which characterizes such cellular malformation, as several among them, and perhaps all, might be cured by an anti-microbial treatment practiced early. The following is the method adopted by Dr. Poucel in the treatment of tumors: He injects with Pravaz's syringe, after taking the most vigorous precautions, in from two to six punctures, from 1 to 3 grams of the liquor of Van Swieten in the most indurated parts of the tumor. After the injection, the liquid must be retained as the retraction of the tumor tends to expel it. These intra-parenchymatous injections are ordinarily but little painful, do not produce salivation, and may be renewed every day. The inflammatory and gangrenous phenomena which are sometimes observed are attributed to the omission of some part of the antiseptic rule. When the cure is about to be produced, it is announced at the end of about twenty sittings or more. Dr. Poucel, therefore, believes that surgeons who have not yet renounced operating for cancer would do well not to undertake any operation before they have submitted their patients to the treatment vaunted by him.

In the treatment of hæmorrhage due to fibromata Dr. Lohlein recommends the preparations of

the ergot of rye and the extract of hydrastis canadensis. He has tried these remedies with success in women who menstruated too frequently, and whose menses are too abundant and too prolonged. Hydrastis is still more active than ergot, and Dr. Lohlein remarks that when the subcutaneous injection presents any difficulty, the ergotine may be administered per rectum either in the form of small enemata or in the form of suppository. In order to obtain the full effects of the hydrastis canadensis, it should be administered from six to ten days before the expected period, 30 drops to be given three times a day. In this way the intermenstrual period is lengthened and the duration of the hæmorrhage shortened.

DOMESTIC CORRESPONDENCE.

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

First Examinations under the New Law—State care of the Indigent Insane—The Lamborn Prize Essays on the Mosquito and its possible extermination—Cultivation of Plants under the Electric Light—A 5-year old Child falls six stories without serious injury.

The first examinations of those proposing to enter the study of medicine and law, under the direction of the Regents of the University of the State of New York, in accordance with the provisions of the new law, were held during the last week of September. In this city and Brooklyn nearly three hundred young men and a few young women were examined at the College of Physicians and Surgeons, the Medical Department of the University of the City of New York, and the Long Island College Hospital. All the students are required to pass satisfactorily in arithmetic, geography, grammar, English composition and spelling, and United States history. In addition, medical students must pass in either physics or physiology, as they may elect, and law students in English history. The same questions on each of these branches were also submitted to students presenting themselves at Albany, Syracuse and Buffalo. It is noticeable that the questions often call for information in regard to very recent matters, so that those who read the newspapers, other things being equal, have the best chance of success. For example, in geography some of the questions are as follows:

7. Mention in the order of their size the largest three cities of the United States, as determined by the census of 1890.

11. What States of Central America have recently been at war?

13. What country of South America recently

changed its form of government, and what was the change?

19. Describe the Congo River, telling where it rises, in what direction it flows, and into what it empties, and give the name of the explorer who first traced it from its source to its mouth.

The percentage required to pass the examiners is 75, but an applicant who fails can come up again as often as he likes. A similar series of examinations will be held in November, January, March and June. The students are allowed three hours in which to prepare written answers upon each subject.

This law, which is similar to that previously adopted in other States, is designed to diminish charlatanism and quackery in both the medical and legal professions. Up to the present time any accredited physician might practice in this State by the simple act of registry with the Clerk of the county in which he desired to practice; and a lawyer's right to practice was as easily secured. Under the new law medical or law graduates, physicians or lawyers in practice, and graduates of colleges or first-class schools are exempt wholly or in part from examination. Beginning with next year, however, the exemption will be contracted, and persons not then fully entitled to practice must pass the preliminary examination, no matter how well prepared for professional work. Even experienced physicians coming into this State to practice may be required to submit to examination upon the subjects indicated; and a certificate from the University of the State will be the only sure passport for the recognition from county boards of health which is now extended to all physicians who take the trouble to register themselves at the office of the County Clerk.

Under the system that has hitherto prevailed, large numbers of the insane in this State who had neither friends nor money were deprived of the benefit of the care and treatment to which they were entitled because of the private pay patients who were received into the State hospitals for the insane. Under the provisions of the law passed at the last session of the Legislature establishing State care of the indigent insane, however, the State Commission in Lunacy has taken upon itself the work of reforming this injustice. The new law recognizes the poor insane as the special wards of the State, and accordingly the Commission has ordered that, beginning with October 1, no private patient in any State hospital shall be allowed to occupy exclusively more than one room or be permitted to have the exclusive services of an attendant, and that no distinction whatever shall be made between private and public patients in respect to the quality and amount of the care and accommodation furnished them. Many of the abuses that have crept into the county asylums under the pay system will be remedied by the new law, and as there are plenty of private

institutions where patients whose friends can afford to pay for them can have all the advantages of the most approved methods of treatment, this reform can only result in much good.

The Messrs. Appleton have just issued a book of considerable scientific interest which is devoted to the Lamborn prize essays on the mosquito and its possible extermination. Early in the summer of 1889 Dr. Robert H. Lamborn sent out a circular to the "working entomologists of the country," offering prizes for the best essays describing original investigations on this subject, and when the competition was completed the first prize was awarded to Mrs. C. B. Aaron, while the second was divided between Mr. Archibald C. Weeks and Mr. William Brentenmuller. Some of the points and observations contained in these essays are worthy of special note. There seems to be no doubt that the mosquito is capable of communicating a poison. The fact that if the insect is allowed to remain long enough to draw out a sufficient quantity of blood from its victim but little irritation follows would seem to prove this; but it is also said that it is capable of inoculating the human species with malarial disease. Lewis has found twenty female mosquitos (and it has been ascertained that it is the female mosquito alone that bites) out of 140 to be infected with hæmatozoa, and McLeod, in commenting on this, calls attention to the serious consequences arising from filaria in the blood. Dr. Finlay, of Havana, asserts that it is his belief that the mosquito is an agent in spreading yellow fever. He says that the insect, after puncturing the skin of a yellow fever patient, retains some of the germs of the disease, and is thus liable to communicate the infection to the next person it visits. So sure is he that the mosquito is the active, if not the only, agent for the dissemination of yellow fever, that he holds that the disease cannot exist where the mosquito does not flourish. In apparent corroboration of this opinion, he states that in the summer of 1885 mosquitos were unusually scarce in Havana, but were very numerous in the autumn, and that during this summer there were but few yellow fever cases, while in October and November the number increased very considerably. Mr. H. Hammond, in *Science*, presents some facts which appear to go to confirm this view. "In 1839," he says, "during a yellow fever epidemic in Augusta, Ga., no cases originated at Somerville, a neighboring suburb among the sand hills. There were no mosquitos at Somerville, which was approached by a rather circuitous route from Augusta. Some years after, a straight, broad road was built through the swamps directly to the sand hills, cisterns were also built, and mosquitos appeared and became an intolerable pest. During the yellow fever epidemic of 1854, a number of cases originated at the sand hills abounding with mosquitos."

One of the methods that has been proposed for the destruction of mosquitos is the propagation of the dragon fly, which feeds largely on this insect. Its great voracity, and the fact that it chooses the same localities as the mosquito, would be relied upon for the extermination of the pest by those advocating this remedy. On the other hand, as militating against the practicability of such a plan, it is alleged that the mosquito is largely a nocturnal insect, while the dragon fly is only diurnal, and that it would be quite impossible to propagate dragon flies artificially with anything like the rapidity with which mosquitos propagate themselves. Mr. Weeks, in his essay, suggests that the best plan to banish the mosquito is to drain meadows, bogs and swamps, and to fill up stagnant pools and level rain-holding hollows contiguous to dwellings. He also says that one remedy very simple and near at hand is the preservation of insectivorous birds.

Mr. Brentenmuller holds the plea, raised in behalf of the mosquito, that in its larval stage it destroys the germs of the miasmata, to be futile and misleading. These germs, in our present state of knowledge, are very indefinite organisms, and there are methods of exterminating them much more effective than the work to be expected from the mosquito, viz.: drainage, clearance and sunlight. Among the natural remedies to be relied upon against mosquitos, he says, are the services of fish and water-fowl. Fish can be introduced into our public lakes, and aquatic birds may be adopted for the purpose of destroying mosquito larvæ near houses and in ponds in well-cleared fields. This naturalist states that he has often observed how infrequent the larvæ are in the Central Park lakes, and he ascribes their absence to the fish and the water-fowl abounding there. Certain artificial remedies are also suggested, such as the use of coal oil in swamps, the larvæ being destroyed by the oil floating in a thin film upon the water. One very interesting point is made by Mrs. Aaron. The public does not rightly understand the migrations of mosquitos, she says. The idea prevails at the seaside that a land breeze brings swarms of them from inland. This notion is based on the supposition that mosquitos are capable of long sustained flights, which is an error. It is usually only during the lulls in the wind that they can fly, and when a strong sea breeze is blowing the mosquitos conceal themselves in trees and large bushes. When the wind dies down, however, they come out from these hiding-places.

The experiments in the cultivation of plants under the electrical light recently made in the botanical department of Cornell University, at Ithaca, have given some rather curious results, and corresponding for the most part with those met with in some similar experiments previously reported from Russia. The first and most notice-

able effect of the treatment is an enormously increased rate of growth, though the plants seem to "run very much to leaf." Thus vegetables, such as peas, shoot up very quickly, and in a few weeks are two or three times as tall as those planted under ordinary conditions. It has been observed in every instance, however, that the reproductive powers are strongly affected, these being sacrificed to mere foliage and rapidity of increase in general size; so that in the matter of buds and fruit of any kind the development is far inferior to that observed in plants grown in sunlight.

There is a little boy five years old in this city, who was apparently not born to die from tumbling down stairs or any accident of that kind. One evening not long since the youngster, while playing on the roof of the tenement house where he resides, slipped into a narrow shaft between that and an adjoining building and fell all the way to the ground, a distance of six stories. Yet, strange to tell, when he was picked up it was found that not only was he alive, but that no bones were broken, and that with the exception of a rather severe scalp wound he was but little the worse for his extraordinary fall.

P. B. P.

TENTH INTERNATIONAL MEDICAL CONGRESS.

To the Editor:—I have the honor to report something more than the fact of a pleasurable time—and the meeting with many eminent men. What I saw and heard by no means embraced the whole scope of the Congress. No one person could take this in, and as its full relation would overcrowd the columns of THE JOURNAL, only a few items will be referred to.

1. *The Management.*—The Congress was well managed, if a great good-natured medical assemblage can be well managed anywhere. Everywhere was present the evidence that almost everything of advantage to its members had been anticipated with that thoroughness of detail which characterizes German methods. It was a fine idea that of holding the sessions in Exhibition Park, a large enclosed area of many acres, amply furnished with space outside and inside. The arches of an elevated railroad that ran through it were utilized for offices; this suggests that our L-roads be made on street fronts and not in the middle as now, and the under spaces made use of for business purposes.

The Sections, eighteen in number, were mostly held in the salons of a large picture gallery. In this way the music of the eye was joined to the music of the voice in speaking. I am compelled to say that most of the speakers could not be heard simply because they did not speak in the chords of the keynote of the auditorium. Some

Americans complained that the Germans did not wait to hear them read through. It is possible that the acoustic difficulties drove them away. Nothing is harder to stand than an address with a delivery which is unintelligible, and doctors are not celebrated for their oratory.

2. *Papers Printed Beforehand.*—Most of the readers had their papers printed beforehand, read from them and distributed copies afterwards. This is a good idea and facilitates the production of the Transactions. It is something worth the consideration of the American Medical Association. It might result in terser papers and it certainly would facilitate business.

3. *General Meetings.*—The general meetings in the Circus Ring were inspiring from their magnitude. One realized a little how many doctors there are at work in the world. It was almost impossible to hear anything in the seat assigned to me because of its remoteness. There were a good many lay visitors to whom it was necessary to accord high places and, of course, they crowded out so many delegates, but so long as this necessity was understood there was no grumbling. Indeed there was the best of feeling.

4. *Pharmacology.*—This Section was a deserved recognition of pharmacists, the same as that which the American Medical Association bestowed at Nashville last May. It marks a step forward and which gives promise of the best results.

5. *The Entertainments.*—They were many and varied and well carried out. As in America, so here, some of the profession overstepped the bounds of sobriety and lost somewhat by it—but the great mass was decorous. The private hospitalities were free and some delegates lived with their Berlin friends. The habit of smoking and making speeches at the table during dinners was new to some. In the speeches of some Americans I noticed a tone of apology when it seemed that none was required; America sent over one-tenth of all the delegates, was put at the head at the imperial reception and had a large share of the general addresses. Ninety-two out of 660 papers, read in the Sections, if the count is correct, were American. In the Health Exhibit, on the gable ends of the Great Hall, the American names of Sims and Rush shone equally conspicuous with Galen, Hippocrates, etc. American ideas were welcomed there also, so that we had no need to apologize.

6.—*The Empress.*—I happened to be at the Exhibition when the Empress visited it and was close to her. There was no fuss nor feathers. In every sense a lady, modest in dress, she showed an intense interest in the various phases of the exhibit as they were shown to her. She appeared in every way a grace and honor to her exalted position. I think she impressed the visitors as favorably as did Mrs. Cleveland, when foreign

visitors were at Washington, in 1887. Her visit to the Exhibition was a mark of respect, and she evinced an interest in medical matters worth remembrance.

7. *Sanitary Exhibition.*—The eminently practical character of the various things pertaining to health in this Exhibition was very instructive. Amidst the multitude it is difficult to particularize. And as the catalogue is complete to it I must refer my readers.

8. *Frozen Sections.*—I refer to those of the Berlin pathological institute. These series were of the greatest interest to me, because for many years I had wished to make such sections, and because they settle some points of great practical value to gynecologists. I refer to those made in the median longitudinal line of the female trunk impregnated and post-partum. In all the sections the vaginal walls were in contact almost to a line. These prove that when in the dislocated uterus the vagina is shortened longitudinally and lengthened laterally, there is a diametrical opposition to the normal vaginal axes. To restore and retain the uterus *in situ naturali*, the transverse muscular fibers of the vagina must be contracted into normal contact. Again, in one of the frozen sections there was a sub-involuted uterus of double size and yet the vaginal walls were in contact. The axis of the vaginal and the axis of the uterus were in continuous curve and alignment. These sections completely support some American positions laid down about twenty years ago. It is to be hoped that like frozen sections of the unimpregnated female will be made in this country, to further sustain or disprove the position that curative mechanical means of uterine displacements must include the abandonment of pessaries that depend for their support upon distending the already distended and shortened vaginal walls.

9. *The Music of the Congress.*—So long as Prof. Shoemaker, of Philadelphia, has put music in the materia medica, the excellence of the medicine music at Berlin should be noted. It is difficult to draw the line when there is so much superiority, but I think that the in-door music at Knoll's Garden on Saturday evening was the best. Of course in music there are different types of great excellence. For example the out-door garden concert by three military bands at the Court Reception at Potsdam, was for fine rendering, exquisite touch and finish of execution, delicate balancing of parts and timbre and timely appreciativeness—a remarkable performance. The music of the band located at the extreme west was so engrossing as to chain me to the spot where I stood and was for the time oblivious to passing events—but taking the ground that the voice is the most wonderful instrument of music, the palm must be rendered to the Knoll's Garden artists who came from London, Stockholm, Moscow, Wiesbaden, Vienna, Berlin, etc. and gave this

concert, the best I ever heard. The good wife, the better musical critic, found it soulful, satisfying and restful. It was splendid medicine to nerves worn out by hard work in the Sections through the week. It gave strength; it imparted vigor; it healthfully toned up the central nerve centers; it showed one secret of German national strength. Such music makes strong because it relaxes nerve tension which long kept up weakens and crazes. It was in line with the beautiful morning hymns with which the military mounted bands, preceding the troops going to parade, roused us gracefully from sleep at six o'clock nearly every morning. It taught a lesson how to confer force by stopping its wasteful expenditures through the brain unduly working. All things that arrest the needless expenditure of nerve force belong to the materia medica, and good music ought to have its place there as Dr. Rush showed many years ago. But it must be good music. I am not sure but that some good music introduced in the Sections of our annual meetings would add to the good understanding of subjects, because a rested brain works so much better than when tired.

10. *Microphotography.*—I saw much fine work and many cameras for the purpose—some of them new. They photograph with the eye-piece and objective a good deal. But I could not find either microphotographs or apparatus which excelled American appliances and work done in 1876. There was no systematic microphotography of the morphology of consumptive blood and foods or drawings of the morphology of the sputum, for example as to American microscopes. An eminent German microscope maker inspected one which I brought and said there were none like the highest objectives (Tolles) or such stands in Germany, simply for the reason that no one would pay for them. This gentleman thanked me for the opportunity of inspecting this specimen of American work.

Personals.—In the largest scientific gathering the world ever saw, there had to be a huge amount of clerical and managerial work which was very creditable to all concerned. I do not individually particularize, but personally know that the general secretary, Dr. Lassar, was deservedly complimented for his arduous labors. The chairman of the Section (of Gynecology), Dr. A. Martin, very ably handled his business. Those who read were notified by postal when they were expected and this saved a good deal of trouble, in a Section whose work was so very much crowded. Dr. Martin is an honor to his nation and profession. In this connection, Prof. von Leyden, managing member of the Section of Internal Medicine, should receive mention for his courtesy, efficiency, interested observation and good management. Do not think these are mentioned to exclude others, but because I am able to speak from personal knowledge—for the Ber-

lin Congress was splendidly managed as to business, hospitality, entertainments, and welcoming of guests, and I desire to give all a chance, but the inevitable delays that came from non-appearance of readers, prolonged discussions made paper-reading short. The privilege of seeing distinguished medical workers from all over the world and of knowing those by sight who had been known long by their writings was a boon. The great good of such congresses is the planting of seeds of thought that may spring up and bear abundant beneficent fruit after the sowers have passed away and know naught of the good they have done. This encourages workers to persevere, knowing that good work honestly done will some time receive the recognition it deserves and thus honor their profession, race and country.

EPHRAIM CUTTER, M.D.

A Delegate from the American Medical Association.

NECROLOGY.

DR. J. MATTHEWS DUNCAN, of London, died at Baden, September 3, at the age of sixty-four years. He was a native of Aberdeen, educated at Edinburgh and Paris, taking his degrees about 1850. He was a coinvestigator with Simpson in developing the anæsthetic uses of chloroform. Dr. Duncan took high rank as a clinical teacher in midwifery and gynecology and general medicine, and not only became extremely popular among the Edinburgh students, but became well-known throughout two continents long before the fortieth year of his age. When the death of Sir James Y. Simpson made a vacancy in the chair of midwifery in the Edinburgh University, Dr. Duncan was regarded as the professional candidate for the place, but the appointment fell to the lot of Dr. Simpson, of Glasgow, a nephew of the deceased professor, who had the votes of the lay-curators of the institution, those having the preponderating weight. Not long after, in 1877, Dr. Duncan was invited to take the professorship of midwifery in the college of St. Bartholomew's Hospital, London; thither he removed and taking up his residence in Brook street, became the neighbor of Drs. Jenner, Gull, Ord, Savory, Habershon, Palfrey and Harley. He became a consultant of the first rank, winning the esteem and affection of the profession as well as those whom he personally served. His writings were many, but rather fugitive in character, and their subjects bore, with especial frequency, on obstetrics and diseases of women and children.

DR. J. NELSON BORLAND, formerly of Boston and Nahant, died August 10, aged sixty-two years. He was a graduate in medicine at the

Harvard University in 1850, and afterward attached to that institution as Instructor in Clinical Medicine, for several years. He was one of the first staff of visiting physicians at the Boston City Hospital, and joint editor of its reports. He retired from practice twelve years ago, and made his home at Waterford, Conn. He was a man of great geniality of manner, a fine presence and a general favorite in every walk of life wherein he moved.

DR. ROBERT ALEXANDER MANWARING, a classmate of Dr. Oliver Wendell Holmes, and for nearly fifty years one of the leading physicians of eastern Connecticut, died at New London, September 1. He came from Colonial stock and was born August 11, 1811. He was a type of the old time general practitioner, kindly, practical and modest.

DR. DANIEL W. KISSAM, died at Brooklyn, N. Y., September 9. He was born in New York City fifty years ago, and received his degree from the College of Physicians and Surgeons in 1865. Since King's, now Columbia College, was founded the name of Kissam has been an oft repeated one on the Catalogue, the first in the long list being Samuel Kissam, one of the two graduates honored in 1769 with the degree of Bachelor of Medicine.

MISCELLANY.

U. S. MARINE-HOSPITAL SERVICE EXAMINATION.—A Board of Examiners, of which Surgeon W. H. H. Hut-ton, of the Marine-Hospital in Baltimore, is Chairman, has been ordered to convene at New York, Oct. 27 for the purpose of examining applicants for admission into the Marine-Hospital Service.

ONE of Reed & Carrick's extensive factories at Goshen, N. Y., was destroyed by fire on the 10th ult. This factory was devoted wholly to the production of their soluble food and lacto-preparata and contained extensive and valuable machinery. They had considerable stock of these foods at their New York office, and consequently there will be no delay in filling orders. The factory will be at once rebuilt three times the size of the one burned, with machinery correspondingly enlarged.—*Dietetic Gazette*.

TRI-STATE MEDICAL ASSOCIATION.—The second annual meeting of the Tri-State Medical Association of Alabama, Georgia and Tennessee will be held in Turner Hall, Chattanooga, Tenn., on October 14, 15 and 16. It promises to be one of the most successful, profitable and entertaining meetings ever held in the South.

A fare of one and one-third rate has been secured on all roads. Procure straight tickets and procure from your ticket agent a certificate showing the purchase, form, and kind of ticket, rate, route, etc. Get Secretary of Association to endorse certificate, present to agent at Chatta-

nooga for return ticket at one-third rate. On C., R. & C. R. R., buy round trip ticket. From some points it may be advantageous to purchase ticket to Lookout Mountain. North of the Ohio, harvest excursion tickets will be on sale on the 14th, one fare for the round trip.

FRANK TRESTER SMITH, M.D., Sec'y.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from September 27, 1890, to October 3, 1890.

In view of the abandonment of Ft. Gibson, Ind. Ter., to which post he is at present assigned for station, Capt. W. D. Owens, Jr., Asst. Surgeon, is relieved from duty at that post, and will, upon the expiration of his present leave of absence, proceed to Ft. Sill, O. T., and report to the commanding officer for duty. S. O. 125, Dept. of the Missouri, St. Louis, September 27, 1890.

In view of the abandonment of Ft. Crawford, Col., to which post he is at present assigned for station, Capt. J. L. Phillips, Asst. Surgeon, is relieved from duty at that post, and will, upon the expiration of his present leave of absence, proceed to Ft. Logan, Col., and report to the commanding officer for duty. Par. 1, S. O. 135, Dept. of the Missouri, St. Louis, September 27, 1890.

Capt. Louis S. Tesson, Asst. Surgeon (Ft. Sidney, Neb.) is granted leave of absence for twenty days, to take effect when his services can be spared by his post commander. S. O. 72, Dept. of the Platte, Omaha, Neb., September 25, 1890.

Capt. John L. Phillips, Asst. Surgeon, leave of absence granted in S. O. 164, July 16, 1890, from this office is extended two months. By direction of the Secretary of War. Par. 3, S. O. 228, A. G. O., Washington, September 29, 1890.

Capt. Louis W. Crampton, Asst. Surgeon (Ft. Sheridan, Ill.) is granted leave of absence for one month, to take effect about October 1, 1890. Par. 2, S. O. 80, Div. of the Missouri, Sept. 30, 1890.

ORIGINAL ARTICLES.

A SERIES OF CASES PRESENTING MINOR LESIONS IN THE MACULA LUTEA.

Read in the Section of Ophthalmology at the Forty-first Annual Meeting of the American Medical Association, held at Nashville, Tenn., May, 1890.

BY G. E. DE SCHWEINITZ, M.D.,

OPHTHALMIC SURGEON TO THE CHILDREN'S AND PHILADELPHIA HOSPITALS; OPHTHALMOLOGIST TO THE INFIRMARY FOR NERVOUS DISEASES.

The lesions of the macula lutea which result from myopia, nephritis and diabetes, anæmia and cardiac disease are well known. Haab (Internationaler Ophthalmologen-Congress, Heidelberg, 1888) has classified the remaining diseases of the macula into several groups:

1. Those due to trauma (*a*) by contusion of the globe without rent in the sclera (*commotio retinae*, of Berlin); (*b*) secondary to penetrating foreign bodies; (*c*) secondary to a neighboring rupture of the choroid.

2. Those characterized by the general term senile macular disease.

3. Those seen in people of depressed nutrition—anæmia, diseases of the stomach, etc.—having at the same time an hereditary disposition to macular disease; and finally,

4. Those in which no etiological factor within or without the eye is discoverable.

In the groups just referred to, at least in the majority of them, a marked failure of central vision is a characteristic symptom. In the series of cases to which I beg your attention for a few moments full acuity of vision is present; general disease in most instances is absent; trauma and other local ocular changes are wanting, and with propriety they may be referred to Haab's fourth group in which no etiological factor within or without the eye is discoverable, that is discoverable in the sense that it is not possible to point with certainty to any one determining cause. These small lesions have certain features in common. They vary in size from one to four diameters of a retinal vein. Usually they are somewhat oval or irregularly round in shape, of varying tints, for the most part grayish-white, or buff-colored, sometimes more decidedly yellow, occasionally associated with some granular pig-

ment, or composed of small collections of yellow and black granulations. Their situation is usually either above or to the temporal side of the fovea in the macular region, and if in relation to any vessels they lie beneath them. For the convenience of study these cases may be classified into several groups:

GROUP 1.—*Asymmetrical lesion—situated in the macular region of the eye presenting the greater error of refraction.*

Case 1.—D. N., a young man aged 19; very nervous; hard student; no general disease. Large irregular discs; many lymph reflexes. In the left eye up and in from the fovea a small oval patch of retino-choroiditis composed of yellowish and black granules interspersed, lying upon a buff-colored background. In the right eye no similar change. O. D. + .50s $\frac{2}{0}$. O. S. + 1.s $\frac{2}{0}$.

Case 2.—Miss M. B., a woman aged 55; blepharitis; unsatisfactory reading power; general health perfect; urine negative. In each eye healthy, oval optic discs. In the left eye a patch 3 by 4 mm. below the fovea characterized by yellow dots and a few pigment granules lying upon a yellowish-white surface. In the right eye no macular changes. O. D. + .75s $\frac{2}{0}$. O. S. + 1. s $\frac{2}{0}$.

Case 3.—Miss M., a woman aged 35; chronic conjunctivitis; typical asthenopia; bad occipital headaches; suffers much from dyspepsia, and has post-nasal catarrh. Oval discs and hazy retinas. In left macula a small, square, buff-colored spot in the choroid below the fovea. No similar change in the right eye. O. D. + .50s \bigcirc — 2.c axis H. $\frac{2}{0}$. O. S. + .25s \bigcirc — 2.50c axis 5 $\frac{2}{0}$.

Case 4.—Miss C., aged 20; suffers much with trigeminal neuralgia; hair prematurely gray; dreads light; has occipital headache; otherwise health good, although excessively nervous. In the right eye an oval disc; retina slightly hazy, and below the fovea a patch of choroidal change about 3 mm. square containing in its centre a cholesterol crystal. In the left eye a nearly round disc, rather pallid, no macular change. O. D. + .50s \bigcirc + .60c axis V. $\frac{2}{0}$. O. S. + .50c axis V. $\frac{2}{0}$.

Case 5.—N. B., a man aged 46; for three months has had running ears; successive attacks of conjunctivitis; at times occipital headache; giddy spells;

ill-defined history of rheumatism. In the right eye a horizontally oval gray disc; small buff-colored patch below fovea. In the left eye similar disc with absorption of the pigment epithelium of the choroid, but no macular change. O. D. + 1. s \ominus .90c axis 165 $\frac{2}{8}$. O. S. + 1. s \ominus + .25c axis H. $\frac{2}{8}$.

Case 6.—Miss P., aged 39; itching and burning eyes; post-ocular pain, worse in right eye; has catarrhal pharyngitis; is deaf in the right ear. In the right eye an oval disc, below the fovea a small buff-colored spot containing a dark centre. In the left eye a normal disc without macular changes. O. D. + .75s \ominus + .60c axis V. $\frac{2}{8}$. O. S. + .50s \ominus + .50c axis V. $\frac{2}{8}$.

Case 7.—Mrs. M., age 35; frequent attacks of headache through brow and temple, aggravated by eye-work. Family physician sends report of perfect general health. In the right eye an oval disc, its surface too capillary. In the left eye an oval over-capillary disc; full lymph sheaths, and above the fovea an irregular oval patch, yellowish, and studded with numerous darker tinted dots. O. D. + .50s \ominus + .50c axis V. $\frac{2}{8}$. O. S. + .90s \ominus + 1.c axis V. $\frac{2}{8}$.

Case 8.—Miss McF., aged 31; burning eyes; blurred print; bad frontal headache; has had rheumatism; no gout; otherwise healthy. In the right eye a large irregular disc; broad scleral ring, and intensely granular macula, and to the outer side of the fovea an irregular buff-colored patch in the choroid. In the left eye a round disc with broad scleral ring. No macular changes. O. D. 2.50s \ominus + .50c axis 75 $\frac{2}{8}$. O. S. 2.s \ominus + .50c axis V. $\frac{2}{8}$.

Case 9.—Miss S., aged 46; suffers much with eye pain and headache; is in delicate health, and hair prematurely gray. In the right eye an oval disc bounded by a black line, and below the fovea a small oval patch yellowish-white in color. In the left eye a round disc with a shallow central excavation and sharply marked scleral ring. No macular change. O. D. + .75s \ominus + .60c axis 120 $\frac{2}{8}$. O. S. + .75s \ominus + .25c axis 60 $\frac{2}{8}$.

Case 10.—Mrs. C., aged 58; in perfect general health, and no recent sickness; discs rather gray; veins full, transverse arteries slightly tortuous. In the right eye a small yellowish patch in the macula above and just at the edge of the fovea. In the left eye no similar change. O. D. + .50s \ominus + .50c axis 165 $\frac{3}{8}$. O. S. + .75s \ominus + .25c axis H. $\frac{3}{8}$.

In this group of ten cases, all with perfect central vision and unaware of any lesions of the eye, general health, with one exception, was good, the well recognized causes of macular disease were absent, a satisfactory reason for the spot of degeneration could not be supplied. It is perhaps suggestive that this occurred upon that side presenting the greater error of refraction. In two the refraction was hypermetropic, and the difference only .50D and .25D respectively; and in the

remaining eight there were seven with compound hypermetropic astigmatism in each eye, and one with mixed astigmatism on both sides, the spot being present in the eye exhibiting the greater anomaly of refraction. If instead of presenting ten cases the number had been one hundred or more, such an association would be more than suggestive; as it stands it may be merely a coincidence. I wish, however, to point it out and learn the experience of my colleagues. When we remember that conus and posterior staphyloma have been ascribed to the influence of astigmatism, that refraction error may cause symptomatic retino-choroidal irritation and even superficial neuritis, it may at least reasonably be suggested that slight macular changes may arise under the influence of anomalous refraction and in asymmetrical cases appear in the more affected eye. Bearing somewhat upon this question is the well known fact, and one that I have often observed in this very series of cases, that under the influence of correction such superficial lesions slowly subside, just as the general irritable condition of the whole eye-ground will disappear through similar treatment.

Still in touch with the present theory of the possible origin of these small lesions under the influence of an error of refraction are those which I have gathered into the second group.

GROUP 2.—Symmetrical macular changes—symmetrical refraction error.

Case 1.—Mrs. R., aged 40; much sick headache; very nervous; limbs swell (hysterical); heart and urine normal. In each eye oval discs with hazy edges. In the right eye a small crescent-shaped patch, buff-colored, below and to the temple side of the fovea. In the left eye streaks in the macula and one small buff-colored spot above. O. D. + 1.50c axis 105 $\frac{2}{8}$. O. S. + 1.50c axis 75 $\frac{2}{8}$.

Case 2.—Mrs. B., aged 44; headaches for years; severe hemicrania without prodromes; of feeble muscular strength; urine normal. In the right eye sharply marked scleral ring around an oval disc; several oval, buff-colored patches in the macula somewhat radially placed. In the left eye lower and inner edge of the oval disc hazy. Exactly similar macular changes. O. D. + .50 \ominus — 1.c axis 165 $\frac{3}{8}$. O. S. + .50 \ominus — 1.c axis 15 $\frac{2}{8}$.

Case 3.—W. D., a man aged 34; complains of blurred feeling when reading, lachrymation and smarting pain in the morning, general health perfectly good; organs and functions normal, although his hair is beginning to turn gray. Large, slightly oval, pallid discs with central lymph sheaths full. In each macula above the fovea a buff-colored crescent more marked upon the left side. O. D. + .50s \ominus + .25c axis H. $\frac{2}{8}$. O. S. + .50s \ominus + .25c axis H. $\frac{2}{8}$.

Case 4.—Mrs. H., aged 42; recent nervous

prostration; occipital and shoulder pain with strained feeling across forehead; reads better in the dusk. In each eye unduly capillary, oval optic discs with hazy retinas and finely tortuous transverse vessels. In each macula slight dot-like changes, and above each fovea a maroon-colored crescentic area. O. D. —.25c axis 135 $\frac{2}{10}$. O. S. —.25c axis 45 $\frac{2}{10}$.

I have quoted four cases to illustrate this point: one an example of simple hypermetropic astigmatism; another of compound hypermetropic astigmatism; a third of mixed astigmatism; and a fourth of simple myopic astigmatism. The lesions are in exact accord with those which have already been described. They differ from the last group in being symmetrical; they resemble the others in being present in people of perfectly good health, or at least in people free from organic disease, and in whom no cause either within or without the eye could be discovered to explain their presence. An exception to this, however, may be Case 4, which in all probability is one of changing refraction, and the spots may have appeared under the influence of this phenomenon.¹

To illustrate the imperfection of the theory which has been suggested that these slight macular lesions may possibly arise under the influence of refraction error and appear on the side of the greater anomaly, a third group has been quoted in which precisely the opposite condition obtained.

GROUP 3.—*Asymmetrical lesion—situated in the macular region of the eye presenting the smaller error of refraction.*

Case 1.—Miss P., aged 25; suffers from general headache and smarting eyes at close work; rather delicate, but organs sound, the delicate health probably being due to lack of exercise. In each eye oval discs with rather full veins. In the right macula a small patch of choroiditis about 4 mm. square below the fovea. O. D. + 1.25s \bigcirc + .25c axis V. $\frac{2}{10}$. O. S. + 1.50s \bigcirc + .25c axis V. $\frac{2}{10}$.

Case 2.—Miss S., aged 47; cardiac asthma; has had rheumatism; no renal change, much headache. In each eye oval disc and sharply cut scleral rings. In the right eye a buff-colored patch above in the macula fringing the edge of the fovea. O. D. + .50s \bigcirc + .60c axis 165 $\frac{2}{10}$. O. S. + 50 \bigcirc + 1.c axis 15 $\frac{2}{10}$.

Case 3.—Mrs. B., aged 61; general health good; blurred vision; urine normal. In each eye small, oval discs, edges clear. In the left eye two small yellowish-white patches bordering the lower edge of the fovea. O. D. + 2.s \bigcirc + .90c axis 150 $\frac{2}{10}$. O. S. + 2.s \bigcirc + .50c axis 60 $\frac{2}{10}$.

Case 4.—Mrs. G., aged 28; brow, vertex, and occipital headache for years, the brow and occip-

ital headache in direct relation to the eyes; general health perfect. In each eye oval discs, rather gray in the outer halves, and in the left eye below the fovea an irregular patch, characterized by numerous yellow dots with some larger buff-colored spots. O. D. + .50s \bigcirc + .50c axis 105 $\frac{2}{10}$. O. S. + .50 \bigcirc + .25c axis 75 $\frac{2}{10}$.

These four cases, chosen from a number which I have seen, are all examples of compound hypermetropic astigmatism, two with the astigmatism according to the rule and two with the astigmatism contrary to the rule, and in all the macular change in that eye exhibiting the smaller error of refraction. It is not improbable that, if this topic were pursued and large numbers of cases gathered together, it would be found such spots occurred more frequently in eyes exhibiting the smaller degree of refraction error, for the very reason that they may represent eyes that are increasing in refraction and lessening the amount of hypermetropia.

We come now to consider the fourth group of these cases, in which it is possible to point with more exactness to a cause for the changes in the eye-ground, and I will ask your attention for a moment to this group.

GROUP 4.—*Symmetrical macular changes—*asymmetrical refraction error; probable influence of constitutional derangement.

Case 1.—M. G., a man aged 54; aching eyes; intense occipital headache; very gouty, suffering at times with severe exacerbations of acute gout; gouty change in the kidneys. Horizontally oval discs, gray, and in each macula numerous round yellowish dots about the size of the head of a pin. O. D. + 2.s \bigcirc + .50c axis H. $\frac{2}{10}$. O. S. + 2.50s \bigcirc + .75c axis 165 $\frac{2}{10}$.

Case 2.—D. L., a man aged 42; severe occipital headache; apparently fair general health; years ago had yellow fever. The urine free from albumen and tube casts, but loaded with uric acid. In the right eye an oval disc, the upper and inner edges veiled. Down and in from the disc a small spot of choroidal change and numerous yellow dots in the macula. In the left eye a round disc, edges veiled, and central lymph sheaths full. Similar macular changes. O. D. + .60s $\frac{2}{10}$. O. S. + .25s \bigcirc + .50c axis 150 $\frac{2}{10}$.

Case 3.—Mrs. A., aged 46; at present in good health, suffering only from headaches attributed to eye-strain and some conjunctival irritation; has had two attacks of puerperal fever, the last with her youngest child, now in his seventh year. In each eye round discs with sharply marked scleral rings, especially below, and in each macular region to the disc side of the fovea several yellowish splotches spotted over with small pigment dots. O. D. + 1.25s \bigcirc + .60c axis 75 $\frac{2}{10}$. O. S. + 1.50s \bigcirc + .50c axis 105 $\frac{2}{10}$.

Case 4.—Miss M., aged 10; recently has had

¹ Dr. G. M. Gould (Archives of Ophthalmology, Vol. xix, p. 31) reports eight cases to illustrate the hypothesis that central choroiditis is due to ametropia, and suggests the name ametropic choro-retinitis.

sore throat (diphtheria?); has had malaria; feels a film over the eyes; much brow pain. In each eye numerous fine dots the size of the prick of a pin and of yellowish color. The urine contains albumen and tube casts. O. D. 1.50 $\frac{2}{3}$ °. O. S. 1. $\frac{2}{3}$ °.

Case 5.—Miss P., aged 24; pain in the eyes, worse when reading; claims to be in good general health, but is readily tired; pain in the back, face pallid and slightly puffy beneath the eyes. Urine of low specific gravity; small hyaline casts. In the right eye the disc is round, the lymph sheaths full, and the macula contains several granular spots. In the left eye the disc is oval, the lymph sheaths full. In the macula granular dots, and one small yellowish patch below the fovea.² O. D. + .25c axis 95 $\frac{2}{3}$ °. O. S. + .50c axis V $\frac{2}{3}$ °.

Any influence of refraction error in these cases probably may be eliminated, and this has simply been recorded for the sake of uniformity. In two of the cases the presence of renal disorder renders the explanation of macular change of ready demonstration. They have been referred to chiefly because they represent a large class where very fine lesions in the macula, which do not in any way influence central vision, which can often be found only by the most careful focusing, and yet which direct attention to an examination of the urine, with the results detailed in Cases 4 and 5. I have on a number of occasions had cases of this character referred to me by competent general practitioners, who were not a little amazed when I sent them word back that the headache which they had supposed due to eye-strain, and consequently coming within my province for treatment, was a headache in all probability due to renal inadequacy, and belonging to them. These cases are in no sense albuminuric retinitis, and I have watched them for long periods of time and they apparently do not develop into albuminuric retinitis. They stay simply where they are, and in some minor degree are an index of renal change; moreover, of a renal change which is apparently perfectly compatible with what appears to be good general health. Perhaps investigation would show that such cases are present in the examples of so-called transient albuminuria; perhaps they are only coincidences—but be this as it may, they deserve attention. In two of the other cases (Case 1 and Case 3) renal change was no doubt at the bottom of the lesion; the one a case of chronic gout with gouty kidneys, and the other in a woman who had attacks of puerperal fever. They are interesting only in the fact of the smallness of the lesion and the presence of accompanying perfect central vision. In Case 2 the fact that the patient had yellow fever, and was the subject of uric acid diathesis in a minor degree,

is of interest. I have elsewhere reported not macular changes, but decided general retinal disturbance in association with oxaluria. Perhaps this case is analogous.

In a number of instances exposure to intense light (sunlight, electric light), has resulted in the appearance of a persistent after-image. Corresponding to the central scotoma evidences of retinitis or retino-choroiditis have been found in the macula. It is to this class of cases that the final group belongs, of which I have only one example to quote.

GROUP 5.—*Slight macular changes—the apparent result of exposure to a bright sunlight.*

Case 1.—Miss B., aged 22, complains of a dark spot before the right eye which followed prolonged exposure to the glare of a sunset upon the ocean, the patient having watched this for a long period of time. No headache, no asthenopia. A careful examination by the family physician discovered no constitutional derangement. In the right eye an irregularly oval disc with central excavation, and in the right macula a dark area, and up and in from the fovea a number of fine, faintly marked, yellowish-white dots. In the left eye no similar dark area, but one or two fine dots. No dark spot complained of before the left eye. O. D. + .50s \bigcirc + .25c axis H. $\frac{2}{3}$ °. O. S. + .75s \bigcirc + .25c axis 120 $\frac{2}{3}$ °.

The dark area in this case was noted two years ago. It persists still, only the scotoma has grown exceedingly faint, and there has been corresponding fading of the macular changes. That this is really an after-image and is on the retina, is evident from the fact that it obscures but does not hide real objects, moves with the motions of the eye, and is projected when the observer looks upon a dark ground. These are the points which Dr. Tuke, in his article on "Hallucinations and the Subjective Sensations of the Sane," considers characteristic of the after-image of a luminous object. An interesting point in this case is the fact that in the right or affected eye there was a patch darker than the surrounding retina which was the cause of the scotoma, both maculas contained yellowish dots, but evidently independent of the influence of the intense sunlight. The lesion, then, was somewhat analogous to that which has been described under the title of *commotio retinae*. It is not my purpose to discuss macular disease from intense light, but I have quoted this example as one having all the symptoms of this disorder save only that perfect central acuity of vision was preserved. It may be interesting, however, to note that there was no change in the periphery of the eye-ground, that the field of vision was normal, and that an attempt to map out a positive scotoma on the perimeter was not possible.

In the absence of microscopical examination it

²Cases 4 and 5 have been referred to in a paper before the County Medical Society of Philadelphia, read April 23, 1890.

is idle to discuss the pathology of these small lesions. They appear to arise in the choroid, and to partake of the nature of a spot of degeneration indicating the portion supplied by a single capillary loop, but not of sufficient extent to seriously involve the retinal elements and produce depreciation of central vision. It is not improbable that some of them may be congenital (in those examples in which no other cause was found), or that they have arisen under the possible influence of refraction error, certainly in some instances through constitutional disturbance; and have found their habitat in that portion of the eye-ground which experience has taught is liable, especially in people with a predisposition to macular disorder, to degenerative changes.

DR. RANDALL asked to emphasize Dr. de Schweinitz' note that in many of these cases full normal vision was present, generally without even relative scotoma; and, further, that even where renal trouble has been found by clinical and microscopical tests there has seemed to be no tendency to an increase of the lesion, but, on the contrary, the lesions rather tend to fade. The albuminuria has proven transient, and no albuminuric retinitis has occurred.

DR. T. E. MURRELL, of Little Rock, Ark., said he saw a case of macular spot—a shadow over the macula, caused by viewing the transit of Venus over the sun's disc with the unaided eye.

DR. CHEATHAM said in reference to Dr. de Schweinitz' cases that only last week he saw a case of central retinitis with H. 3.25 D.; this patient had been exposed to very bright light also. V. = $\frac{2}{5}$. He had seen many cases of marked changes at macula, with central blindness, dating back to the total sun eclipse years ago.

DR. ROBERT TILLEY, of Chicago, has seen some of these cases of macular changes, and has been accustomed to regard them as an evidence of specific lesions either primary or hereditary, and remembers one case in point in his recent practice, in which he had supposed that he had obtained advantage over a brother practitioner in seeing the case a little later, when these spots were more readily observed. At any rate, while weak plus glasses were previously given without satisfaction, the exhibition of specific remedies gave relief and the glasses were cast aside.

DR. DE SCHWEINITZ wished to be understood that the cases of macular change which he reported were entirely independent of the syphilitic taint, and were unrecognized by the patient because they gave no inconvenience. The case of macular disease from intense sunlight was peculiar only in the possession of perfect central acuity of vision. Dr. de Schweinitz thought it had been experimentally shown that the direct influence of sunlight was the cause of the retino-choroidal macular change.

MALARIA AND THE CAUSATION OF INTERMITTENT FEVER.

Read in the Section of Practice of Medicine, Materia Medica and Physiology at the Forty-first Annual Meeting of the American Medical Association, at Nashville, Tenn., May, 1890.

BY HENRY B. BAKER, M.D.,
OF LANSING, MICH.

Dr. Tommasi-Crudeli and others have claimed that intermittent fever is caused by a bacillus.

Drs. Laveran, Osler, Council and others have proved, to their own satisfaction at least, that intermittent fever is caused by a microscopic hæmatozoön.

At the meeting of the American Medical Association in Cincinnati, in May, 1888, I presented what I then considered and still consider to be incontrovertible evidence that intermittent fever is caused by exposure to changes of atmospheric temperature,—that, ordinarily, its causation is quantitatively related to, and apparently controlled by the range of atmospheric temperature.¹ It seems to me that both these lines of evidence, which appear to be so divergent, may be true. I feel sure that my own line is. And I have very great confidence in those who have presented the other line of evidence in which they are expert.

Therefore, although those who have held the germ theory of the causation of intermittent fever have not, so far as I know, accepted the evidence which I have collected and published, yet I feel impelled to again ask attention to it. I attempt this the more readily, because the facts and considerations, which it seems to me to make it appear possible that both lines of evidence may be true, were, in the main, held in mind when I read my paper two years ago, but there was not then time to elaborate, and I, therefore, only referred to but did not fully state them.

I suppose that all here are probably familiar with the literature of the subject of the bacillus of malaria, and also that relative to the hæmatozoön of malaria, discovered by Laveran. I may, therefore, devote my time exclusively to that other phase of the subject, on which I have collected evidence, and which is probably little known.

The most important evidence which has been presented by myself is as follows:

1. Statistics of sickness from intermittent fever in Michigan during a long series of years, arranged to show the relation of intermittent fever to changes in atmospheric conditions, and which have proved, to my mind, that the controlling condition is associated with atmospheric temperature, the sickness rising and falling with the temperature. This is shown by Diagram No 3², which is one of a series prepared to illustrate my previous paper.

Sickness—Average maximum Temperature
 *Indicating what per cent of all reports received, stated the presence of Intermittent Fever then under the observation of the physicians reporting.
 Over 35,000 weekly reports of sickness are represented in this diagram.

2. Statistics relative to intermittent fever in the United States Armies, elaborated from the medical and surgical history of the war of 1861-5. This evidence is graphically shown in Diagram No. 1.³

An abstract of a summary of conclusions based upon the evidence which I collected, is as follows:

"2. The controlling cause of intermittent fever is exposure to insidious changes, or changes to which one is unaccustomed, in the atmospheric temperature.

"3. In the mechanism of the causation of intermittent fever, the chief factor is the delay in reaction from exposure to cool air; this delay, extending to a time when greater heat-loss should occur, results in the abnormal accumulation of heat in the interior of the body, and in disturbed nervous action—the chill; and the final reaction is excessive because of the accumulation of heat,

and, sometimes, because it occurs at the warmest part of the day.

"4. The fever is the excessive reaction from the insidious influence of the exposure to cool air; and it is periodical because of the periodicity of nervous action, and, because the exposure and the consequent chill are periodical, owing to the nightly absence of the warmth from the sun.

"5. Residence in valleys or low lands through which or upon which cold air flows at night, and thus causes insidious changes in the atmospheric temperature, favors intermittent fever.

"6. In our climate, those measures, such as drainage, which enable the soil to retain warmth during the night, and thus reduce the daily range of temperature immediately over such soil, tend to decrease intermittent fever among residents thereon.

"7. In the cure and prophylaxis of intermittent fever, those remedies are useful which lessen torpidity and tend to increase the power of the body to react promptly to insidious changes in atmospheric temperature."⁴

Preparing, now, to forge a link, in the chain of evidence, which was omitted from my paper, Sir William Moore, who has had great experience and observation in India, says: "So-called malarious fevers are caused by sudden abstraction of heat, or chill, under the influence of cold, and more especially of damp cold. These effects of chill are more marked in hot climates, because of the antecedent exposure to great solar heat, the anæmia and skin debility resulting from heat and the disregard of suitable precautions."⁵

I think that my statistics indicate that another reason, for there being most intermittent fever in hot climates, is because the difference between the day and the night temperatures is the greatest in hot climates, and, consequently, the demands upon and resulting disturbances of the heat-regulating apparatus of the body are greatest in hot climates.

Intermittent fever is most prevalent in hot climates. In temperate climates, intermittent fever is most prevalent in the warm months. Here a reason similar to that just given applies,—it is then that there is greatest difference between the day and the night temperatures.

I believe that perspiration is probably a factor in the causation of intermittent fever. I do not base this opinion merely upon the facts just stated,—relative to place and time of greatest prevalence; but mainly upon two facts as follows: Perspiration tends to cause chill, because of the fact that evaporation from moist clothing tends to lower the temperature rapidly. I believe that a chill, especially at the warmest time of the day, is, not infrequently, sufficient to start the disease intermittent fever. Excessive perspiration tends to

³ Jour. Amer. Med. Assoc., Nov. 10, 1888.

⁵ London Lancet, also Medical Age, Detroit, Feb. 10, 1890, p. 66.

change the condition of the blood; and chill tends to change the condition of the blood, in some such way as follows: When the surface of the body is strongly contracted, the blood is driven from all the surfaces, the circulation is impeded, the blood parts with some of its fluid, and, with it, the salts, which pass into the urine; then there comes a demand of the tissues for blood, thirst is great, which, when satisfied, again fills up the blood-vessels. This rapid changing of the proportion of fluid in the blood tends, I believe, toward the solution or breaking up of the red-blood corpuscles. My belief is that the destruction of the red corpuscles is greater than it would be if only the proportion of water in the blood was changed,—that the destruction occurs partly through a disturbance of the proportion of certain salts in the blood. It is not difficult to see how this may be: Excessive perspiration takes out salts, especially sodium chloride, in considerable quantity; the urine passes out salts in considerable quantity. On the other hand the water drunk to quench the thirst, does not ordinarily take salts into the blood. (Except in cases where common salt is given as a remedy, which is sometimes done by non-professional persons.) According to experiments made many years ago, in the circulating blood, in health, the red corpuscles are preserved by sodium chloride from being dissolved in the albumen.⁶ As this paper is not an exhaustive treatise on this subject, but is intended to be suggestive to other investigators, I do not now attempt to collate recent evidence on the changes in the blood. In order, however, to account for the destruction of the red corpuscles, the formation of the pigment, and for the phenomena of intermittent fever, I see no need for the microorganism which is alleged to be parasitic in the blood, in intermittent fever. It seems to me that all of the phenomena can be accounted for about as well without the parasites as with; but it seems to be a general fact in nature that whenever a highly-organized being commences to break down, there are generally organisms that await the occurrence, and when the breaking down process is of elements microscopic in size, I believe that microorganisms are generally there. I accept the evidence of the eminent men, who have reported that they are present in the blood in intermittent fever.

But if we grant that malarial fever is caused by microorganisms, parasitic in the blood, it has remained to be explained how it is that the microorganisms only cause intermittent fever under certain conditions of the atmosphere. That intermittent fever does occur under some conditions, and does not occur under other conditions, has long been positively known. I claim that the statistics which I have collected prove what those

conditions are; and that the relation of those conditions to intermittent fever is quantitative and causal. I refer more especially to the evidence (exhibited in Diagram No. 1) relative to the half million and more cases of intermittent fever which occurred in the United States Armies, during the war, in 1862-4; and to the evidence of the recorded experience of physicians in Michigan, during eight years, which is exhibited, in graphic form, in Diagrams Nos. 2 and 3.

SOME OBSERVATIONS ON THE CORRECTION OF LOW DEGREES OF ASTIGMATISM.

Read in the Section of Ophthalmology, at the Forty-first Annual Meeting of the American Medical Association, Nashville, Tenn., May, 1890.

BY T. E. MURRELL, M.D.,
OF LITTLE ROCK, ARK.

Perhaps no two men entertain identical views, or have like experiences in all particulars in the matter of correcting ametropia. All fixed rules must bend to the inevitable exceptions, and certain general principles only can be said to obtain upon which experience and judgment found creditable results.

It was taught by Donders that it was seldom necessary to correct an astigmatism of less than 1 D. This hypothesis was based upon the practical sharpness of vision. It was considered that when vision is so nearly normal a slight error should give rise to no appreciable annoyance. Larger experience and more extended observations have led to quite different conclusions. We now know that an astigmatism so slight as to be scarcely appreciable by ordinary tests may be the source of very considerable discomfort when the eyes are much employed.

Since so few eyes are absolutely free from corneal astigmatism, the question arises: Where shall the line be drawn between the normal and the abnormal? To every one of large experience in this class of work the answer readily comes up: It is largely a matter of clinical experience and not of optical perfection; since we observe many persons with much astigmatism who make little complaint, while in others, with the smallest appreciable degree, there are the most distressing symptoms.

In the earlier years of my ophthalmic work I was disposed to follow the great master, whose text-book was my sole guide, and ignored all cases where the astigmatism was appreciably less than 1 D. The trial cases made at this time contained no cylinder less than about 1 D. I found myself, however, recording accommodative asthenopia, hyperæsthesia of the retina and various neuroses for which I could not account and for which I could find no remedy. Shrewd observers were

⁶ Dalton's Human Physiology, First Edition, page 56. Human Physiology, Flint, Fourth Edition, 1888, page 432.

not slow to find a clue to these troublesome phenomena. The more that low degrees of ametropia were corrected the less were the number of cases of hyperæsthesia of the retina, accommodative and retinal asthenopias and like obscure conditions.

It is probable there are not so many more persons now possessed of astigmatism than in former years, but the higher development of the perceptive centres has created a demand for greater sharpness of vision and, at the same time, universal education has imposed greater tasks on the eyes than ever before.

Together with these demands come the enervating influences of a high grade of civilization, rendering doubly susceptible all the reflex centres. In addition to this the widely known successes of ophthalmologists lead people to consult them who would in former years have suffered their inconveniences and annoyances of sight in silence. These are doubtless the prominent factors in the immense requirement for astigmatic spectacles.

The eye that is highly trained has a very keen sense of the relative distinctness of test objects. In correcting astigmatism I find it very important to be as exact as possible. I formerly had much of my work to do over by thinking relief would follow if only approximate correction was made, just so the strain was taken off. They sometimes complained worse than without a glass. A person may have an error of 0.25 D. and, with normal, perhaps more than average, sharpness of vision suffer no inconvenience whatever; while if he has an astigmatism of 0.50 D. or 1. D. and an error of 0.25 D. or even less is made in the correcting glass, he will surely make complaint.

A young man once consulted me for eye-strain and nervous troubles, pronounced spinal in origin by his family physician. I discovered a myopic astigmatism for which I prescribed — 1. D.c. 180° for each eye. These were worn for two years, but gave very little relief. Vision was sharp with them too. He was then tried for some time with — 0.50 D.c. 180° each eye, with which he seemed to see equally well as with the first glass. These gave only partial relief. Finally a — 0.66 D.c. 180° each eye was ordered, and with these he has had perfect comfort, all eye-strain completely disappearing in a short while, and now, after nearly a year, he expresses himself as still delighted with his great boon in the possession of the magical glasses. The last change made in his glasses, which brought such relief, amounted to only about 0.16 D.

In another instance I found 0.50 D.c. too strong and 0.25 D.c. too weak, and obtained perfect comfort with 0.33 D.c. This gentleman is to-day one of the most grateful friends I have. A lawyer by profession, he had nearly decided to abandon his profession for some non-literary pursuit on account of persistent and troublesome asthenopia

whenever he would read. With his glasses he now has no trouble, and has started afresh with his professional work.

These may seem very fine distinctions, but they are correct observations accurately and faithfully made. I can very readily conceive how less degrees of astigmatism than are ordinarily corrected may give rise to annoyance in highly neurotic persons, but I rarely find use for the 0.25 D.c. some persons are now prescribing so extensively. There are very few persons whose vision will not be sharpened by a + or — 0.25 c. at some particular angle. In my own case a + 0.25 c. 90° for O. D. and 135° for O. S. materially sharpen Snellen, but I cannot wear these glasses for even a few minutes without distress. I have never felt the need of glasses in my work.

My experience leads me to the employment of a mydriatic in determining astigmatism. I am becoming more and more convinced of its importance. I use atropine only. Homatropine has so often misled me I have altogether abandoned it. It will rarely completely paralyze the accommodation, which is essential if a mydriatic is used at all.

It is sometimes necessary to instil into the eyes a 1 per cent. solution of atropine three times daily for several days before complete relaxation of the accommodation will be produced. The astigmatism found in total paralysis of accommodation is, according to my experience, the actual astigmatism of the eye, and the glass that corrects it will, in the end, prove the most satisfactory glass.

I believe that the partial correction of corneal astigmatism by some undefined manner of irregular contraction of the ciliary muscle, by which an astigmatism found during paralysis of accommodation disappears on the return of accommodation, is the cause sometimes of incorrigible asthenopias. According to my experience an astigmatism found under atropine exists in reality without it, however much it may be masked by accommodative action, and the persistent wearing of the correcting glass will eventually suspend the action of the no longer necessary compensating accommodative effort and with it bring perfect comfort and rest to the eye.

The opposite of this rule will not hold, for an astigmatism found in full accommodation will often disappear under suspension of this power.

A girl 15 years old consulted me by advice of her physician for headaches, to see if they were not due to eye-strain. I found that a + 0.50 D.c. 90° very decidedly sharpened V. in both eyes. These glasses were repeatedly tried with the same results every time—almost doubling the acuteness of V. They were ordered. At first they suited admirably. At the end of a week she returned with the complaint that her glasses no longer gave comfort. A 1 per cent. solution of atropine was instilled into each eye three times daily for three

days and she was again examined. There was now no astigmatism to be found, but only a total hyperopia of 0.75 D. Since the return of accommodation there has been no further astigmatism found and no further complaint. Such cases as this are right often met with, and offer another argument for the use of a mydriatic in determining all errors of refraction and especially astigmatism. This so-called lenticular astigmatism has received a good deal of attention of late. As to its correction a question is involved bearing upon the theories I have here advanced.

The importance of atropine in ascertaining the exact error of refraction is well illustrated in the following case: Mrs. H., aged 26 years, was ordered + 1. D.c. 90° for each eye nine years ago by a well-known ophthalmologist. Two years ago the same gentleman prescribed for her + 0.50 D.c. 90° for each eye. Neither of the glasses relieved a peculiar weariness more or less constant in the eyes. On consulting me not long since, I found she saw best with the + 1. D.c.; it raising V. from Sn. $\frac{1}{8}$ to $\frac{1}{6}$, and with it she could read J. 1 fluently.

I told her I could not be positive whether the trouble was in her eyes or not without using atropine. She consented to it, and a 1 per cent. solution was dropped in each eye three times daily for three days. I now found astigmatism = 1.75 D. 180° in O. D. and astigmatism = 1.50 D. 165° in O. S. Glasses were ordered as follows: O. D. + 1.75 D.c. 90°; O. S. + 1.50 D.c. 75°.

She was directed to wear these constantly. A little awkward at first, her eyes became more and more comfortable, and at last accounts she was highly pleased. In low degrees of astigmatism I have often found V. = $\frac{2}{8}$, with full play of the accommodation, reduced to $\frac{2}{8}$ or $\frac{3}{8}$ under atropine, when the astigmatism becomes an easy problem.

Each of the points brought out in this paper could be fully illustrated from my record book were it worth while. I trust that the narration of my own experiences and observations will call for expressions of opinion from others of larger experience in this particular line of work.

DR. FROTHINGHAM said: As the results of experience are of such importance in the consideration of a question of this kind, I wish to say that I now correct low degrees of astigmatism in nearly all cases of persistent asthenopia. I use atropia less often than formerly, as I find that in many instances I can sufficiently correct the ametropia without resorting to its action. In many cases the patients will not submit to a sufficiently prolonged use of it, or even to a brief action of it, so long as it is possible for them to use the eyes at all. They plead that it is impossible for them to stop work and suffer the inconvenience its action would cause them. In cases of severe

and persistent asthenopia the thorough action of atropia becomes almost imperative and the action of more transient mydriatics possesses no advantage, for prolonged rest of the ciliary muscle becomes necessary. There are cases, however, in which it becomes necessary to know the exact static refraction of the eye in order to prescribe even temporarily. Here the action of homatropine is very valuable. By its action we can often get the desired information in the case of patients who would not submit to the action of atropine, which lasts so much longer.

DR. RANDALL stated that his paper dealt with several of the points raised, and he would forestall it by speaking as to them now. He wished to reiterate the points elsewhere made that ametropia is the rule—astigmatism as well as hypermetropia being found in the majority of cases. Adults as well as children show these errors, the assumption that they are outgrown being wholly unproven. Refraction error is to be expected, therefore, in most cases, whether eye-patients or not—whether it needs correction is, however, a question to be decided only on the merits of each individual case. Small errors may be very important. Accuracy often demands a mydriatic, and hyoseyamine seems the best in most cases, as it is less apt to cause constitutional symptoms than duboisine, passes off in half the time required by atropine, yet gives full three days of total rest after the last instillation (where atropine gives but two), and enforces only two days of returning accommodation instead of eight or ten days, as after atropine. Many cases cannot be measured under mydriatics, even homatropine, but the refraction as measured under full paralysis of the accommodation is the true basis of our study.

DR. LEARTUS CONNOR, of Detroit, Mich., said that 1. If possible the examination of all cases of asthenopia should be conducted under the influence of atropine, as this saves time and promotes exact accuracy. 2. But practically such use is impracticable, owing to the engagements of patients. Further, an experience with several thousands of cases shows that the results of correction of refractive error are usually satisfactory when made without atropine. In fact, a comparison of these results with those obtained under atropine is favorable—the relief to the patient being equally satisfactory. 3. Atropine I have found far more satisfactory than other mydriatics. 4. The use of small degrees of astigmatism I esteem more highly with extending observations of their results. But I do not use them unless the general condition of the patient is normal and a distinct asthenopia continues.

DR. J. H. THOMPSON said he could not agree with the custom of fitting in a routine manner very small degrees of astigmatism, inasmuch that an appreciable astigmatism of low degree, 0.25,

is not by far the cause of the asthenopia complained of. The more I practice the more I am convinced that atropia is not necessary in all cases. In children under 14 years atropia may be advantageously used, but in adults its use may be more annoying than beneficial. Astigmatism and hypermetropia may be corrected very early in adults without a mydriatic. In presbyopia with astigmatism it may be sometimes necessary, but should be avoided if possible. I have reasonably good results without atropia. Low cylinders, especially in minus, are fascinating and will be in many cases accepted, but that is no indication that the glass is necessary or proper for asthenopia. Many cannot, with an anatomically normal eye be dependent upon lowered muscular or nerve tone. Correcting the astigmatism in such cases will not give permanent relief.

DR. HÖTZ, of Chicago, said that he uses homatropine and saw no reason from his own experience to question its efficiency and reliability, and if it answers the purpose for our refraction tests it certainly is preferable to atropine. Though the result under suspended accommodation gives the true refraction, it is seldom practicable to give the glasses this refraction calls for. The astigmatism can and must always be fully corrected, but for the common hypermetropia I find the patient will not accept a full correction; the glass has to be $\frac{1}{2}$ D. less, and sometimes even more of the hypermetropia must be left uncorrected; if you correct more, the glasses will cause as much discomfort as a faulty correction. Perfect vision and the comfortable use of his eyes is what our patient wants, and therefore correct the error of refraction—no matter how great or how little—so far as necessary to attain this end.

DR. LEWIS H. TAYLOR, of WilkesBarre, Pa., said: I have been much interested in listening to the paper just read, and am glad to hear the speaker say that he uses atropine in correcting astigmatism. I almost invariably use it, and for some years past have discarded other mydriatics, homatropine and dubosine especially in my hands being unsatisfactory. I do not quite agree with the speaker as to the uselessness of the quarter dioptre cylinder. I have had considerable experience in its use and have found in many cases most beneficial results, especially when the correction has been made with atropine.

DR. LIPPINCOTT said: In regard to the use of a mydriatic, the circumstances of many of my patients do not permit me to paralyze the accommodation. In such cases I endeavor by repeated examinations to estimate the refractive error, on the principle that half a loaf is better than no bread. However, I consider the use of the mydriatic desirable wherever possible, not only because it tends to secure an accurate result, but because it enables us to obtain the result rapidly, thus saving much time.

As regards the correction of low degrees of astigmatism, I not very infrequently prescribe a cylinder as low as a quarter of a dioptic. It may be remarked that even if the glasses are subsequently laid aside, this fact does not argue against the correctness of the prescription, because it sometimes happens that the necessity for a glass arises from a neurasthenic condition which may last only during a short period, during which the patient is tided over his difficulty by the use of the cylinders.

DR. JACKSON: I believe there is a state of static refraction revealed by the efficient use of any of the mydriatics named. On account of the brevity of its action I, therefore, prefer homatropine for purposes of diagnosis only. It is very generally forgotten that the glass giving the best vision at 15 or 20 feet is not the correction of the ametropia but for hyperopia, an over-correction of $\frac{1}{4}$ D. This over-correction will be annoying as long as it lasts. But the true correction, if annoying at first, will in time disappear entirely.

ON THE UNITY OF DIPHTHERIA AND MEMBRANOUS CROUP.

Read in the Section of Laryngology and Otology at the Forty-first Annual Meeting of the American Medical Association, Nashville, Tenn., May, 1890.

BY D. BRYSON DELAVAN, M.D.,
OF NEW YORK.

The discussion of this apparently trite and timeworn question would seem out of place at this meeting, were it not that, even at the present day, we are still unable to speak with certainty concerning it.

The failure to have secured a more definite conclusion regarding it is in no wise due to lack of care on the part of those who have investigated it. On the contrary, it has engaged the attention of a large number of earnest students; the subject has been studied collectively as well as by individuals, and, finally, the diseases in question are of such common occurrence that abundant material has always been forthcoming upon which deductions could be based. With all this accumulation of material and of effort it would seem strange that sufficient doubt should remain to warrant discussion.

We find, however, in studying the differential diagnosis between diphtheria and croup as commonly given, that there are many conditions which are far from being constant.

Thus, it is tolerably well established that in diphtheria the disease is usually due to some apparent cause of infection; that the diphtheritic poison is itself highly infectious; that the membrane may not be confined to the larynx, but may appear in the throat above that organ; that its presence is generally attended with swelling of the cervical glands; that albuminuria is a fre-

quent symptom of it; and that the appearance of the diphtheritic membrane is characteristic.

On the other hand, it is said that the so-called croupous exudation occurs spontaneously and without the history of infection, while it is not itself infectious; that the membrane does not extend beyond the larynx; that there is no swelling of the cervical glands; that there is no albuminuria; that the appearance of the croupous exudation is distinctly different from that of the diphtheritic.

Unfortunately, the exceptions to the above differential points are so common as to throw discredit upon them and much impair their value. It must be conceded that the causes of infection in diphtheria are sometimes exceedingly obscure and difficult to trace, so that in studying them many sources of error may arise. Again, all forms of diphtheria do not appear to be equally infectious. Cases of supposed croupous laryngitis have been seen in which the croupous exudation appeared also upon the fauces. Swelling of the cervical glands and albuminuria have been seen in croupous laryngitis. Finally, from the usual appearances alone of the exudate it is often difficult to determine the true nature of the disease.

The above hasty analysis of the question from a clinical standpoint indicates that investigation has served rather to hinder than to help in the establishment of a reliable standard of differential diagnosis.

Fortunately, the advances made in modern pathology have enabled us to rely for proof in such matters upon evidence other than that given by the rational symptoms of disease, and when the resources of the clinician fail there is left an appeal to a still higher authority, namely: to the microscopist. While in the present discussion the clinical evidence is largely negative, from the microscopical investigation of diphtheria results have lately been reached which give rise to the hope that at no distant day a positive and definite standard may be attained, by which this disease may be isolated from all others, and the question of the unity or duality of laryngeal exudation be finally settled. Löffler (*Deutsch. Med. Woch.*, January 30 and February 6, 1890), and Prof. T. Mitchell Prudden (*Amer. Jour. Med. Sciences*, April and May, 1889), have reported excellent bacteriological observations upon this subject. The investigations of the latter, made in the bacteriological laboratory of the College of Physicians and Surgeons, New York, are exceedingly valuable and interesting. This observer found that, in diphtheritic matter obtained from various sources, a certain form of streptococcus was always present. To this species he has given the name "streptococcus diphtheriæ." Comparing it with those species of bacteria already known and described he finds that, in its forms and modes of growth, as well as in its effects when

injected under the skin, or into the blood of animals, it appears to be identical with the two well-known species called "streptococcus pyogenes" and "streptococcus erysipelatos." In view of the above we may indulge the hope that the differential diagnosis between diphtheria and croup, doubtful when regarded from the clinical standpoint, may, in the light of bacteriological investigation, become clearly and definitely established, and that this question, at once so difficult and so important, may at last be set at rest.

PROFESSOR FLINT'S DOCTRINE OF THE SELF-LIMITATION OF PHTHISIS.

Read at the Sixteenth Annual Meeting of the Mississippi Valley Medical Association, at Louisville, Oct. 8, 1890.

BY WILLIAM PORTER, M.D.,

PROFESSOR OF LARYNGOLOGY AND DISEASES OF THE CHEST IN THE ST. LOUIS COLLEGE OF PHYSICIANS AND SURGEONS; FELLOW OF THE AMERICAN LARYNGOLOGICAL ASSOCIATION; EX-PRESIDENT OF THE MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Sometime before his death Prof. Flint promulgated the doctrine of the self-limitation of phthisis, and presented it with all of his well known power and great ability to the profession. This very interesting proposition was at the time the subject of free debate in various medical societies, and at a former meeting of the Association I had the honor to partially discuss the position taken by this learned teacher and writer.

The recent years have been full of the wonderful results of the study of pulmonary disease and bacteriologic research, and the possibility of a positive diagnosis has overshadowed the equally interesting question of prognosis. That Prof. Flint's arguments, however, have not been lost to the profession is evidenced by the repeated references to it in recent current medical literature, and many are ready to say with Prof. Stephen Burt, of New York, that "not a few cases of phthisis have a self-limitation." This author, in a valuable paper entitled "Pulmonary Consumption in the Light of Modern Research," read before the New York Academy of Medicine, and published in the *Medical Record*, April 12, 1890, takes the tenable position that "phthisis is an infectious disease, only the soil must be fertile or the bacteria will not take root and grow; that the inheritance of the affection is simply the descent of the degraded cells presenting a vulnerable point for the vagrant germs; that all specific treatment is futile; and though persistent destruction of the infectious matter is our best means of prophylaxis, yet to restore the vitality of the lung tissue is as important as to destroy the tubercle bacilli." Following this comes his affirmation of the possibility of the self-limitation of phthisis. In Pepper's elaborate "System of Medicine," Vol. iii, p. 393, Flint again affirms his

statement that in certain cases of phthisis "the disease may be said to be self-limited."

It is a just inference that this idea has been well received by many excellent physicians and that it has made a deep impression upon the mind of the profession, not more on account of its great champion than because of its plausibility and desirability, for truly as one author says, "it is a comforting thought to the afflicted," and we would add—to the physician also.

I can bring no more interesting question before you; it touches us at all points where we attempt to save life from this dread disease, and it is inseparably connected with our opinion regarding the future of a large proportion of our patients. It is right, therefore, that we should have some fixed idea as to the existence of self-limitation of phthisis and its value in any given case or series of cases.

After having carefully examined the facts cited in support of the proposition, I have no hesitation in distinctly asserting that I find no sufficient evidence to warrant us in accepting the statement that phthisis is self-limiting, or that the element of self-limitation has a decided influence upon the result in any given case. I do not mean that all cases of phthisis necessarily die from this disease, but I do mean that where phthisis is firmly established, there is nothing in the nature of the disease itself that indicates in any stage a fixed boundary—a line of demarcation as it were, but rather that all of its tendencies are progressive and downward.

It is well that there should be in all debate a clear understanding as to the meaning of the meaning of the terms employed, and at the outset I am perfectly willing to accept Flint's own definition not only of the term "self-limiting," but also of the word "phthisis."

Permit me then to quote in full his definitions as given in his argument: "A disease is self-limited when it ends in recovery irrespective of extrinsic influences derived from either hygiene or therapeutics. A patient, whatever be the disease, who recovers without any potential remedies or measure of treatment having been employed, and where there has been no material change in any of the circumstances pertaining to daily life, owes the recovery exclusively to self-limitation." To this we readily agree.

He then defines the terms pneumonic phthisis and pulmonary consumption and says: "I shall consider the terms as applicable to all cases of phthisical disease exclusive of acute tuberculosis and interstitial (fibroid) pneumonia." That there may be no mistake as to his use of words I may add that he uses the terms phthisis, pulmonary tuberculosis, and consumption in the same sense (*Prac. Med.*, p. 271). Using, then, our author's own language, the question is—is there in phthisis, or if you please, pulmonary tuberculosis,

a tendency to recovery without extrinsic influence derived from either hygiene or therapeutics?

Although as early as 1835, Jacob Bigelow, in a paper which Prof. Flint justly calls remarkable, read before the Massachusetts Medical Society, applied the term "self-limited" to certain diseases, it was not until 1858 that the latter advanced the idea of self-limitation as applied to phthisis. (*Am. Jour. Med. Sciences*, 1858.) Twenty years afterward the question was ably reopened by him in the paper to which reference has been made, and his position virtually accepted as proven.

The deductions in this important essay are based upon clinical evidence rather than argued from a pathological standpoint, and if you will bear with me I will first present an analysis which I have made of the cases which are cited by Prof. Flint, and afterward endeavor to show that the pathology of phthisis, so far as we yet understand it, is opposed to the doctrine of self-limitation.

In the first place the argument which Prof. Flint advances is founded upon the deductions made from the history of 670 cases of phthisis. Fortunately these cases are all on record, and I shall not only accept the record of each case without question, but follow his own selection, though to very different conclusions.

Among these 670 cases there were 75 in which either recovery took place or the disease became latent. It is, therefore, in these 75 cases we have to find the proof of self-limitation and by these must the proposition stand or fall. I must beg you to bear in mind as we go along, the definition that "a disease is self-limited when it ends in recovery irrespective of extrinsic influences derived from either hygiene or therapeutics."

We find that in 31 of these 75 cases the statement is merely that "the disease ceased to progress for at least several months, and in the majority of cases for several years." By reference to the record we find that the last examination of each gave evidence that the disease was still present—latent in some, as may occur in phthisis, but not self-limited; for "a disease is self-limited when it ends in recovery," etc., and these had not recovered. As according to our author's own definition 31 of these cases have no definite bearing upon the point in question, we are restricted to the study of the remaining 44.

As self-limitation is independent "of extrinsic influence derived from either hygiene or therapeutics," we at once decline the evidence of 21 of the 44 cases, for in all of these pertinent and generally persistent treatment was pursued. Moreover, three of these cases subsequently proved fatal, and the last examination showed that at least a third of them had still physical signs of phthisis. We object to these 21 histories as not

pertinent. The interest now centers in but 23. "In 15 of the cases hygienic measures constituted the treatment;" but these measures were of such a character as would lead us to hope for favorable results, viz., change of business, out of door life, rest, sea voyages, change of climate, etc. These are potential aids, for as Flint says (*Prac. Med.*, p. 290), "out of door life is of all measures most important." Now, to prove a disease self-limiting, we must eliminate whatever can be reasonably traced to "either hygiene or therapeutics." These 15 cases were given the advantage of favorable hygienic condition, and who shall say they would have recovered without these conditions? Having made use of that remedy which of all others has been found efficacious in phthisis, these 15 cases are certainly not examples of self-limitation.

I have refrained from occupying your time with the details of the author's cases, which, in accordance with his own definition of limitation, have been refused as evidence. The history of these is fully given in his work on phthisis, and I have endeavored to deal fairly and justly with the record.

Let us now apply the test to 8 cases which alone remain. These are numbered 1, 4, 7, 8, 14, 20, 23 and 24 (*Phthisis*, p. 187, et seq.) and are the only ones of which the author says "there was no medical treatment of importance, and no material change in the habits of life, the recovery taking place purely from an intrinsic tendency."

Case 1 is that of a farmer, who having in the winter of 1842-43, expectorated what were thought to be pulmonary calculi, was examined in June, 1843; "the only physical sign noted was feebleness of the respiratory murmur." He was in excellent health 13 years afterward. "Prior to the development of the disease the patient had worked very hard on a farm. He left home for several weeks, and after relinquishing severe labor, engaged in buying and selling new lands in Illinois, a business which required much out-of-door life." Excellent treatment.

Case 4.—A physician aged 28 had hæmoptysis, in October, 1852, and again in January and May, 1853. In May, 1853, he had slight dulness at the right summit, with weakened respiratory murmur and crackling, which accompanied inspiration and expiration. In September, 1854, he reported himself well, "a year after recovery;" *i. e.*, his recovery must have dated from September, 1853, five months only after the above symptoms were noted. However, we find that in September, 1854, there was still a dulness at the right summit and the respiratory murmur was feeble.

Case 7 is that of a constable examined in April, 1856. Six years before he had had a hæmorrhage, and shortly afterwards recurrent hæmoptysis for ten days. During the following year

Prof. Flint met this man from time to time on the street, and he seemed to be in good health. As this man evidently had phthisis for six years prior to examination, what reason is there, in the absence of a later examination, to suppose that he had entirely recovered during one succeeding year? The statement that he seemed well will apply, at times, to many cases of chronic phthisis. "There is no further record of this case. The treatment consisted of cod liver oil for six weeks, generous living, the use of malt liquors, and out-of-door life." Very good intrinsic influences we take it.

Case 14.—A physician, who had cough, hæmoptysis and slight loss of flesh, was examined October, 1857, and found to have evidences of phthisis at the left apex. Five years later Dr. Flint saw him in apparently good health. He had been drinking beer, living generously, with an abundance of exercise out of doors. It seems that in this case and in No. 4, no medicinal agent was used, though the patients were physicians. They both had the influence of riding and driving in the open air while engaged in country practice.

In *Case 24* we find that the patient consulted Dr. Flint by letter in 1859; was relieved of part of her duties as a teacher; took more out-of-door exercise; traveled in the summer. In 1862 had abnormal dulness, feeble respiration, and increase of resonance and whisper at the right summit. Afterwards traveled in Europe; in 1868 had hæmoptysis; in 1869 increase of symptoms, and she died in the spring of 1871. Did this patient recover, and that without change of hygienic condition?

The three remaining cases do, so far as recorded, seem to be instances of recovery from phthisis without medical or hygiene agency.

Case 8 was a clerk, examined in August, 1856, having had cough two months previously and hæmorrhage a week before. There was dulness and feeble respiration at the right apex and subcrepitant râles on both sides. In October, 1856, he was reported well, and was in good health in 1871. The thought is at once suggested, why did he, being examined at a time of greatest danger, not have medicinal treatment? The case is, however, one of great interest, and is certainly an exception to the general rule, as the disease appeared, progressed and abated within a period of five months.

The other two *Cases 20 and 23*, furnish the best evidence in favor of self-limitation, though the record is very short. Two sisters whose parents, three sisters and two brothers, had died of phthisis, were found, one with disease of the left apex, the other of the right. No remedy of importance was given, or change made in the habits of life. Both were well fifteen years afterward. Again the question may be asked, why was not

some form of treatment or change of condition ordered in these cases, as "no effort had been spared to save the lives of their sister and brothers; traveling, changes of climate, together with remedies having been resorted to in vain, although perhaps, with the effect of retarding the progress of the disease." With this, however, we have nothing to do. The record is that these two sisters for whom nothing was done alone recovered. Granting that these two cases, and possibly the preceding one, show evidences of self-limitation, yet they are but three out of 670, and we again quote from Prof. Flint's paper, "Self-limitation cannot be inferred from a single case or a very few cases."

The clinical evidence cited by Prof. Flint certainly does not prove the doctrine of self-limitation according to his own definitions, for we find that in the large experience of its able advocate, among hundreds of cases as recorded by himself, that the argument is sustained by few, and in all fairness we confess a doubt as to the pertinence and value of most of these.

Is not this conclusion in accord with our own experience? What physician to-day expects that in a given number of cases of phthisis as they come to him, any small proportion will recover without the help of medication or change in hygiene or environment? Or to put the question more directly, who has so much faith in the doctrine of self-limitation that he would trust in the slightest degree in planning for the future good of his patients?

So much as we know of the true pathology of phthisis is opposed to the doctrine of self-limitation. In the constitutional predisposition of the general morbid condition which Flint speaks of as the essential disease, we now recognize only that degeneration of the body in whole or in part, which favors the reception and development of the specific factor of tuberculosis. So long as no bacilli are found, the disease cannot be proven to be tuberculosis. The tubercular cachexia is a misnomer except so far as it is limited to conditions which favor the invasion of the essential germ.

In the ordinary case of tubercular phthisis we now know that we have not only the constitutional fault, characterized, as Sir Andrew Clark has it, "by a progression of symptoms with an ulcerative or suppurative destruction of a more or less circumscribed, non-malignant deposits in the lung," but in addition, we have a specific morbid change, the result of a specific cause. I need not weary you with a discussion of the exact relation of the bacillus to tuberculosis. Whether the bacilli are the cause or the result of the rapid disintegration is not the question in point. Whether these or their ptomaines, or both are the active factors, may some day be fully decided. This much we know, that where the changes have

begun which result in those morbid products in which the tubercle bacilli are found, we have to deal with an active, relentless, progressive foe to human life.

Let us but remember that the bacillus readily enters a mucous membrane denuded of its epithelium and passes down to the lymphatics and vessel walls; that according to Netschnikoff and Naegeli it inaugurates a struggle with, and rapidly destroys feeble organic cells, and we must forever abandon all preconceived ideas of the self-limitation of phthisis.

Our author says "there should be no room to doubt as to the accuracy of the diagnosis," and the researches of the bacteriologist have placed within our reach the essential element in the diagnosis of tuberculosis, but the knowledge of the existence of this element is directly opposed to the doctrine of limitation without extrinsic aid.

Therefore, clinically and pathologically, we must have further evidence of self-limitation. I grant you that well proven cases get well. It must be admitted that treatment has in some instances been successful; that resistance has been made to the cell invasion of the bacilli and that the general systemic fault has been corrected. My position is, however, that in every such case there has been some helpful treatment administered, some beneficial hygienic or climatic change accomplished.

Our deductions must, therefore, be:

1. That there is no sufficient clinical evidence to warrant us in believing that by self-limitation as defined by Prof. Flint, pulmonary phthisis may end in recovery.
2. The pathology of phthisis is equally opposed to the proposition.
3. Although phthisis is not self-limited yet limitation is possible through "extrinsic influence derived from hygiene and therapeutics."

One word in conclusion. To no one does the medical profession of America owe more than it does to the memory of Dr. Flint. Though dead, his words live. With reverent hands would we lift the record of his work and in the same fairness which he admired and practiced, would we examine his teachings. In this city which he loved so well, and in which was once his home, no words are needed to recall his greatness.

May the analysis of the argument which we have made, and even the widely different conclusions which we have reached, be counted an honest tribute to the great influence of him whose lips are forever sealed.

MEDICAL CONGRESS IN RUSSIA.—The fourth congress of the Society of Russian Medical Practitioners will be held at Moscow, the day of meeting being fixed for January 3, 1891. The work is to be done in twelve sections.

A NEW OPERATION FOR STRICTURE OF THE RECTUM.

BY M. G. THOMPSON, M.D.,
OF HOT SPRINGS, ARK.

In no reports upon rectal surgery has the writer seen presented the principles and procedure of the following operation for stricture of the rectum, and therefore the novelty is claimed in the title to this report.

Mrs. B., æt. 32, giving history of syphilis, with a subsequent rectal stricture and fistula in ano. The symptoms of stricture, growing worse each month and not having more than one operation on bowels a week, brought the patient under examination July 28, 1890. After inducing anæsthesia examination revealed a fistulous tract from superficial sphincter opening one and one-half inches from anus, also flaps or folds of mucous tissue around the anus; within were infiltration and thickening of mucous and submucous structure, and about three inches above the anus an annular stricture almost occluding the rectum.

After dividing the fistula and superficial sphincter, a pair of uterine dressing forceps were introduced through the stricture, by means of which sufficient dilation was made to introduce a probe pointed bistoury; two incisions were then made well dividing the stricture bi-laterally. Pratt's large dilating speculum was then introduced dilating the rectum to its full capacity, being frequently turned in various directions for the purpose of thoroughly using a douche of warm carbolized water, and curette and silver nitrate to all suspicious pockets.

Keeping up these antiseptic precautions for about twenty minutes and the speculum remaining *in situ* paralyzing all muscular action, no difficulty was experienced in bringing down the stricture with a tenaculum and securing with an Emmett needle armed with catgut suture or loop; the mucous membrane from the stricture to the anus falling in folds and protruding from the anus like external pile tumors, an assistant then holding the stricture in position by means of the loop, the posterior folds of mucous tissue were removed with tenaculum and scissors; then making an incision half way around the anus posteriorly and removing corresponding cicatricial tissue in the stricture, the two surfaces thus denuded were securely brought together with catgut sutures. Nothing was at the time done with the protrusion of mucons folds on the anterior surface.

The usual dry dressing was then applied, and patient taking an opiate was put to bed. No suffering or inconvenience followed. The bowels moved each day and on the eighth day patient returned, when with the aid of sol. cocaine the anterior folds left protruding on the day of the operation were snipped off with tenaculum and scissors. Entire recovery on fourteenth day from

first operation. No trouble has arisen since.

Note the following suggestions, which will improve the plan of procedure:

1. Don't divide stricture before it has been brought down to the anus, and do not allow it to return after dividing.
2. Don't bring the stricture down with the tenaculum, but use hæmostatic forceps to avoid laceration and puncturing.
3. Don't paralyze with speculum; use fingers to avoid rupturing rectum at site of stricture, which accident might cause peritoneal complication.
4. If stricture can not be brought down to anus, denude and stitch to muscle.

THE CLINIC.

VAGINAL HYSTERECTOMY.

A Clinical Lecture delivered at the Woman's Hospital of Chicago.

BY FRANKLIN H. MARTIN, M.D.,

PROFESSOR OF GYNECOLOGY POST-GRADUATE MEDICAL SCHOOL OF CHICAGO.

The first patient which we bring before you today for consideration is one upon whom I propose to perform vaginal hysterectomy, for cancer of the cervix and uterine portion of the vaginal walls. The patient is a nulapara, unmarried and but 28 years of age. As you doubtless know, such an early age and domestic condition are two factors which would not ordinarily lead us to expect cancer.

The patient was referred to my department from the out-department of the hospital, about three months ago, for the purpose of giving her the advantage of galvanism, for what seemed simple hypertrophy of the cervix from repeated attacks of endometritis. She was treated on an average of about once a week by myself or the house physician, until about two weeks ago, when, after an absence from the clinic of a couple of weeks, an examination revealed a condition which left little doubt of a rapid degeneration of the cervix, with distinct infiltration of the posterior walls of the vagina. The degeneration had been so rapid that it was with difficulty I could get a specimen for microscopical examination.¹

A decision was at once made, to operate, and as I have reason to believe from statistics recently gathered, that in the present state of surgery vaginal hysterectomy will give as low mortality in incipient cancer as high amputation of the cervix, I certainly could but give the patient the advantage of the operation which would go the farthest into the healthy tissue beyond the disease.

Preparatory Treatment.—No patient with a cancer of the uterus can afford to wait for any

¹ The microscopical examination revealed unmistakable signs of carcinoma.

imaginary good that may be gained by a long building-up treatment. As well build up a patient before relieving them of the contents of a septic pus cavity.

The patient should be prepared for the operation, effectually but promptly. We seek to get them into the hospital at least four days before the morning of the operation. The urine is examined at once. If convenient the patient should take a steam or Russian bath the first day, and keep herself well protected, with woolen next the skin. The night of the first day a mercurial, say two grains of pil. hydrarg. should be given, to be followed, in the morning, by a sedlitz powder. The bowels should be thoroughly evacuated. The second and last day before the operation the patient is given nothing but the blandest gruels and the bowels are thoroughly washed out four hours before the operation. A bichloride douche is given twice each day the four days preceding the operation, followed in each instance with pure water. No food is allowed for six hours before the anæsthetic is given. A sponge bath of bichloride is given the evening preceding the operation, and the external genitals are thoroughly purified before the operation begins. At this hospital a large dose of brandy is ordinarily given the patient before the anæsthetic, ether, is administered.

It will be noticed that the patient is thoroughly protected as she lies on the table, in body and limbs, with flannel covering. The temperature of the room is 80° F.

Those who have been selected to act as assistants, have thoroughly disinfected themselves, and the few clothes they have on are protected by these aprons and efficient sleevelets, and, therefore, all who have not been duly prepared to assist, and assigned a place, will confer a favor if they will not, under any pretext, volunteer their services.

Operation.—The patient being thoroughly anæsthetized, we will have her put in the exaggerated lithotomy position with the buttock well drawn over the edge of the table, and the limbs supported by two assistants, one on either side, in such a manner that they will each have one free hand with which to hold a Simon's retractor. It will be noticed that the vagina is very narrow, as would naturally be expected in a virgin so narrow, in fact, that it would be next to impossible to remove the uterus through it without enlargement. With this bivalve speculum, for want of something more suitable, I will, by means of the screw adjustment, forcibly dilate the vagina. This brings into relief the strong muscular bands of tension in the posterior and lateral walls of the perineum. With the scissors I will cut through the integument and the muscles beneath on either side, as is occasionally done by an obstetrician to forestall a rupture of the perineum, which seems

imminent, and at once I gain the necessary room and can successfully proceed with my operation.

As the retractors are now in place and held firmly apart, we get a fair view of the cervix and the diseased portion of the vagina. You will notice how brittle the tissue is—breaking down and bleeding with a touch of the sponge. On account of the friable condition of the cervix, which practically precludes the use of the vulselm's forceps, I will first transfix the mass, going high, with a strong silk ligature, which will serve, when tied firmly, as a means of handling the uterus. By means of this ligature, I now draw the cervix well down to the mouth of the vagina and thoroughly cleanse it with a strong 1 in 500 bichloride solution, and after all secretions are washed away by the irrigator, which contains a like solution, of strength 1 in 10,000, I make the first incision through the vaginal mucous membrane, anteriorly, with curved scissors and keeping well away from the diseased tissue, extend the incision posteriorly either way until the cervix is half encircled by it. The cervix is now drawn forward, and the incision is extended either side and posteriorly until the uterus is completely freed from its vaginal attachment, the incision completely encircling it. I now draw the cervix well down and back again, and with blunt-pointed scissors carefully dissect the cellular connection between the anterior wall of the uterus and the bladder. In doing this, you will notice I keep the point of the scissors very close to the body of the uterus, making it almost impossible to wound the bladder. As the dissection advances, I carefully draw upon the uterus until I feel that I am approaching the duplicature of the peritoneum between the two organs. As the assistant now continues the tension upon the cervix, I examine with my finger to ascertain how near I am to the peritoneum. I find by the characteristic yielding impression given that I am about to enter it. With a little pressure with the index finger, therefore, I push through it at its point of deflection from the uterus on to the bladder, and enlarging the opening sufficiently to enter the index finger of the other hand, I forcibly separate the two fingers, laterally tearing an opening through the peritoneum which extends to the unyielding broad ligaments.

Thus we have the bladder separated from the uterus, and the peritoneum open in front around to the broad ligaments. Some operators discard the scissors entirely in separating the bladder and uterus after the vaginal mucous membrane is incised, dissecting the cellular tissue with the fingers. This requires considerable pressure and tearing oftentimes, and I believe the bladder is in greater danger of being torn by the method, than it is in danger of being wounded with the scissors, properly employed, as I have indicated.

As the assistant draws the uterus well forward

now, I will enter the posterior cul-de-sac, keeping as far from the diseased uterus as possible, at the same time looking out for the rectum. The separation is easily accomplished. I scratch into the most dependant portion of the duplicature of the peritoneum and with two fingers enlarge the opening laterally and anteriorly, until we are again stopped by the broad ligaments. We will now thoroughly wash out the vagina again, with the 1 in 1000 bichloride solution, and again thoroughly disinfecting my hands, I will sweep my index finger over the fundus of the uterus in the peritoneal cavity, to ascertain that there are no peritoneal or intestinal adhesions to the organ, which might complicate the operation. Finding none, I withdraw my finger, and insert through the posterior peritoneal opening a soft, thin, flat sponge, (a ligature having previously been attached to it) in such a position that it will keep the intestines (which always show a great inclination to prolapse) entirely out of the field of operation, and also prevent fluids from entering the peritoneal cavity.

By examination of the broad ligaments, I find them so thick and firm that I shall ligate and cut away the base before attempting to apply the clamp forceps; as I do not believe the forceps powerful enough or large enough, to accomplish a satisfactory compression of the whole ligament. As the uterus is drawn well to the right, I will transfix the left broad ligament at its base with a curved perineum needle carrying this heavy double silk ligature, so that the lower ligature will include the uterine artery in its grasp. The lower ligature is firmly tied and the upper one is carried higher and through the ligament at a point, so that the two ligatures when tied, include about a third of the broad ligament. This ligated portion of the ligament is now cut away, and with ease I can apply the large broad ligament forceps (Byford's pattern) to the remaining two-thirds of the ligament. This done, forceps firmly locked, and the tissues apparently well compressed, the remaining portion of this broad ligament is cut away, being carefully to keep at some distance from the blades of the forceps in order to leave tissue enough to prevent it, at any point, from drawing away from their grasp. As all of the tissues in the grasp of the forceps or ligatures must eventually ulcerate off, we can afford to be generous in this respect even at the risk of including a little malignant tissue.

The uterus being now free from its left broad ligament we will deliver the organ, and apply the ligatures and clamp to the right one without further difficulty. The vagina being small, and the uterus rather large, it is with some little difficulty that we accomplish the delivery of the organ. Having succeeded we will apply two ligatures to the base of the broad ligament, as on the other side, and after cutting away the ligated portion,

we easily apply the clamp to the remaining portion. Here we have an opportunity of observing how well the forceps accomplish their work.

The uterus is now severed from its last connection with the body.

The perineum is stitched up with buried catgut sutures, using great precaution to get accurate coaptation of the parts. The forceps are carefully adjusted on either side so as to obtain the minimum tension on the broad ligaments, and we will proceed to make the toilet of our operation.

At a number of points at the original vaginal incision small bleeding vessels are observed as we renew the irrigation. These I will secure with simple hæmostatic forceps. I will now bring down the peritoneal edges posteriorly, and attach, by means of lock forceps, to the edges of the posterior vaginal wall. It is desirable to get all freshly torn or cut edges of the peritoneum, as far as possible, which are liable to form adhesions with the intestines, well out of their reach. All bleeding points having now been secured, and the seat of operation well irrigated, we will withdraw the flat sponge inserted early in the operation, preparatory to our final washing. This is done with sterilized water containing no drug.

Everything being clean and comparatively dry, and the intestines well pushed up, I will bring the blades of the forceps clamped to the broad ligaments, as near together as possible, and parallel; a strip of iodoform gauze is then crowded between them to just beyond their distal ends, and the vagina loosely packed below with a continuation of the same strip. The handles of the two broad ligament forceps having been tied together after their locks have been secured, they are propped in an easy position with iodoform gauze, the vulva is sprinkled with iodoform, and the patient is returned to a warm bed.

After-treatment.—We will now go into the wards where we have a convalescing patient upon whom vaginal hysterectomy was performed Jan. 14, 1890, or about four weeks ago, for cancer of the uterus. She is now able to sit up in bed with the aid of the bed rest, and expects to leave the hospital Sunday. Her recovery has been uninterrupted, ideal, in fact, no pain, no elevation of temperature, no untoward symptoms of any kind.

The iodoform gauze which was loosely packed around the forceps was not removed for seventy-two hours. The patient was given no nourishment for forty-eight hours, and for the first twelve hours not even the smallest quantity of water was allowed. The lips were occasionally sponged with a moist sponge, and her mouth was from time to time rinsed with warm water, great care being taken to impress upon her the necessity of not swallowing even a small quantity. After the first twenty-four hours, as the stomach seemed to be perfectly quiet, a couple of drachms of water

were given every hour, and at the end of forty-eight hours barley-water was substituted. The next day a larger quantity was allowed at longer intervals, and as the stomach was in a condition to assimilate more nourishment, beef tea and thin gruels were gradually added to the diet list, until at the end of two weeks a small amount of solid food was allowed. The bowels were moved at the end of seventy-two hours by means of a saline, followed by an enema of soap and water.

I have stated that the iodoform gauze was not disturbed for forty-eight hours, and then only as much as was unavoidable in removing the forceps. These instruments were carefully removed at this time, the gauze being allowed to remain twenty-four hours longer. At this time (seventy-two hours) we can be reasonably certain that the peritoneum is closed. The gauze was removed and a vaginal douche carefully given of 1 in 5000 bichloride, with a bulbous nozzle with right-angled stream, the distal end being inserted only about two inches, the force of the stream being just sufficient to get a continuous flow, and with every precaution to maintain a free exit. All of these precautions are absolutely necessary the first few days, in order to insure that no water enter the peritoneal cavity, if the latter should for any reason be unusually slow in closing. Sterilized water should always be used to displace the bichloride solution, in order to prevent mercurial poison. Douches of this character were given twice daily after the first three days until all signs of necrosis had disappeared, and then once a day until the present time. Two ligatures attached to the base of the broad ligaments were discharged with the douche fourteen days after the operation.

Summary.—The operation that you have witnessed this morning was first performed in this country in 1850. The mortality at first was so high, on account of the crude methods employed, and a lack of proper understanding of the true principles of surgery, that it was with difficulty that surgeons could be induced to undertake the operation. Even now many surgeons prefer to temporize with scraping, amputation, and, if the patient holds out, high amputation, rather than give the patient at once the benefits of an operation which will give the greatest possible chance of an ultimate cure.

The only alternative between this operation and sure death, for a patient suffering with even incipient cancer of the uterus, is high amputation of the cervix. High amputation of the cervix, according to the latest reliable statistics, in the hands of its most experienced advocates, gives an immediate mortality of more than 6 per cent. In the hands of equally experienced operators, I believe that the operation of vaginal hysterectomy, in the same class of cases in which high amputation would seem to offer a probable

means of cure, will give us a mortality fully as low as statistics give us for high amputation. In this hospital, for instance, with all kinds of cases, some of them almost desperate, we have had no deaths, and the operation has been performed twenty times by three operators, as follows: Dr. Henry T. Byford, 14, Dr. D. T. Nelson, 2, myself, 4.

If the operation can be rendered as safe as high amputation, it does not seem necessary to further argue the question, to convince any one that the more radical one should always be selected for cancer.

It seems to me that vaginal hysterectomy is to be the means of the future of saving many women from one of the most horrible deaths of which it is possible for mortal to conceive. Seek, in your practice, to make early diagnoses of this dread disease, and then be prompt to give your patients the benefit of the most radical and rapid means of relief that we know.

NOTE.—The patients mentioned in this paper both made ideal recoveries, and are (August 6, 1890) in perfect health.

MEDICAL PROGRESS.

RECENT INVESTIGATIONS UPON THE THYROID GLAND.—Since the crucial experiments of Horsely and others regarding the connection between the nervous system and that gland, numerous investigators have applied themselves to the study of the functions of this organ. Recently these articles have been abstracted in *Schmidt's Jahrbücher*. The first from the pen of PROF. RIBBERT (*Virchow's Arch.*, cxvii) deals with the regeneration of this gland after extirpation. The experiments were conducted upon dogs and rabbits and consisted in removing small portions from one half of the thyroid body and at different times after the operation removing that portion of the gland. The careful microscopical examination of these showed that in this, like other glands, there was a functional regeneration. New portions of the gland developed by infiltration from cells in the old alveoli, that were at first small without lumen, but later enlarged, developing a cavity filled with colloid material. Small defects were filled with newly developed gland tissue; larger ones presented upon their edges, new tissue, while the central portions were filled with connective tissue.

DR. HERMAN STIEDA (*Beitrag zur pathol.—Anat. und allgm. pathol.*, vii, 1890) has confirmed the observations upon rabbits, made by Nauwerck in 1888. That these animals bear extirpation of the thyroid when cats and dogs are destroyed by the operation. The relation in weight of the pituitary body in rabbits he found to be 1:3.3,

while in dogs, the thyroid is 15:20 times the weight of the pituitary body. Stieda found that there was an increase in weight and volume of the pituitary body after extirpation of the thyroid gland. The enlargement consisted of vacuolation and an increase in the large cells. Stieda is of the opinion that this enlargement corresponds with an increase in function, that in part takes the place of the extirpated thyroid.

RICH and EWALD (*Arch. f. d. ges. Physiol.*) have found that the removal of the thyroid causes no perceptible alteration in the health of pigeons. Their work was undertaken with reference to the earlier observations of Langendorff and Ewald, in which they referred the difference in the loss of the thyroid observed in dogs and rabbits, to the difference in diet. They, therefore, chose pigeons as representing a pure vegetable feeder, and found that the loss of this gland did not in any way affect the health of the animal.

It would have been of great interest in the light of Stied's communication if these later authors had observed the condition of the hypophysis in the operated birds, and the relation of this organ to the size of the thyroid in birds generally. While so much has been added to our knowledge of the thyroid in the last few years, a careful study of recent literature only shows how much, regarding its functional relations, still remains to be explored.

AN UNDESCRIBED TROPHIC AFFECTION OF THE THIRD PHALANGES.—ROSENBACH (*Central-Blatt für Nerven Heilkunde*, August, 1890) claims to have discovered a hitherto undescribed trophic disturbance in the third phalanges. The disease consists essentially of an enlargement of the tubercle at the base of the phalanx, preceded and accompanied by pain in the part. The disease is almost exclusively found in women, from 30 to 50 years of age, and is especially frequent in those approaching the climacteric. The author has seen one or two cases of the trouble in men, but it is relatively very infrequent as compared with the number of women attacked. The disease is usually symmetrical, attacking both hands in the same way, and confines itself strictly to the dorsal side of the third phalanx, the thumb always remaining free. It is preceded and accompanied by changes in sensibility, formications, heat flashes, numbness, etc., in the region of the ulnar and radial nerves.

The author attributes the affection to trophic disturbances in the nervous supply of the periosteum, similar to the special changes in the nerves of the skin, found in herpes.

The differential diagnosis lies between arthritis deformans and gout. The first is distinguished by a very different localization in the large joints and in the thumb, the irregularity of the swell-

ing, and the involvement of the joint surfaces which remain free in the trophic disturbance under consideration. Gout is less easily differentiated, but here we have the general diathesis and above all the slow increase in the enlargements, without redness or swelling of the parts, and the peculiar local nervous symptoms are wanting.

LISTER ON THE ACTUAL STATE OF ANTISEPTIC SURGERY.—(Tenth International Medical Congress.) Since Koch made known his method of the culture of microbes on solid media, there has been considerable extension of our knowledge of microorganisms, and of the means by which the animal organism defends itself against them. Metchnikoff has demonstrated that the migratory cells nourish themselves like amœbæ and have a special taste for bacteria which they absorb and digest, thus preventing their indefinite propagation. He calls these migratory cells "phagocytes." This theory explains much that seems mysterious in regard to the relation of microorganisms with wounds. For example, in the operation for hare-lip, the posterior termination of the wound is constantly bathed in saliva which contains numerous kinds of septic bacteria. Yet these bacteria do not penetrate the fibrin which glues together the two cut surfaces, which they certainly would do if the surfaces were composed of a chemically inert surface devoid of life. This is due to the "phagocytic" action of the cells which are present in the lymph soon after its effusion.

This theory also explains why the use of silk ligatures which have not been subjected to antiseptic preparation may not be followed by unpleasant consequences. Zeigler has shown that leucocytes penetrate rapidly into the very small spaces between plates of glass or other foreign bodies which are chemically inert and have been introduced into the tissues. These leucocytes ought therefore to be also able to glide into the intervals among the fibers of the silk thread, and to destroy all the microbes which are able to lodge there.

The success attained by Bantock and Lawson Tait without the use of antiseptics appear a stumbling block. But in reality the practice of these surgeons is not devoid of antiseptic means. They purify their sponges; they observe strict cleanliness; this is certainly an antiseptic precaution. They wash the peritoneum with pure water in order to free it from coagula without wounding the peritoneal surface by rubbing it with sponges.

The drainage of the peritoneum is another antiseptic measure; moreover, it is necessary to avoid the application of strong and irritating antiseptic solutions to the peritoneum. But it would be wiser to assure, by means of antiseptics, the entire absence of microbes from the hands

and instruments; as to the water used for the toilet of the peritoneum, it is better to have recourse to a feeble sublimate solution (1 to 10,000 for example) than to simple boiled water.

In the surgery of the rest of the body, the employment of stronger antiseptic solutions does not present the same inconveniences.

As to the spray, Lister regrets that he formerly recommended it to destroy the microbes of the air. There is not sufficient time for the microbes to lose their vitality in the vapor of the spray.

Since he has abandoned the spray, Lister surrounds the site of the operation with cloths soaked with antiseptic solutions. If, besides the spray, washes and irrigations are abandoned, vigilance ought to be redoubled.

Reasoning, by analogy, from subcutaneous wounds, Lister says that a wound made under antiseptic precautions could be immediately sealed by covering the line of union by an antiseptic varnish. But he claims that carbolic acid by irritation excites a secretion of serum so abundant that its issue necessitates an opening. Hence the drainage of wounds.

After the recent method of treating wounds with sublimate, the secretion is less and drainage less necessary.

As to external dressings, some surgeons have thought to unite simplicity and security by using cotton wadding sterilized by heat. But this wadding, being simply aseptic, only prevents infection as long as it is dry; once wet through to its external surface by secretions, it may become a septic mass, and there are always wounds where the secretion will remain abundant.

In some cases, a perfectly antiseptic dressing may be a matter of life and death. For in these cases with abundant secretions, only antiseptic chemicals can prevent the development of septic organisms. With this end in view, Lister employs a combination of the cyanides of zinc and mercury, which is a sufficiently strong antiseptic, and is moreover non-irritating.—Translated by Dr. F. Neuhoff, St. Louis, *La France Méd.*—*Weekly Medical Review.*

LATERAL PROSTATECTOMY.—DITTEL (*Wiener Klin. Wochenschr.*) refers the retention in hypertrophy of the prostate largely to the lateral lobes, and thinks that any operation must reach these lobes in order to overcome their valvular action in causing retention. This was shown by experiments upon cadavers. When a body with normal urethra and bladder was suspended, water injected into the bladder, promptly passed out by the urethra; such, however, was not the case where the prostate was enlarged bilaterally. In these latter cases, when a resection was made of the lateral lobe, the fluid passed rapidly away. The excision of a wedge-shaped piece from the middle lobe was without result.

Dittel has not as yet tried his method upon a living patient but gives full directions regarding the best methods of operating, from his dissection of cadavers. The incision should begin at the point of the ischium and extend to the middle of the external sphincter, circling the latter as far as the raphé. This cut opens the ischio-rectal fossa from which the dissection is rapidly made exposing the lateral lobe of the prostate. The rectum should be previously tamponed, to prevent wounding and aid in separating that structure from the enlarged prostate.

The author recommends an early operation in these cases, while the urine is yet normal and the patient comparatively free from pain.

ALCOHOL AND CHILDHOOD.—PROF. DEMME, of Berne, at the recent International Alcohol Congress at Christiania, presented an interesting report of an investigation which he had made as to the influence of alcohol upon children. Having unusual opportunities for this study from his position as superintendent of a hospital for children, he selected two groups of ten families each, under similar external environment. One group of 57 was manifestly affected more or less by alcohol; the other of 61 was unaffected, or at least very little affected. Of the 57 who exhibited the effects of alcoholism, 20 had inebriate fathers, the mothers and grandparents being moderate drinkers. Only 45 per cent. of these (9) had healthy constitutions. Thirty-one had inebriate fathers and grandfathers, but temperate mothers and grandmothers. Only 2 of these, or a little over 6 per cent., were healthy. Six children had parents and grandparents intemperate; 1 of these survives, a sufferer from epileptic seizures. In remarkable contrast is the state of the 61 children belonging to temperate families, 82 per cent. of whom enjoy good health, 3 have died, and 8 are in bad health. Prof. Demme also reported the results of an experiment on several children, from whom all intoxicants were kept during eight months, and to whom the usual allowance of wine and water was given during the remaining four months of the year. These children were reported to have slept more soundly and longer, and to have appeared in better spirits and more active, during the non-alcoholic eight months than during the alcoholic four months.—*British Medical Journal.*

NEURASTHENIA AND NASAL DISEASE.—The causes of neurasthenia, obscure as they are, are not to be sought in some slightly abnormal condition of an organ such as the nose; and to imagine that local treatment of this, or indeed of any individual organ, is going to reward us with successful therapeutic results, is to subject ourselves to such failures as Dr. More Madden very honestly has recorded. Many women live only for the

gynecologist, and though we would not for a moment impute such conduct to members of a noble profession, there is no doubt that gynecology, in some unscrupulous hands, has not been free from chicanery in a class of patients in whom the loss of nervous control, which is the essence of neurasthenia, has rendered them ready agents to such practices. It would be a thousand pities where rhinology to incur the same reproach. To remove a vital cause of irritation is right and proper, but to assert that the slight pathological abnormalities met with in many nasal organs, even when they are accompanied with nasal catarrhs, is in a real proportion of neurasthenic individuals a potent cause of their troubles is, we think, to take up an untenable position. Those who, in such cases, look only to intra-nasal surgical treatment, and fail to appreciate the necessity of getting behind these apparent symptoms, and treating the general nervous system as of primary importance, will be doomed in their specialistic narrowness to failure. To say that such treatment, even if it does no good, will do no harm, is not correct. Very great aggravation of the patient's sufferings may follow injudicious and meddlesome interference. It is in neurasthenic patients, of all others, that we should exercise the very greatest discrimination in recommending or carrying out surgical treatment.—*Journal of Laryngology and Rhinology.*

HYSTERICAL FACIAL PARALYSIS.—The statement of Charcot that paralysis of the facial nerve, is never of hysterical origin, has recently been negated by HUET (*Nederl. Tijds. v. Geneeskde.*—*Cent.-Bl. f. Nervenheilkde.*) who reports a typical case of central paralysis of the facial nerve in a girl twenty-one years of age. The trouble came on immediately after a severe fright, and was followed by pronounced symptoms of hysteria, globus painful points, vomiting, hemi-anæsthesia, etc. Later hystero-epileptic attacks developed, and she presented a complete picture of hysteria gravis. Van Deventer also mentions a case in which facial paralysis came on in April and was still noticeable the following October. A later observation showed that the paralysis had entirely disappeared. This patient also presented the typical features of hysteria gravis.

CREMATION.—THOUVEUET, before the Section on Hygiene, of the French Association for the Advancement of Science (*La Semaine Médicale*), maintained that the present outbreak of cholera in Spain was due to the exhuming of the bodies of the victims of the epidemic of 1885. He regards cemeteries as vast depots of infection for the pollution of the air and water with pathogenic germs, and the sole remedy for this condition lies in cremation. In conclusion he proposed the construction of crematories in cities and villages, and the mak-

ing of cremation compulsory in cases of death from infectious diseases. He invited the Section to approve his conclusions, but they decided that for the present it was unwise to make any change in the law, as it probably could not be enforced. They strongly *advised* cremation in infectious diseases.

SEXUAL PERVERSION.—MOTET reported to Société de Médecine Légale (*Progrès Méd.*) the case of a young man who was arrested for attempting to cut off the hair of a young woman. In his rooms was found a quantity of hair. This individual had a marked neurotic heredity from both the father and mother. He was an intelligent and skilful mechanic. In 1886, after an attack of herpes intercostalis, he began to act queer and conceive the imperative conception to cut off women's hair. As soon as the shears touched the hair he had an erection, and the cutting was followed by an ejaculation. He was declared insane and irresponsible, and was sent to an asylum, where after a time he recovered from his peculiar propensity, and later resumed his profession.

OPIUM AND COCAINE IN INCOERCIBLE VOMITING.—At the French Association for the Advancement of Science Congress of 1890, in the Medical Section, M. TYSON, of Paris, read a paper on the association of opium and cocaine in the treatment of rebellious vomitings of pulmonary tuberculosis, divers gastritis, etc. In a large number of cases the author claims that the best results followed the exhibition of pills, each containing one centigram of hydrochlorate of cocaine and an equal quantity of extract of opium. Of these from 5 to 6 were given daily, preferably ten minutes prior to the introduction of food or drink into the stomach. The same treatment has been found excellent in allaying the pain, nausea, and vomiting of alcoholic gastritis, cancer of the stomach, dilatation of the stomach, etc. As the pills are very deliquescent, it will be necessary to add the usual corrigens in such cases.—*National Druggist.*

HERNIA.—PROF. KUESTER (*Centralblatt der Chir.*, No. 36) mentions, in connection with radical operations of old and large inguinal hernia, a new danger hitherto overlooked, or at least not referred to. In all these cases the abdominal cavity is so much reduced in size as to admit, but with some difficulty, the protruded intestine. On one of such occasions the patient commenced to vomit and then became asphyxiated. Tracheotomy, promptly performed, relieved the air passages at least in part, of some food which the emesis had forced into it. But the patient, nevertheless, died on the table. Kuester thinks that the stomach should previously have been washed out, and the mechanical expression of its contents obviated.—*St. Louis Clinique.*

SATURDAY, OCTOBER 18, 1890.

SOME MEDICAL PROBLEMS CONCERNING
IMMIGRATION.

It is evident that many important medical questions of the future will depend on the present movement of populations. This is apparent in two ways: First, the increasing movement of the rural population to large towns and cities, and second, the great tide of emigrants that comes flowing in on our shores yearly. In the former the increase in a century has been from one to twenty-five to one in three. This increase has been general all over the older parts of the country. Agriculture is less attractive, although carried on with less muscular labor every year, owing to the rapid improvement in labor saving machinery. A large class of robust, healthy men are constantly filling up the towns and cities, living in less healthy surroundings, and in conditions more unfavorable to health and longevity. They suffer from diseases that are largely influenced by these changed conditions of living; and their children bear unmistakable marks of race degeneration, springing from the hygienic neglect of the parents. As a rule the families of the more prosperous of the city residents, who are born and bred in the city, are "switched on the road to extinction." They are the largest patrons of physicians and suffer from the most complex disorders, while their country cousins of the same race stock are well and vigorous. The vigor and brain force of city populations are only kept up by constant immigration from the country.

This movement of the population is at the expense of its longevity, and is attended with premature exhaustion and decline. The class of diseases that appear in city families of the same social status are rarely seen by the country physician. The acuteness needed to differentiate these obscure diseases, where constitutional degeneration and exhaustion are present, is not called for in the country, because the symptoms are clear and prominent and less complex. The wise city physician early recognizes this decline of vigor and urges a retrograde movement to the country.

It is evident that somewhere in the near future the towns and cities of the country will become crowded beyond their capacity, to support the population rationally, and a receding wave of immigration will set in towards the country. Some great law (not clear at present) will eventually regulate this ebb and flow of population from country to city and back again. In the second great movement of races, viz., the immigration from other countries, the problem is wider and the questions more complex. Once this movement was welcomed, and the vigor and prosperity of the country seemed to depend on it. To-day grave perils appear to gather about this army that is steadily landing on our shores.

For the year past, ending July 1, 1890, half a million persons came to this country to stay. Compared with former years these immigrants are steadily and distinctly deteriorating. While the numbers are increasing the physical and mental status is lower. Large numbers are not only incompetent to become self-supporting, but are diseased in both body and mind. They early become burdens on the community, filling up hospitals, almshouses and insane asylums, and are centres of degeneration, antagonizing every state of healthy life and living. Strenuous efforts are made to shut out convicts, paupers and idiots, with partial success; but mental paupers and anarchists, and defectives of every degree rush into our civilization, and are permanent obstacles to every advance.

The medical problems which grow out of this disorganizing element are more serious every year. Physically the unsanitary conditions which they foster, and the nidus of various diseases which gather about them, are always perils to the community. Mentally they join the armies of the

"squatters" and "camp followers" who prey on civilization, and the evolutionary march of the race. While large numbers of these immigrants are swallowed up in the vast farming regions of the far West, and lay the foundation for populous States and cities, it is the duty of the medical man to insist on boards of health, and strict sanitary regulations, and laws which will require the proper observance of all measures that build up public health.

This incessant movement of strange people in crowded cities and lonely country towns, can be more largely influenced by the physician. If he is a scientific man, alive to the vast formative influences that are about him, and demands sanitation, with education, that shall practically apply to all the surroundings, he is doing the highest work possible in the profession. As a reformer in breaking up the wretched tenement houses, and other nuisances, that these poor immigrants build up, and saving life by demanding better conditions of living, he is approaching very near the great ideal physician. The civilization of America will be very largely controlled by physicians, working along lines of sanitary science, pointing out the laws of heredity, of environment, of climate, education, and other forces which fashion and mould the race. How far these armies of immigrants from country to city and back again, and from all climes of the globe, will be assimilated and at last settle into one great race of homogeneous people, will depend very much on the present teachings and interpretations of the laws of nature by the physician of the city, in the lecture-room or by the bedside, and the country physician in his visits to the lonely farm houses.

POISONS PRODUCED BY BACTERIA.

A few weeks ago we referred editorially to some experimental work of ROUSSY upon the pathology of fever, in which he demonstrated what appears to be a fever producing albuminoid, which he termed "pyretogenin;" we have now to mention the labors of BRIEGER and FRÄNKEL (*Berl. Klin. Wochenschr.*—*Centralblatt für Physiologie*) upon the toxic substance produced by the diphtheria bacillus of Löffler.

Pure cultures of the bacillus were prepared in large quantity in pepton-broth with or without

the addition of glycerine. ROUX and YERSIN had previously separated the toxic substance from bouillon cultures and believed that it belonged to the class of enzymes, a conclusion which the writers cannot indorse. They succeeded in obtaining the substance dry and class it among the albuminoid bodies, the "toxalbumen" as they name them.

The cultures were at first passed through a Chambelain clay filter. The germ free, lemon yellow, clear filtrate proved to be very poisonous to animals and produced symptoms similar to those caused by inoculation with the bacillus including the peculiar paralytic phenomena of diphtheria. When heated to 60° C. it lost most of its toxic properties. It resisted acidifying with sulphuric acid, and steaming to 50° C. An examination for ptomaines and volatile bases gave a negative result. It also failed to diffuse through membranes into water or a solution of sodic chloride. It was precipitated by ammoniac sulphate and sodic phosphate as well as absolute alcohol, the latter method being the one usually employed. After dialysis and drying *in vacuo* the substance was obtained as a snow-white, amorphous, granular powder, easily soluble in water, from which it was not thrown down by boiling, sodic sulphate, sodic chloride, magnesian sulphate, plumbic acetate or by dilute sulphuric acid even when heated. It is precipitated by carbonic acid or other reagents that throw down albuminous bodies. With Million's reagent a red color was produced, as well as the biuret and xanthoprotein reactions. The plane of polarized light was rotated to the left. From these various reactions the writers conclude that this substance is closely related to serum albumen, though the ultimate organic analysis showed a composition closely allied to pepton, with the following percentages: C. 45.35, H. 7.13, N. 16.33, S. 1.39, O. 29.80.

This body in a pure state was very poisonous, 2½ milligrams for each kilogram of body weight of the animal experimented with, proving fatal, though sometimes only after weeks or months. (This confirms earlier observations by Roux and Yersin.) Very small quantities injected subcutaneously caused abscess and necrosis, and later wasting of the body.

The authors believe that this "toxalbumen" is produced from the albumen of the infected part in the ordinary diphtheritic process, and in this

connection recall the "Ichthyotoxicum" which A. and N. Mosso obtained from the serum of the murex, and the poisonous albuminoids obtained from plants by ROBERT and STILLMARK.

Further experiments were frequently hindered by the fact that cultures lost their virulence, and stopped producing the poisonous substances. In cultures that had lost their virulence an albuminoid body was found that could be distinguished from the other by its dark brown color and non-toxic properties.

It will be seen from the foregoing that great progress has been made in isolating the peculiar toxic substances produced by microorganisms. It appears now as though it would soon be necessary to admit, as suggested by Vaughan, before the pathogenic character of microorganism can be said to have been established, that its peculiar toxic product shall have been isolated and studied.

MALPRACTICE SUIT DECIDED.

The suit brought by Mr. Sims against Dr. A. H. Parker, of Chicago, the well-known expert truss adjuster, for \$15,000 damages, was tried before Judge Baker recently, and after the evidence on both sides had been closed and the counsel for the prosecution had presented his side of the case to the jury, the Judge instructed the jury to return a verdict for the defendant. The evidence showed that Sims had worn a truss several years on account of an inguinal hernia before he applied to Dr. Parker, and for several months he had suffered at times with pain on the same side as the hernia. After the truss fitted by Dr. Parker this pain continued to recur, and sometime after he had passed from the observation of the latter, a psoas abscess matured and pointed somewhere about the groin or upper part of the thigh, and not being efficiently treated by thorough drainage and antisepsis by his attending physician, the plaintiff suffered a protracted and painful sickness, but from which he ultimately recovered. His suit against Dr. Parker was founded entirely on the allegation that the truss fitted by the latter had caused the abscess. The evidence on the part of the defense showed that the defendant was an experienced specialist in the fitting of trusses of good reputation; that the truss used was of good quality and proper form, and that the pressure of the pad would have no tendency

to induce the formation of an abscess. There appearing thus no evidence to incriminate the defendant the Judge very properly decided that there was no evidence for the jury to consider, and therefore required a prompt verdict for the defendant.

THE MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

The sixteenth annual meeting of this Association convened at Louisville, Ky., on October 8, 9 and 10. A brief *résumé* of its proceedings will be found in the present number of THE JOURNAL. While in full affiliation and sympathy with the American Medical Association, and in no wise sectional in its preferences or purposes, it nevertheless represents a large and growing constituency, and is numbering in its ranks some of the most promising medical men in this country.

The present meeting was a notable success. DR. J. P. MATTHEWS, its widely-known and popular President, came from a sick-bed to the fulfillment of his official duties, which he performed with heroism, wisely and well. The Secretary and Executive Committee have rendered valuable assistance, and the general arrangements were complete.

A very full and valuable programme had been prepared, and three days did not suffice for its presentation. The papers and the discussions will rank with those of any of our medical organizations, local or National.

We are the more profoundly impressed with the ability as well as of the number of medical men in America who can ably represent the profession when we note the character and the work of the men of the Mississippi Valley as they were convened at Louisville. The writer or the speaker who is impressed with the idea that in any one locality the ability or aristocracy of the profession is centered, is both a man untraveled and unread. The need of the times is that the strength of a score of individual organizations shall be so unified and harmonized that a National representation of our profession shall by such union be secured, and such a National Association as may be possible in no other land.

With reference to the entertainment of visitors it is enough to say that the meeting was in Louisville, and that the profession were able to bring to their help the beauty, brilliancy, the wit and

talent of its fair ladies, and as in times past, so again the receptions were magnificent.

Solong as the Association shall hold to its purpose of strictly scientific work and permits no social attractions to trench upon its working hours, so long it will be in every way helpful to its members.

The popular address by DR. JOHN A. WYETH was a model of its kind, and that portion which compassed the subject of clinical instruction is worthy of permanent record.

The onward progress of medicine in this country will be more and more assured by the multiplication of such meetings as the recent one at Louisville.

EDITORIAL NOTES.

POSTPONEMENT.—The Committee of Arrangements have postponed the next meeting of the Tri-State Medical Association until November 19 and 20.

THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION will hold its annual meeting at Atlanta, Ga., on November 11, 12 and 13. Members of the medical profession are invited to attend. The Secretary is Dr. W. E. B. Davis, Birmingham, Ala.

A DESERVED COMPLIMENT.—Dr. Benjamin Ward Richardson, F.R.S., of London, Eng., has dedicated the sixth volume of his original work "The Asclepiad," to Dr. Joseph Jones, of New Orleans, La., in the following words:

To Joseph Jones, M.D., Professor of Chemistry and Clinical Medicine, in the Tulane University of Louisiana:

A model student of medicine, always seeking, always finding, always imparting, with unwearied industry, new and useful knowledge to the great Republic of Medicine, Science and Art, this the sixth volume of the "Asclepiad" is sincerely dedicated.

Dr. Richardson is the most eminent living British writer and authority in experimental therapeutics and practical hygiene. He has devoted his life to the elevation of the medical profession by his extensive original researches, and to the alleviation of the ills of humanity by his works on insanity and hygiene.

MEDICAL DEPARTMENT OF THE NEWBERRY LIBRARY, CHICAGO.—Excellent progress is being made in the development of a full medical library for the free use of the profession, by the

Newberry Trustees. The present library building is at the corner of N. State and Oak streets. The cases for the medical department are completed and several thousand volumes are on the shelves. On the 2nd inst. two hundred and eighty-five medical periodicals were ordered, namely: from the United States, 95; Africa, 1; Australia, 2; Austria, 15; Belgium, 7; Canada, 5; China, 1; Denmark, 3; East India, 1; France, 47; Great Britain, 20; Germany, 59; Italy, 13; Japan, 1; Mexico, 1; New Zealand, 1; Norway, 3; Spain, 4; Sweden, 3; Switzerland, 2. Arrangements have been made for the regular and prompt reception of all the periodicals subscribed for, and before the end of the present month members of the profession will have access to the medical periodical literature of the world. It is hoped that those who have been freely indulging in expressions of impatience, will show their interest by frequent visits to the library. For nothing else will so much encourage the Trustees to make the library grow, as the frequent use of what they have already provided.

ARTIFICIAL MUSK.—A German chemist named Bauer, has discovered and patented a process for making a laboratory musk. The new product is not identical in chemical composition, with the natural article, but it is possessed of the characteristic odor. The process of its formation is said to be by means of the nitration of isobutyltolnene with a mixture of strongest nitric and fuming sulphuric acids. The manufacture of this substance has been begun on a considerable scale. It is said not to be poisonous.

OPERATIONS UPON THE HYPERTROPHIED PROSTATE.—In a paper presented to the Mississippi Valley Medical Association at Louisville, Dr. Wm. T. Belfield, of Chicago, collects 133 cases of operations upon the hypertrophied prostate, including eight of his own, as follows: 41 by perineal incision, mortality 9 per cent.; 88 by supra-pubic cystotomy, mortality 16 per cent.; 4 by combined perineal and supra-pubic incision, none fatal. In 56 of these cases the essential facts before and after operation are furnished; they had been the subjects of cystitis and dependent upon the catheter for periods varying from one to ten years. In all the cystitis was cured; in 38 (two-thirds) voluntary urination was restored and continued during the time of obser-

vation, six months to two and one-half years; in eighteen this function was not recovered. Fifteen of these 56 cases were complicated with stone; excluding these—since it might be objected that the cure resulted rather from the calculus extraction than from the prostatic operation—there remained 41 cases of uncomplicated prostate operations; of these 32 (four-fifths) recovered the power of urination, in 9 this ability was not recovered.

FATAL POISONING AT BELLEVUE HOSPITAL.—It is reported that a patient in Bellevue Hospital, New York, having typhoid fever, recently lost his life in consequence of an error on the part of a nurse. The house physician had prescribed for the patient a drachm of a mixture containing one part of carbolic acid to sixteen parts of glycerine, but pure carbolic acid was administered instead. The verdict of the coroner's jury censured the nurse for his carelessness. The jury also found that this negligence of the nurse "was in part attributable to the authorities of the hospital, who neglected to label properly the medicine prescribed by the regular physician, and who allowed made-up prescriptions, for internal use, to be mingled in the same chest with poisons of a violent nature, intended for external use only, and the whole to be placed in the control and custody of inexperienced nurse-pupils, and in this case, of one below the average intelligence."

CHLORIDE OF AMMONIUM IN ALCOHOLISM.—This drug is said to promptly and completely overcome the narcotic effect of alcohol. It is possible to restore to the use of his faculties one who has been rendered helpless by intoxicating drink, by administering $\frac{1}{2}$ drachm of the ammonium chloride in glassful of water.

A CHOLERA CONGRESS AT ROME.—An International Sanitary Congress has been invited to convene at Rome for the purpose of taking steps to guard against the spread of cholera.

The fifteenth semi-annual meeting of the District Medical Society of Central Illinois will be held at Decatur on Tuesday, October 28, 1890. Programmes may be obtained on application to the Secretary, Dr. J. H. Miller, Oconee, Ill.

THE MICROBE OF GRANULAR OPHTHALMIA.—*The Lancet*, August 23, quotes the researches of Dr. Shongolowicz, of St. Petersburg, regarding

the microbe of granular ophthalmia, from which it would appear that it is not a micrococcus, as has been described by several observers, but a short bacillus. The length of this rod is from .002 to .00075 millimetre and its breadth from .0003 to .00005. Its preparation and staining are not easily managed, but gentian violet proved to be the best stain. The different segments of the bacillus take very different degrees of stain, and this it is that has given rise to the idea that the organism is a micrococcus arranged in lines or chains. A considerable number of experiments were made by Dr. Shongolowicz on the eyes of animals, but in only two cases did he succeed in producing an affection that closely resembled the granular ophthalmia in the human subject.

THE SALE OF OPIATES.—*The Pharmaceutical Era* says: A paper upon this topic presented the subject in the very plainest of words and forcible language to the members of the State Association assembled at Saginaw. The writer severely took to task that very numerous class of druggists who were found perfectly willing to cater to the trades of those infortunates who have become addicted to the habit of opiate taking. He related how certain ones in order to keep this trade had no hesitancy in reducing the price of morphine, opium, chloral, etc., so as to attract these customers to their stores. Druggists of this class were denounced in no measured terms. The writer took the ground that even though this people must have these enslaving drugs, yet the pharmacist should do all in his power to discourage the habit, and more than that, by putting restrictive prices on the goods show he has no desire to cater to this class of trade.

If opium were reduced one-half in value, the druggist should not therefore give twice as much morphine or laudanum for the same money as heretofore. The remarks of the speaker were highly approved of, his hearers agreeing that this evil had grown to great proportions, until its regulation and proper conduct is a matter that should enlist the serious attention of the public and its law-makers.

It is proposed to amalgamate all the medical societies in Russia into one general association, which will be divided, for scientific purposes, into sections of medicine, surgery, obstetrics, etc., but will be managed by a central committee.

TOPICS OF THE WEEK.

MEDICAL ARCHÆOLOGY.

The Greek correspondent of the *Athenæum* (Syr. P. Lambros), in a letter to that journal, has given an account of the task undertaken by Dr. G. Kostomiris, who, in 1887, published an interesting treatise on ophthalmology and otology among the ancient Greeks. Dr. Kostomiris has since pursued his researches at the Bibliothèque Nationale in Paris, and discovered there a large number of unpublished manuscripts of medical works. In a paper read before the Academy of Medicine he enumerated the works of twenty-four physicians, and also several anonymous treatises, which he considers deserve publication, not only on account of their historical and philological importance, but also on account of their medical value. This last statement may be due to the learned ophthalmologist's enthusiasm, but the interest of the subject is so considerable that it is pleasant to learn that the Medical Faculty of Athens and the Senate of the University have taken up the project to print the pseudo-Hippocratic treatises which have not yet been published, as well as treatises of Kratenas, Galen and Promotus. Funds have been provided from public sources and Dr. Kostomiris is about to devote a year to preliminary work. His first step has been to proceed to Mount Athos to study the manuscripts preserved there. *Brit. Med. Jour.*

DECREASE OF THE INDIAN TRIBES.

That the race of red men in North America is rapidly dying out, and that the policy of the Federal Government, in assigning to them reservations of territory for their exclusive use, has been powerless to arrest this decay, are facts familiar to all. We are, perhaps, too much inclined to regard this decadence as a mysterious and inexplicable blight—as due, not to normal causes, but to the mere contact of an inferior with a superior race. This sentimental view involves at least two obvious errors: first, the assumption that all colored races tend to die out before the advance of the victorious white man; and, secondly, that the causes of the decay of the red man are inexplicable, whereas they are only too obvious. As regards the former point, it must be remembered that some colored races—the negro, for example, and the Malay—hold their own when brought into contact with the whites. The negroes in North America have increased more rapidly in numbers during the present century than their white neighbors, and the certainty that this superior fecundity of the negro will continue constitutes one of the gravest problems that confront American statesmen. The Malay and the Chinaman, not to mention other examples, are quite capable, if allowed fair play, of prospering and multiplying amidst a white population. Hence, the doctrine, so often assumed as self-evident, that the colored races die out as it were by a natural law when brought into contact with the whites, is entirely fallacious. This doctrine has probably obtained currency owing to the fact that in certain familiar cases

it seems to find an obvious illustration. The last native has disappeared from the island of Tasmania. The native Australian is to-day but rarely seen in Victoria, South Australia or New South Wales, and is becoming rarer even in Queensland and Western Australia. The Maori of New Zealand and the Sandwich Islander are both going steadily to the wall before the Anglo-Saxon. These instances, which are sufficiently impressive, strike the imagination, and readily create the idea that the colored man has no chance in the struggle for existence with the white. We have seen, however, that there are several notable exceptions to this apparent law, and we are therefore driven to seek elsewhere than in a fallacious generalization for an explanation of the decadence of the Red Indian of America.

The explanation is evidently to be sought in the changed habits and mode of life which contact with civilization has involved to the red man. In former days he lived an out-of-door life, he was constantly on horseback, he pursued the customs of a nomad, he dressed in skins, and lived chiefly on flesh meat. Now he lives for the most part in close cabins, he dresses in shoddy blankets and calico, and he drinks tea, coffee and rum. Hence he falls a ready victim to scrofula and phthisis. How far the loss of the free nomad life and of the wild joy of battle may have still further depressed the mental condition of the Red Indian may be a question. He comes of a race for whom war has been for generations the only honorable employment, and he seems unable to reconcile himself to a life of toil and industry.

The moral of these facts for us is not that we should all turn nomads in order to avoid phthisis and scrofula, but that civilization is a more or less unnatural process to which a wild race cannot be suddenly subjected without great peril, and that even for long-civilized peoples the civilizing influences have certain dangers which are closely associated with unhealthy dwellings and unwholesome food. The great law of adaptation to our environment, obedience to which is the necessary condition of survival, finds in these matters one of its most striking illustrations. If the red men had been a numerous and powerful people, and if the civilizing process could have been very gradually applied, it is more than probable that in the course of a score or two of generations some degree of adaptability to new conditions might have been developed. But the Indians were comparatively few in number, wholly without association or union, and they were suddenly exposed to the tremendous impact of a high civilization. Hence they have melted away like snow in spring time. The negro has been saved from a similar fate by his extraordinary natural fecundity, his ready adaptability to a settled mode of life, and his capacity for labor.

Of the special causes that have wrought havoc among the red men, the most potent have been phthisis, scrofula, syphilis and drink. To determine the relative influence of these destructive forces would be difficult, inasmuch as in some cases one and in other cases another has probably been the most active. That a change from an active out-of-door life to an in-door life of confinement and inactivity is a most fertile source of

phthisis is a fact of which it would be impossible to overrate the importance. This fact is further emphasized by the law that phthisis increases in virulence in direct proportion to the density of the population, and especially to the proportion of the population engaged in occupations involving prolonged confinement in vitiated air. It is further illustrated by the fact that all successful forms of the climatic treatment of phthisis have this feature in common—viz., that they give the invalid the opportunity of breathing pure air.

The red man seems to have a peculiar proclivity to the evil influences of alcohol. When the opportunity presents itself, he gives way, almost without exception, to wild excess, and suffers a terrible penalty. The same tragic tale is just now being repeated amidst some of the African tribes, to whom the introduction of rum seems likely to render null all the blessings of civilization. How far tea and coffee injuriously affect uncivilized races, to whom their use has been previously unknown, is a point of great interest upon which we have little evidence. It would be a great fallacy to argue that, because certain evil results attend the use of coffee, tea, or alcohol among savage nations unaccustomed to their use, the same results must accrue to civilized peoples. It is obvious that custom and adaptability count for so much that such a crude generalization is inexcusable.—Editorial, *Lancet*.

PERSONAL RELATIONS AND RESPONSIBILITIES.

The *Canada Health Journal* for September has an article on this subject worth consideration. In addressing man, in regard to his neighbor, it says:

"Mind your own business" are words conveying most excellent advice in nearly all circumstances, but what one's own business always really is, has never been, it appears, very clearly defined, and there is one condition or relation in which one is not only justified in prying a little into one's neighbor's affairs, but in which this becomes an indispensable duty. No matter how healthy and vigorous you may habitually be, "dear reader," or how judicious, sensible and careful you may be in relation to your own individual health, and that, too, of your family, a careless, selfish or ignorant neighbor, if not closely looked after, may inflict you with a most malignant or fatal disease. You may even suspect such a neighbor, and avoid him and strive to keep your children away from him and from his, but unknowingly you may seat yourself on the cushioned car or cab seat which he has just infected by sitting on it for a time, or you may stand beside him in the shop or market place long enough for him to infect you; he may, all unintentionally, infect your well, or you may buy from some such one infected food. Your children, in spite of your utmost care, may chance to play or be long enough in contact with his to become infected with a fatal type of scarlet fever or diphtheria. You must, therefore, to a certain extent or in certain circumstances, mind your neighbor's business, or you may suffer terribly for neglecting to do so. In other words, what should be your neighbor's business becomes in these circumstances your own business.

In well organized communities special health officers,

called inspectors, are employed to look after the neighbors. The position or function of an inspector, is an exceedingly important one, therefore, and a man of special fitness, special ability with tact and good common sense, must be selected for it. Without a first-class suitable man, many causes and sources of disease and its spread may be overlooked. For safety, every home in the community in which you live, at least, however humble it may be, must be in as good a sanitary condition as your own; hygienically all must be as perfect as possible. To get the best men for such positions the pay must be liberal. Often municipal authorities do not pay such officials well, because the people,—their supporters, will not sustain them in so doing. Wise supporters, or electors, will take care that the health officials, the most important officials of the municipality, whether city or town, or only village or township, are so paid that they may have the "heart" to do their work well—to be "up betimes" and "vigilant in their calling." And indeed, at best, every man should, himself, take heed, a little, judiciously, to his neighbor's sanitary condition, even before the sense of smell is affected, and so aid the health officers, remembering that "eternal vigilance" is, too, the price of cleanliness and health.

HOSPITAL WORK AT PEKIN.

The London Missionary Society's report of the condition of this station shows that the accommodation has become quite insufficient for the number of in-patients, so that the treatment of the out-patients has become the main work of the institution. Last year the number amounted to 19,243. A great change is observed in the attitude of the poorer Chinese towards amputations, and several of these operations have been performed successfully. One case is recorded in which a cook intentionally chopped off four of his fingers for a curious reason. He was quarreling with another man, and to impress the latter with his courage and indifference to pain he deliberately mutilated himself. In another case a youth removed a portion of the calf of his leg in order to make soup for his sick father with the flesh. The father died, and the son became a patient at the hospital. One hundred and fifty-nine patients were treated for opium smoking. Attempts have been made to get rid of the habit on account of the waste of time it involves, or by reason of the impecuniosity of the victims. Several have conquered it on account of its injurious results on their bodily health. Six are reported to have been cured by home influence, and three by arguments advanced by Christian teachers. *Lancet*.

THE DURATION OF LIFE IN THE MEDICAL PROFESSION.

It is calculated, on the basis of statistics, that the average duration of the lives of medical men in Prussia, from the end of the thirtieth year onwards, is somewhat below that of the total male population of the country, though the latter includes a large number of decrepit and diseased persons, such as the nature of the medical profession excludes.

PRACTICAL NOTES.

RHEUMATISM AND GOUT.

Dr. Satterlee has written a book on this subject, and tells us that he has himself suffered from the ailments which he describes. This renders his remarks of special value, as it is not often anything is written under such circumstances.

In acute rheumatism he lays much stress upon the use of cholagogues, giving the following formula:

R. Euonymin, gr. $\frac{1}{4}$.
Podophyllin, gr. $\frac{1}{8}$.
Aloin, gr. $\frac{1}{8}$.

M. S.—One tablet twice daily as required.

He objects to the salicylates on the grounds which show a very exceptional experience, or a no less exceptional lack of skill in their use on his part. His preference is for the alkalies, which he gives in the following forms:

R. Potassii bicarb, \mathfrak{z} ij \mathfrak{z} ij.
Aque destillat. \mathfrak{z} viij.

M. S.—One fluid ounce to half an ounce of fresh lemon juice, to be taken while effervescing.

R. Lithii benzoat. \mathfrak{z} ss.
Sodii bromid.
Potassii carbonat. pura. \mathfrak{aa} \mathfrak{z} ij.
Potassii acetat. \mathfrak{z} iss.
Sodii phosphat. \mathfrak{z} ss.
Syr. zingiberis

M. et Sig.— \mathfrak{z} ij to \mathfrak{z} ss in half a glass of water, every four or six hours, after food.

He states that this mixture of three bases combined with five acids is effectual and agrees well with the stomach.

Dr. F. Leroy Satterlee recommends the following topical application in cases of gout:

R. Ol. gaultheriæ,
Ol. oliuæ,
Liniment. saponis,
Tinct. aconiti,
Tinct. opii. \mathfrak{aa} \mathfrak{z} ij
M. ft. liniment.

Sig.: Apply to part.

It can be applied freely by the gentlest friction to the inflamed site, protecting afterwards with a generous covering of cotton batting.—*Times and Register*.

SALOL COLLODION.

It is recommended in the *Repertoire de Pharmacie* for July 10, 1890, to dissolve 4 parts of salol in 4 parts of ether, and then add to 30 parts of collodion, and it is stated that the application of the salol collodion to the affected parts in acute rheumatism will be followed by rapid relief of pain.—*Thera. Gazette*.

ANÆSTHESIA IN MINOR SURGERY.

In such cases as opening a bone felon, scraping a small fistula in the gums, removal of epithelio-

ma in the face, or in fact, any small operation requiring a local anæsthetic lasting from two to six minutes, Dobish (*Rundschau*, 1890), recommends the use of the following solution in a Richardson spray:

R. Chloroformi, \mathfrak{z} iiss.
Æther, sulphuric, \mathfrak{z} iv.
Menthol, gr. xv.

M. Sig.: As a spray.

PILL FOR THE TREATMENT OF CHRONIC CONSTIPATION.

In the treatment of chronic constipation Nothnagel advises the use of the following when a laxative is necessary:

R—Podophyllin, 4 $\frac{1}{2}$ grains.
Extract of aloe, 45 grains.
Extract of rhubarb, 45 grains.
Extract of taraxacum, a sufficient quantity.

Mix and divide into forty pills, of which one, two, or three may be taken at bedtime.—*Therapeutische Monatshefte*.

THREATENED ECLAMPSIA.

Prof. Parvizi directs the following in cases of threatened eclampsia in pregnancy: A purgative pill:

R—Extract aloes.
Extract colocynth, \mathfrak{aa} gr. $\frac{3}{4}$. \mathfrak{m}

To be given frequently enough to keep the bowels freely open; also a hot bath each day, with a glass of hot water to be drunk while in the bath. After the hot bath, the patient must be put to bed, and wrapped in blankets. Milk diet.—*Coll. and Clin. Record*.

TO MASK THE ODOR OF ICHTHYOL.

The *Pharmaceutische Zeitung* recommends the addition of 10 per cent. of oil of citronella. The addition is said to be harmless in any case, while in rheumatism it is claimed that it will be positively beneficial. In India the oil is used to a considerable extent as a remedy in rheumatism, and, it is declared, with very good results.

PILLS FOR DYSENTERY.

Boudin, in *L'Union Médicale*, September 2, 1890, recommends the following pills for the treatment of dysentery:

R—Ipecacuanha, 5 grains.
Calomel, 1 $\frac{1}{2}$ grains.
Extract of opium, 1 grain.

To be made into three pills and one given every hour, and used either for dysentery or diarrhœa dependent upon exposure to heat.

CARBOLATED OIL FOR SCABIES.

Carbolated oil (1 to 15) is strongly recommended by Tressilian (*Brit. Med. Journ.*), as preferable, in the treatment of scabies, to any preparation of sulphur.

SOCIETY PROCEEDINGS.

MISSISSIPPI VALLEY MEDICAL
ASSOCIATION.

*Sixteenth Annual Meeting, held at Louisville, Ky.,
October 8, 9 and 10, 1890.*

FIRST DAY.

The Association was called to order by Dr. J. N. Bloom, Chairman of the Committee of Arrangements, who welcomed the members to Louisville, and introduced Dr. Jos. M. Matthews, the President. He made a few introductory remarks but omitted the usual opening address, believing that the time would be better occupied in the scientific work of the session.

The first paper, by DR. FRANK WOODBURY, of Philadelphia, dealt with the complicated question of

INFECTIOUS DYSPEPSIA AND ITS TREATMENT.

The author restricted the subject to gastric dyspepsia and said he believed that the majority of cases of this sort were due to either primary or secondary infection of the stomach. Microorganisms were normally present in the stomach, and usually did no harm, but when there was dilatation or a diseased condition of the mucous membrane, fermentation was set up, and then we were called upon to treat such cases antiseptically. This was best accomplished by washing out the stomach. For this purpose he exhibited a simple but ingeniously devised apparatus.

DR. JOHN H. HOLLISTER, of Chicago, presented a few thoughts upon

HELP AND HINDRANCE TO MEDICAL PROGRESS.

In this paper he briefly reviewed the progress of medicine up to the present, showing how successive advances had been made. He indicated what direction progress would take in the future, especially calling attention to the vast unexplored fields of nervous pathology, and the chaotic condition of our therapeutics. He closed with a brief reference to higher medical education and medical journalism and their relation to progress in medicine.

DR. GEO. HULBERT, of St. Louis, presented a paper on

MECHANICAL OBSTRUCTION IN DISEASES OF THE
UTERUS.

He did not believe that stenosis was a dominant factor, and rejected *in toto* the prevalent theories of dysmenorrhœa. Out of over 10,000 cases examined *intra vitam* and 300 examined post-mortem in no single case was he able to demonstrate an obstruction that would hinder the ready flow of blood, save in the cases of pure atresia. By means of drawings made from post-mortem specimens he demonstrated that stenosis could not come from a simple bending

because of the atrophy that took place at the angle. It would not do in these cases to draw conclusions from forcibly bending a normal uterus or a rubber tube—the conditions were quite different. He regarded the pain in the so-called mechanical dysmenorrhœa to changes in the nervous and vascular supply of the uterus, caused by general conditions. He was confirmed in these views by the fact that an internal os with an opening of but 1-32 inch could discharge 120 times the normal amount of menstrual fluid; also, by the fact that 50 per centum of cases presenting all the physical conditions of stenosis—impermeability to the sound, pin-hole os, etc., never had any pain.

DR. R. STANSBURY SUTTON, of Pittsburg, presented specimens and remarks upon

THE SURGICAL TREATMENT OF UTERINE
FIBROIDS.

He strongly recommended the use of the dam and persulphate of iron in the extraperitoneal method of treating the pedicle.

DR. L. S. McMURTRY, of Danville, Ky., condemned in unmeasured terms the use of electricity, particularly in the soft variety of fibroid. The menopause also, he believed, had but a slight effect in this class of cases.

DR. C. A. L. REED, of Cincinnati, mentioned a case of soft myoma that developed in a woman 57 years of age, twelve years after the advent of the menopause.

DR. SUTTON in closing the discussion said that if the operation of supravaginal hysterectomy was persisted in, he thought it would eventually become as safe as the operation for ovariectomy.

DR. I. N. LOVE, of St. Louis, read a paper on

COFFEE, ITS USE AND ABUSE.

He regarded coffee as an antiseptic, said that it was a stimulant, and aided the secretions. A cup of black coffee was in most cases a better thing to give after an injury, than the dose of alcohol commonly administered. In excessive doses it causes insomnia, indigestion, and irregular heart's action.

DR. X. C. SCOTT, of Cleveland, O., read a paper on

THE TREATMENT OF FRACTURES OF THE FORE-
ARM BY EXTENSION, COUNTER-EXTENSION,
AND FORCED SUPINATION,

which he said was adapted to all fractures of the forearm excepting those of the olecranon process. He exhibited a specially contrived splint adapted to the method. He condemned the pistol-shaped splint, and said that by pressure alone it was impossible to separate the bones of the forearm.

DR. WM. PORTER, of St. Louis, presented a paper on

THE SELF-LIMITATION OF PHTHISIS.

(See page 568.)

DR. A. B. THRASHER, of Cincinnati, O., read a paper on

THE RELATION OF COUGH TO INTRA-NASAL DISEASE,

and mentioned several cases in which cough was dependent upon nasal reflexes. In one of these a violent spasm of coughing could be produced by touching a sensitive area, on the inferior turbinated body.

In the evening DR. JOHN A. WYETH delivered a general address upon

THE MEDICAL STUDENT.

After a humorous introduction, he gave the student of medicine some sound advice regarding his studies and the demands made upon the modern practitioner. The address was exceptionally brilliant, and well received by the large audience present.

SECOND DAY.

DR. JOSEPH RANSOHOFF, of Cincinnati, read a paper on

CHRONIC DISEASE OF THE JOINTS.

The author limited his remarks to diseases of the bones and joints of the tarsus. He mentioned curretting only to condemn it. The mortality was considerable and the chances of obtaining a useful foot were remote. Amputation should be resorted to oftener and earlier in these cases.

DR. H. C. DALTON, of St. Louis, Mo., reported six cases of

GUNSHOT INJURY OF THE ABDOMINAL CAVITY, in which the viscera were injured, with five recoveries and one death. He recommended immediate operation in all penetrating wounds of the abdomen. He condemned Senn's hydrogen gas test, though he thought it might have been useful in one of his cases. One of the cases was a stab wound of the liver necessitating a resection of the seventh rib and the slitting the diaphragm. Up to date the writer had performed laparotomy for penetrating wounds of the abdomen twenty-three times, with twenty recoveries and three deaths.

DR. M. T. SCOTT reported *A Successful Case of Operation for Gunshot Injury of Intestine.*

DR. J. B. MURDOCK, of Pittsburg, read a paper entitled

TORSION OF ARTERIES AS A MEANS FOR THE ARREST OF HÆMORRHAGE.

He relies almost wholly upon torsion for the arrest of hæmorrhage, having used it in arteries as large as the axillary, femoral and popliteal. He claimed for torsion great advantages over the ligature, both on score of sepsis and freedom from secondary hæmorrhage. It was a method quite as safe as the ligature.

DR. G. FRANK LYDSTON exhibited a specimen of what he called *Fungating Chancre*, also a spec-

imen of *Tubercular Testis* and one of *Paget's Disease*. Also a series of skulls and drawings exhibiting some modern studies in criminal anthropology.

DR. C. H. HUGHES, of St. Louis, read a paper on

THE PSYCHIC SEQUENCES OF ENTAILED AND CHRONICALLY ACQUIRED ALCOHOLISM.

The writer especially referred to the degenerations and changes in the ganglionic nervous system. This was one of the reasons why the mild attack of pneumonia carries off the alcoholic. Alcohol stood, he thought, in an intimate relation to the etiology of Bright's disease. He regarded inebriety, whether in its chronic or paroxysmal forms, as a disease.

DR. C. S. BOND read a paper entitled

UREA AND SEROUS MEMBRANES.

He claimed that the serous membranes were frequently early involved in those conditions of inadequate kidney attended by a lessening of the quantity of urea excreted. The author supported his conclusions by detailing several cases in which there was an inflammation of some serous membrane associated with a marked diminution in the amount of urea.

DR. ARCH. DIXON reported a case of

INGUINAL COLOTOMY FOR INTESTINAL OBSTRUCTION.

He prefers the inguinal colotomy to the lumbar operation, for various reasons—principally that it is more convenient, is easier carried out, and the wound is less extensive.

DR. EMORY LANPHEAR, of Kansas City, presented a paper on

THE SURGICAL RELATIONS OF HYPNOTISM.

He was satisfied that in hypnotism we had a means of producing surgical anæsthesia. He finds that only one person out of ten cannot be hypnotized. It may be produced in any one who can fix their attention upon one subject for a sufficient length of time. He preferred the method of holding a bright object just above the eyes for a time, when with soothing words, the patient would fall into the hypnotic state. Several *séances* were usually necessary. He considered that hypnotism was simply an abeyance of the will and reasoning powers while the emotions and perceptions were in a state of full activity.

CERTAINTY IN THE DIAGNOSIS OF TUBERCULOSIS.

DR. THEODORE POTTER read a paper on the above subject. The author said that he believed tuberculosis to be an acute, local infectious disorder, void of the slightest tendency toward self-limitation. The most essential thing in its treatment was to make an early diagnosis, and this was best done by repeated and thorough

examinations of the sputum for the tubercle bacilli.

DR. B. MERRILL RICKETTS, of Cincinnati, considered herniotomy, which he classed among the least fatal of all of the major operations. He laid especial stress upon the necessity of early operation, if there was any doubt of the nature of the tumor an operation should at once be done, as in this way only could a certain diagnosis be made. In one of his cases he had cut down upon a supposed sac of a femoral hernia and had turned out an enlarged lymphatic gland. He thought there was but one operation to do in these cases,—to at once cut down to the internal ring and unite it by sutures. Every herniotomy he believed should be followed by an effort to obtain a radical cure.

DR. HAROLD N. MOYER, of Chicago, presented a paper on

THE HYPODERMIC USE OF ARSENIC.

He recognized the irritant properties of Fowler's solution when injected beneath the skin, and he now used the arseniate of sodium, a salt of stable chemical composition, feebly alkaline and easily absorbed. He found that arsenic was less irritating when given by the hypodermatic method. Out of 127 injections he had never noted inflammation, and nothing approaching an abscess. He thought that arsenic used in this way would prove very useful in chronic skin diseases, nervous disorders, and malarial conditions,

THIRD DAY.

DR. EDWIN PICKETTS, of Cincinnati, made a few remarks upon the difficulty of diagnosing a twisted ovarian pedicle complicating a case of uterine myoma. He described a case of this kind in which sepsis preceded operation, death following on the sixth day.

DR. DAVID BARROW described

THREE CASES OF INTESTINAL OBSTRUCTION.

He advocated early laparotomy in those cases that resisted medical treatment; opium should be avoided as it masked the symptoms. In no case should a patient be allowed to pass beyond the point where an operation would be safe.

In the discussion Dr. J. A. Wyeth approved of the points brought out by the writer. He would, however, emphasize one point, when the obstruction is complete, and the symptoms urgent so that there is no time to complete an operation, he would advocate opening the bowel and so relieving some of the more urgent symptoms. He detailed a case in which this simple procedure saved a life. In answer to a question, he said it was still a mooted question whether the open method should be followed or implantation. It was largely to be decided by the condition of the patient.

DR. R. R. KIME described a

CASE OF EXTRA-UTERINE PREGNANCY

of four years and three months standing. The sac finally ruptured spontaneously, discharging a portion of the contents by the vagina. Later the discharges became foul and the patient showed signs of septicæmia. The uterus was dilated, the sac reached through that organ, and the greater portion of the fœtus removed. Fæces were discharged through the vagina, but ultimately the sac closed and the patient made a good recovery. The writer thought the condition was one of interstitial pregnancy.

DR. SEATON NORMAN, in a short paper, advanced the views that organic stricture of the urethra of recent origin is best conducted by gradual dilatation. Strictures of long standing should be treated by internal urethrotomy, with antiseptic precautions, and especial effort should be made to keep the incisions aseptic for several days. These means favored early healing, and prevented much inflammation, a potent factor in causing subsequent cicatricial contraction.

In a *résumé* of the various operations upon the hypertrophied prostate, DR. W. T. BELFIELD had collected 133 cases, for details of which see editorial notes, page 582.

DR. H. O. WALKER, of Detroit, read a paper on

PERINEAL CYSTOTOMY VERSUS SUPRA-PUBIC CYSTOTOMY.

The writer detailed five operations of supra-pubic cystotomy, in his own practice, with four deaths. He detailed many of the unpleasant consequences of the operation, such as excoriations from dribbling urine, and septic infection. He did not regard normal urine as the ideal antiseptic, a position claimed for it by some surgeons. In looking over the literature at his command, he had found between three and four hundred cases of supra-pubic cystotomy with an average mortality of thirty per centum. A few operators have had a series of cases ranging from three to ten, without a death, the most remarkable of these being that of Hunter McGuire, who had only one death in twenty-one cases. In the perineal operation, out of thousands of cases, the mortality ranges from 5 to 9 per centum. He therefore concludes that perineal cystotomy is safer, simpler, has more rapid results, and is adapted to more cases than the supra-pubic operation.

DR. L. S. MCMURTRY presented a few practical points in *Midwifery*. He thoroughly believed in the antiseptic method; puerperal fever was not a fever at all, but simply sepsis. Especial stress was laid upon the necessity of examining into the surroundings of the lying-in women, the position of the water-closet, condition of the bedding, nurse, syringe, and everything that came in contact with the patient.

DR. T. B. GREENLEY read a paper on the *Ad-*

vantages of Attending Medical Societies and Reading Medical Journals. He cited some amusing incidents in the careers of men who insisted upon doing neither of these things.

DR. J. V. PREWETT presented a paper strongly advocating internal urethrotomy, which he claimed had passed from one of the graver operations, because of antiseptis, to one of very little danger.

Was it Relapsing Fever? formed the title of a paper by DR. A. D. BARR, in which he described a case in which an irregularly recurring temperature presented itself. He thought he had excluded typhoid and malarial conditions, upon which he asks the question contained in the title of the paper.

DR. FRANCIS DOWLING presented a paper

ON THE PREVENTION OF MYOPIA.

Myopia begins usually about the tenth year. It was mostly to be attributed to over-use of the eyes. The condition was hereditary—not directly, but the tendency to it. Deformity and malformations, as well as choroiditis, played a part. The inflammatory exudates stretched the membranes, and so lengthened the long diameter. All children should not study the same number of hours; myopes should have fewer hours and more light. If the general health became impaired, all study should be suspended. Latin letters and larger type should be used, and in myopes reading should be frequently interrupted and the eyes closed or fixed upon a far point. Glasses do not check the myopia, and should not be worn before the fifteenth year. Paracentesis of the cornea is useful in marked cases, and frequently prevents detachment of the retina.

A Plea for the More Extensive Use of Spectacles formed the topic of a paper presented by DR. FRANK T. SMITH. He found a large number of cases in which marked impairment of vision was not noticed. The various reflex conditions formed an important field for the use of glasses. In answer to a question, he said that myopia was never cured by the use of glasses.

DOMESTIC CORRESPONDENCE.

EDITORIAL CORRESPONDENCE.

Annual Meeting of the American Rhinological Association.

FIRST DAY.

The Eighth Annual Meeting of this Association convened at the Gault House in Louisville, October 6, with a full representation of the fellows of the Society. At nine o'clock the records of the previous meeting were presented and approved and other preliminary business considered. At ten o'clock the roll was called and the

regular meeting was formally opened with an address by the President, Dr. Arthur G. Hobbs, of Atlanta, Ga.

The afternoon session of the first day was occupied in an informal consideration of its purposes, interests and the necessary modifications of its rules to best insure the greatest success of the Association. The leading rhinologists of the country were in attendance, and the discussions controlled the entire session.

SECOND DAY.

The reading of papers being in order the first one was presented by Dr. A. B. Thrasher, of Cincinnati, O., upon the subject of "Nasal Reflex." The paper was an able résumé of the literature upon that subject and a thorough discussion of the same. It elicited an extended discussion which was participated in by a large number of the fellows.

The next paper was one upon "Nasal Cauteries," prepared by Dr. E. R. Lewis, of Indianapolis. The doctor is a strong advocate of its use, but emphatic in his demand as to careful discrimination in its use. He based his views upon the personal observation of some two thousand cases. In the discussion of this paper Dr. Thrasher was disposed to be sanguine, as to the use of the cautery, though according to it a measure of merit, but advocated more fully the use of other local remedies.

Dr. Stuckey, of Louisville, read a paper upon "Tonsillar Hypertrophy," referring to their influence upon nasal and aural inflammations and their treatment.

Dr. E. R. Lewis, of Indianapolis, read a paper on "Nasal Cauteries," strongly advocating the use of the storage battery, basing his conclusions upon personal observation of some two thousand cases, and dwelt very fully upon the pathological conditions in which cauterization was indicated. Dr. Thrasher was less sanguine as to the beneficial results to be obtained from the cautery and gave his own views as to the value of other remedies. Nearly all the members participated in the discussion.

The afternoon session of the second day was opened with a paper by Dr. John North, of Toledo, O., upon "Nasal Hypertrophys," in which the neurotic conditions and pathologic conditions of thickened membranes were considered and the whole subject of canterization and of topical applications underwent review.

Dr. T. C. McGahn, of Chattanooga, Tenn., read an interesting paper entitled "Polipii and Other Nasal Growths." This paper was fully discussed. The administration of morphine by the nostril was the subject of a brief article by Dr. C. H. von Klein, of Dayton, O. Other papers were presented and discussed: one by Dr. J. G. Carpenter, of Stanford, Ky., upon "Nasal and Pharyngeal

Manifestations of Syphilis—Results and Treatment.”

“Hygiene of the Upper Respiratory Organs” was discussed by Dr. L. B. Gillette, of Omaha, Neb. “Hay Asthma” was again discussed, the opening paper being by Dr. A. De Vilbiss, of Toledo, O. Dr. Emmett Walsh, of Grand Rapids, Mich., presented a paper entitled “The Relation of Naso-Pharyngeal Diseases to Catarrh of the Middle Ear.”

Papers by new members were omitted the time having been fully occupied by those standing first upon the programme. Members of the profession were impressed with their value, and in the discussions it was evident that men who were specialists in this class of diseases were specially fitted for their most successful treatment. The specialist here, as elsewhere demonstrates his right to be.

Indianapolis was designated as the place for the meeting in 1891.

J. H. H.

MISCELLANY.

LETTERS RECEIVED.

Wm. R. Warner & Co., Philadelphia; Dr. J. O. Roe, Rochester, N. Y.; Dr. T. Wertz, Evansville, Ind.; E. B. Ryan, Bay City, Mich.; Dr. W. L. Beebe, St. Cloud, Minn.; J. W. Harrison, Jersey City, N. J.; Dr. T. E. Murrell, Little Rock, Ark.; Dr. G. E. de Schweinitz, Philadelphia; Antikammia Chemical Co., St. Louis; W. H. Moore, Brockport, N. Y.; Dr. H. R. Purdy, New York; Subscription News Agency, Chicago; Dr. Wm. B. Atkinson, Philadelphia; N. Y. Post-Graduate Medical School, New York; Dr. N. Senn, Milwaukee, Wis.; Dr. S. P. Deahofe, Potsdam, O.; Dr. A. Blitz, Indianapolis, Ind.; S. S. White Dental Mfg. Co., Philadelphia; American and Continental Sanitas Co.; J. Movius & Son, New York; McLean & Co., Atlantic, Ia.; James F. Madden, New York; Dr. H. P. Millard, Minneapolis, Minn.; Dr. Walter Wyman, U. S. M. H. S., Washington.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from October 4, 1890, to October 10, 1890.

Lieut.-Col. Chas. C. Byrne, Surgeon, is relieved from duty as attending Surgeon at the Soldiers' home, near this city, and will report in person to the commanding officer, Ft. Sam Houston, Tex., for duty at that station. Par. 8, S. O. 232, A. G. O., Washington, October 3, 1890.

Capt. Jas. A. Finley, Asst. Surgeon, is relieved from duty at Ft. Totten, N. Dak., and will report in person to the commanding officer, Jefferson Bks., Mo., for duty at that station, relieving Capt. Wm. D. Crosby, Asst. Surgeon. Capt. Crosby, on being relieved by Capt. Finley, will report in person to the commanding officer, Ft. Pembina, N. Dak., for duty at that station. By direction of the Secretary of War. Par. 8, S. O. 232, A. G. O., Washington, October 3, 1890.

Lieut.-Col. Joseph C. Baily, Asst. Medical Purveyor, Medical Director of the Department, is granted leave of absence for one month. Par. 3, S. O. 86, Dept. of Texas, October 3, 1890.

First Lieut. Leonard Wood, Asst. Surgeon, leave of absence granted in S. O. 74, August 3, 1890, Dept. of Cal-

ifornia, is extended one month. By direction of the Secretary of War. Par. 7, S. O. 232, A. G. O., Washington, October 3, 1890.

Major Henry M. Cronkhite, Surgeon, is relieved from duty at Ft. Lewis, Col., and will report in person to the commanding officer, Ft. Trumbull, Conn., for duty at that station, relieving Capt. Robert J. Gibson, Asst. Surgeon. Capt. Gibson, on being relieved from duty by Maj. Cronkhite, will report in person to the commanding officer, Ft. Sam Houston, Tex., for duty at that station. By direction of the Secretary of War. Par. 8, S. O. 232, A. G. O., Washington, October 3, 1890.

Major William H. Gardner, Surgeon, is relieved from duty at Washington Bks., D. C., to take effect on the arrival of Major Joseph K. Corson, Surgeon, and will report in person to the commanding officer, Angel Island, Cal., for duty at that station. By direction of the Secretary of War. Par. 8, S. O. 232, A. G. O., Washington, October 3, 1890.

Capt. Wm. C. Borden, Asst. Surgeon, is relieved from duty at Ft. Sam Houston, Texas, upon the arrival of Lt.-Col. C. C. Byrne, Surgeon, and will report in person to the commanding officer, Ft. Davis, Texas, for duty at that station, relieving Capt. Peter R. Egan, Asst. Surgeon. Capt. Egan, on being relieved by Capt. Borden, will report in person to the commanding officer, Ft. Warren, Mass., for duty at that station, relieving Capt. Geo. McCreery, Asst. Surgeon. Capt. McCreery, on being relieved by Capt. Egan, will report in person to the commanding officer, Ft. Clark, Tex., for duty at that station, relieving Capt. Chas. M. Gandy, Asst. Surgeon. Capt. Gandy, on being relieved by Capt. McCreery, will report in person to the commanding officer, Ft. Shaw, Mont., for duty at that station. By direction of the Secretary of War. Par. 8, S. O. 232, A. G. O., Washington, October 3, 1890.

Major Curtis E. Munn, Surgeon, is relieved from duty at Angel Island, Cal., and will report in person to the commanding officer, Ft. Monroe, Va., for duty at that station, relieving Major John Brooke, Surgeon. Major Brooke, on being relieved by Maj. Munn, will report in person to the commanding officer, Ft. Leavenworth, Kan., for duty at that station, relieving Major Alfred A. Woodhull, Surgeon. Maj. Woodhull, on being relieved by Maj. Brooke, will report in person to the commanding officer, Ft. Sherman, Idaho, for duty at that station. By direction of the Secretary of War. Par. 8, S. O. 232, A. G. O., Washington, October 3, 1890.

By direction of the Secretary of War, the following changes in the stations and duties of officers of the Medical Department are ordered:

Major Geo. M. Sternberg, Surgeon, is relieved from duty as attending surgeon and examiner of recruits at Baltimore, Md., and as a member of the Army Medical Board, appointed to meet in New York City, and will repair to San Francisco, Cal., and take charge of the Medical Purveying Depot at that place, as Acting Asst. Medical Purveyor, relieving Col. B. J. D. Irwin, Surgeon. Col. Irwin, on being thus relieved, will report in person to the commanding General, Dept. of the Columbia, for assignment to duty as Medical Director of that Department, and as Post Surgeon, Vancouver Bks., Wash., relieving Major William E. Waters, Surgeon, now Post Surgeon, and temporarily in charge of the Medical Director's Office. Major Waters, on being thus relieved, will report in person to the commanding officer, Ft. Custer, Mont., for duty at that station. Par. 8, S. O. 232, A. G. O., October 3, 1890.

Major Van Buren Hubbard, Surgeon, is relieved from duty at Columbus Bks., O., and will report in person to the commanding officer, Ft. Spokane, Wash., for duty at that station, relieving Capt. Henry S. Turrill, Asst. Surgeon. Capt. Turrill, on being relieved by Maj. Hubbard, will report in person to the commanding officer, Madison Bks., N. Y., for duty at that sta-

tion, relieving Major John D. Hall, Surgeon. Major Hall, on being relieved by Capt. Turrill, will report in person to the commanding officer, Ft. Canby, Wash., for duty at that station. By direction of the Secretary of War. Par. 8, S. O. 232, A. G. O., Washington, October 3, 1890.

First Lieut. Allen M. Smith, Asst. Surgeon, is relieved from duty at Ft. Snelling, Minn., and will report in person to the commanding officer, Ft. Assiniboine, Mont., for duty at that station, relieving Asst. Surgeon Paul Shillock. Lieut. Shillock, upon being relieved, will report in person to the commanding officer, Ft. Custer, Mont., for duty at that station, relieving Capt. Wm. R. Hall, Asst. Surgeon. Capt. Hall, upon being relieved by Lieut. Shillock, will report in person to the commanding officer, Ft. Schuyler, N. Y., for duty at that station, relieving Capt. Norton Strong, Asst. Surgeon. Capt. Strong, on being relieved by Capt. Hall, will report in person to the commanding officer at Ft. Meade, S. Dak., for duty at that station. By direction of the Secretary of War. Par. 8, S. O. 232, A. G. O., Washington, October 3, 1890.

Capt. Rudolph G. Ebert, Asst. Surgeon, is relieved from duty at Angel Island, Cal., to take effect upon the arrival at that post of Major Wm. H. Gardner, Surgeon, and will then proceed to Vancouver Bks., Wash., and report for duty to the commanding officer of that post. By direction of the Secretary of War. Par. 15, S. O. 232, A. G. O., Washington, October 3, 1890.

Capt. Robert B. Benham, Asst. Surgeon, will proceed from Ft. Hamilton, N. Y., to Mount Vernon Bks., Ala., and report in person to the commanding officer of that post for temporary duty, relieving Capt. John J. Cochran, Asst. Surgeon, who will return to his proper station. By direction of the Secretary of War. Par. 8, S. O. 232, A. G. O., Washington, October 3, 1890.

Capt. C. N. Berkeley Macauley, Asst. Surgeon, is relieved from duty at Ft. Supply, Ind. Ter., and will report in person to the commanding officer, Ft. Lewis, Col., for duty at that station. By direction of the Secretary of War. Par. 2, S. O. 233, A. G. O., Washington, October 4, 1890.

Capt. Robert J. Gibson, Asst. Surgeon, is granted leave of absence for three months, to take effect on being relieved from duty at Ft. Trumbull, Conn., by Major Henry M. Cronkhite, Surgeon. By direction of the Secretary of War. Par. 12, S. O. 232, A. G. O., Washington, October 3, 1890.

Capt. Walter Reed, Asst. Surgeon, is relieved from further duty at Mount Vernon Bks., Ala., and assigned to duty as Attending Surgeon and Examiner of Recruits at Baltimore, Md. By direction of the Secretary of War. Par. 7, S. O. 233, A. G. O., Washington, October 4, 1890.

Capt. Arthur W. Taylor, Asst. Surgeon, is relieved from duty at Ft. Wingate, N. M., to take effect on the expiration of his present sick leave of absence, and will report in person to the commanding officer, Ft. Adams, R. I., for duty at that station, relieving Capt. J. J. Cochran, Asst. Surgeon. Capt. Cochran, on being relieved by Capt. Taylor, will report in person to the commanding officer, Camp Eagle Pass, Texas, for duty at that station, relieving First Lieut. Paul Clendenin, Asst. Surgeon. Lieut. Clendenin, on being relieved by Capt. Cochran, will report in person to the commanding officer, Ft. Brady, Mich., for duty at that station. By direction of the Secretary of War. Par. 8, S. O. 232, A. G. O., Washington, October 3, 1890.

PROMOTIONS.

Asst. Surgeon Edward R. Morris, to be Asst. Surgeon with the rank of Captain, September 27, 1890, in accordance with the Act of June 23, 1874.

Lieut.-Col. Bernard J. D. Irwin, Asst. Medical Purveyor, to be Surgeon with the rank of Colonel, August 28, 1890.

Major Bleucowe E. Fryer, Surgeon, to be Asst. Medical

Purveyor, with the rank of Lieut.-Col., August 28, 1890. Capt. Stevens G. Cowdrey, Asst. Surgeon, to be Surgeon with the rank of Major, August 28, 1890.

APPOINTMENT.

Col. Edward P. Vollum, Surgeon, to be Chief Medical Purveyor, with the rank of Colonel, August 28, 1890.

Official List of Changes in the Medical Corps of the U. S. Navy for the Week Ending October 11, 1890.

Wm. C. Braisted, Detroit, Mich., appointed an Asst. Surgeon in the U. S. Navy.

Medical Director P. S. Wales, detached from temporary duty as member of Medical Examining Board.

Pd. Asst. Surgeon H. E. Ames, detached from temporary duty as member of Medical Examining Board.

Surgeon C. G. Herndon, ordered to Naval Hospital, New York.

Surgeon R. C. Persons, detached from Naval Hospital, New York, and wait orders.

Pd. Asst. Surgeon H. B. Scott, ordered before the Retiring Board.

Surgeon A. F. Price, detached from Naval Dispensary, Washington, D. C.

Pd. Asst. Surgeon Frank Anderson, ordered to Naval Dispensary, Washington, D. C.

Medical Inspector C. H. White, ordered to hold himself in readiness for duty to U. S. S. "San Francisco."

Asst. Surgeon W. C. Braisted, ordered to Army and Naval Hospital, Hot Springs.

Asst. Surgeon L. W. Spratling, ordered to hold himself in readiness for orders to the U. S. S. "San Francisco."

Surgeon C. A. Siegfried, ordered to the U. S. Training Ship "New Hampshire."

Asst. Surgeon N. P. Blackwood, detached from duty in the Bureau Medicine and Surgery and granted leave of absence.

Asst. Surgeon L. H. Stone, detached from the U. S. S. "New Hampshire" and wait orders.

Pd. Asst. Surgeon Jno. M. Edgar, ordered to hold himself in readiness for duty on the U. S. S. "San Francisco."

Pd. Asst. Surgeon J. E. Gardner, detached from the "Albatross" and wait orders.

Official List of Changes of Stations and Duties of Medical Officers of the U. S. Marine-Hospital Service, for the Four Weeks Ending October 4, 1890.

Surgeon W. H. H. Hutton, detailed as Chairman Board of Examiners. October 2, 1890.

Surgeon W. H. Long, detailed as member Board of Examiners. October 2, 1890.

Surgeon Geo. Purviance, granted leave of absence for thirty days. September 10, 1890.

Surgeon John Godfrey, detailed as recorder Board of Examiners. October 2, 1890.

Pd. Asst. Surgeon W. A. Wheeler, to proceed to New Orleans, La., for temporary duty, October 3, 1890.

Pd. Asst. Surgeon C. E. Banks, granted leave of absence for twenty days, October 3, 1890.

Pd. Asst. Surgeon R. P. M. Ames, to proceed to New Orleans, La., for duty, September 13, 1890.

Pd. Asst. Surgeon W. J. Pettus, to proceed to Vineyard Haven, Mass., for temporary duty, October 1, 1890.

Asst. Surgeon S. H. Hussey, to proceed to New Orleans, La., for temporary duty, September 19, 1890. To proceed to Norfolk, Va., for temporary duty, October 3, 1890.

Asst. Surgeon C. P. Wertenbaker, granted leave of absence for twenty days. September 12, 1890.

Asst. Surgeon J. C. Perry, upon expiration of leave to rejoin station at Mobile, Ala. September 29, 1890.

Asst. Surgeon G. B. Young, to proceed to Memphis, Tenn., for temporary duty, September 13, 1890. To rejoin station St. Louis, Mo., when relieved at Memphis, Tenn., October 3, 1890.

CURE OF CLEFT PALATE BY A DOUBLE
FLAP OPERATION AND CLOSURE
WITH THE BURIED TENDON
SUTURE.

Read in the Section of Dental and Oral Surgery, at the Forty-first Annual Meeting of the American Medical Association, at Nashville, Tenn., May, 1890.

BY HENRY O. MARCY, M.D.,
OF BOSTON, MASS.

Nearly all surgical operations have had their distinctive modifications, with surprising gain in the result, based upon the knowledge of the rôle of bacteria in wounds. In large measure, however, the surgery of the mouth, the throat, and the nasal passages, has proved an exception, since all wounds of these tissues, as ordinarily treated, must be looked upon as extremely liable to become infected from the ever-present bacteria, existing normally in the mucous secretions of the tract, and necessarily conveyed to it in respiration and in the taking of food.

Dentistry, as an art, may be said to have commenced with the present generation; as a science, within the last few years; since by the labors of Miller, Nelson, Andrews, and others, the demonstration is ample that dental decay is dependent upon bacterial development within the structures of the teeth. All scientific observers now agree that the preservation of a diseased tooth is dependent upon the removal of the infected portion, and the treatment of the member in such a way as to preserve permanently its tissues aseptic. These principles, when applied to the treatment of a single tooth, are comparatively simple and easy to carry into effect. When the cancellated structure of the jaw, or any of the bones forming the nasal, or oral tract, are involved, the conditions are much more serious, and the limitations, or removal of the infected parts, often form problems very difficult of solution.

Wounds of the soft parts, even when made through comparatively healthy tissues and closed with the greatest nicety, by the surgeon, at the time of operation, often heal very unsatisfactorily, becoming the seat, at least, of a local infection, and repair either fails entirely, or goes on slowly

by the processes of granulation. This has its explanation from the great difficulty of excluding infective material from the wounded surfaces, and the reason why general septic infection with its attendant danger is not more common, is found in the extraordinary vascularity, affording a better protective nutrition of the parts involved.

Plastic surgery of the oral cavity has made comparatively little advance, for the above reasons, although it is almost entirely revolutionized, in other parts of the body, by modern surgical procedure.

Operative measures for the relief and cure of cleft palate generally fail on account of non-closure of the wound, dependent upon infection and difficulty of the retention of the parts at rest, especially at its free, or distal, extremity. During the last few years the attempt at repair is less often made by the surgeon, than formerly, doubtless, in large measure, due to the extremely ingenious and useful mechanical devices in the way of artificial plates, one of the distinctive triumphs of American mechanical dentistry.

I confess myself to have given over the field, as one entirely unfruitful of surgical relief, until within the last year, when I carried into effect, in a single case, the method which forms the subject of this brief contribution.

Miss J., age 25, a strong and healthy woman, has a congenital cleft of the soft palate with only slight indentation of the bony structures. Each half of the uvula is well developed, and by moderate tension the edges of the cleft can be brought into apposition. After a careful explanation of the intended procedure, the patient gladly availed herself of the hoped-for results from operation. Aided by Dr. Charles Bullock and Dr. S. N. Nelson, I commenced the operation by the introduction of a tracheotomy tube. With careful washing and irrigation, the nasal and oral passages were rendered aseptic, using freely a sublimate solution of strength 1-1000. After the introduction of the mouth-gag and packing the pharynx with an aseptic sponge, the soft palate was seized upon either side, the edges slightly refreshed with scissors and split laterally to the depth of about one-third of an inch. The posterior flaps thus formed were carefully joined by a very fine over-and-over tendon suture. A somewhat larger

suture, commencing at the angle at the base of the division of the flap, was carried laterally from side to side, through the centre of the soft palate, a little beyond the line of lateral division. This line of sutures extended quite to the uvula. The approximation of the sides of the wound necessarily everted the edges and by so much increased the fresh surfaces brought in contact, while at the same time it completely buried the line of sutures. The everted edges, presenting in the roof of the mouth, were then carefully joined by a very fine continuous tendon suture. Two double-looped stitches, taken as far away from the central line as possible, were then introduced in order to prevent any lateral strain upon the central wound. The mouth and nose were closed and only rarely required to be cleansed of mucus during the four subsequent days; after cleansing they were dusted with iodoform by means of the iodoform blower. Respiration went on comfortably through the tracheal tube. A large injection of weak beef tea, given once in six hours, served the purpose of food and drink. The wound remained non-infected, and repair ensued as in aseptic wounds in other parts of the body, with the exception of the tip of the uvula, where a small slough formed from over-constriction of the suture.

The above case is reported as an experimental study, and is at least instructive as giving possibilities of better surgical results than those generally obtained in this most distressing deformity. If such seeming heroic procedure, as antecedent tracheotomy, may meet the approval of the profession, is a question for discussion. Without it, all attempt at rigid antiseptic conditions of the parts is seemingly futile. External wounds of the body are readily sealed from bacterial infection by the simple application of iodoform colloid, but thus far all attempts have failed in protecting mucous surfaces by germ-proof dressings, and we are under the necessity of making the cavity itself aseptic, and maintaining it in this condition until repair can ensue, or of accepting the dangers of infection which, when respiration is allowed to go on in the usual manner, generally gives failure in result.

The advantages of the use of the tendon suture in this operation appear to be equal to those claimed for it in operative wounds in other parts of the body; and, if this is true, it is the only suture material to be recommended for this operation. If it shall happen to me to attempt again the repair of these parts, a modification of instruments would simplify, in a considerable degree, the operation. Forceps bent at a suitable angle, the blades protected by rubber tubing to prevent injury of the enclosed parts, would greatly facilitate the seizure and holding of the flap, preparatory to splitting it. The division also can be effected easier by a knife, the blade of which is at a suitable

angle to the handle. The needle forceps also need special adaptation of the curve for the easy introduction of the sutures. Any practical surgeon, however, can effectually operate with the instruments ordinarily at his disposal.

Boston, 116 Boylston St., May, 1890.

DR. JOHN S. MARSHALL, of Chicago, said: At the request of the Secretary of the Section I have consented to open the discussion upon this paper, and through the courtesy of Dr. Marcy I have had an opportunity to give it a somewhat careful reading. I consider the paper a valuable one, in that it presents an entirely new method of operation for closing cleft palate. Whether it will revolutionize the common practice in this operation, time and experience only can establish. It is, however, a step in the right direction, as it looks toward establishing and maintaining an aseptic condition of the mouth during the operation and the process of repair in the wound.

Those of us who have had experience in operations upon the soft tissues and bones, in and around the oral cavity, will appreciate how great a boon thorough aseptic conditions would be in all wounds opening into the mouth, and how difficult it has been to prevent suppuration in compound fractures and other extensive injuries to the maxillary bones. Miller, in his researches, has found more than a hundred forms of microorganisms in the human mouth, including nearly all the pathogenic forms known to science, while the most cleanly mouths are found to be the constant habitat of a variety of forms. It would therefore seem to be an Herculean task to cleanse the mouth and render it thoroughly aseptic even by the method suggested by the essayist.

It has been my practice for years to combat the tendency to infection by the use of solutions of bichloride of mercury, and of carbolic acid of various strengths, the parts being irrigated and sprayed with them at frequent intervals. Dr. Marcy's method, however, could hardly be utilized in cases of severe compound comminuted fractures of the jaw, where many times, under the most favorable circumstances, it requires from two to three weeks to heal the external wound, and serious results might follow such prolonged tracheal breathing and feeding by the rectum.

In the operation of staphylorrhaphy, I believe the aseptic method will prove of great value, though to the patient tracheotomy and the plugging of the throat and nose will seem very formidable, and will deter a great many from availing themselves of the offered benefits.

With the new features of the operation itself, I am still more pleased.

The great difficulties in the way of a successful result in closing of the *vellum palati* have been to obtain perfect coaptation of the freshened edges, the prevention of tension upon the stitches

and perfect rest of the parts. By Dr. Marcy's operation these are largely overcome. In the lateral splitting of the *vellum* along the border of the cleft, the fresh surfaces are greatly increased, and by that much it would seem to add to the chances of successful union.

The method of stitching is unique, and the use of the buried tendon suture adds to the possibility of a successful result, though at first thought it would seem somewhat difficult to accomplish, except by instruments specially devised.

The result in the case reported is, however, no better, in fact, not so good, as in some cases which have been treated by the old methods of operating, as primary union through the whole extent of the wound is sometimes obtained by them. By the old methods about one in four are failures, but Dr. Marcy's method gives promise of better results, and until such time as it has received a fair trial we should withhold our judgment.

I trust Dr. Marcy will keep the profession advised in regard to all his future efforts in this direction, and I assure you it shall have a fair trial at my hands.

A CASE OF STATIC LENTICULAR ASTIGMATISM ACQUIRED BY THE LONG CONTINUED USE OF SPECTACLES HAVING A FAULTY POSITION.

Read in the Section of Ophthalmology at the Forty-first Annual Meeting of the American Medical Association, Nashville, Tenn., May, 1890.

BY GEO. E. FROTHINGHAM, M.D.,
OF DETROIT, MICH.

That dynamic astigmatism of the lens may exist has been recognized since Donders published his classical work in 1864, and it is now generally conceded that an unequal contraction of the ciliary muscle may exist, producing irregular curvature of the crystalline lens and often producing a sensation like that attending accommodation for the *punctum proximum*, with its accompanying fatigue and asthenopic symptoms. This astigmatism has often been observed in practice associated with corneal astigmatism, which it modifies in various degrees, sometimes increasing, sometimes partially, sometimes fully, and at other times over-correcting it. Owing to a cessation of this action as a result of loss of accommodation from age or from the use of mydriatics, corneal astigmatism that had previously been concealed, becomes manifest. Or what had appeared to be a myopic astigmatism may be shown to be a hyperopic corneal astigmatism. The question as to whether this dynamic astigmatism may lead to an altered form of the lens from a spherical to an ovoid form, so as to constitute a condition of

static lenticular astigmatism, is one which has not been plainly demonstrated, though from theoretical considerations we must accept it as a probable result of long continued action of this kind at a period of life when the eye is developing or while the lens responds actively to the contractions of the ciliary muscle. A permanent and symmetrical increase of the convexity of the crystalline lens, leading to myopia, has long been acknowledged as due to the excessive and long continued strain of accommodation. This kind of myopia, sometimes called *plesiopia*, was demonstrated in the early investigations of refraction and accommodation, and Stellwag credits Cramer with having been the first to demonstrate by suitable instruments an increased curvature of the lens in some cases of myopia, just such as is found in emmetropes when accommodating for a near object. While many of the ordinary pursuits of life have furnished abundant opportunity to observe the effect of an overstrained accommodation to produce myopia, only careful observation of cases both before and after, the use of improperly fitting glasses, can be expected to demonstrate the production of permanent lenticular astigmatism. Experiments with cylindrical lenses, for obvious reasons, would be highly improper and would not be submitted to. The faulty position of spherical lenses, so generally met with, and acting in the same way cylinders would, afford us the opportunities for observing the result, if only careful observation of the condition of refraction is made and recorded both before and after the prolonged use of such spectacles. In the following case such observation was made and as published reports of the kind have not come to my notice, I thought it worth while to put this case on record:

W. F. K., aged 19, of Grand Rapids, Mich., came to me on the 19th of October, 1881, suffering from asthenopia. Vision of each eye was $\frac{2}{0}$ +, and there was no manifest error of refraction on subjective test. Græfe's test showed 2° insufficiency of the internal rectus, though he could converge to 2 $\frac{3}{8}$ inches. In reading he found comfort from the use of +1 D. S., slightly decentered so as to act the same as weak prisms, base inward. I next saw him on March 1, 1882. He stated that he was much relieved by his glasses until a short time before this second visit, but that his symptoms had lately returned and he was as much troubled as formerly. His vision was still $\frac{2}{0}$ sharp, and there was no manifest error of refraction or muscular insufficiency. He could use his eyes with comfort for reading only when a convex spherical, 1.50 D. was supplied, and so these were temporarily prescribed and he was advised to rest his eyes by the use of atropia if his symptoms were not soon relieved. On the fourth day after this he returned as bad as ever, and the use of atropia was commenced. On the 6th of

March a careful test revealed hyperopia varying from 0.50 D. to 0.75 D. in each eye. No astigmatism was manifested. Atropia was continued and on the ninth and eleventh tests were carefully made with the same result. Atropia was continued and on the thirteenth an examination showed accommodation completely relaxed and the patient manifested no hesitancy in selecting glasses, H. = 0.75 D. in each eye with no astigmatism. With H. corrected vision of each eye was $\frac{2}{40}+$. Atropia was continued and on the fifteenth and seventeenth tests were made with the same results. Atropia was now discontinued and on the twenty-seventh a test showed H. 0.75 D. in each eye. Convex sphericals, 0.75 D. were prescribed for constant wear, and he was given +1.50 D. S. for reading and instructed to begin use of his eyes gradually by Dyer's method, holding his book at sixteen or eighteen inches distance. The patient was an industrious student of law, and read almost constantly.

I did not see him again nor did I hear from him until the 27th of September, 1886, when I was written to by Dr. R. J. Kirkland, an oculist of Grand Rapids, asking for my notes of his case. The patient had consulted Dr. K. on June 22, 1886, and as he had continued his excessive reading, was again suffering severely from asthenopia, and a test was made which did not call for the glasses he was wearing for distance at the time, *i. e.* +0.75 D. S.; that I had prescribed for him more than four years before. At this date he rejected all glasses for distance, except a $-\frac{1}{80}$ C. ax. 90° .

The following notes of the examination on June 22, 1887, and subsequent treatment, have been kindly furnished to me by Dr. Kirkland: R. E. V. = $\frac{2}{40}+$, with $-\frac{1}{80}$ cyl. ax. 90° V = $\frac{2}{40}$; L. E. V. = $\frac{2}{40}+$, with $-\frac{1}{80}$ cyl. ax. 90° V = $\frac{2}{40}$. Nine instillations of a solution of atropia, eight grains to the ounce, were made within three days, and accommodation completely paralyzed. In this condition his refraction was changed to hyperopic astigmatism in the vertical meridian. Record showed R. E. V. = $\frac{2}{20}-$, with $+\frac{1}{80}$ cyl. ax. 0° , V = $\frac{2}{20}+$; L. E. V. = $\frac{2}{20}-$, with $+\frac{1}{80}$ cyl. ax. 0° V = $\frac{2}{20}+$. After the effects of the atropia had passed off an examination showed a like result, and these convex cylindrics were prescribed for constant use. After this no further trouble was experienced and two years afterward, when Dr. K. reported last to me, the refraction had continued the same and the patient could use his eyes as much as he desired without the least discomfort. In his first letter Dr. Kirkland informed me that the patient had broken his reading glasses soon after he last consulted me, and, on applying to an optician, he had been given +3 D. S., which he had used for reading for the last four years and a half preceding Dr. K's examination. I wrote to Dr. K. stating my belief that

this astigmatism had resulted from the faulty position of these strong lenses, which as usually set by opticians, were probably more nearly vertical than they should be for reading. I requested him to examine with reference to this point and report to me the facts. Fortunately the spectacles had been preserved and a careful examination showed that in reading the visual axis formed a vertical angle of about 23° with the principal axis of the lens, the lenses having their horizontal axes parallel with the surface of the face. The strength of these lenses necessitated the approximation of the book to within about twelve inches of the eye. This would cause the angle between the rays of light and the principal axis of the lens to be about 6° in the horizontal meridian leaving a balance of 17° for increase of refraction in the vertical meridian of the lens, with a consequent lessened demand on the refraction of the eye in this meridian. By experimenting at this reading distance (12 inches) with a convex lens of three dioptries, so placed before the eye that there is formed a vertical angle of 17° between its principal axis and the visual axis, I find the refraction increased in the vertical meridian to the extent of a lens of about 0.75 D. To compensate for this and avoid astigmatism, the crystalline lens must increase its refraction in the horizontal meridian to the same amount (0.75 D.). In a state of spasm of accommodation with the reading lenses off, this would appear, as it did in this case, as myopic astigmatism in the horizontal meridian. But when the spasm of the ciliary muscle was relaxed by the use of a mydriatic it would appear as hyperopic astigmatism in the vertical meridian.

In this case it appears that by this long continued exertion of the ciliary muscle to compensate for the artificial astigmatism, produced by the faulty position of these spectacles, the form of the crystalline lens was permanently changed so as to correct hyperopia of 0.75 D. in the horizontal meridian, while it left its refraction in the vertical meridian unchanged.

In the first series of tests the dioptric system of measurement was observed; in the second the inch system was followed, and in the latter case the 60-inch lens would come as near to the 0.75 D. as could be decided upon by a patient in making a subjective test. Prof. Zeheuder, who made a large series of experiments as to this effect of faulty position of lenses, found that a convex lens of 3 D. rotated at an angle of only 5° , caused decided blurring of vision, and he expressed his belief that permanent lenticular astigmatism could be produced by such faulty position of lenses. The above case, in my opinion, is one demonstrating the truth of this theory. The tests were made in the first instance with the greatest accuracy, both by Dr. J. G. Kennan, my assistant at that time, and by myself. Dr. Kirkland is a

very careful and competent oculist, and that the refraction of the eye had changed is shown not only by his findings in these tests, but by the fact that when asthenopic symptoms became so unbearable in 1886, the patient's distant vision was reduced to $\frac{2}{3}+$ and could only be raised to normal by supplying the cylindrical glasses.

That it was acquired static lenticular astigmatism is shown by the effect of the atropia, the former known condition of refraction, and the result obtained by supplying the required lens. Whether or not this case was of the nature I suppose, the question of proper position of lenses is one of the most important that can engage the attention of those who undertake refractive work, and a large proportion of the time of oculists, must of necessity, be devoted to such examinations. I have known of instances where a most conscientious and skillful examination of the eyes has been made and the whole object of the oculist thwarted by the optician who filled the prescription. Even the most noted opticians often pay little attention to the measurements for frames that are furnished by the oculist, and these measurements are often, I believe, far too hastily and imperfectly made. Almost no attention is paid to that rotation of the lenses that is required to bring their principal axis to correspond with the line of vision, and often we find them set half an inch or so farther forward than they should be, and elevated to the eyebrows, or set down upon the cheeks. In this way great injustice is done to the oculist, who is alone held responsible if annoyance results to the patient, who often never gives him an opportunity to examine the glasses, and correct the faulty position resulting from a disregard of his directions.

One of the most important aids to work of this kind will be the construction of such trial lenses and frames as to allow lenses to be placed in a proper position while tests are being made. Another will be the device of some more suitable adjustable frame for readily making the measurements for the guidance of the optician in making the frames and mounting the lenses prescribed. That some ingenious mechanic will apply himself to this task and give us that which many of us so long have sought, is earnestly wished by not a few whose time is so taxed by the present methods commonly adopted in practice. Whoever trusts this work of fitting the frames to an optician will often find his prescription nullified, and his reputation injured by the incompetence or unfaithfulness of the spectacle venders who style themselves opticians.

I have no doubt that many cases of astigmatism of a low degree may be acquired by a faulty position of spectacles, and that we fail to relieve many cases of asthenopia, either because we do not pay sufficient attention to the position of the lenses while making the test, or in measuring for

frames, or because the optician has disregarded our directions in the matter.

DR. RANDALL called attention to the fact that the change in astigmatism has been proved by the ophthalmometric measurement. Ciliary action is, therefore, excluded, as well as lenticular obliquity. It has been shown that "astigmatism against the rule" is extremely frequent in glaucoma; and further, both clinical and experimental study has shown increase or occurrence of this form of astigmatism with the rise of tension. It may, therefore, be an important prodromal sign of glaucoma.

DR. FROTHINGHAM in closing the discussion said: I have presented this case for the reason that I think it may be of some value in the settlement of this theory. I admit it wants the element of certainty that can only exist where the curvature of the lens is accurately measured both before and after the appearance of the astigmatism. In ordinary practice this measurement of curvature is not made. In this case, however, an altered form of the lens is the only rational explanation that harmonizes with all the observed facts. The paper will furnish my answer to most of the questions raised.

It may possibly be true that corneal astigmatism may have developed in this case, but the direction of the axes of greatest and least refraction do not correspond to what we would expect from corneal change while they do with the theory of acquired lenticular astigmatism from the cause supposed. The degree of astigmatism acquired also just corresponded with the theory advanced. It would be a strange coincidence if changes of the cornea should extend to just this degree, and in meridians to correspond to this.

LENS MEASURER.

Read in the Section of Ophthalmology at the Forty-first Annual Meeting of the American Medical Association, Nashville, Tenn., May, 1890.

BY ROBERT TILLEY, M.D.,
OF CHICAGO, ILL.

The instrument I have to exhibit to you is not my invention. It is a device for the practical ready and accurate measurement of the curvature of lenses, and indirectly, of course, the measurement of the focal lengths of lenses of the average size used in optical devices for the amelioration of defective vision. It is of interest to us in the ready means it affords of checking formulæ for glasses, and in readily and accurately determining the combination of lenses which may come under our observation in our daily dealings with patients. It is not an easy matter to determine, by the method of neutralization, the combination of a compound lens. At any rate, I do not blush to acknowledge that it is not an easy matter for

me. Take any example at random: S. + 4.00 \odot + 1.00 c. ax. 180; or, S. - 2.25 \odot - 0.75 c. ax. 45°. It is not difficult to determine the axis of a cylinder, but this device renders it easier, and at the same moment, with a single turn of the hand, it gives us the radius of curvature, and by inference, the focal power.

I will first explain, by a diagram, the general principle on which the instrument is constructed, and then it will be evident to you that it is capable of doing the work it claims to do, and then the instrument will be handed to you for your own personal demonstration. I have brought a few lenses with me for that purpose.

The diagram (Fig. 1) shows the face of the in-

FIGURE 1.

strument. It is represented as measuring a plano-convex lens of + 3 dioptics. The highest part of the dial is marked 0. The space on either side down to the corresponding part below is divided similarly, the divisions gradually but slightly decreasing. On the face is a movable pointer. When this pointer is directed to zero it means that the surface being measured is a plane, or that the special part of the lens being measured is the axis of a cylinder. The left hand division, you will see, is marked plus and measures the plus lenses; the right hand division in a similar way indicates the minus lenses. The inventor tells me that in his design the order of plus and minus was reversed, but that the manufacturer, without his consent, changed it. That, however, is a detail of no practical importance, although in conformity with mathematical use of plus and minus it had been better the other way.

From the other diagram¹ you will see the mechanism by which the pointer is moved, from which, also, the reason will become plain why the divisions of the dial are not equal. In the upper part of the figure you will see three small rods. They do not need to be specially designated. They are ground to blunt points on the upper parts. The two outside rods are fixed, but can

be moved if it is desirable at any time to adjust the instrument. The middle rod is attached to a solid bar which slides up and down in a slot in the ground plate (A) of the instrument. In the figure this bar is marked B. To the bar is attached a knife-edged chain in contact with the short arm of the rack D. The fixed point of the rack is at E, and is made adjustable by the screw device, shown in the figure at F. At the lower part of the rack are the cogs which work the pinion to which the pointer is attached. The hair-spring is used to take up what is technically called "back lash," to prevent lost motion in the rack and pinion. I will add that whilst the instrument readily measures the curvature of the lens, the dial is so graduated as to show the focal lengths, being specially adjusted for lenses of crown glass; and if a variation is observed in a given lens it may be suspected that the lens is flint and not crown glass. The indices of refraction of pebbles correspond practically with that of crown glass.

It only remains for me to demonstrate the working of the instrument on a few lenses to show how rapidly and with what certainty it can be done.

ON INFECTIOUS DYSPEPSIA AND ITS RATIONAL TREATMENT BY THE ANTISEPTIC METHOD.

Read by invitation before the Mississippi Valley Medical Association at its Sixteenth Annual Meeting, Louisville, Ky., October 8, 1890.

BY FRANK WOODBURY, A.M., M.D.,

FELLOW OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA, HON. PROFESSOR OF CLINICAL MEDICINE IN THE MEDICO-CHIRURGICAL COLLEGE, ETC., ETC.

A cynical Frenchman declared that the treatment of consumption was "opium and lies;" and at times we are tempted to say that the treatment of dyspepsia is the same—minus the opium. If we confine our judgment to the numerous proprietary "sure cures for dyspepsia," now so widely advertised, this conclusion would probably be nearly correct. I hope, however, that the methods of rational medicine may so commend themselves to our favor as to escape condemnation to this category, especially when we may see our patients, by adopting them, cured safely, quickly and more or less pleasantly.

It is proper to state, at the outset, that our present consideration of the subject is limited to dyspepsia solely as related to the stomach; no reference is attempted, or intended to be made to intestinal indigestion, or to the so-called intestinal dyspepsia.

It must be very obvious to all that dyspepsia occupies a very important place in popular nosology; it is as familiar as household words. On the contrary, there is a strong disposition among many of our systematic writers on medicine to ignore the term dyspepsia, or simply to discuss it

¹ The drawing of this diagram having been mislaid, we are unable to reproduce it here.

as a synonym of indigestion. This may be due to the fact that the pathology of the disease, which Trousseau called a subject "vast and obscure," has hitherto been very little understood; on the principle that the proper way to treat a disease which we do not understand is to treat it with contempt. Most of our text-books disappoint the anxious inquirer by paying very little attention to dyspepsia, or merely mentioning it as a symptom, or as synonymous with gastric catarrh or simple indigestion. Some authorities, —Clifford Allbutt, for example— are skeptical of its very existence, and darkly hint that it serves as a convenient cloak for a host of sins of omission in the way of overlooked diagnosis of organic disease. I am willing to admit that many cases of gastric inflammation, gastric ulcer, even gastric cancer, may remain for a long time latent, or merely occasion some disturbance of digestion; but this only illustrates the well-known difficulty of diagnosis of disease affecting the viscera, and certainly is no proof that indigestion or dyspepsia may not exist where no organic affection is present. Time clears up the diagnosis of most stomach disorders, just as it does those of supposed ovarian cysts or of some uterine fibroids in young persons of appropriate sex.

It is true that indigestion, or laborious, slow and painful digestion, may be only a symptom; but, when this symptom is of constant recurrence, and seriously impairs the patient's capacity for work or his enjoyment of the amenities of life and effectually destroys his comfort and ease, substituting discomfort therefor, it is hard to convince him that it is not fully deserving of the title of disease,—by brevet at least. Does it not seem that habitual indigestion and suffering after partaking of food, in an individual, is, at least, something very much akin to disease? One of the Hippocratic aphorisms reads as follows: "Such constitutions as suffer quickly and strongly from errors in diet are weaker than others that do not; and a weak person is in a state very nearly approaching one in disease." Here is a definition of a dyspeptic, 2300 years old: *one with a weak constitution, who suffers quickly and strongly from errors in diet.* Unfortunately, the poor dyspeptic is surrounded by pit-falls which he only discovers by tumbling into them; he is forever finding out that he has committed errors in diet, and is eternally encountering new trials and committing more errors, until he is ready to exclaim, in his extremity: "Wretched man that I am! Who will deliver me from the body of this death?" It is a fact, and a very sad one, by no means unfamiliar to readers of the daily press, that the condition of the dyspeptic sometimes becomes so intolerable that his mind is temporarily unbalanced, and he seeks surcease from sorrow and suffering by suicide. Let no man judge him harshly for the dreadful deed:—

"What's done we partly may compute,
But know not what's resisted."

With reference to the pathology of dyspepsia, I would consider it at least as much entitled to recognition as a distinct disease, in the present unsettled condition of medical nomenclature, as consumption or chorea. Like them, it is characterized clinically by manifestations of nervous disorders; so that Cullen was not very far wrong in considering dyspepsia as a neurosis under the class *Adynamiæ*. Like pulmonary phthisis, also, its most marked symptoms are produced (I believe) by the absorption of the products of parasitic microorganisms. Just as Philip has shown that the symptoms of phthisis are due to the absorption of toxic products of bacilli tuberculosis, I think that many of the clinical manifestations of dyspepsia are caused by poisoning by ptomaines or leucomaines. For when bacteria and other microorganisms have been accidentally swallowed with the food, if they find the conditions favorable in the stomach, they will rapidly multiply there and make it a centre of infection. When this occurs, and symptoms of disorder appear, I think it permissible to follow the general rule and apply to it the term infectious dyspepsia. By this I do not imply that it is also contagious, in the ordinary sense, but merely that the morbid manifestations are directly connected with infection by microorganisms and their products.

Lauder Brunton has gone over this ground in his papers on "Indigestion as a Cause of Nervous Depression," and on "Poisons Formed from Food, and their Relation to Bilioussness and Diarrhœa;" and Sir Andrew Clark has similarly traced the cause of anæmia and chlorosis in young girls to digestive disturbance, or what he terms *fecal intoxication*. We now accept, without reservation, Pasteur's demonstration that there can be no fermentation or putrefaction without the presence of microorganisms; and I think Lister's corollary, that they are also responsible for the occurrence in the living body of inflammation and suppuration, is also generally received and daily acted upon,—at least, by those of us who practice surgery. Therefore, when Abernethy bluntly said that "men eat so much that the food actually ferments in their stomachs," he went at once to the root of the matter, and indicated the true cause of the symptoms in many cases of dyspepsia. Leared has shown that heart-burn is due to the presence in the stomach of butyric acid,—a product of lactic fermentation; and nearly thirty years ago Milne Edwards declared, as the result of his study of acid dyspepsia, that "the phenomena of lactic and butyric fermentation, which are manifested in the digestive tube, may well depend upon the action of infusoria, which live and multiply in the interior of this canal,—a hypothesis which explains the production of two gases found here, viz., hydrogen and carbonic acid."

Of late years the science of bacteriology has made wonderful advance, and especially in the department of bacterial parasitism, or infection, and its relation to disease. It is known that certain microorganisms, under ordinary circumstances, are harmless to the human system; others possess virulence, and produce more or less disturbance of the bodily functions or give rise to the different varieties of specific diseases. Under normal conditions, microbes, principally harmless, constantly find their way into the air-passages and into the stomach, and, indeed, certain varieties are always found flourishing among the contents of this organ.

Abelous,¹ a recent investigator of this subject, found 16 species existing normally in his own stomach, of which 2 were micrococci, 13 bacilli, and 1 vibrio. (Of these the *sarcina ventriculi*, the *bacillus pyocyaneus*, *bacterium lactis aërogenes*, *bacillus subtilis*, *bacillus amylobacter*, *bacillus megabacterium*, and *vibrio rugula* had been recognized previously by other experimenters). The presence of saprogenic microbes in the stomach, therefore, being constant and not incompatible with health, it becomes necessary to inquire why fermentation or putrefaction of the food does not occur after every meal? In other words, how is practical antiseptics obtained by natural process? Three things are to be considered in this connection,—(1) the food, (2) the digestive fluids, and (3) the physical conditions attending the act of digestion. With regard to the food, we observe that effort is made to have it fresh and suitable for digestion; experience having shown that tainted food, or, as we commonly say, spoiled food, very promptly causes serious disorder, both of the digestive organs and the nervous system. The food is also, as a rule, required to be mainly of the kind that the individual is accustomed to eating, as unaccustomed food often produces disorder. The well-known antiseptic character of the digestive fluids is of great utility in preventing the development of microorganisms, but these vary, both in their quantity and quality under morbid conditions. The muscular contractions of the stomach, owing to deficient innervation, or to other causes, are often lacking in energy and efficiency, thus producing what has been called motor dyspepsia, and the movements may also be attended by pain.

With regard to the personal equation or digestive capacity of different individuals, we rarely give sufficient consideration in therapeutics to actual anatomical differences in stomachs. Some persons have stomachs many times larger than others, thus requiring more bulky food and less frequent feeding than the latter, and this difference exists even in early infancy.

As already stated, during healthy digestion

fermentation and putrefaction of the food do not occur; but let digestion be retarded, or let the supply of gastric juice be insufficient in quantity or deficient in its essential elements, or let certain germs be present in unusual quantity, and indigestion, sour stomach, and the usual symptoms attending painful and tardy digestion will be produced. On the contrary, in a case of habitual indigestion, or dyspepsia, if proper measures be taken to keep the pernicious activity of the microorganisms in check, at the same time securing by hygienic and tonic treatment a proper innervation of the stomach, and especially a sufficient supply of gastric juice of good quality, the nervous symptoms, both local and systemic, will at once be ameliorated, and by continuing this plan of treatment (which I have ventured to call the antiseptic method on account of its results), and the selection of a proper dietary, the dyspeptic may be restored, if not to perfect health and happiness, as least as near as he can hope to come to them in this world.

I cannot help digressing a little just here, to note the precautions that civilized man has been taught by experience to take, in order to prevent septic infection of the contents of his stomach. He cooks his food at a comparatively high temperature, and, generally, it is eaten at once, or means are taken to preserve it by refrigeration or hermetical sealing. In thickly-inhabited parts of the world it is the custom to boil the water used for drinking purposes, and, very commonly, some aromatic or slightly stimulating herb or berry is added to make it more palatable. In fact, coffee after roasting has also decided antiseptic effects, and its infusion markedly retards the development of microorganisms in the stomach. Tea exerts a similar action, though to a less degree, but it has the disadvantage of retarding the digestion of albuminoids. Chloride of sodium is a constant feature upon all of our tables, and, doubtless, is one of the great agents in permitting advance in civilization, as it helps digestion, and is a valuable antiseptic. Alcohol has this action also, but possesses the additional advantage of stimulating the nerves of the stomach, thus increasing the rate of its movements, and also the amount of the gastric juice. When used to assist digestion, alcoholic stimulants are considered by Ringer to be invaluable, when used medicinally and with discretion. In the treatment of weak digestion, I often find the judicious use of old Bourbon to be attended by the most happy effects. It is the most reliable form in which to administer stimulants, and is infinitely preferable to adulterated French wines for this purpose.

It might be mentioned here, with regard to the question of treatment, that many of the drugs of established reputation in relieving the symptoms of dyspepsia are also known to be antizymotics. For instance, we may enumerate the cinchona

¹ Recherches sur les Microbes de l'Estomac à l'Etat Normal et leur Actions sur les Substances Alimentaires. Paris, 1889.

salts (quinine is very prominent among bactericidal agents), hydrochloric acid, nitrate of silver, the volatile oils, strychnine, arsenic, the mercurials, iodine and carbolic acid, creasote, beta-naphthol, salicylic acid, salol, resorcin, charcoal, not forgetting alcohol, which is the basis and essential ingredient in the various elixirs, tinctures and bitters. The alkalies, particularly the bicarbonate of sodium, act indirectly as antiseptics, by changing the reaction of the fluid contents of the stomach and preventing the growth of those bacteria which flourish only in an acid medium.

A very prompt and efficient method of preventing the undue development of microorganisms in the stomach is by irrigation of its cavity with antiseptic solutions. Washing out the stomach, or lavage, is a very old method of relieving the symptoms or indigestion, and does not acquire special apparatus for its performance. All that is necessary is to swallow large quantities of water, or other detergent solution, and then make the stomach empty itself by the act of vomiting. This was in use among the ancient Romans, and probably is among the few therapeutic expedients coming down to us from primeval man. The treatment of dyspepsia by emetics is similar to it, though attended by more nausea and disturbance of the general system. The method, which Kussmaul introduced in 1867, is a great improvement upon either of these. He uses a soft œsophageal tube, attached to a stomach-pump, for the purpose of washing out the stomach, and surprising results are obtainable by adopting this treatment. I have used for the same purpose a long tube, to which a funnel is attached, with equally good results, in adults, the tube being introduced through the œsophagus until its extremity enters the stomach. The funnel is then held upright, and a pint or more of fluid poured through it into the stomach; by simply allowing the funnel to hang down the action is reverse, and the stomach is emptied by siphonage. This is repeated several times at each sitting, or until the water returns clear. This plan answers very well in adults, but the pump or aspirator is better for children. I do not wish to give a bibliography of this subject, but will simply refer to a recent paper (John Hopkins Hospital Bulletin for July, 1890), by my friend Dr. William D. Booker, of Baltimore, in which the results of nearly 200 cases of gastrointestinal disturbance in children treated by stomach-washing are given. He reports remarkably successful results, especially for the relief of vomiting due to indigestion, and in summer complaint. I could give some interesting cases occurring in my own practice among adults with confirmed dyspepsia (one of incipient insanity, apparently arrested by washing out the stomach a few times and appropriate general treatment), but I do not wish to extend this communication farther.

I would summarize as follows:—

Laborious, painful and imperfect digestion occurring habitually, when not symptomatic of other disease, constitutes dyspepsia; and when accompanied by fermentation of the contents of the stomach and general toxic symptoms, the result of microbian development, it may properly be called infectious dyspepsia.

The disorder is sufficiently prevalent, and gives rise to enough discomfort and actual suffering in its victim not only to deserve our serious consideration, but also to enlist our best therapeutic skill in their behalf. The excessive growth of microorganisms during digestion is favored by slow movements of the stomach and by defective quantity or quality of the gastric juice. Acid dyspepsia, or sour stomach, may be due to excessive secretion of hydrochloric acid (rarely), but is generally caused by lactic, acetic, or butyric fermentation, due to the presence of appropriate forms of bacteria in the stomach. The object of treatment of infectious dyspepsia is to prevent the excessive development of microorganisms during the digestion of food. This is sought to be accomplished by (1) the use of articles of diet which are not in a fermenting condition, nor readily fermentable; (2) by adopting such hygienic and tonic measures as will invigorate the bodily powers and especially bring the gastric juice up to its normal standard of quality and quantity, and increase the muscular power of the stomach; and (3) by local antiseptic treatment, including the administration of drugs which retard fermentation, and especially by lavage, or irrigation of the stomach, with weak disinfectant solutions, or simply recently-boiled water.

218 S. Sixteenth Street, Phila.

THE TREATMENT OF ACNE.

BY HENRY WM. BLANC, B.Sc., M.D.,

LECTURER ON DERMATOLOGY, TULANE UNIVERSITY OF LOUISIANA;
INSTRUCTOR IN DERMATOLOGY AND SYPHILOLOGY, NEW
ORLEANS POLYCLINIC; DERMATOLOGIST TO THE
CHARITY HOSPITAL, AND TO THE TOURO
INFIRMARY, NEW ORLEANS.

When we consider what a common affection is acne, it is rather remarkable that so little attention is given to it by the general practitioner.

If a youth between the ages of thirteen and twenty-five years asks the advice of his family physician about a face broken out with pimples, he is not infrequently given a large amount of advice and a small amount of arsenic, and told that he will soon outgrow the disease, or *out-live* it, at any rate.

If a young girl is afflicted with the trouble she gets similar advice, but the arsenic is now mixed with a little iron, or some emmenagogue; and she, too, is sent on her way to await the predicted disappearance. But does this spontaneous cure come to confirm this advice?

In a few instances I have seen involution take place in about two or three years, leaving the skin red, rough and irritable; but in a large majority of cases the eruption remains as a constant annoyance and disfigurement to its unfortunate possessor, until its latent cause has become sufficiently aggravated to demand for itself, as a separate disease, a special form of treatment, when both affections improve together—the effect together with the cause.

Though acne is never severe enough to threaten life, nor even to produce pain to any marked extent, its common location upon the face is apt to be a source of great annoyance and embarrassment to the patient, not only from the redness and prominence of the pustules, but because of the pitting of the skin which not infrequently follows these when the disease remains long untreated.

Acne may be due to a variety of causes, but the commonest of these is indigestion. This word must be taken in its broadest sense as implying impeded function of some portion of the gastro-intestinal canal. It behooves the physician, then, who would treat this affection successfully, not only to search out the causes of indigestion directly located in the alimentary canal, but also to thoroughly inform himself of the condition of the liver, the blood and the reproductive organs, inasmuch as the function of the stomach and bowels may be directly impeded by poverty of the blood or torpidity of the liver, on the one hand, and, in a reflex way, by dysmenorrhœa, or irritation of the external genitals, on the other.

It has become my habit to lay down rigid rules of diet for acne patients, which must be strictly adhered to even in the mildest cases. These rules are framed with a view to increasing the alkalinity of the blood, and promoting daily evacuations of the bowels. A vegetable and fruit diet is recommended in some cases, meat being altogether interdicted, and in others a small quantity being allowed only once a day. Green vegetables should not be dressed with vinegar or mustard, and all salads and pickles are forbidden. Milk, and the alkaline mineral waters may be drunk at or between meals, but tea, coffee and other stimulants must not be taken. In case of weakness an occasional whisky toddy may be taken before meals; though it is not recommended. Nothing is to be eaten between meals, and nothing to be eaten just before retiring. It is needless to say that rich pastry, and other food containing fatty substances, nuts, etc., are not to be partaken of.

These rules will apply in nine cases out of ten. But occasionally we meet with people who cannot drink milk, or with whom fruit does more harm than good. Of course, a special diet must be planned for these particular cases.

The bowels must be made to move daily. To accomplish this an orange or an apple taken an

hour before breakfast, or the juice of a lemon mixed with a small quantity of water, will frequently be all that is necessary. But sometimes the habit of constipation is so strong that it requires something more active than the fruit acids to bring about the desired result. If the patient is weak and anæmic, or if the skin has a waxy look, and the sebaceous openings are relaxed (patulous) and inclined to form numerous comedones, it is well to give some remedy which would be a tonic to the system and at the same time have a laxative effect upon the bowels. I do not know of anything which will produce these two results better than the magnesium cum ferro mixture, which may be ordered as follows:

R—Magnesii sulphatis, ʒj;
Ferri sulphatis, gr. iij;
Acidi sulphuric. dil., ʒj;
Acquæ cinnamomi, ʒvj. ℞

S.—Tablespoonful in a little water two hours before breakfast.

The dose here given is usually enough to produce one action a day, but should it be insufficient another tablespoonful may be taken at bedtime.

Sometimes the iron is not indicated, or it may be more desirable to give a medicine which can be made up in pill form. For this purpose nothing is better than cascara sagrada. This is frequently administered as a fluid extract, but its disagreeable taste is against it as a medicine for constant use, and consequently I have fallen out of the habit of using it in solution, giving instead the following pill:

R—Ext. cascariæ sagradæ, ʒss;
Ext. hyosciami, gr. iv. ℞
Ft. pil. No. 20.
Sig.—One pill morning and evening.

This pill may be taken before or after meals, as the patient finds it most convenient, and serves the purpose of giving tone to the bowels, so that when stopped after two or three weeks of use the constipation which usually attends the stoppage of laxative medicines, is not apt to occur. The hyosciamus is added to this pill in order to prevent griping, but I have acquired the habit of prescribing it always with the cascara pill, for I believe it has a special action of its own in other forms of skin disease, such as erythema (urticaria) when attended by constipation, and in which I have given it with marked success.

The bowels being regulated, what are we to give as a tonic for the general condition of the system? Cod liver oil and iron are apt to be the first agents suggested to our minds, but if these are not given in their most digestible form it is best not to give them at all. Both of these are apt to upset the stomach, and in acne gastric digestion must be carefully guarded all the way through. Indispensable as cod liver oil is in many strumous cases, I think it can be dispensed

with by the majority of acne patients. If iron is to be used it should be in exceedingly small quantity—and as it is to be administered for some weeks, we can afford to give it in small doses—and I do not know of any preparations better than the phosphorus compounds. A number of these preparations now on the market have given very good results as stimulants to the mucous membrane of the stomach and as aids to digestion. They differ chiefly in the relative quantity of iron, quinine or strychnine which they contain. Horsford's Acid Phosphate is a tonic which has given me satisfaction when I knew that the stomach was at fault, and may be given in doses of a dessert-spoonful just before meals in a small quantity of water, and again just before the patient goes to bed. This is sometimes made into a lemonade with sugar, but I prefer to have it taken without being sweetened.

A valuable remedy in acne, particularly the pustular variety, is the sulphide of calcium. This is given in pill form, or as tablets in doses of one-tenth to one-fourth of a grain repeated every two hours. As nearly all druggists keep tablets or gelatine-coated pills of this drug, the patient may be instructed to procure these and carry them about in his pocket, taking them at intervals until six or seven are taken in a day. Not infrequently this drug acts like a charm and the formation of pustules rapidly diminishes under its administration, while at other times the action of the remedy is entirely negative. This negative action may be explained in many cases by the proneness of the drug to become stale, the *sulphate* having formed by oxidation, when, of course, the pills may be expected to be inert. It is probable, also, that to the impurity of the drug may be attributed the digestive disturbances it occasionally produces, for if this were not so it would be impossible to account for the fact that many persons with delicate stomachs can take the sulphide of calcium for weeks at a time.

The forms of acne due to disorder of menstrual flow, masturbation, and the like, are to be treated internally exactly as these troubles are usually treated when uncomplicated with this disease, and we will not pause here to consider methods familiar to every general practitioner. However, a word or two in reference to this subject may not be out of order. With acne that comes upon women arriving at the climacteric there is almost always an accompanying rosacea due to the same cause. This rosacea, as is well known, consists of a redness of the nose and frequently of the cheeks, forehead and chin, the result of dilatation of the superficial capillaries. These patients blush easily, and the skin becomes particularly red and irritable at the time the menstrual flow is to come on. The common complications of "heart-burn" and palpitation in cases of this sort, has suggested remedies which regu-

late the circulation, contract blood-vessels, and act as general stimulants; and when these are used the results are apt to prove satisfactory.

Apropos of acne due to masturbation, I have a patient at this moment—an octoroon boy, nineteen years old, who has been under my observation, off and on, for a year, and always gets relief from my treatment when he discontinues the sexual irritation. When first seen by me he was a masturbator, and on being told of its injurious effects he stopped the practice for a while, and greatly improved under local and constitutional treatment. Thinking himself cured, and being told by his companions that continence was injurious to a man's health, he plunged into another form of sexual excess—with women, and the acne came back on him in as bad a state as before. Several times he has reformed, and each time he has improved, during the past six months. Latterly I have ceased to treat him with drugs altogether, and am awaiting the result of a newly-formed resolution to discontinue bad habits.

For the external treatment of acne a variety of lotions and ointments have been suggested, though I propose to mention here only some of those that have proven satisfactory in my own hands. But before rehearsing any of these remedies too much stress cannot be laid upon the necessity for opening at regular intervals the comedones and pustules that constitute the disease. For this purpose the acne lancet and comedo-compressor are used. This process requires time and patience, for the patulous orifice of the comedo, as well as the pustular apex of the advanced lesion alike require the use of the lancet. Many patients have been led to believe, from one source or another, that the lesions are aggravated and that pitting is produced by the use of the lancet. Their minds should be disabused of this at the beginning of treatment, and the assurance given that if these lesions are left alone the chances of permanent disfigurement are much greater. For external use sulphur has given me better results than any other agent that I have applied to the face. This may be made into an astringent wash, and is particularly useful in acne rosacea, where the blood-vessels are dilated and the surface irritable. The best of all the washes known to me is the well known *lotio alba*, of which the following is the formula, slightly modified:

R—Potassii sulphidi,
Zinci oxidi,
Zinci sulphatis, āā ʒij;
Glycerinæ, ʒii;
Aquæ rosæ, q. s. ad. ʒiv. ʒ

S.—Apply to skin after having thoroughly removed oily secretion.

The sensation which this produces is a puckering of the skin, accompanied by a feeling of dryness. Patients have complained to me that it made their skin feel wrinkled. The condition which accompanies these sensations is desirable,

but I find it better to alternate this action with a salve which acts more directly upon the horny layer, and which can be rubbed down into the comedones and open pustules. For this purpose I have devised the following combination, which is to be applied morning and evening after having thoroughly washed the face with hot water and the alcoholic soap lotion:¹

R—Sulphuris præcip., ʒiiss;
Acidi salicylici, ʒj;
Ext. ergotæ fluidi, ʒij;
Lanolini, q. s. ad. ʒj. ℞

This prescription I use constantly, and have found it serviceable in all affections involving the sebaceous glands. The sulphur is here rendered more antiseptic by the salicylic acid which, in turn, softens the horny layer of the skin, thus permitting a freer action of the application. The ergot, besides acting locally upon the dilated capillaries causing them to contract, also from its fluid character, aids the lanolin in its penetrating powers. It being understood that the external treatment of acne is the treatment of sebaceous glands the function of which is disordered.

More severe than the method just recommended is Unna's ichthyol treatment. This substance (usually the sulpho-ichthyolate of ammonium) is dark brown in color with a pitch-like consistence, and has a strong penetrating odor, more or less disagreeable to the majority of patients. It is usually too stimulating to the skin in ointments of over fifty per cent., but combined with vaseline, in the proportion 30 per cent. of ichthyol and 4 per cent. salicylic acid, it may be expected to give good results in acne, provided that the pustules are opened in the usual way, and the proper remedies exhibited for the purpose of removing any ascertainable exciting cause. One of the worst cases of acne that I have ever treated was cured with the following ichthyol salve:

R—Ichthyol, ʒvj;
Acid. salicylic, ʒij.
Vaselini, q. s. ad. ʒij. ℞
S.—Apply to face night and morning.

In conclusion, it would be well to say a few words with reference to the care of the skin during the course of treatment, bearing in mind that acne is not cured either in a week or a month—usually several months elapse before the patient can be discharged cured—and sometimes a few cases, with obscure constitutional symptoms, will hang on till the beginning of another year. I once cured a case of acne of two years' standing in the short space of ten days, and the delight of my patient was only exceeded by the surprise of her adviser when he saw the result. This rapid cure has been a puzzle to me ever since. But we were referring to the care of the skin during the

usually prolonged period of treatment. This consists in keeping it free from all external irritants, such as the soot and dust of the atmosphere, and in constant washings, to be followed by frictions with a hard towel.

It is well to use some bland soap for washing, with a view to removing the oily secretion of the sebaceous glands, so abundant in this disease, and at the same time freeing the glands of a secretion which, by decomposing at their orifices, might excite them to inflammation. A good lotion, which will subserve this purpose, and which may be used by busy persons whose occupations will not permit them to use disfiguring applications on the face during their hours of work, is the following evaporating wash:

R—Acid. boracic, ʒij.
Glycerinæ, ʒij.
Spt. vini, ʒj.
Ether sulphuric., q. s. ad. ʒiij. ℞
S.—Apply to face during the day.

This may be allowed to dry upon the skin and left there without attracting attention.

If asked to sum up in a few words the proper plan of treatment for acne, I should be inclined to say that it consisted in *strong and constant antiseptics WITHOUT, and the correction of disordered function WITHIN.*

42 Baronne Street.

ADMINISTRATION OF MORPHINE BY THE NOSTRILS.

Delivered before the American Rhinological Association, Louisville, Ky., October, 1890.

BY CARL H. VON KLEIN, A.M., M.D.,
OF DAYTON, OHIO.

In the administration of morphine by the mouth, there is generally, besides an inprecipitate taste, a great deal of hacking and spitting; in many to such an extent that it produces an irritation of the throat, especially of the soft palate. If used repeatedly it excites the same irritation of the lips and tongue as in the use of opium, and has been known to blister the mouth. In persons not accustomed to the taste of morphia it produces nausea and vomiting.

Dr. Billroth¹ reports in the case of a lady who took small doses 0.007 gram (gr. 1-9), and even 0.003 gram (gr. 1-22), saw such anxiety, nausea, and vomiting, that although suffering intense pain, she refused to take the remedy again. Cases of the same nature have been reported by Laborde.

Wernick² has called attention to the occurrence of a paræsthesia of taste after the use of morphia.

As a rule where persons are found to dislike the taste of morphia, or where it is desired to have a rapid physiological action, the hyperdemic is

¹ This soap, called by Hebra the *spiritus saponis calvus*, is made as follows: R—Saponis viridis. ʒiv alcoholis diluti, ʒij. M. cola et adde spiritus lavandulæ. ʒj. M. et ft. lotio. If too strong it may be mixed with water.

¹ Wiener Med. Wochenschr., 1868, p. 763.

² Archiv. f. Psychiatrie, Bd. ii, p. 174.

resorted to; this, too, finds opposition on account of puncturing the skin and the danger of producing abscess.

The new method of administering morphia through the mucous membrane of the nose which I will now describe, has been thoroughly tested by me in over one hundred cases where the immediate physiological action of morphia was necessary. I have found it to be the most reliable, tasteless and prompt action than given by the mouth or hyperdemic. It requires much smaller doses than taken by the mouth, and no larger than when taken hyperdemically.

The manner of administering morphia through the olfactory canal is simply by snuffing it up the nasal chambers in the same manner and in the same way as snuff tobacco is used. You divide the dose intended in two equal parts, each part placed upon the end of the thumb and snuffed up into the nostrils. The membrane being very soft and delicate it instantly appears to absorb. I have tried it on myself on several occasions, and it seemed almost instantaneous absorption; no more than fifteen seconds after the introduction I have blown my nose and nothing could be found in the secretion. However, in poor qualities of morphia the drug will not absorb as readily.

In cases where the nasal chambers are incrustated and covered by dry secretion, the cavities should be cleansed before administering; care should be taken not to snuff up too strong to engulf in the throat. If the drug is of a poor quality it will produce sneezing, but the narcotic effect will be the same.

The administration I have now described you will find, besides the tasteless and rapid action, to retain the narcotic effect for a longer period than taken by either mouth or hyperdemic.

NERVE DEGENERATION IN CHRONIC ARSENIC, LEAD, AND ALCOHOLIC POISONING.

BY JOHN FERGUSON, M.A., M.D., L.R.C.P.,

DEMONSTRATOR OF ANATOMY, MEDICAL DEPARTMENT, UNIVERSITY OF TORONTO, AND LECTURER ON NERVOUS DISEASES
SUMMER SESSION OF THE SAME.

The whole question of neuritis and nerve degeneration is one of very great importance; and all cases that throw light upon it are of value. The three following examples are of considerable interest in this respect. The first case, the detailed account of which was read before the Ontario Medical Association in 1887, is now given in a very condensed form.

The patient, a consumptive, had been taking large doses, m. 20 and 30, three times a day for a lengthy period, of liquor arsenicalis. She had been advised to do this by some one as a cure for consumption. She continued the use of the drug,

in spite of much gastro-intestinal irritation, and headache. At last severe pains began in the legs. These pains extended to other parts of the body, and were very intense. At this stage I saw her. There was evidence of neuritis. There was also paralysis of some muscular groups, particularly anterior tibial, permitting toe drop. Tested by galvanic and faradic currents, there was marked degenerative reaction. On the death of the patient the nerves and muscles in the most affected parts were submitted to examination. The degeneration in the nerves was pronounced in its nature; and there was an advanced state of muscular atrophic degeneration as well.

The other case was that of a man about 45 years of age, who had been employed in a lead works for many years. His principal work in the establishment was to run shot. In this work, large quantities of lead were melted and tempered, for the making of shot, by having a certain proportion of arsenic added when the lead was molten. As the arsenic was being added there would arise a volume of fumes; and this, of course, was inhaled freely. The person in question several times had lead colic. He suffered greatly with neuralgic pains in different parts of the body; but especially in the right side of the chest. These pains were no doubt due to neuritis. He had drop wrist. Finally, he died rather suddenly in the condition of acute imbecility and general paresis. The nerves and muscles of the most implicated regions were examined and found to have undergone a most extensive amount of degeneration. In the extensors of the forearm muscle fibre could hardly be recognized in some parts; while the nerves in some places were completely destroyed, in others only in a state of inflammation. There were the reactions of degeneration to the usual electric tests.

The third case is one of alcoholic neuritis. The patient was a well developed man, 39 years of age. He had been a very free beer drinker all his life. Latterly, he kept a hotel, and was in attendance at the bar nearly all the time; and constantly taking "nips" with those who were drinking. He began to complain of pains in his legs, anterior tibio-fibular region, which he thought were rheumatic. There was also some failure of eye-sight. I told him his trouble arose from his drinking and insisted upon abstinence from liquors of all kinds. This led to a change of physician for a time. He grew worse. Toe drop set in. Eyesight became more and more impaired. When I saw him again there were marked evidences of muscular atrophy and degeneration. He died in an attack of delirium tremens. In this case there was a combined condition of inflammation and degeneration of the nerves. The musculo-cutaneous and anterior tibial nerves were in an extreme state of degeneration. The musculo-spiral was also much affected.

The muscles supplied by these nerves were greatly wasted and essentially atrophied. Prior to death there were abundant evidences of degeneration by the electric examination of the affected regions.

THE CLINIC.

MYOMATA UTERI, AND SUPRA-VAGINAL HYSTERECTOMY.

A Clinical Lecture delivered in the Medico-Chirurgical Hospital, Philadelphia.

BY E. E. MONTGOMERY, M.D.,
OF PHILADELPHIA.

Through the kindness of Dr. J. Bart. Webster, of Atlantic City, an alumnus of this college, it is my privilege to bring before you a patient with the following history:

Clara —, æt. 38 years, colored, was admitted to the hospital two days ago, suffering from abdominal distension. She had noticed an enlargement some four years ago, which has gradually increased since, until now it is a very serious burden. Her principal distress is from the weight and pressure. The growth has not been attended by any marked disturbance of the menstrual function. The general appearance of the patient is good, showing that her nutritive functions have not been influenced.

Inspecting the abdomen when the muscles are relaxed by ether, we see the distension is nodular and irregular. A large mass can be seen upon either side, the larger to the right. Palpation discloses that these nodules are hard and firm, while the whole mass is freely movable. By previous vaginal examination, a mass or nodule was found in the pelvis behind the uterus. The uterus is involved in the growth and cannot be separated from it. Without further examination, the majority of you are ready to pronounce it a case of uterine myomata. The hard firm growth, its association with, or involvement of the uterus, the absence of fluctuation, and the slow progress all confirm the diagnosis made.

These growths are made up of tissue analogous to that of the uterus, and have their origin in localized spots within its walls. Where the muscular tissue predominates, the tumor is soft, its growth rapid, and the line of demarkation ill defined. Usually, as a tumor increases in size, the connective tissue about becomes thickened, forming its capsule. These tumors may early become encapsulated and their growth arrested, after which enucleation is comparatively easy. They may exist singly, or the uterus may contain a large number, in the latter, the condition is known as multiple myomata. To the latter class belongs the case now under consideration.

It may be well to remember that these growths

are also designated according to their relative position in the uterus. All these growths originate in the walls of the organ, and as they increase in size, those nearest the mucous membrane are forced into the cavity, becoming what is known as submucous tumors, when such a tumor is attached by a large base we call it a sessile tumor, when by a small one, a polypus. The latter tumors may be extruded from the uterus and hang by a long pedicle.

If the growth is situated in the wall of the organ, equally distant from the peritoneal and mucous surfaces, it is designated an interstitial, or mural tumor; while a tumor extruded beneath the peritoneum is called a subperitoneal. To the latter class belongs the tumor we have under consideration.

These tumors vary in size from that of a pea to those weighing 80 and 100 pounds.

The symptoms of the disease, will depend much upon the size, and the situation of the growth. The intra-uterine and submucous, and those interstitial which project well into the cavity of the organ are likely to be accompanied by hæmorrhage and uterine colic. In every case of continuous or repeated hæmorrhage, occurring in women, during the period of active menstrual life, you should examine carefully to determine the presence of polypus, or submucous tumor. In the subperitoneal variety, hæmorrhage may be slight, or entirely absent. The principal symptoms in such case will arise from pressure. The influence of the tumor will depend upon its situation; thus a small tumor low down in the pelvis may cause much more suffering than a much larger one situated in the abdominal cavity. The period of active growth is during the menstrual life of the individual. Subsequent to menopause, the growth either remains quiescent, or diminishes in size.

In considering the operative treatment of a patient, near the climacteric, it is well to remember that the latter is usually delayed, owing to the turgescence of the organ produced by the presence of the growth.

What shall be our treatment in the case before us? We have the choice of medical, electrical, and surgical.

Medical Treatment.—A great variety of remedies have been lauded for their imagined efficacy in delaying the growth, or causing the absorption of these growths; but in estimating the value of any plan of treatment, it should be known that their progress is often capricious, the tumor decreasing or disappearing without any assignable cause.

The remedies which have been found the most effective, are the bromides, the ammonium chloride, calcium chloride, and the various oxytocics. The first named drugs have been given quite largely, but it must be confessed with doubtful

utility. The calcium chloride was recommended by Sir Jas. Y. Simpson, because of its power to produce calcareous deposits in the vessels and capsule of the tumor, but unfortunately its action could not be limited to the growth; the coats of the large vessels and valves of the heart were also affected. The most effective remedy, undoubtedly, is ergot. It may be given by the mouth, by the rectum, or hypodermically. The drug exerts its action in two ways; first, through its action upon the muscular coats of the arteries, second, by intensifying the contraction of the uterine fibre, thus favoring the pedunculation of the tumor, either beneath the peritoneum, or into the cavity of the uterus. In order that this treatment should be effective, there must still remain enough healthy muscular fibre to be stimulated, and so arranged as to exert its force upon the tumor. The number of tumors in this case leads me to fear that it would not be effective. Another, and more important objection to its use in this case is the element of time. The most that we could accomplish would be a slight reduction in the size of the growth, and treatment would need to be continued an indefinite time.

Electrical Treatment.—The observations of Apostoli, based upon accurate dosage of electricity and its judicious application, have demonstrated its marked beneficial effect. His observations have been confirmed by such careful and experienced men as Sir Spencer Wells and Mr. Keith. In cases of hæmorrhage, the application of the positive pole intra-uterine is very effective in controlling and arresting it.

You will ask why we do not use electricity in this case? I reply, for the reason that it would require some months of treatment before this patient would obtain much decrease in size; time which she can not afford, hence we are driven to resort to surgical measures.

Surgical Treatment.—Now we may have our choice of two procedures under this head, viz.: the removal of the appendages, or the supra-vaginal removal of the uterus. The first operation would be done with the purpose of establishing menopause artificially. We do not consider this operation serviceable here for several reasons: first, the removal of the appendages does not always bring about, at once, a cessation of menstruation; second, the tumor would still be left, and cause distress by its weight and pressure; third, the operation, in many cases, is more difficult than the removal of the tumor, and in some, from being spread out over the mass, can not be accomplished. We shall proceed, then, to the operation known as supra-vaginal hysterectomy.

As a preparation for the operation, we have the patient's bowels thoroughly evacuated by repeated doses of saline, the abdomen carefully washed with soap and water, and afterward with acid sublimate solution, devoting especial atten-

tion to the pubes and pit of the umbilicus. Having etherized the patient, we expose the abdomen and cover the body above and below with blankets, the exposed surface is surrounded with towels wrung out of an antiseptic solution. An incision is made in the median line, using probe-pointed scissors to complete the incision through the fascia and peritoneum. The incision extended from the umbilicus to within an inch of the pubis. The tumor was with some difficulty lifted up, and was held closely to the brim of the pelvis by the contracted broad ligaments. This formed so broad a stump that its ligation was not feasible. The finger was pushed through the base of one broad ligament close to the uterus, two large forceps applied to the ligament, which was cut between them. After the opposite ligament was treated in the same way the remainder of the uterus was surrounded with an elastic ligature and the tumor cut away. The broad ligaments were ligated with braided silk. The stump was transfixed with pins and a wire *serre noue* applied, after which the elastic ligature was removed. The abdominal cavity was cleaned, the stump pressed down in the lower angle of the wound and the peritoneum stitched about it with catgut sutures. The entire wound was closed with chromatinized catgut sutures. The dressing of the wound, after dusting with iodoform, was iodoform gauze and absorbent cotton. The stump was carefully isolated in dressing the wound. The duration of the operation from the entrance to the exit of the patient was one hour.

The patient will be placed in a warmed bed and surrounded with hot bottles to prevent shock. Neither food nor drink will be given by the mouth for the first few days. If she complains of thirst we will inject slowly into the bowel from one half to a pint of warm water. Nourishment will be given in the same manner. If she complains of severe pain, morphine will be given hypodermically, but we will endeavor to limit her to the one dose, as this drug, by locking up the secretions, limits the power of eliminating poisonous compounds, promoting the probability of septicæmia. Should there be any elevation of temperature, we will, at once, begin the administration of a saline, thus forcing the intestines to drain the peritoneum.

MEDICAL PROGRESS.

EXPERIMENTAL TUBERCULOSIS. —GRANCHER and MARTIN (*Le Bulletin Médical*), on November 19, 1889, deposited in the Academy of Medicine, Paris, a sealed paper, in which they claimed, by a mode of treatment, to have succeeded in preventing the evolution of experimental tuberculosis in the rabbit. The publicity given by Koch

of his results, has led them to publish their researches sooner than they wished. In their experiments they chose rabbits and injected the bacilli into the veins, as by this means constant lesions of the liver, spleen and lungs are produced, lesions which invariably prove refractory to local treatment. As the tuberculosis thus conferred is always fatal, we have a means of measuring the value of any method tending to confer immunity or to cure after infection.

They have always followed a uniform plan, a like quantity of a virulent culture of the tubercle bacilli being injected into the veins of two rabbits, the one to serve as a control animal—the weight of each animal being taken daily to guide in the application of the treatment. In the past two years they have experimented upon 42 rabbits, of whom 15 were control animals and 27 were treated in different series. The results generally conformed to the following series: December 31, 1889, seven rabbits received in the vein of the ear a like quantity of a virulent culture. The control animal died twenty-three days after inoculation; the rabbits treated lived 126, 176, 176, 184, 189 days respectively; the sixth one is still living 229 days after inoculation. Autopsy in these cases was almost negative, spleen small, liver healthy and free from bacilli; but in the perilobular spaces a few embryonal cells were found, showing a tubercular process in the healing stage.

They have obtained a diminution of the virulence of the bacilli by successive cultivations. The first of these series kills the rabbit, when injected intravenously, in from fifteen to thirty days. From this point the virulence successively diminishes to the tenth, but the last three cultures do not reproduce themselves and are without effect upon rabbits. The second and third are mortal, but after a varying time dependent upon the resistance of the animal. Variations are still more marked with cultures 4, 5 and 6. The first series of inoculations were made on August 27, 1889; five rabbits received in the ear vein one-half a Pravaz syringe full of culture No. 6. September 3 the same rabbits received culture No. 3, and again the same culture on September 12, September 26 culture No. 2, and at last, on October 15, culture 1. At this time three fresh rabbits were inoculated for control experiment. These latter died October 28, November 2, and November 5 respectively, with the classical lesions of experimental tuberculosis. Three of the vaccinated died in the same time and with the same lesions. Two survived until December 17 and January 7, 1890, respectively; they both presented mild tubercular lesions. This demonstrated conclusively the insufficiency of vaccination with the weak cultures 6, 3, 3, and 2. Very good results have been obtained by multiplying the vaccinal cultures and stopping with No. 2. In a series of nine rabbits, with two control animals,

inoculated with the deadly culture No 2, January 23, five of these animals are still alive seven months after infection. Immunity is not so conclusively shown in these cases, as the results of inoculation of control animals with culture No. 2 are by no means certain.

A last series was composed of eleven animals vaccinated with cultures 6, 5, 4, 3 and 2, from January 30 to March 25. April 10 the vaccinated rabbits and two control animals received culture No. 1. The controls died twenty-three and thirty days after inoculation. The vaccinated have resisted still more, two dying June 16 and 26, two the 7th and 29th of July, four on the 4th, 7th and 9th of August. Three are still living four months after the most virulent inoculation.

In conclusion the writers think they have succeeded in giving the rabbits a prolonged resistance and in conferring an immunity for an undecided length of time.

THE OPERATIVE TREATMENT OF UTERINE MYOMA.—A. MARTIN closes an elaborate paper on the above subject (*Zeitschrift für Geburtshilfe und Gynakologie*, Band XX, Heft 1, 1890), with the following deductions:

1. Enucleation *per vaginam* should be confined to those cases in which there is a limited distension and beginning extrusion of the growth.

2. When a multinodular condition of the uterus exists, the organ still being movable in the pelvis, the size of the growth and that of the vagina corresponding, *extirpatio uteri vaginalis* is to be recommended in cases requiring operative interference.

3. In the case of large tumors which must be removed by laparotomy, enucleation should first be considered. In all instances where it is possible it is the duty of the surgeon to leave the ovaries, tubes, and as large a portion of the uterus as may be, for carrying on the female functions.

4. When it is not possible to save the uterus, total extirpation together with removal of the tumor by abdominal section is advisable, instead of partial removal—thereby doing away with all future discussion as to the intra- or extra-peritoneal treatment of the pedicle.

CHOLERA INFANTUM.—Many observations have been made with the aim of discovering a pathogenic organism in cholera infantum. HENOCHE came to the conclusion that we must at present regard the origin of this disease from microorganisms as merely a hypothesis. BAGINSKY (*Centralblatt für Klinische Medizin*, 1890, No. 36) has also made investigations which have led him to conclude that there is no specific organism which produces the disease. He states, however, that he found several varieties of microorganisms, which in his opinion together were the chief etiological factors. Jaksch states that the green

color so often seen in severe forms of this disease is due to the presence of a bacillus. Baginsky, in his paper referred to above, gives a very good account of the symptoms, sequelæ, and treatment of cholera infantum. He lays great stress on a peculiar eruption which often appears. It takes the form of roseola-like spots, which are found sometimes spread over the whole body, and sometimes only on the extremities. They disappear after about two days without desquamation, and are of no prognostic importance. Occasionally another form of exanthem is noticed, which may be regarded as an erythema. This also quickly disappears without unfavorable symptoms being foreshadowed by it. Amongst the sequelæ of cholera infantum Baginsky draws special attention to a condition which may be compared to that which occurs in Asiatic cholera, which this author designates "cholera typhoid." It is characterized by the following symptoms. The child becomes sleepy and apathetic; the temperature is high; there is great thirst; the stools are loose and contain pus and mucus in various proportions, and fibrinous threads are occasionally present. Pulmonary complications often supervene, such as bronchitis or broncho-pneumonia; pyæmic abscesses break out; the urine contains albumen, or there may be complete retention. The child lies with half-open eyes, and xerosis of the cornea often results. As regards treatment, the same author advises calomel, resorcin, and naphthalin, together with antiseptics, in the lighter cases; at the commencement of an attack, if the child be strong and well nourished, it is well to wash out the stomach. It is also important to place the little patient on the lowest diet possible, or even to withhold food altogether for a few hours. The latter precaution applies not only to artificial feeding but also the mother's milk. On the other hand, during this period it is advisable to administer brandy, sherry, tea, or coffee in iced water, and, if exhaustion be very pronounced, subcutaneous injections of ether. Gradually the child must be given weak gruel, milk thinned with iced water, etc. If complications occur, the various symptoms must be treated according to the usual methods; and the same remarks apply to sequelæ. Astringents should never be given; they are not only useless, but may even lead to evil results.—*Lancet*.

ACTINOMYCOSIS.—MATLAKOUSKI (*St. Petersburger Medicinische Wochenschrift*) reports a successful operation for removal of this condition in a man 46 years old. Six weeks before coming under observation the patient noticed a small, round, movable tumor under the angle of the jaw, which seemed to come without any special cause. The tumor grew, was not painful, and soon lost its sharp outline, seeming to infiltrate the surrounding tissue. Later a small abscess formed

that discharged a small amount of pus. Upon examination the hardened outlines of the infiltrated tissue could be distinctly felt. The tumor was completely extirpated, in the same way as a new growth in the same region would have been removed. Healing took place by granulation, and after two years and a half there was no return of the malady.

DANGER OF ERGOT AFTER PARTURITION.—MME. GACHES-SARRAUTE (*La Semaine Médicale*) in a paper before the French Academy for the Advancement of Science, stated that she would supplement the old rule that ergot should not be given before the child and after-birth had been expelled, by an additional one that ergot should not be given at all. Not even in those cases complicated by severe hæmorrhage. The foundation for these views lies, she thinks, in the fact that the uterus is never completely emptied in parturition—there always remain some shreds of membrane or clots. These according to her view, are a very grave source of infection, and a frequent cause for sub-involution and late infection recognized clinically in the several forms of metritis. Her own practice is to completely empty the uterus in all cases, and to be sure that this has been done she carries the hand into the uterus. The writer recognizes the danger of this practice as ordinarily performed, but says that with a thoroughly aseptic hand, with the nails carefully trimmed to avoid wounding the uterine tissue, it is attended with little risk. On the contrary, if the uterus is thoroughly emptied and washed out with sterilized water, hæmorrhage is immediately arrested and involution is a rapid process occupying but a few days.

She claims for these apparently heroic measures, almost complete freedom from the secondary accidents, now, unfortunately, too common.

CATHARTIC TREATMENT OF PERITONITIS.—LANPHEAR, of Kansas City (*Medical Review*, July 12, 1890) discusses the cathartic treatment of peritonitis and gives the history of a number of cases successfully treated. He claims that opium possesses, really, but little curative power over the inflammatory process; that it retains within the bowels irritating fecal matter that can but increase the trouble; that by completely checking peristaltic movements it leads to the formation of adhesions; that it stops excretion and so prohibits the elimination of the poisonous products of inflammation; and that by benumbing the sensibility it gives the physician a feeling of (false) security which is undesirable. Upon the contrary, the administration of the saline cathartic has the power of arresting the disease if given in the stage of invasion; here the peritoneum is simply congested, or just taking on an inflammatory action—the pain is not very severe, the

abdomen is not greatly distended, the fever is not high; but the physician it called, recognizes the danger and immediately gives the saline. If it be the initial stage of a simple peritonitis, if it be the beginning of a puerperal peritonitis, or if it be the sthenic stage of a septic peritonitis, the indication for the cathartic is clear; in either instance the blood-vessels are turgid with blood—the circulation impeded; the taking away of a considerable amount of serum from the abdominal viscera must profoundly affect the peritoneal circulation and assist in restoring the normal state. Besides, the active peristaltic action prevents the formation of bands and adhesions if the inflammation goes on; and experience at the bedside demonstrates that as the inflamed surface is relieved from engorgement by the emptying of the intestinal vessels, the temperature and the pulse rapidly decline, while the pain disappears almost as speedily as under opium. If the disease has gone on to the second stage where the fever is high, the pain intense, the tympanites marked and the pulse rapid and wiry, cathartics are not so strongly indicated, though small doses of sulphate of magnesia and tincture of belladonna may often be given with advantage; here the danger is collapse, and as vital force must be conserved, violent purgation is not justifiable and opium must be given—not to check the peristalsis, nor to “put the bowels in splints,” but to deaden the pain in the many terminal nerves of the peritoneum, to sustain the heart and prevent shock. The bowel must be kept free from irritating fecal matter, by enemata if possible, by a good cathartic if necessary; tympanites must be controlled by turpentine, either internally or by stupes; and the strength must be maintained by milk, whisky, etc.

His conclusions are:

1. The saline treatment should be adopted early in simple, acute peritonitis.
2. Small doses of calomel may be given to mild purgation in cases seen after the disease is fully developed.
3. Cases which fail to be relieved by cathartic measures should receive early operative interference.
4. Whenever peritonitis has gone on to that stage where the formation of pus is known, or even suspected, to have taken place, abdominal section and drainage are imperatively indicated.
5. When the existence of tubercular peritonitis is diagnosticated, or strongly suspected, operation (exploratory incision) is justifiable.
6. Opium is only indicated in the second stage of peritonitis, and then not because it “forms a splint” but because it relieves pain, sustains the heart and prevents shock—thus combatting the tendency to death.

A HEAVY BRAIN.—OBERSTEINER (*Centralblatt*

für Nervenheilkunde und Psychiatrie) describes the brain of a man 53 years of age who recently died in the poor house of Vienna. The previous history of the individual was fairly well known; born in Vienna of Jewish parents, in excellent circumstances, he wasted a rich heritage and finally died a pauper. The brain weighed 2,190 grams, after making some allowance for some possible post-mortem inhibition, 2,028 grams. The microscopic examination showed no special alteration in the histological structure and the various convolutions had about their normal arrangement.

The author takes this opportunity to make some remarks on the weight of the brain in general. He dismisses as untrue the statements regarding the extraordinary weights assigned to the brains of Cromwell and Lord Byron. The only authentic instance in which a brain has weighed over 2,000 grams he assigns to that of Turgenjeffs, who died in Paris in 1883. The autopsy was made by Broardel, Ségond, Descond and Magnin, and the brain weighed 2,012 grams. He dismisses as unreliable the observation upon the brain of Rustan, who was found to have a brain weight of 2,222 grams.

Bischoff mentions the brain of a woman that weighed but 820 grams who was apparently not idiotic, but in whom insanity was given as the cause of death. J. Hess examined a brain in Obersteiner's laboratory that weighed but 788 grams. It belonged to a woman 67 years of age who lived in the poorhouse, and who must have manifested sufficient intelligence to have conducted herself properly, and attended to the ordinary affairs of life within the limited range of her experience. The microscopic examination of this interesting specimen showed vacuoles throughout the brain, due probably to old encephalitis.

TREATMENT OF POST PARTUM HÆMORRHAGE.

—DIRSKA (*Berliner Klinische Wochenschrift*, No. 8) recommends in post partum hæmorrhage that the uterus be firmly grasped by one hand, while with the other all clots are removed, and walnut-sized pieces of ice be conveyed to the uterine cavity and upper portion of the vagina. It is necessary that the uterus be compressed for at least fifteen minutes. The author has always succeeded in stilling post partum hæmorrhage by this method, and in thirty cases of placenta prævia centralis when it was applied, was so fortunate as to save the lives of all his patients.

POISONING BY BOILED CRAWFISHES.—DRS. ZORIN and MARLEKOFF, of Nikolaiev, report a series of cases of acute gastro-intestinal catarrh recently observed in which the disease had been undoubtedly caused by the ingestion of commercial boiled crawfishes. Some of the cases proved fatal.

THE FIELD OF OPERATIVE LABOR.

Conservative surgeons were formerly regarded as those whose training and inclination led them to adopt any other probable curative surgical methods in preference to operative procedures, unless the latter were imperatively demanded. They were not ready to suggest the employment of the knife as a radical measure at the very outset, if any other means of relief were attainable. It is a question whether such a description would be applicable to the conservative surgeon of the present day, who with different surroundings of his patient, and with precautions that were not formerly available, feels much more secure in assured results from the use of the knife. It was something creditable, only a few years since, and in the memory of even young practitioners, to be conservative in the treatment of injuries and surgical diseases of the abdomen and the brain; and he who would needlessly, as it was then considered, operate instead of palliating by any other possible or plausible method, would be regarded as a meddler, if not, in some instances, almost a murderer, should the result be unfavorable.

Since the introduction of the various rational aseptic and antiseptic auxiliaries to direct surgical art, and the more favorable prognosis which they assure, he who would fail to employ them or to accept the principles of personal cleanliness upon which they are based, or would hesitate to resort to the use of the knife in cases in which modern advancement has plainly shown its applicability as an almost certain means of relief to

suffering, would no longer be considered a conservative surgeon, but as a halting unprogressive and unenthusiastic companion in the ranks of a constantly advancing army of modern practitioners. To open the abdomen, except in extreme cases of necessity, was not long since regarded as almost a barbarity; but happily the limits of operative interference are now being clearly defied by the best surgeons, so that caution and tact are keeping pace with boldness and skilled manipulation. Conservative surgery has, therefore, advanced in its scope and field, being active and aggressive where it was formerly passive and non-interfering; but it exercises its watchful care and supervision over all the accessories which are now regarded as essential to the successful issue of every important, or even trivial, surgical operation.

While, however, the use of the knife has been greatly extended to the relief of injuries and morbid conditions in the highly sensitive and impregnable visceral regions, we cannot be blind to the fact that in medical cases such direct radical surgical measures may be resorted to injudiciously, where medical treatment alone is indicated. The favorable reports which are so often made, in medical journals and in the proceedings of medical societies, of the results of operative interference in medical cases, or in those which are semi-surgical in their character, may sometimes mislead the inconsiderate and induce a practitioner who is ready, with open mouth, to swallow any novelty, to treat a case from the standpoint of the surgeon rather than from that of the medical attendant. This is a danger not to be overlooked, and the young practitioner should not be so much dazzled by the brilliancy of such reputed surgical triumphs as to be thrown off his guard in arriving at a decision as to the line of treatment best adapted to the case in hand. There is danger, too, that if some of these severe operations are proven by experience, under aseptic and antiseptic influences, to be but seldom fatal, they may come in time to be looked upon too lightly and to be approached too familiarly by those who may not recognize their difficulties, or who may fail to appreciate the narrowness of the boundary line between success and failure. Thoughtful surgeons everywhere are anxiously contemplating the field of operative labor, with apprehension that it may be invaded by the un-

skilled and the unscientific beyond whose reach the bold and brilliant surgery of the present day occupies a lofty station. All honor to those modern minds and hands that have so ennobled the science and the art!

CARE OF THE INSANE.

In the evolution of organic types we notice a constant reversion to preëxistent forms. So strong is this atavistic tendency that a six-toed ancestor will send through many generations his acquired deformity, and we shall find it appearing again and again even though it skip one or more generations. So in the development of political and social institutions, there is a constant tendency to revert to a primordial type, and the patriot cries out, "Eternal vigilance is the price of liberty."

The humane and scientific care of the insane has been achieved after a struggle extending over one hundred years, in which, more than once, the tide of superstition and ignorance threatened to overwhelm the small but heroic band battling for the rights of these unfortunates. One would suppose that this question had been definitely settled, but now and again the reversion type shows its deformed head. We refer especially to an article read by DR. J. M. DODSON before the Wisconsin State Medical Society. In this paper we have an indictment, strong in that personalities are avoided, against the county care of the insane that has reared itself upon a foundation of false economy, synonymous with neglect. How true this is, is shown by the report of one county receptacle in New York State that proudly boasts of a reduction of the *per capita* costs to \$1.06 per week. That such a sum cannot furnish proper food, supervision, care and medical attendance goes without saying

Dr. Dodson points out the fact that chronicity and incurability are not necessarily convertible terms, and makes a stirring plea for enlightened medical supervision of the chronic insane. He closes with an appeal to the members of the State Society to aid in the erection of State institutions for insane, with separate provision for imbeciles and insane criminals.

THE French parliament contains 42 physicians, only one of whom belongs to the Conservative party. The remainder are either radicals or liberals.

FEMALE PHYSICIANS IN EARLIER TIMES.

In 1596, a license was granted in the city of Norwich, England, to DAME ADRIAN COLMAN, widow, late wife of DR. NICOLAS COLMAN. The license was given this lady to administer to women and children, on the grounds of her having been experienced in the art of physic during the lifetime of the said Nicolas. In 1560, the Bishop's court of Norwich licensed DAME CECILY BALDRYE to practice the art of chirurgery. One hundred years later, a dentist, ROBERT PURLAND, received a permit to practice from the Bishop of the same diocese. This is cited to show the scope of power of the ecclesiastics of those early times. It is not generally known that in the early Middle Ages much of the military surgery of that period fell into the hands of women, who were not unskilled in simple cures. In the old troubadour song about Aucassin and Nicolette, we are told that when the hero got his hurt, Nicolette looked him over and found his arm out of joint and "put it in again." In the feudal times it was the custom to educate the girls, belonging to the nobles, in practical matters pertaining to medicine and surgery, especially the healing of wounds. But by the time of the sixteenth century, the sphere of women, at least in the German army, had fallen off several points, from the dignity of the original treatment of the wounded, to a compound of nurse, camp-follower and something even less desirable, which is best expressed by the title of the official, who had charge of them, namely, "hurenwaibel," or whoresergeant. In camp, the sick and wounded were collected into a special hospital tent and nursed by these ladies. On long marches they were carried along in wagons, or left behind in villages or cities, under the care of a "spittelmeister."

EDITORIAL NOTES.

NEW YORK STATE MEDICAL ASSOCIATION.—The seventh annual session of this Association was held at the Mott Memorial Hall, New York, on October 22, 23 and 24. The occasion was in every way enjoyable, and helpful in sustaining the reputation of this young and vigorous body. There was a discussion on "Intra-Cranial Lesions," and another on points bearing upon "Prophylaxis in the Obstetrical Chamber." Were there no other attractions these would certainly

have repaid an attendance from any portion of the Union, while the other papers upon the programme were of present interest and practical value. This Association is a model organization, divided into Societies and Districts, responsible to the parent State Association, which in turn claims allegiance to the American Medical Association. With this first-named body, the system of delegates has been abandoned, each member immediately upon election becoming endowed with the privilege of representing his own views, and subject only in matters of legislative interest to the will of the majority. All elements of factional discord are thus sought to be eliminated, and so far has resulted in banding together a class of physicians who only needed a stimulus for the best of work.

CHOLERA INTELLIGENCE.—According to official returns from Spain, 1,814 fresh cases of cholera and 959 deaths occurred during the month of September, thus bringing the totals since the beginning of the epidemic up to 4,870 attacks with 2,516 deaths. There is but little fresh news as to the distribution of the disease in the Peninsula, but it is evident that the city of Valencia is still most severely attacked. At Massowah the epidemic is decreasing; indeed, on the 29th of last month it was regarded as having ceased. No fresh intelligence comes from Aleppo, but quarantine restrictions are maintained and renewed against arrivals from the Gulf of Alexandretta. From a report made to the Russian Government by a physician entrusted with a special mission to Persia, it would appear that cholera is tending to recede from the southern boundary of Russia, such extension as is taking place in that part of Asia being in the direction of Mesopotamia; and it is predicted that its movement is *via* Van and Bitlis to Mosul and Bagdad. Two rumors of cholera in England, one in the Port of Liverpool and one in the St. George's sanitary district, near Bristol, both turned out on inquiry to be mere attacks of so-called English cholera.

THE report of the Pennsylvania State Board of Health as to the number of registered medical practitioners in that State has just been issued. There are 8,318 practitioners, of whom 641 are of foreign birth, every nation, with the exception of Spain, being represented. The re-

port contains the names and residences of each practitioner, with the name of the college from which he graduated and the length of time he has been practicing.

IN MEMORIAM.—Resolutions on the death of Dr. T. B. Harvey, of Indianapolis:

The members of the Mississippi Valley Medical Association now assembled in Louisville, Ky., desire to extend to the bereaved family of our beloved Vice-President, Dr. T. B. Harvey, our heartfelt sympathy.

In his untimely death this Association has sustained an irreparable loss. Dr. Harvey was beloved by each and every member of this Association, in whose interest he labored with such untiring energy. A brother to the older and father to the younger members of his chosen profession, we can but think of him with tearful eyes and aching hearts.

And while we thus mourn the loss of this noble man, we sincerely sympathize with the grief stricken members of his family, and although knowing full well that no words from us can lessen their deep sorrow, we send them this message of condolence and sympathy.

Resolutions on the late Ex-President of the Mississippi Valley Medical Association, Dr. William H. Byford, of Chicago:

We, the members of the Mississippi Valley Medical Association, now assembled at Louisville, Ky., desire to extend our heartfelt sympathy to the bereaved family of our late Ex-President, Dr. Wm. H. Byford, who has, since our last meeting, been removed from our midst.

We desire to convey to his family expressions we feel at this grand man's untimely death. There has been taken from us a noble man to whom a worthy successor will not soon be found. This Association especially has lost a kind and good friend and brother, and we join with all others of our profession in mourning his untimely death.

F. C. WOODBURN, M.D.,
WM. PORTER, M.D.,
DUDLEY REYNOLDS, M.D.

October 9, 1890.

THE GROWTH OF HARMONY BETWEEN MEDICINE AND PHARMACY.—The *Western Druggist* has the following editorial comment on the desideratum of closer relations between physicians and pharmacists: "Now that the American Medical Association has established a department of pharmacy, it is probable that more intimate relations will soon be established between the various State Pharmaceutical and Medical Associations. As soon as this is accomplished a new field will be opened up for work of mutual value to both physicians and pharmacists. A number of the pharmacal associations have sent delegates to the medical conventions, and in a few instances the physicians have been represented at pharmacal

meetings. Members who are both physicians and pharmacists and feel a sympathy for both professions are in a position to make serviceable delegates and should be selected on that account." The incentives to harmony between these two honorable scientific callings are constantly increasing, for the standards in both are being constantly carried higher. There are men in both professions—whose minds are so thoroughly infused with the scientific spirit of the period—that they can meet as peers, no matter where or what the platform is on which they meet. Science is the leveller of minor distinctions as between individuals, and the time will doubtless come, if it has not already come, when cordial and comfortable delegate-relations may be realized between the bodies to which those individuals belong. Breadth of views and honest work must open many doors that have hitherto seemed to be closed, and yet as the good work of harmony goes on, the specialization of scientific work of the two professions must also go on; so that while on the one hand they are drawn together, on the other hand the enormously increasing demands upon each will tend to keep them in their own special spheres.

DR. MONTROSE ANDERSON PALLAN, died in New York City, October 1, after a brief illness. He was the son of a physician and was born in Vicksburg, Miss., in 1836. He was graduated from the Academical Department of the University of the City of New York in 1853, and from its Medical Department in 1856. After studying in London, Paris, and Berlin hospitals, he began the practice of medicine in St. Louis. During the war he was a medical director in the Confederate Army, from which he was sent to Paris in 1864 to obtain medical and surgical supplies. Soon after his return he was captured, and he was held in New York on his parole till the end of the war. Dr. Pallan was appointed Professor of Gynecology in the New York University in 1874, and he held the position until his death.

OFFICIAL REPORT ON THE FIRST ELECTRICAL EXECUTION.—Dr. Carlos F. Macdonald, the State Commissioner in Lunacy, of New York, has made an official report to the Governor, in which he expresses a favorable view regarding the use of electricity as the capital punishment in the case of Kemmler. He holds that the first contact was

fatal and that the death was painless. In future executions, however, he would suggest certain changes in the apparatus. He would have the law so amended as to provide one single central execution plant, equipped with a specially designed dynamo capable of generating a 3,000-volt current, and that instruments for measuring the current be placed in the death-chamber and properly managed by capable men. Dr. Macdonald states that the efforts of interested parties to invest Kemmler's execution with "an air of repulsion, brutality and horror" will fail of their object and that, when all the facts in the case are rightly understood, there will be no doubt in unprejudiced minds that the first execution was a successful initiation of the new means of capital punishment.

MURDER OF AN ASYLUM PHYSICIAN.—Dr. George W. Lloyd, an assistant superintendent at the King's County Insane Asylum, Flatbush, New York, was shot and killed almost instantly, October 10, by an escaped lunatic, who had been at large some months and who had returned to the asylum, armed with two pistols, with the avowed purpose of murdering as many as possible of the officials who had been concerned in his former detention. He had no special antipathy against the slain physician, less in fact than against two or more others, but meeting Dr. Lloyd first, he shot him and sought to escape, without carrying out further his murderous designs. Dr. Lloyd was an able and promising young physician, whose early cutting off is peculiarly tragical and painful, and none the less so, if it be true, as is alleged, that the authorities did not exercise due vigilance in following up their escaped charges and were content to report the facts of the escapes, and to enter them up on their records as patients discharged. This sad event may prove a salutary lesson to our alienists in regard to the escape of dangerous inmates from their asylums.

THE percentage of graduates among the physicians in Illinois was only 48 per cent. before the registration law went into effect; now it is 91 per cent.

DR. WALTER RIVINGTON says that to improve the medical profession in Great Britain, it is necessary to diminish the overcrowding, and the too free use of alcohol.

TOPICS OF THE WEEK.

TIMELY PRECAUTIONS.

The *Pacific Medical Journal* states that the San Francisco Board of Health have discussed the existence of cholera in Yokohama, and by resolution have declared that city an infected port. The quarantine officers have been ordered to use extra vigilance in examining all vessels from the Orient, and most vessels with their cargoes, and the baggage of both passengers and crew are now disinfected. This is the only wise course to pursue. If the germs of cholera are landed on our shores they must come by the vessels from over the Pacific, and the San Francisco Board of Health with its quarantine officers must be held responsible. In this instance quarantine should be effective—should it, however, prove futile, the next measure to adopt, and which in truth should be enforced now, is to follow the advice of the State Board by placing our cities, towns, hamlets and individual premises in such a state of order and cleanliness that the disease can find no accumulated filth in which to incubate its germs.

SPECIALTIES AS THEY MAY BE.

Subdivision to extreme minuteness has been the modern tendency in pathology, in the description of morbid processes and of all departures from normal conditions. On account of the sublimation and refinement to which it has been subjected, that subject has been generally regarded as one which was not sufficiently attractive to become popular. The same tendency to subdivision has been apparent in the department of surgery, and to a certain extent this is unavoidable, because that important department necessarily requires a regional apportionment of its study and practice; but the result is that specialism is thus allowed to invade and appropriate to itself several distinct and separate fields.

While the general surgeon is improving and perfecting operative procedures upon all the important organs and cavities, the surgical specialist seems to be concentrating his skill upon regions bordering, in the two sexes, chiefly on the natural outlets, rectal and genito-urinary. While the value of their services in this direction must not be underrated, we trust that the time may be far distant when, with the present tendency to subdivision of surgical labor or of localities for special operations, it may become necessary to set apart organs, instead of regions, for special operative interference, and thus to still further increase the number of specialties.

And we are now reminded that we have more than once expressed the view, editorially, that it was not a happily chosen designation of one important and useful class of practitioners of a surgical specialty, that they should be denominated "Genito-urinary Surgeons." In what respect, we have inquired, are they, as individuals, more "genito-urinary" than any other surgeons, or, indeed, any other of their professional brethren? If membership in the "Association of Genito-urinary Surgeons" is not limited to the "male persuasion," would not the admission of the female element produce a confusion of terms

—for are not the latter quite as "genito-urinary" as the other sex, and would not the Association, so far as anatomical construction and physiological capabilities are concerned, be composed of two distinct classes of genito-urinary members?

But this is only a passing thought. What we wished to say, before we entered upon this diversion or divergence from our theme, was, that there is danger, in time, that the subdivision of specialties may become so minute that each organ of a series or apparatus—say the genito-urinary chain of organs—may become the central figure of a specialty. Is it possible that in those days we may have bladder surgeons, urethral surgeons, perhaps penal surgeons? Then, too, it is not beyond the range of possibilities that we shall have vaginal surgeons, who will call the intra-uterine surgeon into consultation should the disease under treatment invade the precincts allotted to that specialist? Judging from the rapid advances of specialism in the past, what may we not expect from it, in its various ramifications, in the not very distant future?—*College and Clinical Record*.

FERULA SUMBUL IN CHOLERA.

It is stated in one of the daily papers that several medical experts have been sent by the Russian Government to Asia Minor to test by experiment the treatment of cholera with ferula sumbul, a plant growing in Turkestan, and possessing antispasmodic properties. Musk root, as the root of this plant is called from its strong musky smell, has been used for a long time by the Russian physicians as a remedy in cholera, dysentery, and febrile diseases of a typhoid or adynamic type. Sumbul root is official in the British Pharmacopœia, and as obtained in this country is in circular pieces, consisting of transverse sections of the root, with a wrinkled epidermis of a light brown color. It is employed as a stimulant, like the aromatic oils in general. It specially resembles valerian and musk, and is used in the same class of cases as these drugs. It will be interesting to know definitely whether sumbul possesses any special property in the treatment of cholera different from that of the other aromatic stimulants in use at the present time.—*Lancet*.

SEPULTURE IN ITALY.

Italy claims, and with justice, to have led the movement by which cremation is being adopted throughout Europe as a means of disposing of the dead. The first crematorium was established on January 26, 1876, at Milan, and on December 31, 1888, there were in the peninsula twenty-one communes having crematoria in constant working; and other twenty-one communes in which crematoria were either in course of completion or in contemplation. After all, Italy is only returning to a usage which belonged to her classic period, but the circumstances that caused her to return to it do her little credit. In a highly interesting report, issued by the Government Statistical Office, on the "Condizioni Igieniche e Sanitarie dei Comuni del Regno," we read a frightful account of the mode of interment practiced within her borders, and even now but partially reformed. As recently as

1885, out of 8,258 communes only 7,864 had one or more cemeteries of their own, while 120 communes availed themselves of cemeteries constructed on the territory of a neighbor. In 274 the dead of the commune were interred in churches or receptacles hard by, and in 628 the only means of disposing of the corpses (of the poor, we presume) was to throw them into a common pit (*fossa carnaria*). Nor was this all. Of these charnel pits, 258 were within the inhabited radius, and 40 were at less than the regulation distance from this radius—that is, 200 metres. In other words, the mode of interment practiced in war, and excused only on the ground of necessity, was the established, every-day custom in 628 Italian communes five years ago. No wonder that the resort to cremation meets with such ready acceptance throughout the peninsula. Concurrently with the introduction of the crematorium, however, which only in exceptional quarters is available for the poor, public agitation is to be maintained. And we are hence glad to state that both in this country and elsewhere preparations are being made, by way both of improved sanitation and by the provision of means of isolation, to meet any imported infection. In France there is an evident determination to insist on the strict enforcement of the regulations as to notifying residence by persons who are allowed to pass the frontier from Spain, and several who have failed to comply with the rules as to this have been both fined and imprisoned. *Lancet*.

ALARMING FATALITY.

The Secretary of the Health Department of Yokohama recently reported that for the four days from August 29 to September 1, inclusive, there were sixty-two cases of cholera with fifty-one deaths. From the beginning of the epidemic the whole number of cases had been three hundred and eighty-five of which two hundred and seventy-nine died. The number of cases reported is not surprisingly large, but the death-rate is alarmingly high, indicating either wretched unsanitary conditions, unskillful treatment, or a very malignant type of the disease. It is probable that all these influences have to do with the high mortality, but more than likely the controlling one is the lack of popular sanitation.—*Pacific Med. Journal*.

UNIFORM NOMENCLATURE IN ANATOMY.

The establishment of a uniform nomenclature in anatomy, which was taken in hand by German anatomists about a year ago, has now become an international affair; and the committee appointed for the purpose, which has hitherto consisted exclusively of Germans, now numbers three foreign members—namely, Leboucq of Geneva, Cunningham of Edinburgh, and Romiti of Pisa. The expenses of the task are to be borne by the learned corporations of Germany, because the Anatomical Society, which began it, does not possess the necessary funds. The Prussian, Bavarian and Saxon Academies of Science have contributed 1,500 marks (nearly £75) each, the Academy of Vienna 1,000 guildens (about £85), and the Anatomical Society 1,000 marks (nearly £50). The completion of the work will be entrusted to a commission,

presided over by Professor von Kölliker of Würzburg. The preliminary work is to be done by an anatomist of special qualifications, including the necessary philological attainments.—*Lancet*.

THE STUDY OF OPHTHALMOLOGY IN HUNGARY.

In consequence of the alarming increase of granular ophthalmia in the south of Hungary, the Minister of the Interior has arranged that courses of instruction on the treatment of this affection shall be given to medical practitioners in different centres. These will last a fortnight. The first course, which is now just completed, was given in the Eye Hospital at Maria-Theresiopel. Other courses will be given both there and at Szegedin. Practitioners attending these courses will receive a Government allowance for their traveling and other expenses.

THE QUESTION OF SHOCK DURING OPERATIONS UNDER ANÆSTHETICS.

A correspondent, referring to recent notices of deaths under chloroform, draws attention to the fact that it is expressly stated that in one case deceased was not deeply under when the operation was commenced and completed; whilst in the other, death occurred before the patient was completely anæsthetized. Many observers have noticed what they regarded as reflex syncope during imperfect anæsthesia, and Dr. Lauder Brunton, we believe, both in his lectures and in his "Pharmacology," laid down that imperfect anæsthesia rendered the patient peculiarly liable to cardiac failure through afference of sensory impressions conveyed from cutaneous or visceral nerves. It is certainly a commonly recognized phenomenon that tying the spermatic cord, handling the intestines and dragging upon intra-abdominal viscera produce, even under chloroform, not only marked variations in the pulse, but also variations in the rhythm of respiration. During the experiments made by the recent Hyderabad Commission, it will be remembered that no such interference with the heart's action appeared to occur in dogs, at least as far as the Commission were able to reproduce in the lower animals the more complete conditions of the experiment as presented by human beings undergoing an operation under chloroform. In settling this and kindred questions, we shall probably have to recognize as a factor the difference arising from the greater or lesser elaboration of the nervous system in the animals, human or otherwise, under investigation.—*Lancet*.

THE MEDICAL DEPARTMENT OF THE BRAZILIAN ARMY.

The medical department of the Brazilian Army is being reorganized. The officers and their ranks are as follows: 1 inspector-general (general), 3 first-class surgeons (colonels), 9 second-class surgeons (lieutenant-colonels), 27 third-class surgeons (majors), 85 fourth-class surgeons (captains), and 75 assistant surgeons (lieutenants). The pharmaceutical officers are: 1 first-class pharmacist (lieutenant-colonel), 2 second-class pharmacists (majors), 8 third-class pharmacists (captains), 32 fourth-class pharmacists (lieutenants), and 44 assistant pharmacists (sub-lieutenants).

PRACTICAL NOTES.

SALIPYRIN.

Prof. Gutmann (*Deutsche med. Woch.*), gives an account of a series of experiments which he has made with salipyriu in the Morabit Hospital, Berlin. Salipyriu is a combination of 57.7 parts of salicylic acid and 42.3 parts of antipyriu— $C_{18}H_{18}N_2O_4$. It is a white powder without smell, of slightly acidular taste, easily dissolved in alcohol, but not in water. Professor Gutmann's therapeutic experiments gave the following results: 1. Salipyriu lowers the temperature in fever. In cases of high continuous fever, a first dose of 2 grams, and four succeeding 1-gram doses at intervals of an hour, proved most successful, and reduced the temperature by about $1\frac{1}{2}^{\circ}$ to 2° C. The lowest temperature is reached in about three to four hours, then a rise follows, until nearly the original height is reached in four to five hours. Perspiration, more or less profuse, usually accompanies the fall of temperature. In common with all other antifebrile remedies salipyriu has a more powerful effect in cases of less resistant intermittent fevers. 2. Salipyriu is as beneficial in cases of acute rheumatic fever as salicylic acid (and its preparations) and antipyriu; but it is equally inefficient in preventing relapse. The quantity prescribed *pro die* was usually 6 grams, distributed over six doses given every two hours. 3. Salipyriu is effective in cases of chronic rheumatism of the joints, and rheumatic sciatica. 4. Salipyriu was found to have no disagreeable secondary effects, even where patients took 6 grams daily for a fortnight or longer. In one case only an eruption over the whole body was observed, which disappeared after three or four days. The color of the urine is not affected by salipyriu. Taking the results of his experiments together (which experiments extended over more than 2,000 grams) Prof. Gutmann comes to conclusions that can scarcely be called highly encouraging. He finds that salipyriu may be used for the same therapeutic purposes as antipyriu and salicylic acid, but that where an antifebrile effect is intended the dose of salipyriu must be double that of antipyriu.—*Brit. Med. Journ.*

MILK AND TYPHOID FEVER.

Dr. Vincent, physician to the Geneva Board of Health, has just published a careful report on the typhoid epidemic which raged in that city last spring, particularly in the Quartier des Paquis. He succeeded in tracing the outbreak to the milk with which the people in general, and the inhabitants of that quarter especially, were supplied. The most culpably negligent and untidy system

of cleansing the milk cans prevailed; indeed, in one extensive dairy he saw a milkman spitting on his hand in order to lubricate them for the scouring process to which he presently subjected the inside of those receptacles. Another source of the mischief was found in the carelessness with which the watering of the milk was practised—any water, pure or impure, being reckoned suitable. He strenuously urges on all who wish to escape the risk of contracting typhoid to boil their milk, and to see it done themselves. Milk sold as already boiled had not, in many cases, according to his experience, been properly boiled at all. The most perfunctory methods of boiling he found in constant practice. The moment the milk began to stir in the boiler and to bubble a little it was regarded as boiling and taken off the fire! Even had the boiling-point been adequately reached, he insists that the milk should still be kept on the fire for some minutes, if it is to be made perfectly innocuous. On the present system he thinks the microbes it is sought to destroy have every chance of surviving and of propagating their kind to increased activity.—*Lancet.*

USE OF ALKALIES IN DYSPEPSIA.

Germain Sée, in an article published in the *Semaine Médicale*, says that alkalies frequently fail to do good in dyspepsia, owing to improper methods of administration. He recommends that 45 to 60 grains sodium bicarbonate, dissolved in warm water, be given at the time of the greatest acidity, which is generally two or three hours after meals. Smaller doses do not sufficiently neutralize the acid, while larger ones may do harm by leaving the stomach contents alkaline, the object being to keep the gastric juice at its normal acidity. In dyspepsia, with insufficient secretion of hydrochloric acid, such as is met with in anæmia and neurasthenia, alkalies in small doses should be given half an hour before meals. It has been experimentally shown that this increases the amount of acid secreted. General hygienic and dietetic treatment should not be neglected.

QUININE AND PREGNANCY.

Merz (*Bulletin Méd. de l'Algérie*, January and February, 1890) concludes that, by setting up uterine contraction, quinine may cause abortion during the first three months of pregnancy. During the last three months that drug hardly ever provokes labor. The action of quinine during the middle months is uncertain; it certainly appears to grow less noxious as pregnancy advances. From the above conclusions it is evident that quinine ought to be avoided during early pregnancy, unless there be dangerous symptoms due to paludism.

SOCIETY PROCEEDINGS.

New York Neurological Society.

Stated Meeting, October 7, 1890.

THE PRESIDENT, L. C. GRAY, M.D., IN THE CHAIR.

TUBERCULOUS MENINGITIS.

DR. W. B. PRITCHARD presented the brain of a patient who had died from this cause. When first seen by the speaker the man was suffering from obstinate insomnia and headache. A few days subsequently the thermometer had shown some elevation of temperature, but this had never exceeded 103° at any time until shortly before death. The mental disturbances were very marked from the beginning. There was complete loss of memory, right-sided ptosis, difficulty and finally loss of speech, and the rapid development of symptoms of complete bulbar paralysis. The apparent immediate cause of death was the involvement of the vagus. There was decided right hemi-paresis. A very offensive purulent discharge from the nose was persistent, which continued until death. The autopsy had revealed over the right parietal bone a cavity about the size of a silver dime, the necrosis being presumably tuberculous in character. Over the patient's right eye there was a linear scar with a depressed fracture, but no apparent affection of the brain from this cause. At the base of the brain there was found a thick, tenacious material. The medulla, pons, crura and cranial nerves were involved, and the dura was covered along the convexity of both hemispheres with what was presumed to be masses of tuberculous deposit.

CAN WE DIAGNOSE HYPERÆMIA OR ANÆMIA OF THE CORD AND BRAIN?

DR. WILLIAM A. HAMMOND read a paper with this title. The writer had for many years been familiar with a group of symptoms which from their etiology and general characteristics were indicative of cerebral disturbance. Some twenty-five years ago, after considerable observation and many experiments performed upon living animals and the human subject, he had come to the conclusion that they were the result of an increased amount of blood circulating in the brain. The theory which the writer had advanced was, that natural sleep was due to a comparative anæmic condition of the brain, normal wakefulness to an abnormal quantity of intra-cranial blood. Persistent insomnia was the necessary accompaniment of the pathognomonic symptom of the affection in question. Without wakefulness then, there was no cerebral hyperæmia, with cerebral hyperæmia there was always wakefulness. If this symptom was associated with pain in the head, heat, and feeling of distension, vertigo and

hallucination, and was increased by the recumbent posture, and drugs which increased the circulation in the brain, there could be no doubt of the diagnosis of cerebral congestion in such a case. The writer had made many experiments with ergot and was convinced of its efficacy in diminishing the quantity of intra-cranial blood. In conclusion he said that if a patient came to him suffering from insomnia, pain in the head, vertigo, hallucinations, suffusion of the face, cephalic heat, and other striking symptoms of perhaps less special importance, and when he found the symptoms disappear under the influence of remedies, such as the bromides, ergot, ice and douches of cold water to the nape of the neck, cups in the same locality, usual blood-letting, or spontaneous hæmorrhage, position, and other means calculated to diminish the amount of intra-cranial blood, he did not see how an escape was possible from the deduction that the patient was suffering from cerebral hyperæmia.

DR. M. A. STARR said that while he did not wish to be understood as representing those who opposed Dr. Hammond's views, still his convictions at present were those expressed by Dr. Gray in his paper read recently before the Society. The symptoms which had been explained by the existence or assumed existence of cerebral hyperæmia were many of those symptoms which could be produced by other causes; such, for example, as wakefulness, which was often noticed in individuals when very much exhausted. In puerperal women who had suffered severe hæmorrhage. He had also certainly observed it in patients who were anæmic. Therefore to say that wakefulness necessarily indicated a hyperæmic brain was to advance a theory which was hardly tenable. Certainly hyperæmia of the brain might under certain conditions be diagnosed, but it was a very open question whether this could be done when only wakefulness was present. As to the question of drugs, they had been very much surprised to hear it stated by Dr. A. H. Smith and Dr. Peabody, at a meeting of the Practitioners' Society last winter, that those gentlemen had been treating cases of supposed hyperæmia of the brain with nitroglycerine and nitrite of amyl. These drugs, which were supposed to increase the supply of blood to the brain, were being given upon the hypothesis that they dilated the entire arterial system of the body, and the brain would therefore be relieved to a certain extent of blood. The reasoning at least appeared sound. The speaker thought it impossible to base a diagnosis upon any individual symptom.

DR. J. LEONARD CORNING thought this was not scientific reasoning. The truth might probably be more nearly arrived at by careful induction. If a man came complaining of headache, having a congested face, with a pulse of high tension, whose symptoms could be promptly re-

lieved by pressure upon the carotids, the jugulars, or bandaging of the legs, might such a patient be assumed as suffering from congestion or anæmia of the brain? The speaker thought congestion. Suppose quinine or alcohol should be given to such a patient and it was found that the symptoms were aggravated, it would be certainly concluded that the trouble was congestion.

THE PRESIDENT said that of course Dr. Hammond spoke with authority, this they were all prepared to admit. The fact that he was able to do so had much to do with the acceptance of his conclusions without criticism. Still no dictum in relation to a scientific point could be allowed to stand on personal authority alone. The conclusions must bear the force of investigation and be supported by fact. Dr. Hammond must not consider the discussion as having the least personal bearing, but as merely the expression of a general desire to elucidate the problem as far as possible. Dr. Hammond had stated the symptoms of cerebral congestion as being sleeplessness, with a certain feeling of compression or oppression about the head and a flushing of the face.

DR. HAMMOND here suggested that he had said these symptoms were increased by the dependent posture, or by anything which would increase the circulation.

DR. GRAY accepted the correction and went on to enumerate the conditions in which these symptoms might be found. For instance, insomnia was common enough in mental diseases and worry, melancholia, overwork, constipation, and in many conditions in which there was nothing to show that there existed any hyperæmia of the brain. In the early stages of intra-cranial syphilis there was a condition somewhat of the nature of hyperæmia. But then in Bright's disease, in which there was hyperæmia and congestion, there existed a condition of stupor. If the list of causes of insomnia were gone through, it would be possible to find a certain train of symptoms which would lead to the assumption of existing anæmia in some, and hyperæmia in others. Experiments had recently been made on the brains of animals, the report of which differed from those of other recorders, as to the point made that the brain rose or increased in volume during the waking period. It was an open question whether this was not due to cellular action producing an increase of blood. As to the association of sleeplessness with the recumbent posture, of course the extended observations of the author of the paper were deserving of due consideration, but so also were the more limited observations of the speaker in this respect, and he had not been able to verify the association. The question before them was not as to the existence of cerebral hyperæmia or anæmia, but as to whether it could be clinically diagnosed. Flushed face might be dependent upon chorea, general paresis or injury to the brain. It was

impossible to say whether the symptom was brought on by hyperæmia alone. The feeling of oppression and sense of fulness in the head was found associated with errors of refraction, insufficiency of the ocular muscles, changes of climate, errors of diet, etc. To assume that in all those conditions there was hyperæmia of the brain was assuming a good deal, and more than could be proved. It was a point which had not been demonstrated by any pathologist, as to whether there could exist by itself an increased amount of blood in the cellular tissue or other finer structures of the brain without causing disease of the surrounding parts. It was strange that Dr. Hammond, after five months' preparation of the subject, had cited no autopsies in confirmation of his theory.

DR. C. L. DANA said he thought it was now generally agreed that there was such a condition as cerebral hyperæmia, and that it could be recognized in its acute forms. Such a state might be produced by drugs, congestive neuroses, trauma, etc. The question was and is, what was the condition at the base of that functional disorder which had gone by the name of cerebral neurasthenia? whether its initial stage was that of hyperæmia or the hyperæmia was a secondary process. An acute and chronic hyperæmia of the brain were conditions admitted to exist, but it was preferable to say functional cerebral neuroses or psychoses, where the hyperæmia was a secondary process, and that seemed the inevitable conclusion to those who watched these cases. Many patients among the neurasthenics showed symptoms of congestion of the brain, others of this class did not in any way present the symptoms of the classic type of cerebral hyperæmia, but showed the condition so shaded down that it was necessary to set aside all the symptoms generally described. There was something at the back of the hyperæmia. The hyperæmia of the brain was secondary to some disorder of the vaso-motor nerves, or to some functional condition involving the whole nervous system. As to insomnia and cerebral hyperæmia, that question was obsolete. To state that sleep was produced by anæmia and wakefulness by the return of the normal amount of blood to the head was, the speaker thought, in the light of modern neurological studies, a theory which could be described as unworthy further investigation.

DR. HAMMOND thought that his points had been unanswered in the arguments. When Dr. Dana said that the neurologists of to-day ignored the theory of the physiological changes during sleep, a theory which the speaker might claim as his own, he thought Dr. Dana in error. He would remind them that he stated that headache presented innumerable causes for its existence, and it was only when he found it with flushed face, and vertigo, and when it was increased by the de-

pendent position of the head, that the diagnosis was certain. Then he knew his patient had hyperæmia of the brain, all the neurologists in the world to the contrary.

THE SENSATION OF ITCHING.

DR. E. B. BRONSON read a paper on this subject. Notwithstanding the fact that the special senses in their present state were so far removed in respect to the knowledge they yielded to consciousness from common sensations, there doubtless was a period when the distinction did not exist. Their differentiation had been the result of gradual and long continued processes of evolution. There could be little question that the sensory organs to which the several senses owed their special attributes had all originally developed from simple nerve endings that gave but the vaguest intimations of external objects. In this evolution the impelling force had been derived from the two grand principles of life, known as the instinct of self-preservation and the instinct of reproduction. There still remained to the skin and mucous orifices a variety of sensations, others more specialized, including a special sense with perceptive faculties, and finally the most important representative of the reproductive instinct, the aphrodisiac sense. The only sense with which the skin was endowed, that could be called perceptive, and that was worthy of comparison with seeing, hearing, smelling and tasting, was the sense of pselaphesia. In included the sense of contact which was seen in its most primitive form; its most important element was the pressure sense, while the temperature and muscular senses were more or less auxiliaries. Common sensation was represented in the integument in its highest positive aspect, by the voluptuous sensations, in its lowest negative aspect by pain. Returning to the question, what relation to the sensory organs of the skin and to their sensations, did the sensation of itching bear? The author believed that there was sufficient evidence to locate the essential seat of pruritus in the epidermis. From elaborate research the author has drawn the following conclusions: 1. That there was a sense of contact independent of the sense of contact; 2. That this sense of contact was the sense disturbed in pruritus; 3. That it primarily concerned simple nerve endings in the epidermis; 4. That the disturbance in pruritus was of the nature of a dysæsthesia, due to the accumulated, or obstructed nerve excitation with imperfect conduction of the generated force into correlated nervous energy; 5. That scratching relieved itching by directing the excitation into freer channels of sensation sometimes, substituting for the pruritus either painful or voluptuous sensations; 6. That the voluptuous sensation might attend pruritus was a manifestation of a generalized aphrodisiac sense, representing a

phase of common sensation that had its source in the sense of contact.

DR. L. D. BULKLEY considered Dr. Bronson's paper one of the most scholarly he had ever listened to. He then referred to some studies he had made as to the reflex character of itching. For instance, if the itching sensation were on the finger of the right hand irritation or pinching of that finger would cause a reflex sensation in the neighborhood of the scapula of the same side. He had only found one or two instances in which it was transferred to the opposite side.

DR. STARR asked whether it was ever thought that itching was a symptom of central nervous disease. Patients with locomotor ataxia were said to be frequently troubled with itching around the arms, scrotum, and perineum. He had never seen a case confirming this.

DR. B. SACHS had never seen it in organic nervous disease, but in functional disorders, such as crural neuralgia he had known the itching to be more obtrusive than the pain. It was a frequent condition of profound anæmia and often observed in hysterical women, and in cases of hystero-epilepsy.

Philadelphia County Medical Society.

Stated Meeting, September 10, 1890.

THE VICE-PRESIDENT, JOHN B. ROBERTS, M.D.,
IN THE CHAIR.

DR. BENJAMIN T. SHIMWELL read a paper on
A NEW METHOD OF DELIVERING THE FŒTAL
HEAD.

Nature's manner of delivering the fœtal head has been followed by obstetricians from time immemorial; recognizing the fact that the occiput is born under the symphysis pubis in normal labor. The face and chin stretch the perineal body, then force their way out, requiring an especial amount of care to prevent tearing of this tissue. The extent of injury to the pelvic floor is not properly appreciated; if the superficial tissue of the perineum is safe the attendant congratulates himself on his possible skill; or if aware of deeper injury, feels grateful that no apparent injury is shown to the watchful eyes of the nurse or patient's friends.

Thus do thousands get out of the confinement-bed ruined in health, carrying into the future injuries that must of necessity bring ill-results. Various plans have been suggested to support and accommodate the perineal body to the oncoming head.

It is strange how often the anatomical construction of the perineum is overlooked, and considered merely as a space-filler. It is by this that so much injury is done. The gynecologist's specialty lives by these results.

These are the reasons, hastened probably by experience gained in the above manner, that have induced me to write this paper. The theory that will be advanced, backed by my application of it in a great number of cases, is evidently new; if not, it has not come to my knowledge by reading or otherwise. The advantage of this method is the saving of the pelvic floor from injury, either superficial or deep. No attempt is made to show expedition, but a modification of the ordinary method of labor changing the direction of the impinging force.

Naegele says that 70 out of every 100 vertex presentations are in the first position, the other 30 are occiput to right and posterior. The remaining positions are exceedingly rare.

When the head presents in the first position the body of the child must not be overlooked. The back of the child must present to the front and left, the chest to the back and right; therefore at right angles with the vertex presentation of the head at the superior strait. The important point in this theory is the rotation of the head to the symphysis pubis. The manner of the rotation of the head is mooted. Pajot claims that the shoulders participate in the rotation, but contradicts himself when he further says: "That it is above all the shape of the child's head which decides the character of the movement;" also, "that the occiput will, therefore, be carried forward less on account of the direction of the forces which impel it, than because of the necessity for accommodation of the cephalic surfaces to the pelvic surfaces." All writers admit that after expulsion of the head occurs restitution takes place, that in a case of first position, after the head is delivered, the head turns with its occiput to the left thigh—that is, in the direction that the head presents at the superior strait; this is an untwisting of the neck.

Gerdy claims that this is "an external expression of a movement of the shoulders within the pelvis, by which the biacromial diameter passes from the transverse to the antero-posterior diameter, the head following the internal rotation." The folly of this assertion is on its surface. The head is free and the neck and body are constricted by the vagina and uterus, and if rotation does take place, can we overlook the anatomical relation and action of the atlas vertebræ? Would not the weight of the head allow of the rotation internal without its external manifestation?

Penrose (Hirst, vol. i, p. 571) says: "While the head has rotated, the body of the child, still in the cavity of the uterus, has been tightly grasped by the firmly contracting walls of the uterus, and has not participated in the movements of the head; hence the shoulders are still oblique at the superior strait, consequently the neck of the child is twisted." The latter theory, according to my experience, is the true one. The

fact of the anatomical construction of the cervical vertebræ of the child cannot be overlooked. This arrangement allows of a rotation of one-fourth of its circumference to take place without injury to the spinal cord. Therefore, if Pajot's theory of the accommodation of the cephalic surfaces to the pelvic surfaces, rather than the application of the force, is true, then it can be seen that rotation of the head is possible without the shoulders. Then, again, the head is not free to wobble around the pelvis when it has reached such a condition of flexion, neither is the neck a rigid body depending on the shoulders for its position. If the theory of shoulder rotation is so, then nature's method is superfluous; for why should the biacromial diameter be changed from its oblique position, which is nearer the antero-posterior diameter, to the transverse, then rotate back again beyond its former position to the antero-posterior?

Playfair believes in partial rotation.

Believing, then, that the shoulders still maintain their oblique position through all the stages of the delivery of the head, what occurs when rotation brings the occiput directly antero-posterior? This has been accomplished by the rotation mentioned of the atlas on the axis vertebræ to one-fourth of its circumference; this having occurred, the delivery of the head takes place, then immediately external rotation or restitution occurs, that is, the neck untwists.

The outlet of the female pelvis is four inches antero-posterior and transverse. The antero-posterior is possibly increased a half-inch by extension of the coccyx. These measurements are decreased by the soft tissues; this is more marked in the antero-posterior by the rectum and perineal body. As the head in the last act of delivery begins to extend, we have presenting the cervico-frontal diameter, which is four inches; this has to pass through a space that is but four inches, possibly four and a half inches, lessened by the perineal body, which is at this stage excessively stretched and attenuated. As the safety of the perineum is an exceedingly important matter, it occurred to me that this might be accomplished by lessening the size of the impinging body and transferring the extending head into another direction. It is the nose and chin that rupture the pelvic floor, therefore if the direction of this force can be changed to some other point than the junction of the levator ani muscle, it can be easily seen how injury to this muscle can be prevented.

When the labor has reached this stage, I place the woman across the bed on her back, knees well drawn up, then compel her to breath with her mouth wide open to prevent bearing down. As the head presents in the oblique direction and to reach the antero-posterior diameter it rotates, twisting the neck, the first step in the method is to reëstablish the direction of the first impinge-

ment; this is not done until the cervico-frontal diameter is reached; *this must be complete*, then forcing the head into extreme flexion by grasping the presenting occiput by the hand (in non-instrumental labors), I begin my rotation; the first step is to untwist the neck; this accomplished, the head presents cervico-frontal to the left anterior. I then take advantage of the same anatomical construction of the cervical vertebræ that allows of the normal rotation, and rotate one-fourth in the opposite direction, that is, to the left. The cervico-frontal is then transverse, the neck lying on the labia of the left side, the forehead beginning to engage the soft tissues of the right labia. What is now presenting to the antero-posterior diameter, or, what is more important, to the perineum? The biparietal diameter, which measures three and one-half inches, therefore less tension on the perineum. The possibility of delivering the head in the transverse diameter has been questioned. The articulation of the head to the spinal column is wisely arranged; if no other object than birth was intended, it has well served its purpose. The diameters of the extending face are those of a right-angle triangle, the hypotenuse of which is four inches, the perpendicular three inches, the base two and four-fifths inches. The mechanical advantage of this is apparent. If the measurements had been those of a triangle, the impossibility of delivery is easily seen, the head could not be born as long as the perineum existed. The sweep of the extending head would be the same at the chin as at the forehead, and the perineum would be torn in every case and in every succeeding labor; but the measurements are those of a right-angle triangle, and of a necessity the chin must recede when complete extension takes place, so when extension is made in the transverse diameter of the inferior strait the chin does not impinge on the ramus of the ischium.

Having got the head into this position, I begin the last stage of the delivery of the head. The head has been all this time in extreme flexion, then extension is performed, the soft tissues of the labia push aside, and nose follows on forehead, chin on nose; delivery is complete, and the pelvic floor is safe. The head then untwists to its normal position.

DR. E. E. MONTGOMERY: I think that the members of the Society are greatly indebted to Dr. Shimwell for the graphic presentation of this method of dealing with the delivery of the head and effort to save the perineum. This certainly is a violation of that old principal which has been handed down the ages, that "meddlesome midwifery is bad." When we consider that all progress in obstetrics and every step in advancement has been in violation of this principle, this thought may not be considered an objection to

this procedure, which certainly seems to be one which should be serviceable. But, not having had experience myself, I am unable to say more than these few words in commendation of it.

DR. J. M. BALDY: It seems to me that the remarks of Dr. Montgomery in regard to meddlesome midwifery are true as regards pathological processes, but not as regards physiological processes. Certain it is that in almost everything in which we have attempted to interfere with physiological processes, we have found that they have been carried on a great deal better by Nature herself than by any so-called improvement that we have made on her. If Nature had meant that the head should be delivered in the transverse diameter of the outlet, she would have given us some indication of such desire. On the contrary, she has shown us very clearly and distinctly that the head was to be delivered in the antero-posterior diameter. It is probable that the head can be delivered in the transverse diameter, as Dr. Shimwell has pointed out, if all the measurements are of average size; but all of us know perfectly well that it is the exceptional head that we come across, and not the typical head. Many of the heads are large, and the higher we get in the stage of civilization the larger the head. The normal head may go through, but I doubt not that Dr. Shimwell will run across many cases that he will not be able to deliver in the transverse diameter. Unless the head will pass easily, we have here no room for extension of the outlet. It is a fixed quantity bound by bony walls—the ramus of the ischium on both sides—and there can be no distension. On the contrary, in the natural methods of delivery, we have free room for extension taking place through the perineal body and the soft part of the lower part of the pelvis. Now, it may be that there is danger to the levator ani muscles from over-distension, but at the same time I conceive, and it has been my experience, that the danger to these muscles is greater in proportion to the amount of interference we give to the perineum. In other words, we have here a hard body starting from a given point and progressing at a certain angle to a certain point at which it meets a plane of resistance, that plane of resistance being the soft parts of the pelvic floor, and, if you will, principally the levator ani muscles. There is a well-known physical law, that any body moving in a given direction and meeting with an obstacle, will be deflected at a certain angle. We have this occurring in delivery of the head. The head comes down and meets a resistance, which, although not a fixed resistance, is sufficient to cause deflection in the line of least resistance. This line of least resistance is the opening of the vulva. If resistance is given to the head at that point, the head is prevented from bulging through the vulvar orifice, and the *vis a tergo* being still active,

must be spent at some place, and that place is at the point of contact of the head with the pelvic floor. Taking the head, which is bulging the perineum and presenting at the vulva, we hold it back by pressure on the perineum, or by some other method; then we are going to have the greater part of the *vis a tergo* exerted at this one point. These soft tissues of the pelvic floor are capable of yielding to a certain point, and when they come to that point, they are going to give, and there will be a tear of the levator ani muscles and of the other tissues involved. This is where, I believe, the vast majority of tears of the perineum come in. All teachers teach that the head should be held back in some way or other, so that the vulvar orifice is not allowed to expand, and the head protrude, as Nature intended; and by this misapplied force we bring about the accident we are trying to avoid. I have found in the cases in which I allowed Nature to take her course almost entirely, keeping the fingers from the head and perineum, excepting to make slight pressure and lift the head up against the pubic arch, that they have done better and I have had fewer tears, and those that have taken place have been of a minor degree as compared with those where I tried to prevent injury by supporting the perineum. Any support of the perineum whatever is pernicious. I believe that all the teachers and all the books are at fault in that respect. Nature did not mean to have the head held back and have the whole force spent on one part, when we have the elasticity of all the soft parts well anchored, so as to yield and to give room for the head to pass. Supporting the perineum prevents the proper stretching of these tissues, and prevents any good they may do in bulging the perineum and forcing the vulvar orifice open.

DR. SHIMWELL: I am exceedingly sorry that some of my friends who have used this method successfully have not spoken. Dr. Baldy has raised the objection that a large head could not be born transversely, but the same objection applies to the antero-posterior position as well. He overlooks the fact demonstrated by the mathematical figure, that we gain, as the chin is delivered, a fraction over $1\frac{1}{4}$ inches. The head is born without impinging on the soft tissues of the pelvis.

I have tried this method successfully for a year and a half, both in primiparæ and in multiparæ. I have used it both in cases terminated without instruments and in those where the forceps have been required on account of loss of tone or from malformation on the part of the head or of the pelvic outlet.

In regard to Nature—Nature is not always a good worker. If so, why should we have a disproportion between the head and the pelvis? The outlet should be made equal to the head. With regard to the increase in the size of the head with

advancing civilization, I know that; but is the pelvis unchanged? Is it not rather lessened? Has it not changed its size and shape?

The points advanced are, I think, no argument against the method. It is a safe method; it is an easy method; and the delivery is accomplished with perfect safety to the child and to the mother.

Stated Meeting, September 24, 1890.

THE VICE-PRESIDENT IN THE CHAIR.

DR. CHARLES B. PENROSE read a paper on

THE TREATMENT OF HÆMORRHOIDS BY EXCISION.

My object in presenting this paper is to urge the more general use of Whitehead's operation of excision in the treatment of certain cases of hæmorrhoids.

In 1887 Mr. Whitehead, of Manchester, reported¹ three hundred consecutive cases of hæmorrhoids which had been successfully treated by the method of excision and suture. His operation is performed in the following manner:

1. The patient is placed on a table in the lithotomy position, with the hips well elevated.
2. The anal sphincters are then thoroughly paralyzed by digital stretching.
3. The mucous membrane of the rectum is divided at its junction with the skin around the entire circumference of the bowel.
4. The mucous membrane, with the attached hæmorrhoids, is dissected from the submucous tissue, and the cuff or cylinder thus formed is dragged below the skin margin.
5. The mucous membrane above the hæmorrhoids is then divided transversely, thus removing the pile-bearing area, and the operation is completed by suturing the upper margin of the severed membrane to the free margin of the skin.

The advantages claimed by Whitehead for this method of treatment are based on pathological and on surgical reasons. He considers that the internal hæmorrhoids, which are generally regarded as localized distinct tumors, amenable to individual treatment, are, as a matter of fact, component parts of a diseased condition of the entire plexus of veins surrounding the lower rectum, each venous radicle being similarly, if not equally affected by an initial cause, constitutional or mechanical.

The operation of excision is the only one which removes this whole diseased area. It is, therefore, demanded for this pathological reason. It is, in addition, surgically more perfect than any other method of treatment, because it provides for the readjustment of healthy tissues with the object of securing primary union and rapid convalescence. It does not leave the sluggish ulcer of the cautery, nor is it attended with the pain and slow convalescence of the ligature.

¹ British Medical Journal, February 6, 1887.

My experience with this operation is limited to ten selected cases. Only those cases were selected in which there existed a complete circle of hæmorrhoidal tumors surrounding the lower margin of the rectum, since for such cases Whitehead's treatment of excision seems to be most particularly adapted.

The details of the operation are simple and easy to execute. In dividing the mucous membrane from the skin it is best to begin at the posterior margin of the anus in order to prevent the blood from obscuring the field of operation. No skin should be sacrificed, even though there appear to be redundant tags around the margin of the anus. The skin always retracts somewhat and the tags shrivel and disappear before firm union has taken place. Failure to observe this rule may result in subsequent serious trouble. Kelsey² reports the case of a woman who had been subjected to a so-called Whitehead operation and who presented herself to him with a complete circle of excoriated mucous membrane, extending from one inch outside the anus. It is probable that in this case the operator had sacrificed too much skin.

On the other hand, the upper section of the mucous membrane should be made in the same horizontal plane throughout, in order to prevent subsequent ectropion ani.

The dissection of the mucous membrane from the underlying tissue is exceedingly easy except in some cases of old—or long standing—piles. The attachment of submucous tissue is very loose, and separation can be effected with the finger or with the handle of the scalpel. It is not always possible to dissect the piles completely from the underlying structures, as they may involve not only the mucous but the submucous tissues, and in such cases it is necessary to cut partly through the piles until the healthy mucous membrane above is reached. Repeated attacks of inflammation, of course, render closer the adhesion of the pile area to the underlying structures. In one of my own cases, where the piles had existed for forty years, and had frequently been inflamed, the adhesions to the two sphincters were so close that a few muscular fibres were cut away during the removal.

The amount of blood lost during the operation is surprisingly small. Whitehead states that he has often operated on severe cases and not found it necessary to twist a single vessel. In five of my cases no hæmostasis was necessary. Bleeding is avoided by adhering closely to the mucous membrane in the dissection, as the larger arterioles lie beneath the submucous tissue. The arterial bleeding occurs in those cases of old piles which have been subjected to previous operation or to attacks of inflammation, and in which dilatation of the rectal and anal arteries has taken

place secondary to dilatation of the hæmorrhoidal veins. The bleeding from the upper divided edge of the mucous membrane can be reduced to a minimum by following Whitehead's method of inserting the sutures as each portion is divided, or by adopting Marcy's plan of introducing a circle of shoemaker stitches of catgut around the mucous membrane above the piles before cutting the mass away.

Whitehead's advice is in all cases to remove the complete cylinder of mucous membrane, whether or not the whole of this area appears to be diseased. He gives this advice for the reason which I have already stated, that he considers the individual piles as but part of a general pathological condition, involving all the lower hæmorrhoidal veins of the rectum.

Whether we accept this pathological view or not, it is best to follow this plan, and to make a complete circular division of the mucous membrane, as by this method the best surgical results are obtained, and ectropion ani prevented. I have seen a case in which only one-half of the circumference of the mucous membrane of the rectum was removed, and a few hours after the operation an œdematous swelling formed in the other half, which has now resulted in a hæmorrhoidal tumor almost as annoying as the one for which the operation was performed.

In attaching the mucous membrane to the skin, Whitehead uses the interrupted silk suture. He never removes the sutures, but allows them to ulcerate through—a process which is very easily accomplished. In my own cases I have used the continuous catgut suture.

The treatment of these cases after operation is very simple. It is rarely necessary to use opium or the catheter. An opium and belladonna suppository introduced immediately after the operation is in most cases all that is required. The bowels can be moved in from twenty-four hours to four days, and with very little pain. Absence of pain after Whitehead's operation is due to the thorough paralysis of the sphincters, and to the fact that no source of irritation is left beyond that of a clean linear incision, united without tension and without strangulation of tissue.

A glance at the histories of my own cases shows that they were all cases of aggravated hæmorrhoids, in which the piles covered the whole circumference of the lower part of the rectum. In all the cases the disease had existed for many years, and two had been subjected to previous operation by the ligature.

In only one case was there anything like free bleeding during the operation.

In all the cases a suppository of one-half grain of extract of opium and one-half grain of extract of belladonna was introduced immediately after the operation, and this was all the opium required except in three cases, in which one-

sixth grain of morphine was subsequently administered.

The catheter was used in only three cases, and in these for a period not longer than twenty-four hours. The length of time that the case is confined to bed depends to a great degree upon the social standing and the disposition of the patient. In my case it varied from two to ten days. Every case should be able to sit up in four or five days, and to resume work in ten days or two weeks.

The bowels were opened without pain in from twenty-four hours to four days after operation.

No complications of any kind followed these operations. Union takes place quickly, and generally one dressing, taken off when the bowels are moved, is all that is necessary. In no case was there incontinence from paralysis of the sphincters, or any tendency to stricture, from contraction of the scar.

Since the publication of Whitehead's paper his method of operating has been tested by many surgeons. The operation cannot be criticised on surgical grounds, as it is certainly the most perfect plan of treatment, surgically speaking, which has been proposed.

The immediate removal of the tumors, the coaptation of healthy tissues, and primary union, are substituted for slow strangulation by the ligature, or removal by the cautery and healing by granulation.

The applicability, or the necessity, of this operation in all cases of hæmorrhoids, is, however, open to criticism. If we accept Whitehead's views in regard to the pathology of piles, and believe that the whole venous plexus surrounding the anus and the lower end of the rectum, is in a pathological condition in every case of hæmorrhoids, even though there may be present only one or two isolated tumors; then, of course, the complete removal of this area is indicated.

But, that this view is not true is proved by the thousands of cases which have been permanently cured by the ligature and the clamp. The method, however, is indicated in all cases of aggravated hæmorrhoids where the vascular tumors cover the whole or the greater part of the circumference of the bowel. In such cases the operation presents no great difficulties. Statistics show that it is at least as safe as operation by the ligature or the clamp, and it is certainly followed by a more rapid convalescence, and much less pain and discomfort.

DR. W. D. GREEN: I have had the pleasure of witnessing only a small number of Whitehead's operations, but I fully agree, and I think that those who have tried the operation will fully agree with Dr. Penrose, that the method of excising through the whole circumference of the bowel, the pile-bearing mucous membrane, and drawing down upon the upper segment and then attach-

ing this to the lower segment without including the skin, has the advantages, first, of removing all possibilities of the return of the trouble; and, secondly, as Dr. Penrose has stated, in making a clear, clean, linear incision around the circumference of the bowel. Nearly all of us have seen the immense amount of suffering which the older operations by means of the clamp and ligatures, and even the cautery, have entailed. In the cases of the new operation which I have seen, recovery has been rapid and complete. In one case, that of a woman well advanced in life, upon the day after operation, when I got to the house, I found her comfortably seated in a rocking-chair. The physician who had the case in charge before the operation had given her freely of some medicine to open the bowels, and on the morning after the operation, without any pain and without any tenesmus, she had a large, well-formed motion. In the old method, in which for days the physician was called upon to administer opium, either by suppository or hypodermically, in large amounts, and in which the patient and the physician both looked forward with dread to the time—five or six, or ten days after the operation—when the bowels were to be opened, is by this method entirely obviated.

I have seen, in the few cases which I have watched, no pocketing or trouble about the line of incision. The two freshly cut surfaces unite very quickly—very much more so, it seems to me, than in mucous surfaces elsewhere. Even when the bowels were moved within twenty-four or thirty-six hours, I was surprised to find that there was no trouble.

It strikes me that the continued suture has advantages over the interrupted. Being introduced and made fast at one point, and then carried out and in around the circumference of the bowel, if catgut be used, at the time when union usually occurs the suture is probably dissolved and passes away without any trouble; or, if silk be used, by simply introducing the scissors and cutting close to the knot and giving an easy pull, the whole suture is removed without any pain or bleeding.

I must confess that the operation presents to me by far the best method of removing the pile-bearing membrane when it exists and involves one-half or more than one-half the membrane around the circumference of the bowel.

(To be continued.)

AMYLENE HYDRATE IN EPILEPSY.

Nache agrees with Wildermuth as to the value of amylene hydrate in epilepsy, even where bromides have failed, and where the attacks are not only very frequent but severe. He uses a 10 per cent. solution of the drug, and gives from one to two tablespoonfuls a day (from thirty to ninety grains). Nache also believes that *petit mal* and nocturnal epilepsy are benefited by the drug.

DOMESTIC CORRESPONDENCE.

A General Index for Medical Journals.

To the Editor:—A physician more remarkable for commercial instincts than for scientific attainment, once spoke contemptuously of the library of the late Prof. Jewell, saying that it contained "nothing but a lot of old medical journals." We think he but voiced a sentiment, all too common in the profession, but one we are sure that will meet with little sympathy from the original workers and writers in medicine. To these the files of the standard journals are about the most valuable books to be found in a medical library. In medical societies it is generally possible to pick out the man who subsists largely upon textbook pabulum, and it will be generally observed that he is not the most interesting contributor to the proceedings. The industrious student knows that he has not exhausted a subject until he has gone through the files of the great journals.

We hold it to be axiomatic that any journal that is worth a subscription is worth binding, and no journal that does not have a complete index to each volume is worth binding,—therefore it is not worth taking.

The labor of consulting journals, even when properly bound, is very considerable. The examination of the files of THE JOURNAL necessitates the handling of fourteen volumes and the running of as many indexes. For any one to properly appreciate this work, they should examine the indexes of the last thirty or forty volumes of the *American Journal of the Medical Sciences*. While this labor is somewhat lessened by index *résumés* they are but clumsy excuses for a general index—at least once in five years every medical journal of any importance should issue a general index. The only medical periodical of any importance that does this is *Schmidt's Jahrbücher*, and every earnest worker will agree with us when we say that this feature alone gives an unequalled value to that publication.

In these days of labor saving contrivances it is not too much to ask our publishers to print a general index;—we do not ask that they be given to us, but humbly petition for the privilege of buying them. HAROLD N. MOYER, M.D.

434 West Adams street, Chicago.

A Correction.

To the Editor:—In THE JOURNAL of the 18th inst., in the report of the Mississippi Valley Medical Association Proceedings, your reporter stated that I "reported six cases of gunshot injury of the abdominal cavity in which the viscera were injured, with five recoveries and one death." My paper was *confined* to the report of cases of

penetrating *stab* wounds of the abdomen, and hence *gunshot* wounds were not considered. By correcting the mistake in your next issue you will oblige Very truly yours,

H. O. DALTON, M.D.

NECROLOGY.

Robert Stevenson, M.D.

Dr. Robert Stevenson, of Adrian, Mich., died of apoplexy in the city of Vienna, Austria, August 9, 1890. The *Adrian Press*, in an eloquent tribute to his memory says: "The sad news of Dr. Stevenson's death occasioned a general feeling of sorrow, for no man was more widely known among our citizens, and to the people of the county than he, and surely none were more universally esteemed and respected. His skill in his profession, and his genial social nature, gave him a wide popularity, and always made him a welcome visitor in the sick room. He carried perpetual sunshine in his countenance, and under all circumstances, and upon all occasions, was a perfect type of the old-school gentleman, affable, courteous, genial and cheery, yet always maintaining a dignified bearing that proclaimed him the true gentleman. He was a man of broad culture, sympathetic nature, pure character and unquestioned integrity. For many years he had been an honored member of the Presbyterian church. He was also a member of Adrian lodge F. & A. M., of Adrian Commandery.

"He was born in Ireland in August, 1823, and obtained his medical education at the University of Glasgow. His first service was as surgeon on a whaling ship. After a six months' cruise he sought his fortunes in America. He settled in the city of Adrian, where he has since resided and built up a practice that heralds him as one of the leading physicians of the State. Dr. Stevenson became a member of the American Medical Association in 1876, and has usually attended its annual meetings; he was a member of the Michigan Medical Society, and also the Southern Michigan Medical Association. Dr. Stevenson was a delegate from the American Medical Association to the British Medical Association, and to the Tenth International Medical Congress, which was held at Berlin. He was married in 1851, and of eight children born to him, four are now living."

DR. CHARLES STEEL THOMSON, born in Toland, Conn., April 6, 1801, and a son of Dr. Gurdon Thomson, a medical celebrity of a hundred years ago or more, died recently in New Haven, Conn. He was a graduate of the Yale Medical College, class of 1822, and since 1883 was the oldest living graduate of that institution.

BOOK REVIEWS.

THE DISEASE OF THE SKIN CALLED PAGET'S DISEASE. A contribution to the Study of the Cutaneous Psorospermes and of Certain Forms of Cancer.

MALADIE DE LA PEANDITE MALADIE DE PAGET, par DR. LOUIS DARIER. Paris: G. Masson, 1890.

In 1874 Sir James Paget described the peculiar inflammation of the nipple and areola of the breast that preceded the development of cancer. This condition has since been called malignant papillary dermatitis. It remained, however, for Darier (*Sur une forme de psorospermosé, ou maladie de Paget. Société de Biologie, April 13, 1889*) to demonstrate the parasitic nature of the affection. He has also contributed several important chapters to this monograph.

The work opens with a definition of Paget's disease, which is said to be a parasitic affection, belonging to the group of cutaneous psorospermes, characterized by chronic inflammation of the skin, its glands, and their ducts, followed by epithelial proliferation. Up to the present this disease has been considered a special affection of the breast and mammæ, but other regions may be affected; there is recorded an undoubted example of its location in the scrotum.

The first portion of the work is devoted to an historical consideration of the literature, etiology, symptomatology and diagnosis. There is little in this portion to call for special remark, as it is largely based upon the older descriptions of the disease.

Chapter ii of the second part contains an unpublished memoir from the pen of Darier on a case of Paget's disease of eleven years' standing, but without epithelioma. The histological investigation included an examination of scales taken from the surface, and a portion of excised skin. The scales were examined directly and after treatment with reagents. The best results were obtained with the iodine solution of Gram. It is well to macerate large squames in ammonia water before mounting them. Preparations made in this way and stained with hæmatoxylin brought prominently into view the protoplasmic contents and the eucapsulating membrane. A portion of the excised skin was prepared in osmic acid, but the results were poor; another part hardened in alcohol and stained with picro-carmin showed clearly the relation of the parasite to the diseased structures. Lesions were found in the epidermis and true skin. Darier was not able to obtain a special stain for the parasites. In diagnosing a case of Paget's disease it is only necessary to scrape the part and look directly for the parasite among

the normal epidermal scales. They are recognized by their size, being usually somewhat larger than the cells from the deeper layers of the epidermis. The cyst wall has a distinct double contour, and within this there are frequently two or three and sometimes more protoplasmic bodies containing nuclei. If these structures are hardened in alcohol, a peculiar effect is noted in that the protoplasmic contents shrink away from the cyst wall in places, so that ray-like prolongations extend from and attach the protoplasm to the enveloping membrane. These characteristics are ordinarily sufficient to distinguish this parasite from any cell found in this situation.

The writer made some experimental inoculations upon rodents, but without success. Upon his own skin the writer likewise failed to obtain a growth, though they were kept for eight days in contact with a scarified part. Cultivations were attempted upon damp sterilized sand. At the end of sixteen days the cyst remained perfect, but the protoplasm retracted. The author classifies these bodies in the group of oral psorospermes, and considers them truly parasitic.

The writer refers the development of epithelioma in these cases to a simple cell proliferation brought about by the chronic inflammation due to the presence of the parasite.

The author closes the volume with sixteen conclusions, some of which we have already referred to. He would place Paget's disease in the same class as the vegetating follicular psorospermes, which ought also to include the molluscum contagiosum of Bateman. The disease, while manifesting a strong predilection for the breast, is not confined to that region. The affection is curable in the earlier stages and the treatment should consist not in excision, but the application of antiseptic remedies.

While it is perhaps presumptuous in the writer to criticize the French of this book, there certainly are too many repetitions and too many obscure sentences. They seriously mar a monograph of rare interest and value.

The work is illustrated by four excellent plates, one of which is colored.

FLUSHING AND MORBID BLUSHING; THEIR PATHOLOGY AND TREATMENT. By HARRY CAMPBELL, M.D., B.S. (London). London: H. K. Lewis, pp. 270.

Under this remarkable title the author has gathered a large number of observations on what may practically be described as a minor symptom of instability in the nervous centres. As is now the fashion, these manifestations of vaso-motor irregularity are explained by discharges in cortical brain areas whose existence are as yet hypothetical. A flush is described as "a nerve-storm in which a rush of blood to the skin and a sense of heat are generally the most obtrusive manifesta-

tions." The distinction between flushing and blushing is indefinite with the exception that flushing is usually connected with some sexual irregularity and blushing is excited by some emotion. In justification of the term morbid or pathological blushing a number of cases are cited (p. 135), some of which follow:

Æt. 27 (man). Was a soldier, but compelled by excessive blushing to give up his profession.

Æt. 28 (man). Has recently had to give up the study of medicine through excessive blushing.

Æt. 32 (man), minister. Is so afflicted by blushing that he has latterly entirely given up duty.

Another patient is a commercial traveller (!) and a telephone clerk is so badly affected that he turns scarlet even when speaking through the 'phone. From this list it may be seen that the British male is sometimes slightly effeminate.

Nothing new, important, or useful is brought out in the book, and it is impossible to feel that all the labor it represents has been judiciously expended, when so many important fields of enquiry are open and offering such rich harvests to those who will till them.

MISCELLANY.

HEALTH IN MICHIGAN.—For the month of September, 1890, compared with the preceding month, the reports indicate that puerperal fever, influenza, membranous croup, erysipelas and diphtheria increased, and that measles, inflammation of brain, cholera morbus, cerebro-spinal meningitis and cholera infantum, decreased in prevalence.

Compared with the preceding month the temperature was lower, the absolute humidity was less, the relative humidity was more, the day ozone and the night ozone were less.

Compared with the average for the month of September, in the four years 1886-1889, pleuritis, influenza and scarlet fever were more prevalent, and small-pox, puerperal fever, typho-malarial fever, inflammation of brain, whooping-cough, cerebro-spinal meningitis, typhoid fever and measles were less prevalent in September, 1890.

For the month of September, 1890, compared with the average of corresponding months in the four years 1886-1889, the temperature was lower, the absolute humidity was less, the relative humidity was more, the day ozone and the night ozone were less.

Including reports by regular observers and others, diphtheria was reported present in Michigan, in the month of September, 1890, at 57 places, scarlet fever at 54 places, typhoid fever at 73 places, and measles at 18 places.

Reports from all sources show diphtheria reported at 8 places more, scarlet fever at 6 places more, typhoid fever at 12 places more, and measles at 6 places less in the month of September, 1890, than in the preceding month.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from October 11, 1890, to October 17, 1890.

Capt. Andrew V. Cherbonnier, Medical Storekeeper, retirement from active service on October 12, 1890, by operation of law, under the provisions of the Act of Congress approved June 30, 1882, is announced. By direction of the Secretary of War. Par. 11, S. O. 246, A. G. O., Washington, October 13, 1890.

Official List of Changes in the Medical Corps of the U. S. Navy for the Week Ending October 18, 1890.

Surgeon George A. Bright, detached from temporary duty at the Naval Academy, and placed on waiting orders. Surgeon J. G. Ayres, detached from temporary duty at the Naval Academy, and placed on waiting orders. P. A. Surgeon George P. Lumsden, detached from the U. S. S. "Boston" and granted three months' leave. P. A. Surgeon E. W. Auzal, detached from the Naval Academy and ordered to the U. S. S. "Boston." Surgeon Howard Smith, ordered to appear before the Retiring Board at Mare Island, Cal.

LEGAL ASPECTS OF SPINAL CONCUSSION.

Read in the Section of Medical Jurisprudence, at the Forty-first Annual Meeting of the American Medical Association, at Nashville, Tenn., May, 1890.

BY S. V. CLEVINGER, M.D.,
OF CHICAGO.

My paper was announced with the above heading through inadvertence, but it does not matter, as there can be but one scientific consideration of the subject, and whatsoever pertains to the medical features of this derangement necessarily concerns the legal, as a broken head or leg should be nothing else in law than what they are in medicine. There are, however, artificial matters not properly involved in the question of the real existence of injuries of any kind, that burden law books and works on medical jurisprudence.

The fact that there may be a preponderance of subjective symptoms in alleged concussion cases does not make such accidents peculiar in a medico-legal sense, for several forms of insanity and many physical ailments, at times, discussed in courts possess this same disadvantage. But turning from those rather hackneyed matters let me present a fresh aspect of the subject in a paper on

ERICHSEN'S DISEASE, AS A FORM OF THE TRAUMATIC NEUROSES.

"What's in a name?" says Shakespeare. Instead of being distinctive, names are too often sources of confusion, as botanists, zoölogists and anatomists are aware. Plants in the system of Linneus were specifically named "montana" when they were not exclusively mountainous; animals called "fluviate" were, later, found oftener in lakes; the "pituitary gland" is neither pituitary nor a gland, the arteries were named as air receptacles, and so we might multiply misnomers indefinitely because of the attempts of our ancestors to make names superficially descriptive. About twenty-five years ago Erichsen described a variety of derangements following upon concussion of the spine. Now nothing could be simpler, apparently, than the expression "spinal concussion," and nearly everyone fancies that no misunderstanding could arise in the use

of such a term. Nevertheless that very title has in itself occasioned great misunderstanding, because it had a restricted as well as a general meaning.

The cause of this confusion dates from Erichsen's description of the different kinds of ailments that may arise from blows to the back, such as severe direct injury to the spine causing demonstrable cord lesions, slight indirect or remotely occasioned back injuries, sprains, strains, wrenches and twists of the spine, wherein occurred cord compression by extravasation or inflammatory exudations, nutritive cord alterations, and a "functional disorder" to which he gave no name, but which came to be known as the disease "spinal concussion," caused by a spinal concussion. In the interests of scientific medicine I named that so-called functional disorder "Erichsen's disease" because John Eric Erichsen was the first to describe a particular group of symptoms that often follow upon concussions.

That distinguished London surgeon wrote to me as follows:

I assure you that I feel much gratified and very highly flattered by having my name appended by you to the group of symptoms so very characteristic and remarkable, when taken in the concrete, which I believe that I was the first to describe, which result from that peculiar form of spinal injury now recognized under the term of "spinal concussion."

Had Erichsen given any sort of a name to this disorder, however arbitrary that name might have been, there would have been less occasion for the wrangling that has occurred in court rooms all these years.

Instead of entangling ourselves in the endeavor to explain that spinal concussion symptoms may sometimes be induced by a spinal concussion, misunderstanding is impossible when we say that a concussion of the spine may originate a vast range of troubles, such as dislocation of the vertebrae, cord injuries, etc., and it may also cause Erichsen's disease.

What then is Erichsen's disease? It is a serious disturbance of the functions of the spinal cord without there being demonstrable cord lesions. Such disturbance can be best accounted for by supposing that the spinal sympathetic system has been deranged, secondarily interfering with the blood supply of the cord and its membranes, con-

joined with other vaso-motor phenomena such as emotionalism, flushings, cardiac rapidity, hyperidrosis, sleeplessness, headache; directly due to the original sympathetic system derangement. The fact that the group of subjective symptoms and objective signs are distinct from other disorders sufficiently set it apart from other ailments or traumatic neuroses, and justify its special title. The claim is sometimes made that naming diseases after individuals is unscientific and burdens our nomenclature unjustifiably. This is true only in a certain sense and it is easy enough to formulate a law when such christening would be proper. The golden mean can be observed in this as in other respects, and the matter is one of such great importance that I do not hesitate to take up time in its elucidation. No trivial reason should justify such naming, but when there is an eminently proper cause for so doing, such as in this instance, the medical profession would profit by having the discoverer's name forever associated with the disorder.

If a disease *can be accurately* named descriptively, then the descriptive name should be preferred, but the risk is run that with the advance of knowledge the name ceases to be descriptive and too often is absolutely erroneous and misleading. At one time the sacrum was dubbed sacred as the seat of the soul, because supposed to be imperishable.

A formidable disease became universally prevalent after the return of Columbus from America and we were threatened with its perpetuation as the American disease, just as at one time its companion was known as *Französische-Krankheit*; but as attention was called to the fact that the greatest pretenders to piety were the most numerous sufferers a diversion was made in favor of the title "holy sickness." The etymology of the word "syphilis" is obscure, and hence the name is arbitrary and becomes as much of a *nomen proprium*, as had it been called Smith's or Jones' disease. Gonorrhœa is a misnomer, because it means a flow of sperm.

Huxley opposes descriptive names, in the main, in zoölogy, and holds that it is far better that we should forget the etymology of any animal name, and use it merely as a title without regard to its origin.

Descriptive naming is carried to extremes by savages in such appellations as "Sitting Bull," "Red Jacket," "Man-Afraid-of-his-Horses," and the tough element in our cities describe one another as "Shorty," "The Bruiser," etc. I merely mention this as an offset to the radical claim that diseases should in no case be named after those who first described them. Purely arbitrary names that convey no descriptive meaning often have decided advantages, the foremost advantage being that an arbitrary name such as Bright's, Addison's, Grave's disease cannot pos-

sibly mislead. You receive the history of the disorder in the name and are compelled to learn what it was that Bright, Addison and Graves discovered.

I was disposed to the belief that this sort of thing could be overdone, through naming of such obscure complaints as Thomsen's disease, infrequently occurring disorders such as the Cheynes-Stokes breathing, Argyll-Robertson pupil, but as the law of survival of the fittest would overtake inappropriateness in this regard, I now incline to thus honor discoverers, and we all realize that little enough honor is accorded by any delver in our profession, however conscientious and gifted.

Let me tell you of an instance where immense advantage would have been gained by avoidance of attempts to describe a disease in a name: The terrible form of insanity now called "paretic dementia" by alienists was first described by Bayle in 1822-26. Later Calmeil missed the opportunity of his life, because, while he clearly recognized the differences it presented from other forms of insanity, he did not attach his predecessor's name to the malady as he should have done. So doing would have saved thousands of insane from the gallows, the guillotine, the prison. Could we have had Bayle's disease, instead of the present abominable array of misnomers, every physician would have known something about it, and recognized it as an entity, instead of to-day having to learn that there is a disorder that suddenly attacks some overwrought business men, oftener the rich than the poor, the ambitious rather than the drone, the intellectual rather than the thoughtless; the trouble that killed Sir Walter Scott, and other historical personages, a trouble whose pathology has been worked out even better than has been that of pneumonia; a mental ailment that presents distressing problems mainly because so few know what is absolutely known concerning it. It is too late to call it Bayle's disease, it is with the utmost difficulty that the recent designation "paretic dementia" is favored. I speak to you of the affection that has been called in our books "general paralysis of the insaue," "progressive general paralysis," "general paralysis," "general parcsis," "paralytic dementia or dementia paralytica," "progressive paresis," and their equivalents in French and German. Not one of these descriptive names really described the disorder, and excellently educated physicians, not versed in this particular matter, have been led into deriding the very existence of the complaint, *through taking the name as descriptive*. Fordyce Barker, of New York, who was a specialist in everything, aroused the applause of the court room mob in the Guiteau trial by swearing that there was no such thing as "general paralysis" except in death. Yet doubtless not one in that court room but would have thought he understood precisely what was meant

had the atrociously lying name "softening of the brain" been used instead.

A volume could be written upon the accursed influence of that word grouping: "softening of the brain." It has been used in a metaphorical sense for a century. In the ignorant mind satisfactorily descriptive of what to the pathologist is complex, and often involves sclerosis, atrophy, or putting it popularly, "hardening of the brain."

While pathologist of the Chicago County Asylum the certificates I filed from the thousand city practitioners included in "softening of the brain" at least fifty dissimilar insanities, such as melancholia, paranoia, atheromatous insanity, hebephrenia, mania, katatonia, circular insanity, confusional, stuporous insanity, and even terminal dementia. Every insanity almost was "softening of the brain."

Every physician in the world should remember that from the standpoint of the alienist there is no such disease as "softening of the brain." The pathologist can tell you of numerous kinds of brain softening; red, yellow and white, that are merely degenerative processes more often associated with paralytic than mental phenomena, subsequent to extravasations, embolisms, thromboses. Whosoever speaks of "softening of the brain" as a mental derangement either caters to ignorance or is himself ignorant of alienistic science.

Turning again to scientific nomenclature we find precision in electrical science in the naming of measurements: farads, volts, ampères, ohms; and in currents: the faradic, galvanic and franklinic, after Faraday, Watts, Ampère, Ohm and Franklin. Very true the names themselves convey no meaning to the uninstructed in electrical science, just as the term Erichsen's disease would compel some attention as to what was meant, though every ass would suppose he knew what was included in "concussion of the spine" and "softening of the brain."

Oppenheim, of the Berlin University, carefully studied the effects of concussion accidents and incidentally some nerve injuries, and included all under the title "Traumatic Neuroses," and forthwith that name has been adopted by several writers in lieu of spinal concussion. The impropriety of this is evident when we reflect that while Erichsen's disease may be a traumatic neurosis, sciatica, paralysis agitans, chorea, myelitis, epilepsy, and myriad diseases may also be traumatic neuroses, so that term is too generic, and the fact that Erichsen's disease is one of medico-legal importance does not warrant so sweeping a designation in which can be included thousands of other ailments.

S. Weir Mitchell, during the late war, made extensive researches with regard to direct injuries to nerves, and the traumatic neuroses described in his book differ widely from those investigated by Oppenheim.

Sperling and Kronthal, in the *Neurologisches Centralblatt*, June 1-15, 1889, report a case that died from cardiac and pulmonary disease, the autopsy revealed arterial sclerosis to a marked degree with occasional hyaline and fatty degenerative spots in the entire arterial system, particularly in the cerebro-spinal vessels. The trunk of the sympathetic was peculiarly degenerated. There were scattered degenerative spots in the white part of the cord and in the gray of the lower dorsal region and a small hæmorrhage in the mid-dorsal region. This sympathetic and arterial degeneration lends great plausibility to the theory I advanced that the spinal sympathetic was the main seat of the disorder.

Meynert, in the *Wiener Klin. Woch.*, 24, 26, 1889, locates the seat of the "traumatic neuroses" in the forebrain. Now no one can have a greater regard for the opinion of this famous cerebriologist, but occasionally Meynert can be as wrong as Charcot or Pasteur, and much of this fallability comes from the impossibility of a single mind, however trained, to grasp all aspects of the limitless field of human knowledge. In these days it is the ignorant alone who claims to be instructed in *all* departments of medicine and surgery.

The depths of our attainments are inversely as their breadth, and the specialist is narrow whose career was not begun as a general practitioner. To be a pathologist and nothing else, a neurologist and nothing else, may confer ability in some few particulars but breadth of thought can only be brought to bear upon a special line through previous observation in many fields.

Meynert has studied the minute anatomy of the brain but he has not studied spinal concussion in its entirety, and his immense knowledge of the cerebrum is misapplied in endeavoring to locate the vast range of general vaso-motor phenomena in a simple lesion of a restricted part of the brain.

Instead of a wrangle over the threadbare legal attitudes this matter can assume I should be glad to have the views of my confrères upon the pathology of the neurosis and the advisability of naming it after the great London surgeon Erichsen.

DR. HERBERT JUDD, of Galesburg, Ill.: In connection with the discussion of the "Legal Aspect of Spinal Concussion" I beg to say that during the past twenty years I have known of twenty-six cases, all in the State of Illinois, of so-called concussion of the spine, that have been brought to my notice, and which I have watched with some interest, while the cases were under consideration by attorneys for corporations, against which claims for damages had been preferred.

I have known of many other cases of this disorder, in which there existed grave doubts of the

patient having sustained any injury, but the twenty-six cases referred to can be verified by the files of papers in the office of the attorney of the Chicago, Burlington and Quincy railroad company, at Galesburg, Ill., and the affidavits and evidence there preserved. When the liability of the railroad company for whatever damages the claimant had sustained was conceded, there were but few of the cases litigated, but were settled prior to suit in some cases and prior to trial in others. In all the cases I especially allude to the genuineness of the claim, that of permanent injury from shock or concussion of spinal cord, was denied by the railroad attorney, upon the candid opinions of surgeons and physicians obtained by the company. In every case, however, the railroad attorney negotiated the best settlement possible, and usually regarded it as good policy to pay liberal sums rather than to submit to a trial when courts could not give protection against perjured, prejudiced and ignorant testimony.

Some of these cases had "litigation symptoms" for a long time prior to settlement. Several of them were so serious as to render the patient bed-ridden and helpless, but in all of them thorough and complete recovery resulted. In most of them recovery was rapid and rather astounding, and it was noted that improvement followed swiftly after the "damages were paid."

Understand that in all these cases, the only question in controversy was that of actual injury. They were cases in which the symptoms were subjective, and the condition of the patient could be determined alone upon his statement, to which too much credence is often given by physicians. These were cases where it was deemed the best financial policy to submit to black-mail to avoid legalized robbery, the amount of which depended upon the sympathies of a jury with a claimant, and their unreasonable prejudice against corporations, all of which they assume to believe are immensely wealthy and able to stand the assessment.

I know of no case of actual patent injury, caused under such circumstances as to create a legal liability, where there was any serious trouble in arriving at a fair and just sum to be paid as damages, satisfactory to both parties; nor do I ever expect to see such a case of actual permanent injury, in court and on trial where the question of liability has been conceded.

All such honest, just claims can be and ordinarily are settled out of court. I have little faith in book cases of spinal concussion.

These special cases I have referred to had their origin in the hints, and suggestions and help of Erichsen. The study of Erichsen began with date of accident to train; the patients were crammed with directions for fraud. The cases I have in mind were carefully watched and traced up after settlements were made. This was done

as a source of information and to verify if possible the views of fraud entertained; and, as I have already stated, every one of them recovered, and in several of them the fraud became so apparent as to cause some notoriety to the patient, and some unenviable notoriety to the advising physician, especially in a few cases of complete recovery after a long and no doubt laborious siege of "total disability."

I believe there is a maxim of the criminal law that every person is to be regarded as innocent of crime till proven to be guilty. It seems about time that surgery should have and act upon a maxim, that every person claiming disability from concussion of the spinal cord, where no objective symptoms are to be discovered, is to be considered as planning for your aid in enabling him to rob some employer; until you can by your own knowledge of the case discover that injury actually exists.

If physicians would or could consider and treat all cases of alleged spinal concussion without regard to, or any consideration of the desires of the patient to reap a money compensation, there would be less difficulty in effecting cures. If the physician would confine his services strictly to his own duty to effect a cure, and refuse to consider or meddle with the financial or pecuniary plans of his patient, he would attain much more brilliant success in his treatment. If he in good faith endeavors to effect a cure, and not to establish a case of permanent injury for the pecuniary benefit of the patient, or to gratify his avarice, he would find few cases of the disease under consideration.

How many cases of concussion of the spinal cord can any of you recall in your own practice, where the patient fell from a load of hay, or was thrown from his own wagon, or fell from a barn loft, or received injuries or met with an accident for which no one but himself or his own family were blamable? If you would consider these cases as you consider and treat spasms in children during the first and second dentition, or fits resulting from worms, you might be led to better means of improving the physical condition of the patient. If you would refuse to minister for the benefit of the patient's estate, and apply your skill to his person, you might acquire more success. If you would exert your proper influence to keep your patient out of the hands of the "calamity lawyer," and to shut out from his mind all present consideration of the possible pecuniary gain, you would have taken a giant step towards his cure.

Is it not our duty as physicians to benefit the physical man, even at the expense of property?

Is not health worth more than riches, even honestly gained? I have said this much with the sincere desire for the good of the profession. Facts are "brutal things" to deal with.

DR. CLARK GAPEN, of Omaha, agreed with Dr. Clevenger that the disease described by Erichsen under the name "spinal concussion" should be named "Erichsen's disease," not only to fix it more accurately, but because a large amount of obloquy attends the subject which Erichsen ought to bear. His book is said to have cost English railways fifty million dollars, and American railroads as much more. Dr. Gapen had taken Erichsen's cases and classified the symptoms under objective and subjective heads, and was amazed to find how few were the objective. His experience had in the main agreed with that of Dr. Judd in that most of the cases were either hysterical or malingering; moreover, many of the symptoms, as flushing, increased temperature, emotionalisms, were in fact cerebral symptoms rather than spinal. Page has shown how difficult it is to injure the cord owing to its looseness in the bony canal and the fact that it is surrounded by fluid. Actual injury is very rare and usually well marked from the outset.

DR. HAROLD N. MOYER, of Chicago, stated that he was rather astonished at Dr. Judd's statement that concussion cases did not occur unassociated with damage claims. Dr. Judd's experience must be limited indeed to allow him to make a remark of that kind, for in the past five years Dr. Moyer had seen a large number of concussion cases in which there was no suspicion of a damage suit, and these did not differ at all in course, symptoms, duration or termination from those that had been the subject of legal contention. Dr. Moyer heartily agreed with Dr. Clevenger in suggesting the propriety of the term "Erichsen's disease;" while it is not all that one could desire, yet it is such a great improvement upon that of "spinal concussion" that it should be adopted, at least until the pathology and morbid anatomy of these conditions shall be better understood.

In reply to Dr. Moyer; DR. JUDD said he had been in active practice twenty-two years, that he had seen concussion cases in which there was no suspicion of a damage suit, but that all such cases recovered; that litigation cases did not recover until paid for.

DR. ORPHEUS EVERTS, of Cincinnati, said: I approve the suggestions of the paper, and think the adoption of the term "Erichsen's disease" proper and useful. If a definite term is used by a medical man referring to disease, such as "Bright's disease," "Basedow's disease;" as to surgical operations, such as "Battley's operation," etc., it is generally, or presumably, because he has definite ideas respecting conditions thus named after original investigators, while more general terms, such as "spinal concussion," "kidney disease," etc., do not convey such definite ideas, or other than vague notions of some disorder of organs named, however slight or severe, or however caused.

It is convenient, however, for practitioners who are not scientific to have these general terms for use in emergencies—they sound well, and if delivered with proper expression go a great way in confirmation of one's reputation for wisdom. For example, the term "softening of the brain." If one meets with obscure but serious cerebral symptoms all that is necessary is to say, with becoming gravity and a look of significance, "softening," and the whole business is settled.

"Congestion" used to be the favorite term by which to account for failure in treatment of various forms of disease, terminated often unexpectedly by death. All the baffled practitioner had to do was to shake his head, and say "congestion." Such terms are convenient—for the concealment of ignorance. The name of Erichsen is worthy of commemoration, and may well be associated with a form of disease which he has so well described.

DR. KIERNAN, of Chicago, had the clinical experience of Dr. Moyer. That railroads were not always of the type described by Dr. Judd was shown by the Chicago railroad "jury fixing" cases. That spinal concussion existed, the case reported by Dr. McIlvaine, of Peoria, would alone demonstrate. A female victim of a railroad accident had been suspected by Dr. McIlvaine of being a malingerer. She had secured damages, but the spinal disease had gradually progressed into helplessness and death. Dr. Kiernan had himself seen similar cases.

DR. G. FRANK LYDSTON, of Chicago, said: I consider the work which Dr. Clevenger has been doing upon the subject of so-called "spinal concussion" a most important advance in medicine. His adoption of the term "Erichsen's disease," while open to some objections, is on the whole a wise and useful plan. The laity have already learned that spinal concussion is an omnibus which may be made to cover much malingering. By the adoption of the term "Erichsen's disease" we will at least compel the humbug to learn his lesson over again. The term will certainly convey to the malingerer the idea of a distinct and definite affection which he must substantiate by plain and positive proofs. I am aware that it is not easy to evolve order out of the chaos of symptoms which characterize the results of concussion of the spine, but as far as may be I believe that Dr. Clevenger has accomplished it. His explanation of the pathology of the varying phenomena of Erichsen's disease, is thus far the only rational and intelligible one in medical literature. I regret that he has not said more of his theory to-day. Personally I would advise those who are not familiar with his views, to read his book. If others derive the same benefit from its perusal that I have done, they will feel amply repaid.

DR. CLEVINGER, in closing the discussion, stated that he had been astonished at the im-

provement of some patients after the settlement of damage claims, but this seemed to be due to the relief from worry which the conclusion of the suit afforded; but it would be presumption to affirm that such cases were *entirely* cured until years had elapsed and unprejudiced opinion been engaged. This "quick cure by settlement" savored too much of the unscientific assertion of Herbert Page, who was the most ordinary special pleader for railways.

While both Dr. Gapen and Dr. Judd had been opposed to Dr. Clevenger in recent suits against corporations, and seemed to look at the matter from one standpoint, the latter had frequently been called as expert for either side, and sometimes for both sides at the same time.

The statement that there were no vaso-motor centres in the spinal cord, and hence the symptoms were cerebral, was rather surprising, when the sympathetic system is so intimately united to the spinal all the way down the cord length, and such ordinary matters as constipation and hæmorrhoids producing brain troubles show that such "vaso-motor" difficulty as emotionalism need not have its origin necessarily in the head.

The intimation that subjective symptoms were always false, when made the basis of claims against railways, is on its face absurd. Physicians have to judge from the consistency of symptoms whether they were real or not.

Contrary to Dr. Gapen's findings, Dr. Clevenger had devoted all his spare time for three months in analyzing Erichsen's cases, and found an abundance of objective signs in all. But it depends upon what is meant by "objective." To the uneducated the galvanometer and electrical indications convey no meaning. Paralysis and insanity of the gravest kinds would present nothing "objective" to the biased witness. There are cases in which no honest opinion can be reached, and in such it is best to allow the mind to remain a "scientific blank," as Huxley advises. Only the untrained imagine they must have a positive opinion upon everything under the sun. Sometimes a little waiting will determine matters.

A case examined a year ago presented nothing but purely subjective symptoms, and to-day there is atrophy of an arm. In another instance a laborer fell partly into a coal hole, with one leg in and the other out, and after a year is unable to do any work, but there was such an utter absence of anything in the way of electrical or other findings, and so many of the ordinary symptoms of Erichsen's disease were missing, that Dr. Clevenger told the lawyers that everything depended upon the credibility of the witness, and he preferred having nothing to do with the case as it stood at present.

We find many instances, in and out of the books, of fatal issues among patients accused of malingering. We occasionally find a conscientious

railway surgeon who acknowledges that railway accidents do not always improve health, and that a few dollars' settlement will not resurrect the dead.

A NEW METHOD OF LARYNGEAL AND BRONCHIAL MEDICATION BY MEANS OF A SPRAY AND TUBE DURING THE ACT OF DEEP INSPIRATION.

Read in the Section of Laryngology and Otology at the Forty-first Annual Meeting of the American Medical Association, Nashville, Tenn., May, 1890.

BY J. MOUNT BLEYER, M.D.,
OF NEW YORK

I bring before you a novel method and use of the ordinary cold spray. By the extra aid of a hard rubber tube six inches in length and three-quarters of an inch in diameter on both sides of its openings, through which a cold spray with tip pointing downwards is passed and held in the mouth between the lips which are clasped over the tube. With this tube, spray, and position of the lips and deep inspirations any desired medicated fluid amounting from a half to one ounce may be forcibly inhaled during the act of ten deep inspirations, and thus reach the deeper portions of the respiratory tract, without coughing, gagging, or immediately expectorating the fluid thus inhaled. The time occupied for re-expectorating the fluid medicament thus inhaled varies in different individuals. Some begin lightly within from five to ten minutes after the inhalation, others again half to three-quarters of an hour later. The sputa which is expectorated for several hours after contains a certain amount of the medicated inhalent used, showing thereby that the desired medicament used remains in contact with the diseased parts long enough to have its therapeutic effect.

The Method of Making an Application.—The patient is placed in an upright position, or, better, standing. The collar or tight dress about the neck is removed so that nothing interferes with taking deep and slow inspirations. The position of the head is an important point to be observed. It must be inclined backwards during the act of each inspiration so as to destroy as much as possible the rectangular curve that the windpipe makes with the oral cavity. The patient before being made to use these two instruments, must be shown how to take deep inspirations and slow expirations without exerting himself. He must also be taught how to hold in the breath for a few seconds after each inspiration. Those are some of the cardinal points to be looked after in order to get the results from each inspiration. These points are easily acquired by patients. When once understood how to make use

of such inspiratory and expiratory powers, without the spray and tube, then begin the same method over again; with this exception that the instrument (spray and tube) are now used for practice, as if the patient was taking an inhalation. Place the tube half its length into the mouth; the lips are clasped over it. The spray is placed into the opening of the hard rubber tube into which the spraying tube is inserted so that its inner end protrudes not more than one-quarter of an inch. This point regarding the size and position of the tube is very important. The best motor power for the propulsion of the spray, to my mind, is compressed air. The pressure need not exceed 60 lbs. This will suffice for any application.

FIGURE 1.

It will be found during the act of deep-forced inspiration that the vocal cords separate and, still further, on inspiration they will separate to their entire extent. In the subsequent expiration they will again approach each other. During inspiration the vocal cords form a wide and almost pentagonal opening, and under favorable circumstances one can on examination then see the bifurcation of the trachea; as seen in the accompanying drawing.

The epiglottis stands nearly erect, if not, through its anatomical formation, is curled upon itself or may assume another shape. These physiological facts are known to every one who practices with a laryngoscope.

The tube serves as an adjunct to the propulsion

of the specified inhalent. The tube, and the act of deep inspiration, also diverts the attention of the inhaler, and thereby calling into action another set of muscles favoring the passage of the inhalent. During the act of deep inspiration the tongue lays flat in the mouth, and as described before, the vocal cords and epiglottis are now in a position to permit the passage of the medicant, and assisted in reaching the desired spot by the propelling force of compressed air.

I have made numerous experiments with this method of application upon the dog and rabbit before using it upon my patients, the details of which are beyond the scope of this paper. Never-

FIGURE 2.

theless, I will give a short description of one of these experiments in order to show the effectiveness of this method in the application of medicaments in a fluid state to the deeper portion of the respiratory tract.

A healthy dog weighing fifty pounds was placed upon a table. The mouth was opened and the rubber tube inserted to its proper length. The mouth was then fastened over the tube by straps made for the purpose. The tube being open the respiration was thus carried on undisturbed. The spray was then attached and the animal made to inhale. The substance used was a strong solution of the extract of rhatany, the quantity sprayed being half an ounce. This almost immediately brought out a bright

FIGURE 3.

redness of the larynx, trachea, and of the bronchi, which entirely disappeared after the discontinuance of the spray in about two hours from those parts under examination.

The sputa, however, continued to be red some five hours longer; at this point the animal was killed and a post-mortem examination was made. Quantities of the fluid inhaled were found depos-

ited throughout the trachea and smaller bronchi. Other experiments made with the same end in view gave similar results.

It is a well known fact that finely divided substances do penetrate into the air cells, as in the case of colliers, grinders and others who are constantly inhaling pulverized particles and matter while engaged in their occupations. On the other hand it is extremely doubtful if any of the medicaments used in any of the numerous inhalers at present in vogue ever reach the walls of the ultimate lung alveoli. The conditions under which and the extent to which sprays and vapors enter the lungs are to a certain extent satisfactory, most authorities who have written upon the subject and carried on experiments in this line, as, for instance, those made by Dr. Arthur Hill, Hassall, of St. Remo; Fournie, D'Émarguay, Tavernier, Bataille, Schnitzler, Störck, Fieber, and others which tend to confirm my own observations.

FIGURE 4.—Position of the larynx during the act of deep inspiration.

The advantages of the method I have described are as follows:

1. Cheapness of the instrument, which is simply a hard rubber tube.
2. The advantage of the continued effects of the remedy as the time between each application lasting five hours, until another is necessary, and then the patient can satisfactorily make it himself and thus keep up the remedial effects.
3. No cough or gagging is excited whatever, as compared with the use of the spray alone in making laryngeal application.
4. The quantity of fluid inhaled at each sitting is half to one ounce in from three to four minutes' time.
5. When applied to the larynx, trachea and bronchi no spasmodic contractions arise during its use whatsoever.
6. Irritating medicaments in solution can be thus applied without exciting much cough. I often use nitrate of silver, thirty grains to the ounce, iodine, tannic acid, peroxide of hydrogen of full strength without any trouble or bad effects.

My results in the treatment of (Störck's disease) or ozæna of the trachea, acute and chronic bronchitis, laryngitis, tracheitis, phthisis, etc., have given me such satisfaction that I bring this method before your notice.

For the want of more time I was compelled to shorten my paper.

Several drawings accompany this paper. Figure 1 demonstrates the exact position of the lips around the tube during the act of deep inspiration.

Figure 2 shows a Sass' glass downward pointing spray passed through the hard rubber tube, the spray points looking out at the opposite opening a quarter of an inch.

Figure 3 shows the tube.

Figure 4 illustrates the position that the vocal cords take during the act of deep-forced inspiration.

Tubes are made by Tiemann & Co., New York City.

83 2nd avenue, New York City.

MULTIPLE NEURITIS.

BY ARCHIBALD CHURCH, M.D.,

PROFESSOR OF NEUROLOGY IN THE CHICAGO POLICLINIC.

Case 1.—William A. V., aged 30 years, an unmarried bookkeeper of German descent, presented himself in my service at the Polyclinic April 17, 1890, complaining of numbness and weakness of both hands and of the left leg and foot. Physically he had always been in fair health but for years had drunk to great excess and had been subject to delirium tremens several times. He also used tobacco inordinately, smoking and chewing continually, and was greatly addicted to venery but gave no history or indication of venereal infection. Two weeks previously he first noticed the numbness and weakness mentioned. Coming on gradually it reached during the first week the stage shortly to be described. When first seen the patient was tremulous, uncertain in speech, with dilated pupils and the general manifestations of a prolonged debauch. At this particular time the critical illness of an uncle was making additional demands upon his strength, as he was compelled to watch with him day and night and had lost much sleep. He presented an irritable pulse of one hundred beats, a normal temperature, a fair digestion, an active bowel and was moderately well nourished. His attitude when standing was natural, but he walked with a decided limp, dragging the toe of the left foot, which was advanced and brought to the ground in an uncertain, dangling, flail-like manner, the muscles failing to properly control the ankle-joint. The anterior tibial group of muscles were found completely paralyzed and the other leg muscles weakened. On the anterior surface of the leg there

was a narrow, comparatively anæsthetic area about an inch and a half broad extending from the tibial tuberosity to the ankle. Upon the dorsum of the foot it spread out in a fan shape and embraced the four outer toes. Elsewhere on the lower extremities sensation was fairly normal to all ordinary tests. In the area described he had a subjective feeling of numbness, prickling and sometimes of steady pain. There was tenderness over the head of the fibula and on the dorsum of the foot. Light touches with a pencil or a bit of cotton wool could not be appreciated, but sensation to painful stimulus was not appreciably impaired or the ability to note broad variations in the temperature of objects brought into contact with the skin. The weakness of the foot extensors produced well-marked foot-drop so that the foot could not be voluntarily flexed to a right angle with his leg. The plantar patellar and peroneal reflexes were greatly diminished on this side. Electrical examination of the anterior tibial muscles showed that they had lost faradic excitability and only a very slight contraction could be elicited by the anodal closure of the galvanic current, thus indicating the presence of degenerative nerve changes.

In the upper extremities the grasp was greatly reduced and for the ulnar fingers almost abolished. Commencing near each elbow over the internal humoral condyle a markedly anæsthetic zone extended along the ulnar border of the forearm embracing exactly the distribution of the internal cutaneous nerve and in the hand the cutaneous distribution of the ulnar. This area was the seat of numbness and of burning sensations, which he described as like the feeling produced by long immersion of the parts in snow followed by exposure to heat. Sometimes there was steady aching and again sharp, darting pains. Over the course of the ulnar nerve marked tenderness to pressure existed. The inner group of forearm muscles reacted feebly to both galvanic and faradic stimulation, anodal and cathodal contractions being nearly equal. Such a degree of paresis was present that marked difficulty was encountered in all delicate or intricate use of the fingers such as buttoning clothing, writing, etc., and strong muscular effort with the hands was impossible.

A diagnosis of alcoholic multiple neuritis was made. Discontinuance of alcohol was firmly insisted upon and for a few days a combination of chloral and bromides was exhibited to control the nervous excitement under which he was laboring. Later massage locally with galvanism and tonics containing a little strychnia caused speedy physical improvement and a steady gain in the direction of the palsy, though some diminution in the bulk of the muscles on the inner side of the forearms appeared and the left anterior tibial group became much wasted. By June 20th, or two months after the first visit, the patient had prac-

tically regained the use of his hands, so that he had returned to his clerical employment, and sensation was much improved. In the leg there was still much weakness. In the erect position with the heel upon the floor he could barely raise his toe from the ground but walked without any noticeable limp. A complete and comparatively rapid recovery seemed promising, when the man fell into his old drinking habits and failed to attend the clinic.

Case 2.—Mrs. Mary C., an American widow of 58 years, with six healthy grown children, and who had never had a day's illness in her life, or even a headache, was attacked last April by the prevailing epidemic of influenza. The disorder ran a usual course but was followed within a week of its subsidence by stabbing, darting, burning and severe pains in all four extremities accompanied by great hyperæsthesia with intense itching and scalding sensations. The condition was severest in the hands and feet and did not extend much above the elbows and knees but peculiar sensations along the spine were described. She would complain that she must be lying on some lumpish object, and afterwards there was a sensation of a tumor in the thorax loosely attached to the spine which floated and bumped about as she moved in bed. The attending physician treated her for some weeks, and on numerous lines, but principally with rheumatism in mind. No relief was secured. The days were passed in agony and the nights in torture which morphine did not control. At the end of two weeks the hands and feet were powerless. Subsequently the case went into the hands of Dr. A. E. Hoadley, with whom I saw the patient July 10th last. At that time the severity of the attack had passed, but there was still great weakness of the hands and feet with painful hyperæsthesia. The bedding in contact with the affected area the patient described as feeling "wooly, coarse and like a bundle of rushes." Her stockings felt "as if made of coarse twine and full of knots." She was constantly rubbing and chafing her hands, but in a gentle way, for any pressure or roughness was intolerable. The grasp was greatly reduced and she could with difficulty stand upon her feet. The pricking, burning, itching sensations, though lessened, were hard to endure. The bowels which had been sluggish for many years, had been thoroughly flushed by daily copious injections and now small doses of morphine secured some rest at night, the first she had enjoyed for many weeks. Wrist, plantar and patellar reflexes were absent. There was tenderness over the nerves in the affected area. The finger nails were roughened, scaly and marked by transverse ridges. The skin about the nails and as far as the second phalangeal joints was shiny, red and atrophied. No muscular atrophy was apparent, but the legs were flabby and the forearms somewhat emaciated, pos-

sibly not more than the prolonged confinement to bed might explain.

Electrical examination was not made as a diagnosis of multiple neuritis seemed justified without it. The patient has steadily improved in all respects and is now walking about the house or even going to market, and able to be of some service to herself and her family. She still complains that her shoes seem full of nails and pebbles and her bed of switches, but a quarter or an eighth grain of morphine secures a fair night's rest and a modification of the distressing subjective troubles which with the paresis certainly, though slowly, are growing less. The constipated habit of this woman is notable in this connection. She states that all her life she has been remiss in attention to her bowels often allowing a week, ten days or even a fortnight to pass without securing a passage or even attempting it. This condition may have played an important part possibly in the etiology of the neuritis as it could furnish a general auto-infection or, if you will permit the expression, an auto-sewer gas poisoning, but in accordance with the opinion of foreign and American observers who have reported similar sequelæ of *la grippe*. I am inclined to assign a causal relation to the influenza.

Case 3.—James M., a married Irish teamster, of 50 years, presenting no family or personal history of any interest in this connection, was taken with the grippe Jan. 10th of this year, and was moderately ill for a few days. He recovered apparently, however, and went back to his work feeling comparatively well. On Jan. 18th he felt a weakness and stiffness in the left calf which was worse on the following day. On the third day the other leg was affected and two days afterward he could not stand at all. Weakness in hands and arms promptly appeared so that he could not use his knife and fork, dress himself or exercise any considerable muscular force. The face, tongue and head were in no wise and at no time affected or the control over the bladder and rectum. For another ten days he gradually grew worse but since that time has steadily improved. There was considerable tenderness in the extremities but no great pain and no disagreeable subjective sensations aside from the feeling of powerlessness. In June, at the request of Dr. D. J. Doherty, I first saw the patient and found the disease retreating. He could stand fairly well and with the aid of two canes could walk in a very feeble, uncertain way from one chair to another. The knee jerks, wrist and plantar reflexes were much diminished but undoubtedly present. There was some tenderness over the affected muscle groups and affected nerves, with tendency to wrist and foot drop. The hands showed greatly diminished power and the right hand and left foot were most affected. Later, repeated electrical examination showed diminished reaction to both forms of cur-

rent but no inversion of the galvanic formula, whilst there was perceptible shrinking of the flexor group of muscles on the right forearm, of the dorsal interossei of the right hand and of the anterior tibial group of the left leg. He is at the present time steadily gaining in every particular and the outlook is good for complete recovery within the next ten months. Little treatment has been employed, but he has had such rubbing and massage as he could give himself with the intelligent assistance of his family and plenty of faradic electricity also applied by himself, serving greatly to entertain him. In this case, as in Case 2, a prolonged search for every source of infection has been negative in result, unless *la grippe*, which suggestively preceded the neuritis be assigned as the cause, and this I am inclined to believe is the fact.

Case 4.—Mr. S., an unmarried merchant of 31 years, was referred to me March 31st, 1890, by Dr. Ferdinand Henrotin. Two months previously he had for a day or two felt a "queer bruised sensation" in the left thumb which passed away in a few days. Shortly afterwards he spent several weeks in Mexico, where he had a number of "chilly, creepy nights," could not keep warm with any amount of clothing, and such nights occurred irregularly up to the time he came under observation. A month before, after getting slightly chilled on a street car, there was numbness in the fingers of both hands which persisted without intermission and spread up the palms, more noticeably in the left hand. This strange feeling was intensified by rubbing, by cold or heat, and was described as the sensation produced by sharp clapping of the hands. Objective sensation was not noticeably impaired, but he found his fingers clumsy and that he could not button his collar or cuffs, without extreme difficulty, manœuvres which require at once much dexterity and some strength when the linen is stiffly laundried. In every other respect the patient seemed to be in perfect health and there was not the slightest indication of any infection, chemical or otherwise. Malaria was suspected, but persistent and careful exhibition of quinine in full doses produced no betterment. Electricity and massage gave no rapid improvement. The peculiar sensations, however, gradually diminished, but in August still persisted to a slight extent. At this time a number of doses of salicin were given for a furuncular outbreak and in forty-eight hours the nerve trouble disappeared and has not returned up to this writing (Oct., 1890). It is therefore possible that a rheumatic condition furnished the background for the very mild neuritis.

Other cases following typhoid fever might be given, and one in the person of a well-known surgeon, in which there was implication of the

musculo-spiral of the left arm, probably due to a pharyngeal abscess which had produced well-marked systemic infection. Such instances, however, fall under the observation of all.

The clinical recognition of the fact that certain palsies are due to alcohol, lead and diphtheria, is of sufficient antiquity, but a knowledge of the anatomy of these conditions is quite recent, and constitutes one of the notable advances in modern neurology. Under the term multiple neuritis have been grouped many forms of paralysis and neurotic derangement formerly most variously distributed, for if a spinal nerve be injured by traumatism or inflammation, such injury will be manifested almost solely by variations in its functional activity correlative to the amount, extent and nature of the morbid condition, and furnishing the widest variety of symptoms. In default of certain knowledge concerning such processes, these symptoms quite naturally were variously interpreted by different observers, with plenty of resulting confusion.

The ability of peripheral nerves to resist the extension of inflammation by contiguity must have attracted the attention of every one who has seen the lumbar plexus dissected by a psoas abscess; but, on the other hand, they are peculiarly susceptible to certain toxic and infective agents, circulating in the blood, which determine in them varying grades, and possibly kinds, of inflammatory action, with a tendency to spread centrifugally along their trajectory to the ultimate filaments. Upon examining nerves so implicated they will be found affected in two general ways: Either the phlogistic activity will be mainly confined to the proper nerve elements, the axis cylinder and the medullary sheath, or it will be interstitial, involving the endo- and peri-neurium; yet all variations between and embracing these extremes are to be encountered. Now as spinal nerves are motor and sensory, it results that variations between complete abolition of both these functions and the slightest impairment of either may result from a neuritis. But they also contain vaso-motor filaments, interference with the function of which gives rise to circulatory and trophic disturbances of greater or less importance. Consequently among the symptoms of this disease, as well remarked by Buzzard in his Harveian Lecture on this subject, "pain is sometimes present and sometimes absent, numbness may be slightly or strongly pronounced, muscular atrophy, which is sometimes conspicuous, may be entirely wanting, whilst the result of electrical examination may vary to a remarkable extent." Impairment of motion or muscular power, however, is in some degree always present. This may be accounted for on the ground that motion requires a more complicated nervous action than sensation—upon which, indeed, it mainly depends. In the lower orders of animal life sensation precedes motion,

and throughout the nervous system, as in other fields, the higher and more complicated or widely differentiated the function or apparatus, the more is it susceptible to derangement.

Formerly cases of multiple neuritis, when not attributable to alcohol, lead, diphtheria, gout or rheumatism, were thought to be of spinal origin and sometimes were described as acute ascending myelitis. In 1864 Dumesnil described a case of paralysis presenting lesions of the peripheral nerves upon post-mortem examination, and two years later a second similar instance. The next mention was made by Eichorst in 1876, followed by Joffroy in 1879, Leyden in 1880, Grainger Stewart in 1881 and in 1884 the accumulated information in regard to this condition was ably presented by Buzzard in the Harveian Lecture already mentioned.

The lesions are confined mainly to the ramifications of the nerves and, as a rule, are more pronounced the farther they are removed from the central apparatus. There is a well defined tendency to symmetry, so that both upper or both lower extremities are affected in the same manner. Rarely, and only in cases of long standing, indications of extension to the spinal cord are found. Wherever the affected nerve trunks are superficial or turn about bones they present an intensification of the process, which explains the painful points usually found in such localities. As before indicated, the inflammation has a centrifugal tendency, following the nerve to its ultimate distribution, and even destroying the terminal muscle plaques and other end organs in severe cases, with resulting atrophy of the parts to which they pertain. Practically and histologically the lesion, irrespective of the initial cause, does not vary in any material particular from the degeneration caused by nerve division, and in the progress of the disease regeneration takes an exactly similar course to that presented by divided nerves reunited after the occurrence of degenerative changes; that is to say, repair proceeds from above downward. Obersteiner and Gombault, however, insist that the degeneration due to lead and similar poisoning differs from the traumatic sort in the persistence of the axis cylinder in the peripheral segment.

The causes of multiple neuritis are legion. They are divided by Starr into four groups substantially as follows:

1. Toxic agents, including lead, alcohol, arsenic, bisulphide of carbon, illuminating gas and possibly phosphorus.

2. Infectious agents such as produce diphtheria, variola, typhus, typhoid, malaria, syphilis and tuberculosis. I would include the infection of epidemic influenza and septicaemia in its broadest sense.

3. An epidemic influence in many tropical countries causing an outbreak of multiple neuritis such

as is termed kakké in Japan, and beri-beri in India and Brazil.

4. Cases are attributable with more or less plausibility to gout, rheumatism, exposure to cold and over-exertion, while in some instances no cause can be assigned.

From these brief considerations it is to be readily seen that this disease may present many different clinical aspects. The most diverse symptoms are encountered, inasmuch as any loss of function or perversion of function attributable to spinal nerves may be the leading feature of an individual case. Subjectively the sensory symptoms, which are usually a pronounced feature, vary from slight numbness or strangeness of feeling to the most exquisite hyperæsthesia or absolute anæsthesia. Ordinarily certain areas will be anæsthetic to touch but extremely painful, constituting the *anæsthesia dolorosa* of the pedantic. Sensations of pins and needles, creeping, crawling, burning, tingling, and pains of a tearing, boring, twisting, even lightning-like character are the burden of the patient's incessant complaints. The hands and feet may become so sensitive that the weight of clothing, the contact of the hand, or even a breath of air cannot be tolerated. Over the affected area there is tenderness to pressure almost invariably, and this is greatest where the nerve trunk is readily accessible. There is often lessened ability to recognize temperatures in the affected parts, to locate tactile impressions or to distinguish degrees of pressure. The reflexes subserved by the nerves in question are diminished, or more usually make complete default, and this condition of even the knee-jerk in diphtheritic palsy of the ordinary pharyngeal form is a diagnostic sign of great weight (Gowers). Where the condition is due to alcohol and rarely to other causes, a peculiar mental state is noticed in which the moral sense is notably perverted. Such patients will detail with great particularity long experiences which are absurd and impossible upon their face, and their statements in regard to their own condition are quite unreliable.

As the great rule the distribution of the disease is strangely symmetrical, usually involving the lower extremities below the knees and the upper extremities below the elbows. Though no nerve is exempt, the musculo-spiral in the arm and the anterior tibial in the leg are ordinarily selected, causing wrist-drop and foot-drop by the motor paralysis which is one of the primary and most constant, as well as the most important symptoms. The development of paralysis may extend over a period of two or three days or as many months, usually commencing with febleness in the legs and aching in the calves, followed shortly by implication of the upper limbs and attended by some or all of the sensory disturbances just mentioned. When the respiratory nerves are involved it constitutes a grave feature, and may rapidly lead to

a lethal termination. Depending upon the severity of the attack and the rapidity of its onset, trophic disturbances sooner or later appear. In the area of distribution of the affected nerves there may be profuse sweating, producing a miliary or even bullous eruption and a macerated condition of the integument. The dystrophy is manifest in dryness of the skin with cuticular desquamation, falling of hairs, and roughness or even shedding of the nails. The fingers may present the peculiar erythematous, glossy skin characteristic of nerve injury, and mottling and flushing with alternate paleness of the parts is frequently noticed. The muscles are often flabby and plainly wasted. In uncomplicated cases the sphincters are never affected. Electrical examination may develop the reaction of degeneration, but ordinarily something short of the typical formula is found, and only the slightest modifications or none at all may be detected in mild cases, as is readily explained by considering the anatomical peculiarities of the disease.

Depending upon the severity of the individual case, its cause and the possibility of removing that cause, the course of the disease is from three to twenty months and, except nerves of vital importance are implicated, almost always terminates in recovery, which is usually preceded by a recurrence of the sensory disturbances as the nerves regenerate. In the later stages massage, douching and electrical exercise of the muscles to maintain nourishment and to prevent spastic or position deformity, are all of great value, but must be employed with intelligence and moderation. Any break in the integument must be carefully attended to, as healing is slow and a tendency to ulceration prominent.

It is probable that further study of this interesting but wide group of diseased conditions will result in establishing differential features of importance in classification, prognosis and treatment.

167 Dearborn St., Chicago.

SOME REMARKS ON THE RELIEF OF REMOTE NEUROSES, BY THE RES- TORATION OF OCULAR EQUILIBRIUM.

BY FRANK ALLPORT, M.D.,

OF MINNEAPOLIS, MINN.

PROFESSOR OF CLINICAL OPHTHALMOLOGY AND OTOLGY IN THE
UNIVERSITY OF MINNESOTA.

The subject of ocular insufficiencies and over-sufficiencies appears to be one of those crazes that occasionally strike the medical profession with cyclonic force. Like cyclones, these crazes are unexpected in their attacks and frightfully devastating while they last. Their careers are short-lived, but they leave many aching hearts behind

to tell the story of over-credulous patients and over-zealous physicians.

We can learn but little, it is true, without experimentation, but in the name of suffering humanity, there should be some limit placed, beyond which the pitiless drug or knife of the medical man may not leave its mark.

What a multitude of mistakes must be laid to the demon of "reflex" action, who, like a fitful spirit, flits hither and thither in our human anatomy, and ever and anon lays his icy hand upon some one of our organs and claims it for his own. How quickly the medical profession grasps at the hint. Immediately a long chain of diseases is looked upon from a different standpoint. Women are ruthlessly laid upon the operating table and castrated. Children are circumcised; teeth are extracted and noses are cauterized. In short, the abiding place of "reflex neuroses" may be found in any organ of the body, and is liable to an invasion by ignorant zealots. Meanwhile the physician is in a hopeless state of bewilderment. The commonest diseases assume a mysterious appearance, and he fears the presence of the lurking "reflex" behind every muscle, nerve and tissue in the body. It matters not whether a patient complains of his eyes or not, clip, clip go the scissors, and his muscles are severed. It matters not if the child's prepuce utters a note of warning. Off it comes. It matters not whether the woman ever complains of her ovaries. Down she must lie and in a twinkling they are laid on the table beside her, and the surgeon imagines he has achieved a signal triumph, especially if he can show that he has made a great many such operations in a very short space of time.

Why do not physicians conscientiously narrate to us the ultimate results of these cases, upon which they base such wonderful reports? Because they are ashamed to do so! After they have tried them for a time, and the results are finally forced upon them, they simply quietly lay away their hobby and say nothing about their conclusions. But does it teach them a lesson? Unfortunately no! They are ready for the next visionary dream of some over-zealous enthusiast, and are soon deep in the mysteries of the latest "reflex." Where and when will this insane chasing of a will-of-the-wisp cease? How many of the crippled, the maimed, the halt and the blind must be arrayed before us like the ghosts of Richard's victims, before we are contented to inoculate our practice with a little common sense? The answer is as visionary as a "reflex neurosis." But it is to be hoped that the time is not far off; that the day of our salvation and the salvation of our patients is at hand.

One gleam of sunshine I have been able to extract from the general gloom, has helped me over many a dark place. It is this: Never attack an organ, unless that particular organ is causing dis-

tingent uneasiness. If an organ is diseased to an extent sufficient to warrant interference, it will usually make its pathological condition evident.

The latest candidate for the approbation of the medical man, is the influence exerted upon the nervous system by insufficiencies and oversufficiencies of the ocular muscles.

The subject of tenotomies for ocular insufficiencies is not a new one. But the subject of graduated tenotomies for ocular insufficiencies, and their effects upon the different organs of the body, is comparatively a new one. Tenotomies have, until recently, meant a complete cutting away of the tendons from the eyeball, and this has referred more particularly—almost exclusively, I may say, to insufficiencies of the internal recti muscles. To Dr. Stevens, of New York, is to be given the credit of having elaborated the subject of graduated tenotomies and advancements, for the relief of reflex and remote diseases, and of having called attention to other varieties of insufficiencies, besides those of the internal recti muscles. To Dr. Stevens must also be given the credit of having systematized this entire subject, and of having given us an exact and intelligent nomenclature. His methods of operating are of the very best, and are of such a nature as to make them valuable to every ophthalmologist. His instruments for operating are as near perfection as can be made, and his phorometer renders the detection of insufficiencies easy and systematic. His claims to cure headaches, head neuralgias, etc., will find sympathy, approbation and acquiescence from all ophthalmologists. But his claim to relieve general chorea, epilepsy, paralysis and other grave and remote neuroses by graduated tenotomies, is so extreme as to warrant the unfavorable verdict rendered by almost the entire profession. His claims were so broad, and his personal statistics so surprising, that it became necessary for the profession either to accept or reject the grounds upon which he stood. Therefore the New York Neurological Society determined to thoroughly and impartially investigate the subject. Accordingly in March, 1887, with the acquiescence of Dr. Stevens, a commission was appointed, consisting of Drs. Segnin, Starr, Birdsall, Moore, Webster, Dana and Foster (the two latter being appointed by Dr. Stevens himself), to consider the value of Dr. Stevens' treatment. This commission was not compelled to bring in a report at any specified date. This was left to themselves. They were requested to bring in their report whenever they had arrived at a conclusion. They were merely asked to consider the subjects of chorea and epilepsy, these being the subjects upon which Dr. Stevens laid the greatest stress, and in which he claims (without, however, substantiating his claims by intelligent statistics) to cure 50 per cent. of all cases submitted to his charge. A preconcerted plan was agreed upon that was

undoubtedly fair to all, by which patients were placed under Dr. Stevens' care, and observations of progress taken from time to time. This plan appears to have been carried out honestly by the members of the commission, although claims to the contrary were advanced by Dr. Stevens. The total number of cases sent to Dr. Stevens for treatment was 28; 23 were epileptics; 5 cases of chronic chorea, and all had some form of insufficiency. Fourteen of these cases withdrew for various causes: 5 were unable to attend regularly; 2 were declined by Dr. Stevens because of organic disease; 5 were withdrawn by mutual consent of the members of the commission sending the cases and Dr. Stevens, for satisfactory reasons, such as non-attendance, etc. Three were discontinued because they grew worse instead of better under the treatment; hence only 14 remained and became available for observation. These cases were under treatment for periods varying from several weeks to thirty months, and the result showed that no cases were cured. One case was much improved, 5 cases improved, 7 cases unimproved, and the result in one case was unknown. From these results it will be seen that six cases were claimed to be improved; three of these cases were from Dr. Stevens' own private practice, and no exact notes of their previous condition were available. In five cases the improvement was very slight; the sixth case was an epileptic who did about as well under Dr. Stevens' treatment as under the bromide treatment. Some of the patients were made worse instead of better, and in some diplopia and vertigo were developed.

Such in brief was the result of the commission appointed in March, 1887, and which reported in November, 1889. Their labors appear to have been carried on in a spirit of honesty and fairness. They declare that inasmuch as Dr. Stevens has utterly failed to achieve the great results he claimed, this method of treatment is not worthy to be classed among the principal agents for the cure of chorea and epilepsy. This appears to have been agreed to by even those members of the commission selected by Dr. Stevens himself; Dr. Dana (one of Dr. Stevens' friends), even going so far as to say, that while when he entered the commission he was prejudiced in favor of this method of treatment, the result of his observations had been to make him lose faith in its efficiency. One remarkable fact is, that Dr. Stevens reports to have cured 50 per cent. of the cases of epilepsy and chorea submitted to him in his own private practice. He further claims that the cures materialized promptly; but the commission reports that no cases were cured, and there were practically only three cases that made even doubtful improvement, and the course of improvement in them all was protracted.

The fact of the matter is, Dr. Stevens appears to be enthusiastic and very zealous in his investi-

gation of this subject, and has arrived at a point where he claims too much and where his claims have no reasonable hope of being sustained by a fair and impartial examination. If he merely advocated the use of this remedy for headaches, head neuralgias, etc., he would have many endorsers, but as it now stands the breadth of his claims is only equaled by the members of the profession who are his open antagonists. Notwithstanding the fact that the commission was appointed with the acquiescence of Dr. Stevens, and that the commission and Dr. Stevens labored together for a period involving two and one-half years, Dr. Stevens, at the meeting in November, 1889, brings in a protest against the reception of this report by the Society. If he did not wish to work with the commission he should have said so at the start; if he wished to object to the method in which the commission was prosecuting its labors he had ample opportunity to do so. But he accepted the cases that were sent to him (with the exception of the fourteen that were rejected), and treated them presumably to the best of his ability, and it would seem as if he should stand by the results. He even has the poor taste to vent his spleen by unjust and personal allusions to the members of the commission, and it is gratifying to learn that such allusions were passed by in dignified silence by the Society, the personal character of the members of the commission being sufficient guarantee against bigoted animosity cutting any figure in its labors. It appears to me that if such neuroses are dependent upon a lack of ocular equilibrium, Dr. Stevens, with the immense labor that he has put upon the subject, the undoubted information he has acquired, and the great skill that he unquestionably possesses, should be able to achieve exact results, and that successful operations, directed against these conditions, should be positive and rapid in their consequences and not protracted and unsuccessful.

For my part I have little faith in graduated tenotomies. I believe that if a muscle is worth tenotomizing at all, the operation should be complete, and that an absolute separation of the tendon from the eyeball should be brought about. In Dr. Stevens' method the tendon is picked up by a pair of fine forceps and the middle fibres are cut, leaving the two lateral margins of the tendon intact; this looks well in theory, but according to my observation does not materialize in practice. The fibres that are cut are supposed to fall back and become attached to the globe at another point. I do not believe that this is the case. I believe that the fibres fall back during the operation, but in a short time thereafter, in the course of healing and cicatrization, the fibres pull back to their original place of attachment. This statement I have repeatedly verified by observations upon the human being and animals, by first making graduated tenotomies, and, after a while, re-

opening the conjunctiva and carefully observing the condition of affairs. Dr. Stevens himself, I understand, sometimes finds it necessary to repeat this operation from fifteen to twenty times on a single person. If this is the case, and some of his cases are under observation for two and one-half years without achieving decided results, it would appear to me that the operation should be condemned and a search made for some new remedy. I believe there is a great deal of nonsense in the subject of ocular insufficiencies and tenotomies, when presented in its most favorable aspect, and it appears to me that almost all of the hundreds of cases that I have examined by Dr. Stevens' phorometer have had some varieties of muscular insufficiency. To summarize then: I believe that errors of refraction and ocular insufficiencies are a fruitful source of headaches, head neuralgia and other neuroses, situated in and about the eyes and head. I believe that such diseases can be remedied by the proper adjustment of glasses and by proper tenotomies. But I do not believe that chorea, epilepsy and other remote neuroses are produced by errors of refraction or by muscular insufficiencies, except as such abnormalities indirectly cause an impairment of the general health, which might in its turn present a favorable soil for the growth of the various neuroses. I have but little faith in graduated tenotomies, and believe that if a tenotomy is indicated at all, the complete operation is necessary.

THE CLINIC.

A CASE OF NEPHRORRHAPHY.

A Clinical Lecture delivered at the Jefferson Medical College, Philadelphia.

BY W. W. KEEN, M.D.,
PROFESSOR OF SURGERY.

The case I shall show you to-day is rare. It is a case of floating kidney, and I propose to sew it fast to the loin. The patient is a young woman, 31 years old, who was brought to me by Dr. Coleman. Her history is briefly this: Five years ago, while reaching for a package of goods upon a high shelf, she suddenly felt something give way in the right lumbar region and also, as she clearly remembers, heard a distinct snap. She almost fell from the weakness caused by the shock, the package fell to the floor, and she was unable to lift it again because of the pain induced by the effort. From that time to this she has always felt it a labor to lift even comparatively light weights, because of pain in the region of the right kidney, shooting into the groin and thigh of that side. For the last three years she has been practically an invalid. With this there has been at times disturbance of the urinary function, the urine now and then becoming scanty and high

colored, but never, as far as observed, containing albumen. Beside this there have been occasionally very marked digestive disturbances, such as diarrhœa, nausea and anorexia. Menstruation is affected but little, but she has thought that at such times and occasionally during the intervals there has been some enlargement of the tumor, which made its appearance after her accident five years ago. If she lies upon her left side, this lump falls with a "thud" to a lower position upon the left side of the abdomen. At the internal border of the tumor I can distinctly feel the pulsation of a large artery, presumably the renal. By a slight manipulation the mass can be pressed forward, and it then falls below the umbilicus and to the left of the middle line. It is like a ship at anchor which swings with the tide to the limit of its hawser. The size of the tumor corresponds to that of the kidney. Its shape is approximately renal but the hilum cannot be distinctly made out. Again, percussion over the right renal region gives a certain amount of resonance, not perfectly clear, but distinctly different from that upon the left side; and there is also a sense of diminished resistance. My colleagues, Profs. Brinton and Parvin, have examined the patient and concurred in my diagnosis.

The kidney is subject to two forms of mobility, which should be carefully distinguished: 1. The moveable kidney, which, while surrounded by its fatty envelope, is to a certain extent moveable in the space behind the peritoneum; 2. The floating kidney, which is provided with a more or less complete meso-nephron, that is a reflexion of peritoneum analogous to the mesentery and mesocolon. A simple moveable kidney may become in time a floating kidney by gradually pushing before it a process of the peritoneum, as does the testis in its descent. Mr. J. Grieg Smith says that the condition is always congenital, but I cannot believe this, for in almost all cases that we see there is a clear history of recent discovery of the tumor, and in very many of an accident to which it is reasonably attributed.

If a patient come to you with such a trouble, what are the means of diagnosis? In nine cases out of ten the patient is a woman, and in nine cases out of ten it is on the right side. Rarely it is the left kidney, and still more rarely both are moveable. Occasionally the patient is a man, moreover, you will find a tumor that can be freely pressed into various regions such as the loin, the umbilical or hypogastric region; you may be able to make out the kidney shape and feel the hilum and possibly the renal artery pulsating, as I can distinctly feel in this case. You will then examine the loin by percussion and by bimanual palpation. But these tests may lead you to a false diagnosis. Three of us have examined this case with care and are reasonably sure of our conclusions; but it is possible we may have mistaken

for a moveable or floating kidney a tumor of the ovary, a uterine myoma with a long pedicle, an omental tumor, a tumor of the pancreas, or even a mass of impacted feces, and it may be that the facts will not bear out our opinion. If this be the case, I shall close the lumbar wound and immediately do a laparotomy, for there is in this case also in Douglas' pouch a prolapsed and painful ovary, which undoubtedly causes much of her suffering. Even if there is a floating kidney, a later laparotomy may be required to extirpate the ovary.

In most cases, if there are no symptoms, let the patient alone, or be satisfied to apply an appropriate bandage and pad.

Dr. Thompson S. Westcott has lately investigated for me the literature of this operation, nephrorrhaphy, and he finds there are recorded over a hundred operations with only two or three deaths.¹ One of these fatal results occurred in a case operated upon by Ceccherelli, and can be directly charged to the operation, as sutures were carried around the twelfth rib and the pleura was opened, the patient dying of pleurisy within three days. Hahn, of Berlin, reports one fatal case in twenty of his own operations. Mr. Lawson Tait has performed the operation three times, and, contrary to the testimony of all other surgeons, condemns it as useless. One of his patients died long after leaving his care, as he believed from suppuration due to the operation. To allow a floating kidney to remain without operation is by no means devoid of danger. The kidney which I showed you last week, removed from a case of hydronephrosis with abdominal urinary fistula, I believe to have been originally a floating kidney in which hydronephrosis was developed. Besides this not infrequent result, a floating kidney, as you see by this case, is a source of constant discomfort and ill health in many cases. If you find the physical signs are those of a large cyst of the kidney, the organ should be removed.

Shall I here perform a nephrectomy? This operation has been done a number of times for floating kidney and I think most unjustifiably. Nephrectomy for a floating kidney otherwise healthy is entirely unjustifiable. Nephrorrhaphy should always first be attempted. If the operation is unsuccessful and the health is still impaired, then, and then only, should the far more dangerous operation of nephrectomy be done. The patient is placed upon her left side with a good-sized pillow under the lower ribs, so as to increase the space between the twelfth rib and the crest of the ilium on the right side. The incision is midway between the last rib and the iliac crest over the edge of the quadratus lumborum, the same incision as is usually made for nephrectomy or colotomy. I shall cut down until I expose the transversalis fascia at the edge of the quadratus, and then by

opening the fascia I shall come directly upon the perinephric fat, which I shall then tear. I shall use silk sutures as catgut is too quickly absorbed. The question how I shall pass the sutures is important. Hahn, of Berlin, who proposed and first practiced this operation in 1881, at first passed his sutures only through the perinephric fat, and partial failure resulted in at least one of his cases. Again it has been recommended to pass the sutures through the fibrous capsule of the kidney, but this is very liable to tear, and failure has occurred after this procedure. I propose to pass my needle, as I have done in two other cases with admirable success, through the substance of the kidney itself and sew the organ fast to the lumbar aponeurosis, and then leave the wound open to granulate and thus insure a strong broad cicatrix. I would speak particularly of the importance of not pressing back the kidney into place until you are ready to grasp it; for in my last case, having found the organ and entrusted it to an assistant to hold in place, I cut down and came upon what I had every reason to believe was the kidney, but in reality was the liver, which lies close above the wound. The kidney had slipped out of place. The peritoneum was of course opened. I finally hooked up the kidney and made it do duty in closing the peritoneal wound. The case did perfectly well. I saw the patient a few days ago in perfect health, and she expressed herself as delighted with the result. It is surprising how rapidly the wound in the loin closes. In the last case referred to I put in several loose stitches intending to tighten them the next day, and I was surprised to find at the first dressing in twenty-four hours an even surface and the wound nearly closed.

I am now down to the perinephric fat, which I open, and in the light of the previous case to which I have just referred, it is important to know how to distinguish kidney from liver. I have thought over this not a little. The point usually made is that the liver moves with the diaphragm in respiration, while the kidney is fixed. But in these cases where the kidney has such excessive mobility, this rule is useless. Sometimes you can get your finger around and feel the whole contour, and especially the upper border of the kidney; but in my last case the kidney was in the pelvis. The color may give you some help. The kidney is dark-bluish in color, while the liver is more of a dark mahogany red. Manipulation will displace a floating kidney but not the liver. I shall now proceed to tear through the perinephric fat. The condition of mobility has been said to be due to absorption of the perinephric fat, but in this and my two preceding cases I have found no deficiency of fat. This operation is much more difficult than exposing a normally placed kidney. The mobility of this kidney is in marked contrast to the slow rhythmic

¹ Annals of Surgery, August 1890

respiratory movement of the liver, which I can now perceive through the peritoneum. The kidney slips suddenly out of sight and reach, and I can bring it back to view by guiding the abdominal tumor, so that I have no doubt of having the kidney. I now harpoon it by a tenaculum, draw it into view and hold it securely with a volsella. The movement of my fingers round the organ, instead of doing harm will do good, for it will excite some inflammation that will help further to fasten it in place. I now examine to find out whether the kidney is healthy or not. No disease is apparent to sight or touch, hence I shall not remove it. Now for the sutures. I take a half curved needle threaded with sterilized silk thread, and pass the stitch through both edges of the upper angle of the wound in the fascia and in passing from one edge to the other through the kidney substance about half an inch deep. Another is passed in a similar way at the lower angle, and four additional stitches, two anteriorly and two posteriorly, through only one lip of the wound and then through the parenchyma of the kidney, complete the fastening. Each stitch is followed by a little bleeding—surprisingly little. I shall put in two stitches through the edges of the large wound to tighten up to-morrow if I so desire, but I shall leave the wound open so as to get a good thickness of cicatricial tissue, just as I would do in case of radical cure of hernia.

[NOTE.—The patient's temperature only rose 0.2° after the operation, and except considerable pain in the right groin and hip, she made an excellent recovery from the operation. The permanent result can only be known at least a year later.]

MEDICAL PROGRESS.

ELECTRO-PUNCTURE OF AN AORTIC ANEURISM.—TILLMANNS presented to the German Surgical Congress (*Centralblatt für Chirurgie*) a patient upon whom this operation had been performed. The aneurism appeared in 1885, but grew rapidly after the patient lifted a heavy weight in 1888. He complained of dizziness, anxiety, palpitation, sleeplessness, and especially of a severe pain under the right shoulder blade, and in the right arm. A small soft, pulsating tumor presented itself in the second intercostal space at the right border of the sternum. From April 17 to July 9, thirteen electro-punctures were made, under strict anti-septic precautions and with local anæsthesia, a long steel needle connected with the positive pole was carried about 5 centimetres into the sac, while the positive pole, connected with an ordinary metal electrode, was placed upon the surface near the tumor. Each sitting lasted from five to ten minutes, with a current strength of from 10 to

20 milliampères. If the current is too great (30 milliampères) the needle may become heated, and so burn the skin, which should, if possible, be avoided. To prevent pain and carefully regulate the current, a water rheostat should be placed in the current. After each application the patient was placed in bed and an ice bladder applied over the tumor. After the eighth puncture the patient was allowed to return to his home; with the thirteenth the treatment ended. The results were excellent, and nearly two years after the operation the patient reported that all subjective trouble had disappeared. The pulsating tumor of the breast, covered with thin skin, has grown firmer and shrunken, and can now scarcely be seen. He is not completely cured, however, as deep pulsation can still be felt.

Tillmanns has employed electro-puncture in a second case, with an aneurism the size of a man's head. Some time after the sixth puncture the patient died from rupture of the sac. Here, as in the other case, improvement was noted from the punctures, the outer portion of the tumor becoming firmer.

In these cases the literature teaches that a cure is only rarely reached by electro-puncture, though results are more favorable the earlier the treatment is begun—commonly, however, it is only palliative, and often useless.

THE GALVANO-CAUTERY IN PURULENT OPHTHALMIA.—Purulent ophthalmia, when seen sufficiently early and before any ulceration of the cornea has had time to develop, will generally give way before the usual lotions and mild cauterization with nitrate of silver. The outlook may, however, be different when these cases are seen late, and when more or less extensive ulceration of the cornea has been set up; for their vision may be seriously threatened, if even the organ should escape total destruction. It is in such cases as these that M. ABADIE has reaped admirable results from the use of the galvano-cautery. For instance, a lad of 20 came amongst the out-patients with his eyes in a lamentable condition, the result of gonorrhœal contagion. There was a history of three weeks' duration of this state of things. Both corneæ were extensively ulcerated, and so deeply that the anterior chambers were invaded, while even the iris had not escaped, but was infiltrated, and had the appearance of being covered with a greyish membrane. The conjunctivæ and eyelids generally were so involved that it was with difficulty the latter could be everted. The case being considered desperate, it was deemed useless to pursue the routine treatment. Rapid arrest of the destructive process was attempted by means of the galvano-cautery, which was freely applied to the suppurating surfaces, while the milder cauterization by silver nitrate was repeated twice daily. Eserine drops as well as iodoform

insufflations were from time to time had recourse to, while boric acid lotions were frequently applied. This was the sum of the treatment which was vigorously kept going for five consecutive days. At the end of this time quite a transformation was effected. The eyelids could be opened freely, the sclerotic was assuming a normal aspect, while the corneal defect was being rapidly repaired and the anterior chamber closed in. Then after three months of further application of spray douches, the two corneae had become so far transparent that a double iridectomy was undertaken, after recovery from which the patient was able to read average print, and has since resumed his occupation of stone-mason. Another case was that of a man 58 years of age, who contracted a purulent ophthalmia which owned a similar cause to the foregoing, but who presented himself the third day afterwards for advice. He was ordered the silver nitrate treatment for eight days, at the end of which time his eyes appeared out of danger. Milder lotions were substituted, but the patient, feeling himself, as he thought, altogether cured, was remiss in his attention to instructions, with the result that the whole mischief was re-kindled, if anything more intensely than before, for the discharge became very abundant. This time, however, the application of silver nitrate was powerless to prevent the development of an extensive corneal ulceration, which progressed with such rapidity that the urgency for more energetic measures was evident if the cornea was to be saved from destruction. The galvano-cautery was therefore applied for four days in succession, while the nitrate of silver and iodoform applications were kept up as in the previous case. Es-erine was not used, as the anterior chamber was not here involved. In six days the ulceration was no longer visible. The patient is still under observation and the douche treatment. The cornea, which was saved from perforation, is opaque at the borders, but the centre is perfectly transparent, and vision is relatively good. The advantages of the galvano-cautery have already been shown in the treatment of perforating ulcers with hypopyon. The method of Sæmisch may be with advantage replaced by the cauterization of the ulcerated surface by penetrating with the galvano-cautery through the centre of the ulcer to the anterior chamber, and thereby readily liberating the hypopyon. In conclusion, it is claimed for the galvano-cautery, combined with the application of a 2 to 3 per cent. solution of silver nitrate, that it is quite possible to cure all forms of purulent ophthalmia, whatever may be their gravity, and that even in cases where the cornea may be seriously involved, and where, under older views and methods, it would be deemed as irrevocably lost.—*Lancet*.

A NEW DISEASE OF THE BREAST.—SCHIM-

MELBUSCH (*Centralblatt für Chirurgie*) speaks of a peculiar disease of the female breast, that has been as yet but little observed in Germany. The disease has been described in France by Reclus under the name *maladie kystique*, and by Rorsnig in Denmark as *multiple cysten*. Von Bergmann during the past year has seen three cases of this kind. In all of them both breasts were equally affected, the skin over them was movable, but the gland tissue proper presented a number of hardened masses that felt exactly like small stones contained in a sack. Anatomically these masses are found to be hardened gland tissue that has undergone cystic degeneration. The tumor is a cyst-adenoma; the acini soften, become cystic, and by confluence present larger spaces. The tumor is purely epithelial, and presents a very different condition from that in cysto-sarcoma and chronic mastitis, in which the interstitial tissue plays the principal part.

AMOEBOID MOVEMENTS IN THE RED BLOOD CORPUSCLES OF ANÆMIC PERSONS.—BROWICZ (*Centralblatt für Klin. Med.*) claims to have discovered striking movements in the blood of anæmic patients. He has observed the phenomena so far in four cases: one of pernicious and one of simple anæmia, a third of septiciæmia, and a fourth case of cancerous cachexia. The blood was observed in a fresh state upon a simple glass slide, and under an ordinary cover-glass. No special arrangements were needed for keeping the blood warm, as the movements would continue for hours, if the preparation was not allowed to dry. A power of 600 diameters was used.

It seems that Hayem has observed similar movements, but referred them to some parasitic infection of the blood, but Browicz regards them as a sort of Brownian movement, dependent upon some change in the chemical structure of corpuscles or plasma. That this explanation is probably correct he infers from the fact that the movements often continue for days, at an ordinary temperature, and long after the white corpuscles in the same preparation are lifeless. This he holds to be inconsistent with the known range of vital action in protoplasm.

EARLY DIAGNOSIS OF CANCER OF THE UTERUS.—DR. T. A. REAMY, in a recent clinical lecture, spoke very interestingly on the subject of the "Early Diagnosis of Cancer of the Uterus." He said: I have had exceptional cases at 22 and 23 years of age, but if the patient is beyond 30, or if she has had children or miscarriages, insist on an examination, and see if she may not have carcinoma in the first degree. Hæmorrhage and wasting discharge are the early symptoms. Do not wait for pain and the characteristic odor, the cachexia or pallor. Do not wait especially for odor and pain. Make a digital examination.

You can generally detect a roughness or breaking down of tissue, and then a visual examination by the speculum should be made. We may find ectropion and may be degeneration, and think we have cancer, when we have not. If, in operating for a lacerated cervix, we find suspicious looking tissue, cut it away, for if the tissue is not an epithelial growth it is next door to it, and should come away. The importance of the early diagnosis of cancer of the uterus, is emphasized by the fact that two-thirds of my 150 cases per annum, which come under my care, have advanced so far, one-half of them even before they come under the care of the family physician, as to make a possible cure by operative proceedings very doubtful. Why is the early diagnosis of this disease so frequent? For the reason that the real cause of cancer is not known. It is, nevertheless, true that with the exception of one single authority of prominence, Sir James Paget, so far as I am acquainted with the opinions of authors, all agree in the belief that cancer is primarily a local disease. There is very probable predisposition in constitutions, tissue inheritance, yet the consensus of opinion is that cancer is a local disease.

The early diagnosis of cancer is one of the most important points in the practice of our art. Its importance cannot be overestimated. If we are to do anything we can do it with so much more hope of success if done early. Many of the cases met in hospital practice are so far advanced in the disease before they seek the advice of the surgeon, and the operation is consequently more extensive and attended by more danger than if an early diagnosis had been made and surgical treatment employed. He had been on duty at the Good Samaritan Hospital for eighteen years, and the number of cases which came to him there early enough was very small indeed. Medical treatment amounts to nothing. Surgical treatment if employed early may save, so hence this is the only treatment worthy of consideration. This woman gives a history of prolonged menstruation. Whenever a woman comes to you between the ages of 35 and 50 years, and tells you that she is menstruating too freely, too long, or at intermenstrual periods, do not give way to the popular opinion that the woman is suffering from the change of life. The irregularity in menstruation, which signals the approach of the menopause, is that the woman will miss a period or two and not have too frequent or excessive menstruation. This woman menstruated too freely, then had an occasional show at intermenstrual period.

It cannot be said that much progress has been made during the past forty years as regards the recognition of fully developed cancer. Bennett's monograph on "Cancerous and Cancroid Growths," published in 1849, shows a pretty

thorough knowledge of the subject under consideration. He says: "The microscope alone, and independently of all other kinds of observation, can seldom determine the presence or absence of cancer." With regard to the microscopical diagnosis of cancer, we have not improved very much over Bennett. This distinguished author was also well up on other points for his day. He says, in regard to the local origin of cancer: "A cancerous growth is for some time purely local. In this indolent state a tumor may often be exercised and permanently eradicated. Even when the growth has become moderately cancerous, ablation is said to have been occasionally followed by success." "There was a time," says this author, "when phthisis was thought to be necessarily fatal. Morbid anatomy has expelled that error, as it will doubtless do regarding cancer."

At the present time, however, surgeons generally unite careful microscopical examination of the structures in a suspected case with the clinical study and microscopical appearances, thus recognizing the malignant character of tumors much earlier than formerly. Here lies one of the most important advances. It points the way to extirpation of the growth in its earlier stages, while it is yet local; thus largely increasing the chances of cure. Virchow's experience with the Emperor Frederick shows how difficult it is sometimes for the most experienced pathologist to give a positive opinion regarding the malignancy of a growth, especially when so located as to permit of the removal of a very small portion for microscopical examination. However, our knowledge of cancer, especially cancer of the uterus and the breast, has been much extended during the past ten years. Surgeons have also learned to distinguish more accurately operable and inoperable cases, and thus save the patient from severe, useless, and dangerous operations. These conservative results, derived from our knowledge, are next in importance to the cure of disease by early operation. It is no small matter to save a surgeon from a surgical operation which could do no good. The benign affections of the cervix uteri which may be confounded with the malignant are chronic inflammation, endometrial inflammation with its results, erosions, granular degenerations, ectropium.—Cincinnati Letter, *Times and Register*.

TREATMENT OF TUBERCULAR JOINTS AND ABSCESSSES BY INJECTIONS OF IODOFORM.—BRUNS, before the German Surgical Congress (*Centralblatt für Chirurgie*), recommended the injection of iodoform into cold abscess and tubercular joints. The foundation of the treatment, he thought, lay in the known power of iodoform over tubercular granulations. The iodoform was used in the form of an emulsion in glycerine or olive oil, one

part to ten or twenty. The preparation is carefully sterilized before each injection. After weeks or months the abscess becomes smaller, and in from two to four months completely disappears. In Brun's clinic one hundred cold abscesses have been treated in this manner, and 80 per cent. have been cured. Of these, ten have been cases of burrowing abscess from caries of the vertebræ, in which a permanent cure resulted, so that Bruns believes that the caries itself has been healed. The treatment is also recommended in tubercular empyema.

Similar good results were obtained in the treatment of tubercular joint affections, as the writer demonstrated in over fifty cases. In parenchymatous synovitis or capsular fungus, a hollow needle is passed into the joint and from one-half to three drachms of the emulsion forcibly injected. If the abscess is in the neighborhood of, or has broken into a joint, then the cavities should be emptied and so much of the emulsion injected as will just distend the abscess cavity or the joint. Fixation of the joint is only necessary when considerable pain has been caused by the injection; the rule is that it subsides rapidly, and the patient may be allowed carefully to use the joint. The parenchymatous injections should be made as often as once in eight days, while in the cases of enlarged joint cavity, or peri-articular abscess, each two to four weeks is sufficient. The first sign of improvement—lessening of the pain—is not to be looked for under six or eight weeks, the swelling decreases after the first injection and at last completely disappears. Peri-articular abscesses shrink to small knots that cause no further trouble. Motion in the joint may be partially, or indeed, fully restored. In severe cases and old people, a complete recovery is not to be looked for, though here we can expect a diminution of pain, swelling and improved use. The author recommends the operation because of its simplicity, adaptability, results, and freedom from danger.

In the discussion Heusner said that in the past four or five years he had treated numerous cases in this way, with excellent results. He specially mentioned a woman with tuberculosis of the wrist joint which was cured by ten injections.

Trendelenburg had treated 135 cases in this way. Results were various, but in 68 per cent. of the cases it could be said to have had a marked influence upon the disease, though cure was not an invariable result. The wrist seemed favorably affected more frequently than other joints. He also used the method in tuberculosis of the soft parts, lymphatic glands, testicles, etc. Several injections into the lungs had also been made.

Riedel enquired what relation a sequestrum had to the treatment. He was answered by Krause that frequently spondylitis healed under this treatment, notwithstanding the presence of

a sequestrum. Heusner said that in the cured cases no changes remained, while in those that were not affected the disease remained as it was before treatment. The case of the woman with the tuberculous wrist had originally been set down for amputation.

THE USE OF HYPODERMIC INJECTIONS OF CAFFEINE IN THE TREATMENT OF POST-PARTUM HÆMORRHAGE.—DR. MISRACHI highly recommends the use of injections of caffeine in cases of post-partum hæmorrhages where rapid assistance is necessary, and especially when the physician first reaches the case after there has been already considerable hæmorrhage (*Centralblatt für Gynäkologie*, No. 27, 1890). Especially in country practice this remedy may be of great value, particularly as it is possible for the physician to have under his care cases of diphtheria or erysipelas, and to have been unable to produce such complete disinfection as would warrant the insertion of the hand. According to the author, caffeine acts more rapidly than ergot, and produces a more effective result even than ether, although the latter is a more rapid stimulant. He administered it in the form of a solution, of which a hypodermic syringe would contain four grains of caffeine, and gave three or four injections at once,—in other words, injects hypodermically about sixteen grains of caffeine. He employs caffeine, rendered soluble by the benzoate of sodium, equal parts of each being dissolved in warm water. The author claims that this remedy so employed produces most remarkable results in arresting bleeding and in acting as a stimulant, and that, therefore, benzoate of sodium and caffeine in small packets should always be carried by country practitioners.—*Therapeutical Gazette*.

THE FLAGELLA OF BACTERIA.—LÖFFLER (*Centralblatt für Bakteriologie*) has succeeded in obtaining a special stain for flagella. He employs a special mordant after attaching the bacteria to a cover-glass by drying. The mordant fixes the coloring matters, fuchsin or methylriolett, in these extremely delicate structures. He has found that the bacillus of cholera and many other forms have but a single flagellum, while a large number are bunched at the end of the spirilla and the micrococcus agilis. Some are not found at the end of the bacillus, but seem to pass out from all parts of the body, as was found in the case of the typhoid bacillus. The number of these structures varied greatly in the same species, from which the writer concludes that they are very delicate, and easily washed away.

PLENCKII'S solution for cauterizing condylomata: Hydrarg. chlor. corros., aluminis, cerussæ, camphoræ, alcohol, aceti vini, equal parts.

SATURDAY, NOVEMBER 1, 1890.

KOCH, VIRCHOW AND TAIT.

At the Tenth International Congress, when the great bacteriologist appeared amid salvos of applause, it was said that the spirit of skepticism seemed also to be there to mock his arguments. There was likewise a consciousness that the controversy of the age was looming up, but that so far it had been only one-sided. None, however, were present who doubted the sincerity of the new prophet, who was there to acquit himself without honor even in his own country. He may not quite have come up to the expectation of presenting an infinity of unknown truth, but he could not justly be said to have failed in his logic, even though disposed to prove too much. There was no dearth of illustration and no poverty of facts. Against KOCH was VIRCHOW, the biological champion, startled, perhaps nettled, yet still generous, but not to the verge of abandonment of long cherished doctrines. From without there also came an echo from MR. LAWSON TAIT, surgeon and controversialist, that if ever he got together enough bacteria to make a poultice, he would slap it on the next wound he had to dress. Tait cares nothing for glamor, or we might hesitate to credit this statement as having been made in all soberness.

All these are workers of honorable purpose and dauntless spirit, who have made additions to our knowledge, and despite their over-zeal have deserved well of their generation. Each one of them has furnished aids to diagnosis and suggested many approaches to perfection in hygiene.

LISTER, too, with his practical mind, has at the very least taught us the necessity of attention to the details of cleanliness. His methods, now much simpler, may at first have been overloaded with ceremony, but this may have been essential for the enforcement of his doctrine. Nature, at all events, has been given a clearer field.

It is quite in keeping with our mental requirements that in studying species with their environments, we desire to be informed of their offices. To succeed in this we must dwell in the microcosm itself, just as in the greater world, we learn the flora by frequent excursions. Difficulties particularly beset the microscopist, bewildered as he is by numbers and limited to the study of forces, rather than of functions. He subconsciously deals with analogies, and drifts to insufficient conclusions by reason of marshalling his facts in a one-sided way. All minds, however, have this temptation.

Now, how stands the question? Many investigators are at work along other lines than those adopted by Koch, mainly in the search after the various microbes to be found in the healthy mucous cavities. BESSER, of Vienna, and STERNBERG, of our own country, have discovered many duplicates in the respiratory surfaces, quite enough to establish the ubiquity of these unseen enemies. But of course this is no argument in favor of their harmlessness, since their power is resident in their multitude, not venomous *per se*, but generators of other poisons. These forms follow the same law as the animal cell, both, according to Virchow, being to the other implacable foes, in that their immunity from extinction is due to their rapid, vigorous and constant reduplication. The conflict is likely to be eternal, and no culture-field is to be barren of its proper verdure. May we not as well state it at once, that as in the movement of nations, the soil invites and the tribes flourish because of the ease of living.

Koch claims that much of the study has not gone forward because of the obstacles in the way of the methods now in vogue. But as some have asked, have we yet struck the right trail—have we not been more picturesque than anxious; have we not been rejoicing over a newborn idea and been too much swayed by our hopes? Have we not been expecting that all forces will yet be found vested with form—not so much individuals but atoms—and atoms of a peculiarly vindictive

spirit, at once powerful and prolific. Clearly all this is against the economy of nature.

In the relation of the microbe to disease, there is a somewhat dominant suspicion of circumstantial evidence—a confounding of cause with consequence, or, as might be averred, an inability to discriminate between enemy and missionary. Perhaps, as some claim, these germs may constitute a phase of universal law, and may be merely products of a congenial soil; seeds which have sprouted only because they did not fall on stony ground. Patient observation may yet wring out the secret, possibly in the near future, but to our present ken a discovery of yet greater grandeur is to come. Meanwhile all hail to Koch, who first lifted the veil.

THE TEACHING OF ANATOMY.

This subject received considerable attention at the recent meeting of the British Medical Association. MR. LAWSON TAIT, in his Address in Surgery, paid his respects to it in his usual vivacious and somewhat reckless style, and it received full attention in the Section of Anatomy and Physiology.

Mr. Tait's strictures upon the prevailing methods of anatomical teaching were mainly bestowed upon two points—needless attention to details, and what he characterized as "that senseless system of biological training which has set in as a fashion at Cambridge, at Oxford, and at Edinburgh." In regard to the first point, the waste of time spent on details that are of no practical use to the physician, there are probably few who will not to a certain extent agree with him. One of the illustrations which he uses is perhaps even better than he was aware. "I remember," he says, "that we had to learn that the anterior cavern of the fourth ventricle of the brain ran a course which was backwards, outwards, downwards, forwards and inwards, and we were enabled in the most improper way to remember these unimportant facts by the word 'bodfi.' Has 'bodfi' ever served any of you at the bedside? Is there any conceivable condition of human accident in which 'bodfi' could assist you to relieve your patient?" Leaving aside, for the present, the question of the possible utility of a knowledge of the cavities of the brain, in regard to which there might, perhaps, be room

for difference of opinion, it is evident that the instruction resulted, in this case, in a mere memory of words, without any clear idea of the things described, which can only be a delusion and a snare to anyone who depends upon it. The description which he quotes does not apply to any portion of the fourth ventricle, and is evidently intended for the descending course of the lateral ventricle. But whatever may be thought of the aptness of the illustration, there can be no doubt that medical students are often compelled to spend a great deal of time in committing to memory facts which, as taught, have no interest for them, which they will never use in practice, and which they will proceed to forget as soon as possible after passing their examination.

Without a definite knowledge of the manner and extent of biological teaching at the universities mentioned, it would, perhaps, be unsafe to express an opinion as to the justice of Mr. Tait's criticisms on this point. It is safe, however, to say that a system of instruction which aims merely at teaching the student those things for which he will have practical use will never supply the best training, even from the utilitarian point of view, and this for several reasons. In the first place, it is impossible to foresee just what knowledge may be available. In the second place, isolated facts are less easily remembered than when they are studied in their connections with each other, which can only become clear by a comprehensive knowledge of the subject. Finally, and most important of all, it is only the cultivation of a scientific habit of mind that can deliver the physician from the danger of falling into a routine of empiricism. On this point there was a happy unanimity in the debate above referred to in the Anatomical and Physiological Section. Nearly all the speakers emphasized the importance of teaching anatomy as a science, as well as in its practical applications.

We incline to think that a defect in much of the anatomical teaching of the past has been a failure on the part of teachers to appreciate the difference between their office and that of an anatomical treatise. The teacher should know all that is in the text book and more, but to tell his students all that he knows is a fatal defect. It is far better for him not to know all about his subject than not to know what to emphasize and what to pass over in his teaching. Above all, he should bear

in mind that his teaching is of use only as it imparts to his students a clear comprehension of the structure of the human body. No amount of familiarity with text books, or even with his own lectures will serve them instead of this, and probably few will ever reproach him in after life for having given them too much of it.

HEALTH OF EUROPEANS IN EAST AFRICA.

SURGEON KOHLSTOCK, of the German contingent now occupying the tropical possessions of that nation in East Africa, has issued a timely and rational note of warning regarding the risks to health sustained by some of those Europeans he has met in that part of the world. As director of the sanitary arrangements at the German headquarters, near Saadani, he has had an excellent opportunity to form opinions and to note results, which together with the sense of responsibility that impels him to give them to the world is, in no small measure, a guarantee of the care with which he has collected his facts and made his deductions. His first warning is in regard to intending colonists and traders: "Let no one," he says, "think of settling in East Africa who has phthisis in any stage, even the pre-tubercular, if he does not want to leave his bones in its soil." At first, this point of danger was not recognized in the Fatherland, and the inspecting work of medical officers, in the case of those setting out as colonizing parties was carried out in a somewhat perfunctory fashion. But the climatic influences of the region soon made their effects apparent, and nine subalterns were among those who had to be sent home—precisely those in whose families pulmonary phthisis had existed. For a man of thoroughly sound physique, the two diseases to be dreaded were dysentery and malarial fever. The former, according to the experience of Dr. Kohlstock, responds satisfactorily to the measures usually observed at the various European centres in the East, the disease, among the German troops, ordinarily running as favorable a course as in British and French garrisons. The fever is dangerous only when the patient is precluded from taking rest and is compelled to continue at his work as, for instance, on necessarily forced marches. As a general rule, the malarial patient who can rest soon gets well. If the case is stubborn, the

patient must be transferred to the sanitarium, upon higher ground and back from the coast. A liberal allowance of fresh butcher's meat has been found to be the most efficacious diet in malarial troubles, and indeed, the risks arising from them have been greatly reduced by the excellent nursing and accommodation now available to most of the patients. Dr. Kohlstock regards it a mistaken practice to entirely cut off the resident's supply of alcoholic drink, as a precaution against malarial invasion; he prefers that the East African German should, within the limits of moderation and temperance, live as nearly as possible as he did at home.

These observations merit the attention of all those who are borne on the great wave of colonization that is setting more and more strongly to the dark continent, whatever be their mission, whether religious, mercantile or military, but an especial emphasis may properly be made in regard to the importance of a careful preliminary medical examination of the physical condition and antecedents of every person about to expose himself or herself to the peculiar risks that the African climate imply. Only selected cases should be encouraged to make the venture into those regions; and least of all, perhaps, should those who confess to a predisposition to pulmonary tuberculosis, be sped upon that journey.

EDITORIAL NOTES.

A NEW MEDICAL JOURNAL.—The publishers of the *New England Medical Monthly* announce that, on January 1, they will commence the publication of a new journal to be called *The Prescription*. It will command the able editorial supervision of Dr. W. C. Wile, of Danbury, Conn. It will be devoted exclusively to practical therapeutics, and will give a world-wide *résumé* of remedial agents, and the favorite formulæ for their exhibition. The newer remedies will receive ample consideration. For the small sum of \$1 per year this valuable monthly may be added to the physician's list of journals, and we are confident that it will abundantly repay the outlay.

NEW YORK PASTEUR INSTITUTE.—This institution was opened February 18, 1890. Dr. Paul Gibier, the Director, states that during the

period from that date to October 15, 610 persons have been presented for treatment. In 480 of these cases the animals attacking them were not mad. In 130 cases the anti-hydrophobic treatment was applied, it having been demonstrated by veterinary examination that the animals inflicting the wounds were affected by hydrophobia. All the patients thus treated are at this date enjoying good health.

LAGUEAU finds that the fatality from various diseases is greater in the Paris hospitals than in private practice. He gives the following percentages :

	Private Practice.	Hospital.
Typhoid	12	19
Variola	12	17
Measles	5	23
Scarlatina	6	9
Whooping cough	6	23
Diphtheria	30	64

ACCOUNT BOOKS OF PHYSICIANS ARE PRIVILEGED.—A recent decision before the general term of a New York City court has been rendered to the effect that, a debtor who is a physician cannot be compelled to deliver up his books of account to his receiver, who has been appointed in proceedings supplemental to execution. By the order appointing the receiver, the latter acquired title to the accounts ; but not to the books as well. "In the complicated affairs and relations of life the counsel and assistance of clergymen, physicians, surgeons and those learned in the law often become necessary, and to obtain it men and women are frequently forced to make disclosures which their welfare, and sometimes their lives, make it necessary to be kept secret. Hence for the benefit and protection of the confessor, patient or client, the law places the seal of secrecy upon all communications made to those holding confidential relations, and the courts are prohibited from compelling a disclosure of such secrets. The safety of society demands the enforcement of this rule." For this reason, it was held, that the physician's account books, containing information which would be privileged as concerns his patients, are not subject to discovery and inspection in an action between the physician and a third person.

HEAVY PENALTY FOR CRIMINAL MALPRACTICE.—The verdict against the New York abortionist, McGonegal, of fourteen years in the State Prison, for his fatal malpraxis in the case

of an unfortunate young woman, will be regarded as a righteous and reassuring judgment. This man had quite a large practice among the tenement house dwellers in upper New York, and used his profession as a cloak for habitual criminal practices. A fourteen years' sentence to a man of his age is apparently tantamount to a life-sentence. He was a regular graduate in medicine, from the University Medical College, class of 1852, but his name had been omitted from the *Medical Register*, or "green-book," by reason of his unsavory reputation. McGonegal's heavy punishment should have a salutary effect, as showing that the law is still potent and in full force against a class of criminals which has generally escaped the consequences of its evil deeds. And it may well be doubted if the public conscience is as fully alive as it should be to the gravity of the offense, murder namely, that is implied in the perpetration of criminal abortion; so long as public opinion is backward so long will the law be more or less of a failure in dealing with this form of murder.

THE Transactions of the annual meeting of the American Climatological Association held at Denver, Colo., September 2, 3, and 4, will be published in *The Sanitarian*, commencing with the November number. Address A. N. Bell, M.D., Editor, Brooklyn, N. Y.

THE *Bristol Medico-Chirurgical Journal* is responsible for the following :

The Tenth International Medical Congress.—A local doctor just back from the Congress tells me that a Berlin paper contained the following "Programme of Papers in the Special Department." He does not think, however, that any of the papers were read.

Prof. Dr. von Moltke: "On the Bleeding which may be Applied to whole Nations."

Prof. Miguel: "On the heaping up of Gold Molecules in the Arteries of State."

Dr. Brömel: "On the bad results of the Irou Cure in International Diseases."

Prof. Dr. Bismarck: "On urgency of Speech as a Symptom which follows v. rishing Omnipotence."

Dr. Salisbury: "On the Colonial Fever."

Dr. Officiosus: "On removal of Sleeplessness by the use of the *Imperial Gazette*."

Prof. Lesseps: "On the antiseptic Resection of Isthmuses and the Cupping of Shareholders."

Dr. Milan: "On the central Disturbances which occur when One takes off the Crown in a Hurry."

DR. KOCH has ceased to make experiments in the cure of consumption, and it is presumed that his method of treating the disease has been a failure. This on the authority of a newspaper of recent date.

TOPICS OF THE WEEK.

THE MEDICAL ART IN ANCIENT EGYPT.

An interesting chapter in the legendary history of medicine was opened up recently by Dr. Grant (Bey) of Cairo, at a meeting of the Aberdeen Medico-Chirurgical Society. The subject, that of ancient Egyptian theory and practice, was, indeed, sufficiently archaic to guarantee that it should not be too familiar to attract and instruct even a cultivated audience. The lecturer directed his attention chiefly to a consideration of the work of embalming. In this connection he carefully explained the different methods pursued, the *rationale* of the process, and the results attained. We shall not now enter into these details, but we note with satisfaction that one important collateral matter, that of Egyptian sanitation, has not been overlooked. The impossibility of anything like soil contamination under a system which converted burial into a mere process of antiseptic preservation is obvious. Though certainly less efficient for this purpose than the destructive agency of cremation, it was probably superior to the many imitative methods introduced by modern mummifiers. When the body had been prepared by means of evisceration, stuffing with bitumen, cassia, myrrh, etc., immersion, virtually pickling, for a further term of seventy days in salt, and bandaging in cloth cemented with gums—the series of arrangements under the most perfect system employed—there obviously was little chance of putrefactive decay or infective mischief arising from it. But it was not thus alone that the ancient possessors of Egypt yielded an unconscious obedience to scientific laws which are only now finding their full explanation. They were also most scrupulous in guarding their sacred river against the entrance of impurity. Though some allowance must be made for the fact that such questions as the disposal of sewage must have been simpler of settlement in the days of the Pharaohs than in our own, the example of their more cleanly practice in this respect might well be copied by modern vestries and riverside proprietors. Egyptian medicine has not handed down to our time many valuable traditions. We know, however, that within the scope of professional magic which worked its “cures” in the temple of Isis, the present fashionable novelties of bath treatment, massage, and hypnotism were carried out with elaborate care. So the cycle of time, while it bears us on to new and newer spheres of discovery and activity, ever keeps in touch with those vital conditions which underlie all treatment and are never irrational, save when they are misinterpreted.—*The Lancet*.

INEBRIETY IN GREECE.

Dr. Joannes Phustanos sounds a note of alarm as to the threatened decadence and destruction of the Greek nation by alcohol. Though he denounces only ardent spirits, and does not include wine as an alcoholic beverage, he declares that the abuse of alcoholic drinks has of recent years been sadly extending in Greece, every day adding to the number of the victims. The remedies proposed consist of a reduction of the duty on spirituous liquors

and the formation of temperance (moderate drinking) associations. In Britain, however, the increase of taxes on spirits has in the main lessened the sale, and abstinence societies have been the most successful in coping with this evil. This wail over the present extension of inebriety in Hellenic lands is the more remarkable that in former times Greece was the arena of heroic anti-alcohol legislation. The Greek vineyards were all but completely destroyed by the Turks in the fifteenth and sixteenth centuries. The Athenian lawgiver Draco sentenced drunkards to death, though Solon reserved that fate only for inebriates who were also magistrates, and who were found drunk in public. Pittacus ordained that drunkenness should entail a double punishment for crime. Locrian legislation showed some consideration for the medical profession, for while all others who drank were liable to execution, on those who had the authority of a physician's prescription for tasting wine no capital or other penalty was inflicted. This praiseworthy attempt to stay the ravages of so perilous a disease in the classic battlefield of national freedom has our warmest sympathy, and we trust that never again will the ancient epithet of “hard drinkers” be justly applicable to the Greek female population.—*Brit. Med. Journal*.

THE BACILLUS OF TYPHOID FEVER.

The existence of a pathogenic microorganism in enteric fever is strongly upheld by some bacteriologists, especially on the Continent. Most English observers consider the point not yet proved. In sections of the intestines in cases of typhoid fever numerous bacilli are constantly found; they are grouped together into well-marked colonies, and are not distributed throughout the superficial tissues as in dysentery. They are best demonstrated by staining the sections in a solution of methylene blue, and then washing out the excess of stain in water containing a few drops of acetic acid. The colonies are then seen as small dark-blue masses, the rest of the tissue being a lighter color. In drinking-water, soil, or fæces, it is almost impossible to recognize them, owing to the presence of large masses of bacteria which are of no practical import. M. Holz (*Zeitschrift für Hygiene*, viii, 1890), publishes some of his investigations with regard to these organisms. He states that they can only be recognized by comparing their appearances and properties with pure cultures. In order to render their detection more easy, Chantemasse and Vidal added to the gelatine on which they were to be cultivated a solution of carbolic acid, 25 per cent. On this nutrient material the typhoid bacilli flourished, whilst the growth of the others was retarded by the carbolic acid. For the examination of drinking water Holz recommends the following method: To the water to be tested is added a 25 per cent. solution of carbolic acid. This mixture is allowed to stand for three hours, and inoculations on nutrient gelatine are then made. If a free growth of colonies takes place, these are composed of typhoid bacilli, all bacteria growing in a similar manner being destroyed. Grauscher and Deschamps have introduced another test. They mixed with the suspected liquid a solution of aniline gentian violet, and then inoculated

gelatine plates with the colored solution. The colonies of typhoid bacilli were then stained violet, whilst the general mass of the gelatine remained colorless. Holz found that this reaction occurred most readily in a slightly acid medium. The most reliable test, according to the same observer, is a combination of the first of the above methods with potato gelatine. For the preparation of this material raw peeled potatoes are well mashed, and then squeezed in linen, the resulting juice being filtered until clear brown liquid is obtained; to this is added 10 per cent. of gelatine. The reaction of this nutrient fluid is acid. On this the typhoid bacilli grow in a very characteristic manner, and especially remarkable is the transparency of the colonies, so that they can be easily distinguished by their mode of formation from all other bacteria. A number of microorganisms found in food and water cannot be cultivated on the potato gelatine, but some forms of molds and *torulæ* grow in profusion. This drawback may be prevented by the addition of 25 per cent. of carbolic acid to the water or liquid to be investigated, then by allowing the mixture to stand for twenty-four hours, and finally cultivating on potato gelatine. If colonies then appear Holz considers that the presence of typhoid bacilli is proved.—*The Lancet*.

HAY FEVER.

In the *State Board of Health Bulletin* (Tenn.), Dr. Daniel F. Wright, of Clarksville, a member of the Board, advocates the idea of the curability of this pestiferous malady. He thinks that by anticipating the annual recurrence of the disease and resorting to a locality free from its etiological factors for several consecutive seasons, the unfortunate individual will secure an immunity from his trouble that will be permanent. He speaks in high terms of Roan Mountain (Cloudland), in upper East Tennessee, and from his article we submit the following extract:

"Let it not be supposed, however, that I am about to set forth the specific virtues of some new drug for this purpose, or even those of certain mineral waters impregnated with miraculous chemical ingredients. The only merits possessed by the waters here consist in their perfect purity; and the atmosphere is beneficial simply from its coolness, moisture, and its freedom from dust of all sorts, including that vegetable dust which is constituted of the pollen of various plants. Very few of the plants which constitute the Roan Mountain *flora* give any pollen to the atmosphere, by far the greater number consisting of *conifera*, *ferus*, and *labiates*, while the great moisture of the air prevents the rising and diffusion of such as might otherwise irritate the nostrils of visitors. In short, the qualities of air and water are simply negative—they simply fail to supply the irritants which are elsewhere the exciting causes of hay fever.—*Southern Practitioner*.

THE MEDICAL PRACTICE ACTS IN MINNESOTA.

The result of seven years' operation of Medical Practice Acts in Minnesota has been to reduce the ratio of physicians to population from 1 to 650 to 1 to 1,250.

Hundreds of charlatans have been driven over to Michigan and other unprotected States. In comparing the proportion of physicians in Minnesota to that existing in European countries like France and Italy, it must be borne in mind that, where the population is scattered, the work is far greater than when people are closely packed in thickly populated districts. It is doubtful if one man can attend 1,250 people as easily in Minnesota as he could 3,500 in Italy.

The present law has been in operation for three years, and in that time 205 candidates presented themselves, and 77 of these were rejected. Many other incompetents were doubtless deterred from presenting themselves by the fear of rejection. The Examining Board has conferred a priceless boon upon the citizens of Minnesota, and its appeal for support and coöperation from the physicians of the State should be universally responded to.—*N. W. Lancet*.

MANSLAUGHTER BY A FAITH HEALER.

The practice of faith healing has received a severe check, if not its death blow in the city of Toronto. A certain well known citizen, who had for some time been the subject of diabetes, and had been dieted for it, thought he would give himself the benefit of the newest fashion, and accordingly placed himself in the hands of a Mrs. Stewart, one of the apostles of the new art. Being by her instruction freed from all dietetic restrictions, he speedily died of diabetic coma, and an inquest being held the jury found that "he came by his death through the gross ignorance of Mrs. Stewart, who undertook to cure him of his disease, in not advising him to continue the restricted diet prescribed by his former physician." Mrs Stewart is consequently now awaiting her trial for manslaughter. We forbear to comment upon a case which is still *sub judice*.

A JAPANESE LUNG DISEASE.

In a work recently published on Japan, Dr. Vincent, a medical officer of the French navy, describes a disease of the lungs which he believes to be peculiar to that country. It is caused by a parasite, the *distoma pulmonale*, and is characterized by hæmoptysis occurring several times a day for ten or fifteen years, or longer, and ending in dangerous hæmorrhage. The *distoma pulmonale* is cylindrical in form, and measures from 8 to 10 millimetres in length and 5 to 6 in breadth. It has a very muscular buccal sucker. Its ova are 0.13 of a millimetre in length and 0.07 in breadth, oval in shape, brown in color, and covered with a thin membrane. The parasite makes its abode in little cavities at the periphery of the lungs which communicate with the bronchi by narrow openings. These cavities contain epithelial debris, red blood corpuscles, leucocytes, and innumerable ova of the distoma—all these elements being blended together in a sort of pulp, which is expectorated from time to time.—*Brit. Med. Journal*.

DRUNKENNESS.

Alcoholic drunkenness is equally devoid of conscience and shame. It goes everywhere, without invitation or welcome. Whatever it touches it soils. It degrades and disfigures everything within the range of its influence—whether the familiar affairs of everyday life, or the noblest efforts of human genius. Drunkenness really seems to be insanity—reinforced and doubled—lunacy itself run mad.—T. L. Wright, *Times and Register*.

PRACTICAL NOTES.

THE USE OF SULPHONAL IN DIABETES MELLITUS.

According to Casarelli sulphonal has an efficacious action in the treatment of saccharine diabetes.

The author summarizes as follows:

1. Sulphonal exercises a favorable influence in diabetes. Thanks to this remedy we notice a diminution of sugar and of the quantity of urine, a diminution concomitant with the polydipsia.

2. This amelioration manifests itself but to a slight degree, it is true, but even after the use of 1 to 2 grams a day, but it becomes marked after dose of three grams in the twenty-four hours repeated several days in succession.

3. Even when continued for a long time, sulphonal in doses of 2 grams does not provoke any unpleasant secondary phenomena. Given in doses of 3 grams a day, it is at first well tolerated; but if continued it is soon followed by extreme somnolence and vertigo. But a reduction of the dose will soon do away with these troubles.

4. The good effects of sulphonal are equally well manifested with an absolute meat diet. If we stop the sulphonal in this case we will at once find abundant sugar in the urine.

Casarelli gives to this substance marked preference to antipyrin, which in his hands has given markedly inferior results in the same condition.—*The Bulletin Médicale.*

THE TREATMENT OF DIABETES MELLITUS.

We will suppose a case of diabetes of arthritic origin. You will first prescribe the dietetic regimen which is likely to give the best results, along with the lithiated arsenical treatment.

1. Let the patient take before breakfast and dinner 5 grains of carbonate of lithium in a tumbler of Vichy or Vals water; two drops of Fowler's solution should be added to each dose.

2. Give after meals, in a little coffee sweetened with saccharin, 1 gram (15 grains) of antipyrin.

3. Sponge the body all over every day with warm water containing a little *eau de Cologne*. Energetic dry friction with a hair glove after the sponge bath.

4. Require the patient to rinse the mouth, after carefully brushing the gums, after meals, with the boracic acid mixture above given.

5. Pursue with rigor the following dietetic treatment: A diet exclusively of eggs, meats of all kinds, fowl, game, mollusks, crustaceans, cheese. All green vegetables are permitted except beets, carrots and turnips.

Urge the free use of fatty foods, such as sardines in oil, tunny-fish with oil, sour herring with oil, pork, butter, *pâté de foie gras*, "*rillettes*,"

bacon fat, etc. For soups recommend principally cabbage soups, bouillon with poached eggs, chicken broth, onion soup, mutton broth, clam broth, etc. All these soups should be taken without bread or crackers.

For bread, allow gluten bread, soja bread, fromentine bread; with each meal allow three ounces of boiled potatoes. To sweeten drinks, use pastilles of saccharin. Tea, coffee, maté, kola are permissible.

Prohibit all amylaceous foods, bread, panada, macaroni, rice, pies and cakes, custards, puddings, sugar, sweetmeats, chocolate, preserves, all fruits.

Milk is forbidden unless taken in very small quantity. All sauces and gravies containing flour are also forbidden.

For drinks, allow with the meals wine diluted with Vals or Vichy water, but little pure wine, no brandy or other distilled liquors.

6. Regular daily exercise to be taken. All bodily exercises are favorable. Insist especially on walks in the open air, mountain excursions, fencing, boxing, joinery.

Such, gentlemen, are the bases on which should be established the regimen of diabetic patients.—*Dujardin-Beaumetz, Therapeutic Gazette.*

ANÆMIA WITH AMENORRHŒA.

R—Acidi arseniosi, gr. j.
Ferri sulphat. exsicc., ʒ ss.
Pulv. pip. nigr., ʒ j.
Pil. alces et myrrhæ, ʒ j.

M.—Et div. in pil. No. xl.
Sig. One twice a day after meals.

—*J. Milner Fothergill.*

ALBUMINURIA.

R—Potass. acetatis, ʒ j.
Chloroformi, ʒ ss.
Acid. benzoic, ʒ ss.
Aquæ, q. s. ad ʒ viij. ℥

Sig. f ʒ ss every four hours.

When the prescription given above fails to give any tangible benefit, I then substitute the following:

R—Potass. acetatis, ʒ ij.
Acid Benzoic, gr. xx.
Sacch. lactis, ʒ iv.
Aquæ, q. s. ad ʒ iij. ℥

Sig. f ʒ j every two hours.

—*Prof. Waugh, Philadelphia.*

CHILBLAINS.

Prof. Morrow is credited with this apparently excellent formula for chilblains:

R—Acidi carbolic, ʒ j.
Tincture iodini, f ʒ ij.
Acidi tannici, ʒ j.
Cerat. simplicis, ʒ iv.

Misce bene ut ft. ungt.

Sig. Apply two or three times a day.

SOCIETY PROCEEDINGS.

Philadelphia County Medical Society.

*Stated Meeting, September 24, 1890.*THE VICE-PRESIDENT, JOHN B. ROBERTS, M.D.,
IN THE CHAIR.*(Concluded from page 625.)*

DR. JOSEPH PRICE, of Philadelphia, read a paper on

CERTAIN CAUSES OF MAJOR PELVIC TROUBLES,
TRACEABLE TO MINOR GYNECOLOGY.

With the present popular cry of "conservatism," in reference to operation in cases where it is held that all treatment should be tried previous to real surgical interference, it is worth while asking whether the preliminary treatment should not itself be abandoned in the hands of those who plead most pathetically for it. Their cry is not a scientific plea, but in most instances a *personal bid* for indulgence while they try to accomplish something, without acknowledging on the one hand that there is little or nothing to encourage them in their work, so far as results are concerned; and on the other, that there are abundant proofs from the cases that have come out from under their hands, with one treatment or another, that manifold really major surgical affections arise merely from treatment recognized as orthodox from the standpoint of minor gynecology. So far as my own experience is concerned, I do not hesitate to put minor gynecology in a causal relation with a vast amount of the necessary major pelvic surgery coming under my attention.

First among these causes may be mentioned the Emmet cervical operation. Like many other surgical operations, this, when first explained by its distinguished originator, was done in season and out, by everyone, without the least consideration of its contraindications. Very many minor tears of the cervix, in which a cosmetic effect only is obtained by operation, are made distinctly worse by operative interference. In many cases the pain becomes insufferable, from the lighting up of a dormant or unrecognized pelvic trouble, and operation is required to undo the mischief of an unnecessary cervical closure. This fact has been recognized by Emmet himself, and he has counselled the careful selection of cases in order to escape these disastrous results. It should be set down that where is preëxisting pelvic disease, even though slight, no cervical operation ought to be tried unless absolutely required by the condition of the patient. Another operation which has met with much approval in many directions, and which some measure of success seems to follow in some cases, is the forcible dilatation of the cervix. It is clear that where there is antecedent inflammation of the pelvic viscera, that is of the

genito-urinary system, such an operation as surgical dilatation of the cervix cannot be free from danger. In order to relieve dysmenorrhœa by this procedure, it must evidently be due to stenosis of the os or cervix. The question here arises, can it be told, in dysmenorrhœa, wherein its causes lie? Sometimes, but not infallibly. The fact is, that in many women where a stenosis would be diagnosticated, there is no difficulty whatever attending the menstrual flux. This being the case, it is evident that a diagnosis cannot be made by simple observation without a careful study of all the symptoms. Again, in many women the causes for this condition are complex. It will not do to lose sight of this, and conclude that because a flexion exists dilatation will remedy menstrual pain. It is to be remembered that if there is coëxisting pelvic inflammation dilatation will increase it, and, under certain conditions, cause it if absent. Rapid dilatation of the cervix is a distinct traumatism, and along with it run all the dangers incident to septic absorption that attend any other violent procedure, and where traumatism incident to natural causes is confessed to be the cause of so much subsequent mischief, it ought not to be *expected that operative injury can be harmless*. This conclusion, reached inferentially, has been abundantly confirmed practically on the operative table by much of my later pelvic work. In a number of cases with a history of preceding dilatation, the after-operation has exhibited an inflammatory condition of affairs as complicated as any other in my experience. Some of the dilatations were done with preëxisting disease, which was made worse by this interference, while others were done simply to relieve the dysmenorrhœa, and resulted in the establishment of a complicated surgical disease in which operation was *necessary purely to save life*. All in all, I believe that, judged simply by its remoter effects, the operation of rapid dilatation is a dangerous one, and *results oftener in subsequent harm than in lasting good*. The surgical injury to the cervix is, in many of these cases, more pronounced than the tears of the cervix which it is the intention to remedy by Emmet's operation. In this case there is operation at each horn of the dilemma, and the results are often equally bad at both. Simple closure of the cervix in cases of pelvic disorder, almost certainly exacerbates the symptoms. The necessary inflammatory action set up in the suture tract, is transferred along the lymphatic or venous channels to the seat of the earlier inflammation, this is lighted up anew, and goes on in its development until a pelvic peritonitis is kindled or rekindled, which at last entails a major operation. The minor gynecologist, as such, who has no regard for or appreciation of the relation of the commonly advocated general closure of perineal and cervical tears to major surgical complications,

cannot but be a great factor in the causation of the same. In Pepper's System of Medicine, Vol. iv, there is on record a case in which the operator hoped to cure a pelvic inflammation by the derivative effect of a perineal or cervical operation. Needless to say, pelvic operation was afterward done. Such a cure is no less ridiculous than the so-called "faith" cure, and is certainly more *actively* harmful.

That the inconsiderate use of the uterine sound has been responsible for much inflammatory pelvic trouble, is scarcely to be disputed. This is not because the sound is of itself a dangerous instrument, but because it is put into the hands of every tyro, as an instrument of diagnosis. If used at all, it should be in the hands of those with whom its application, by reason of their skill, will be exceptional, not usual, and the rule should be, that in the hands of the non-expert it should be forbidden. The more expert and experienced the specialist, the more rarely will the instrument be required. My own rule is, that in cases in which it might at first seem indicated, a little patience and diligence will obviate the necessity of employing it. The indiscriminate use of the sound and electrode, is the most serious *mechanical* objection to the employment of electricity. Every sitting for the electrical treatment is prefaced by the use of the sound, and followed necessarily by the introduction of an electrode of some form. This is by a class of men who, in the main, have had no *previous gynecological training or education* whatever. In such hands such methods can only be harmful, and we are now reaping the fruits of their work in a class of pelvic operations not surpassed in the complications presented. Along with the sound may be placed the curette in the same category. Dilatation, with curetting of the uterus, have placed to their credit a long *series of major operations*.

Another class of cases coming under this head are those in which there has been a long time during which intra-uterine applications have been made. All the caustics in the catalogue have at one time or another been in favor, as cure-alls, in intra-uterine therapeutics. Nitric acid, chromic acid, nitrate of silver, and the rest. For a woman to have undergone a routine treatment with this list, and to have escaped pelvic inflammatory trouble, is little short of a miracle. A careful inquiry into many of the cases coming under my care directly and indirectly, reveals the history that all sorts of minor procedures were tried, only to fail and apparently hasten the necessity for operation. I shall refer to and illustrate these points by the citation of cases in the discussion.

DR. E. E. MONTGOMERY: I fully second what Dr. Price has said with regard to the frequency of troubles necessitating major operations which result from the various methods of procedure in minor gynecology. I do not think that any per-

son who has practiced gynecology has not met with cases of inflammatory trouble of the uterus travelling to the ovaries and to the peritoneum, giving rise to conditions which have been described as peri- and para-metritis, which have resulted from the use of the uterine sound. When we consider the fact that the uterine sound has been a part of the routine method of examination of many physicians practicing this branch of the profession, it is not surprising that these troubles should so frequently occur. The uterine sound, as has been stated, should not be introduced in any case until the patient has been thoroughly examined, and the presence or absence of any inflammatory condition in the uterus, or about it, has been eliminated. The practice of Emmet's operation upon cases as soon as they consult a physician for treatment, where a slight laceration is found and the physician at once attributes the symptoms to this lesion and performs the operation, has justly led to its discredit. The operation is undoubtedly one which, in some cases, is of great benefit; it is, however, in properly selected cases. No case in which the presence of other inflammatory conditions has not been eliminated or cured by proper methods is suitable for the operation. One reason, I think, why Emmet's operation has proved so disastrous in many of these cases is the fact that, as the result of sub-involution of the mucous membrane from this lesion, we have an increased amount of secretion which, after narrowing of the cervical canal by the operation, is unable to escape freely; consequently, the uterus becomes dilated to a certain extent, and this favors more rapid extension into the Fallopian tubes and the development of serious trouble. One cause of the extension of inflammatory trouble from the uterus to surrounding parts is insufficient drainage from the cavity of this organ. Dr. Price very justly condemns the use of irritating materials which have been employed in the cavity of the uterus. Many who have proposed agents for the treatment of inflammatory troubles in the cavity of the uterus have seemed to labor under the idea that the only method of curing these inflammatory lesions was by destroying the mucous membrane in which they originated. The application of nitric acid, chromic acid, nitrate of silver in stick, and the like, results in relief by destroying the mucous membrane from which the secretions take place. In this way inflammation may be caused which may extend to the deeper structures of the uterus and to the pelvis. I fully agree with the importance of care in the treatment of these various classes of cases, to avoid adding to the discomfort and to the crippling of patients.

DR. JOHN C. DA COSTA: I am glad to hear Dr. Price speak of the dangers of minor gynecology.

cology, but I do not know how we shall get along without it, unless we adopt the rule (which he leads us to infer from his paper is his) that in all these ailments we open the abdomen and remove the tubes and ovaries. I hardly think that Dr. Price is right in attributing the major pelvic troubles to gynecological treatment, for, from the little that he has said, I think that we may infer that the pelvic trouble already existed, and the practitioner made a mistake in treating the uterus rather than the uterine appendages. I am glad to hear him speak in regard to Emmet's operation. I have heard long lists of cases reported with the statement that "all recovered without bad symptoms." That has not been my fate. One of the hardest fights that I have had for a woman's life has been after an operation on the cervix. Many unnecessary operations are done on the cervix. They are often done by men who want to make a record—by men who practice gynecology without knowing much about it. They see a torn cervix, and, without knowing whether or not the symptoms are due to that, proceed to operate. They do it, also, without properly preparing the patient beforehand. Where a lacerated cervix needs operation, as a rule, it needs previous treatment. If the cervix is put in proper condition, there will not be the same liability to bad results.

There is probably no instrument that is more used in minor gynecology than the dilator, and there is probably no instrument that can be more abused than the dilator. Professor Goodell has reported to this Society many cases in which forcible dilatation has been used with grand results. I have used forcible dilatation in many cases, and have never had any bad results. The reason is that, when I began the study of gynecology, I was taught how to use it properly and not to use it in every case. Take the sharply bent womb, and all the pessaries made will not straighten it. You must put something inside, either a dilator or a sponge tent. Again, let the uterus become congested and the mucous membrane swollen, closing the uterine canal and causing dysmenorrhœa. You can cure that case in from two to four treatments by dilatation, while you may treat it by other means for months without doing good. The dilator is a surgical instrument, and one which must be handled carefully. You must know how to do your work before you attempt to use it.

Now, in regard to the use of the sound. I hear gentlemen state that they can outline any uterus without the sound. I have tried that, but have never been able to do it. Take a uterus enlarged, like this sketch, and I defy anyone to say in what direction the canal runs. It may be a uterus in the normal position with a fibroid of the posterior wall, or it may be a retroflexed uterus with a fibroid on the anterior wall, or a

plastic mass between the uterus and bladder. It behooves us to use the sound carefully. If a man tries to force the sound into the canal, he will certainly do damage. If, however, he will outline the shape of the uterus as well as possible, and then bend the sound to fit as nearly as may be, and then make effort after effort, he can, in the most distorted uterus, get the sound in without damage. Then, in regard to the curette. These usually have a sharp, cutting edge. Such an instrument is hardly safe for an able practitioner to use, and is not safe at all in the hands of an unskilled person. Where inflammation extends from the uterine cavity to the tubes, after the use of the curette, it is not so much from the instrument as from the man who uses it.

I should be loath to give up intra-uterine applications. I have used them a long time, and, while sometimes pain has been caused, they have never done any serious damage. As Prof. Wallace used to say, "Some uteri are sensitive to the slightest touch, and some are as stupid as oxen." When you make an application, you must know the uterus which you are treating. Nitrate of silver used to be a common application, but it is one of the worst that you can make. It will, as a rule, produce cicatricial contraction of the canal. Nitric acid, although so much stronger than nitrate of silver, is not so apt to do this; but nitric acid is rarely required. In a case of fungous granulation, I should not hesitate to scrape out the whole inside of that uterus and make a strong application, and after watching the patient for a short time, send her home, and not expect to have any trouble. This is because I know my cases. I do not do it to every case. I think that Dr. Price will find that the dangers from minor gynecological operations are more because of want of good, sound judgment in the practitioner, and not so much in the operation itself. I cannot agree that pelvic troubles are always due to these minor operations.

DR. JOSEPH HOFFMAN: I have put on record in the Obstetrical Society a case where the uterus was perforated by the curette, and this case serves to show that the remarks of Dr. Da Costa enforced the argument which Dr. Price endeavors to bring out, to wit, the danger from the widespread use of the uterine sound, the curette, and the dilator, as advocated by some. I believe that, if we took all the gynecological instruments invented and put them together and multiplied them by ten, we should have no such instrument as gives such bad results as the dilator. It is easy for Dr. Da Costa to claim that he knows when to use it and when not to use it. I think that he over-estimates his ability to say whether he has ever done harm by it, for patients rarely come back after they are harmed. I have seen to-day two patients that had been treated by the curette, and from whom I have removed the ap-

pendages. In one case that I know of, the uterus was torn by the dilator, then a sponge-tent was put in and allowed to remain I do not know how long. You know the rest. In the case in which the uterus was perforated by the curette, the operation was done by a gynecologist of considerable experience. Nevertheless, the uterus was ruptured and peritonitis was brought on and abdominal section was necessary to save life. I have to-day had two other women who were treated by minor gynecology; they were both left very miserable. In one the vagina is much contracted and the pelvic viscera are certainly affected. In one of these cases, especially, electricity was used *ad nauseam*. The history is this: first, dilatation and scraping; then, closure of the perineum; and then, opening of the abdomen. In regard to operations on the cervix and perineum, we are to remember that operation on the perineum is not so apt to cause trouble as operation on the cervix.

What operations on the cervix are necessary? Every cervix with a slight laceration does not require operation. Some of these heal without suture, although traces of the damage may remain. The preparation of the patient often shows that operation is unnecessary—puncture and the ordinary derivative procedures so reducing the size of the cervix that the laceration almost disappears. In regard to ulceration of the cervix, I do not believe that there is such a thing, except as the result of bad laceration or specific disease. In laceration the ulceration is only apparent; it is really an erosion due to eversion and hypertrophy.

The curette in some cases seems to be a necessary evil which we cannot do without. I have found it useful in getting rid of putrid *débris* from a miscarrying uterus, in the early weeks of pregnancy, when the use of the finger is thoroughly clumsy and painful, if not impossible, without previous dilatation with a tent. In the presence of such detention, the use of the tent is not without danger, since, during the period of its presence in the cervical canal, all channel of escape for decomposing material is shut off. I can say that I have had no bad results, that I know of, in the use of the instrument.

DR. WILLIAM E. ASHTON: The question of the use of the dilator depends upon one or two facts. First, as to the condition of the uterine appendages and their surroundings; and, secondly, properly selected cases. I do not imagine that anyone would use the dilator when we have present acute or chronic inflammation of the uterine appendages. I think that anyone who has had experience in the use of the uterine dilator would hesitate to employ it except in selected cases. I believe that where we have the pelvis perfectly free from local disease, and in cases where the uterus is strongly anteflexed and perfectly mov-

able, and upon the introduction of the sound we find that there is a point of intense pain at the internal os, we shall find in a certain proportion of cases that good results are obtained from the dilator. It is nonsense to talk about the causes of dysmenorrhœa. It is only a symptom. The vast majority of cases of dysmenorrhœa are cases which have a distinct tubal or ovarian origin. It would be absurd to rapidly dilate in such cases. In regard to Emmet's operation, I agree with Dr. Price in reference to minor gynecological operations dealing most disastrous results in the pelvis. I grant that there are cases, in which the uterus is in a state of subinvolution where a plastic operation will bring about a cure, but I do not believe in operating on the uterus if there is any diseased condition of the appendages. Any manipulation under such circumstances is apt to set up inflammation. Four years ago, I had a case of bad laceration of the cervix in a woman, with pus tubes on both sides. I refused to operate on account of the disease of the appendages. She then went to New York, and was operated on by a prominent gynecologist, and died of large abscess, the result of the operation lighting up the old inflammation.

DR. DA COSTA, in answer to Dr. Ashton: I probably did not make myself clearly understood. I do not want it understood that I would do an operation on the cervix if there was inflammation in the pelvis, such as pus tube or anything else. My teaching is: When there is violent inflammation in the pelvis, not to do any operation on the uterus, and to hesitate to use the sound.

DR. J. M. BALDY: I think that there is no question in the minds of gynecologists that Emmet's operation is a much abused operation. I think that it is also true that the vast majority of these ill-advised operations on the cervix are done by men who have no gynecological experience and who know very little about gynecology. I can recall two cases in which I was recently called to operate on the cervix by general practitioners, and by whom I was informed that the lacerations were very bad and that the woman was suffering greatly. On examination, the tears proved to be comparatively slight, and needed no interference. There are some cases in which a cervix operation at first sight appears justifiable. These are cases in which the cervix is torn to the vaginal vault. I care not if the cervix be torn on both sides to the vaginal vault, if there is not eversion and erosion, or much scar-tissue, there is no reason for operation. I should be loath to give up forcible dilatation in certain cases. It is not to be done in every case of dysmenorrhœa, for the vast majority of cases of dysmenorrhœa are due to ovarian or tubal disease. I believe that in the vast majority of cases where trouble follows the use of the dilator, there has been preëxisting pel-

vic trouble. I do not think that a carefully done dilatation in a healthy pelvis will do harm. It is admitted that it does tear uterine tissue, but that this can cause trouble, unless the wound becomes septic, I am not prepared to admit.

The use of the sound in the hands of a doctor is in inverse proportion to his skill. The man who is skilled rarely uses it. In such cases as have been mentioned by Dr. Da Costa, I see no use for the sound. I do not see anything essential that it could tell. I must say that I have not seen a uterus of the exact shape he has figured on the board. In the vast majority of cases I have been able to tell which was fundus and which was tumor. If we are dealing with fibroid, it makes no difference what wall of the uterus it occupies. I do not suppose that I use the uterine sound once a month.

The curette, I think, is a valuable instrument, but it is abused and used indiscriminately. After abortion, I find it most valuable. In some cases of chronic endometrial disease it is valuable. I believe that it will remove almost all necessity for intra-uterine treatment. I find such applications rarely called for except, perhaps, the application of nitric acid or iodine, after the use of the curette. I think that the dull curette is useless. The only rational instrument to use is the sharp curette. I was recently called some seventy miles to see a case where the physician assured me that the uterus contained nothing, as he had twice gone over it thoroughly with the dull curette. I used a sharp curette and removed large masses of placental tissue. The sharp curette can be used with as little danger as any other instrument, if used properly in skilled hands.

DR. J. M. FISHER: I am engaged in treating a number of uterine troubles with electricity. Dr. Price has stated that the use of the electrode is fraught with much danger. That the introduction of any instrument into the uterine cavity carries with it a certain risk is not denied, but that the electrode is especially responsible for many of the diseases can certainly be questioned. There are certain diseases of the uterine tissue and lining membrane that can be most effectively treated by properly applied galvanism. I can cite one case in which the use of electricity saved the patient from undergoing a major pelvic operation. A woman, forty-two years of age, had a fibroid uterus with hæmorrhages, so that she was confined to bed half the days of the year. At the time that I was called she had been laid up for nine weeks and was exsanguine from loss of blood. She had been treated by two good practitioners, and, failing to give her relief, operation was proposed and about to be done. I made a positive application of electricity, and after the first or second application, the hæmorrhage was arrested. Four applications, extending over a period of

twenty-one days were made. This was in November and December, 1889. After that she menstruated regularly until May, when she was again seized with hæmorrhage. I was out of town, and the bleeding continued three weeks. On my return I made a positive application of electricity, and since then the menstrual discharge has been regular, lasting three or four days.

DR. C. P. NOBLE: I am convinced, as the result of my experience, that the less the uterine sound is used the better for the patient. Recently a case passed through my hands in which the question of pregnancy was mooted. She afterwards fell into other hands, and the sound was passed three inches and the patient was supposed not to be pregnant. She was, however, seven months pregnant, as subsequent events showed. The information given by the sound is often delusive. I, however, cannot see how the simple passage of the sound, provided it be clean and passed through a speculum, with a clean cervix, should set up pelvic inflammation, provided such trouble does not already exist. This, however, is neither here nor there, for I do not see that we need to use the sound in diagnosis. In small uteri it is not needed, because the organ can be outlined bimanually; while in large uteri, where tumors are present, the instrument may not reach the fundus, and so give incorrect information. I must agree with Dr. Baldy, rather than with the author, in regard to rapid dilatation. I should be loath to give it up. I have never seen harm follow rapid dilatation in any case. This is due to the fact that dilatation has been used in cases in which the disease is limited to the uterus. I agree that it is useless and dangerous to dilate the uterus when tubal disease is present. In uterine disease it is capable of doing a great deal of good. I am quite sure that a certain number of cases of tubal disease are set up by a narrow cervix. The secretions of the uterus cannot gain egress and set up endometritis, and the inflammation travels into the tubes. In these cases, if the cervical is dilated to allow the free egress of secretions, it will be a positive factor in the prevention of tubal inflammation. In such cases as were mentioned by Dr. Ashton, of acute anteflexion, the dilator does a great deal of good. In fact, in regard to all these minor measures which have been mentioned to-night, I find them of service, but the fact must be emphasized that they are useful only when the disease is limited to the uterus; and that the uterus should not be operated on, in any way, in the presence of pelvic inflammation, particularly abscess.

Why we should give up the curette I cannot understand. There are many cases of hæmorrhage from the uterus due to uterine disease purely, where there is no ovarian or tubal disease. In such cases the use of the curette will permanently control the hæmorrhage. I think that

one reason septic trouble follows minor operations is because antiseptic precautions are not observed. I think that is the case with the dilator. If used on the office table, it is impossible to employ complete antisepsis. If such precautions are used, and there is no extra-uterine inflammation present, I do not think that inflammation will follow any of the minor gynecological operations.

DR. PRICE: I am sorry that the discussion has taken the direction that it has, for it does not give me an opportunity to express myself thoroughly; it does not give me an opportunity of pulling out a number of telegrams; it does not give me an opportunity of calling things by their right names. I have thrown down the gauntlet, and no one has quite taken it up. Some one has spoken of minor gynecological methods. In a recent article a writer prefaces what he has to say by giving details of methods for the treatment of "ordinary gynecological troubles." I do not know what "ordinary" gynecological troubles are. If it means from 9 o'clock to 3 in an office, with a nurse and a Sim's speculum, peeping at crevices and taking ten dollars from each patient, then I understand it. He is the great mischief-doer. He tinkers, dilates, cures, and passes the sound, and in from four to six weeks I get a telegram to come and open the abdomen to save the patient's life; that the woman is leaking; that she has a pulse of 130-140, with a temperature of 104°. This occurs weekly. A speaker stated that there is no harm in electricity. Three fibroids in that jar have pus in them as the result of the use of electricity. Of the twenty specimens in that jar removed during August, 50 per cent. followed dilatation, closure of the cervix, the use of the sound and the curette. These specimens have come from four clinics in this city and from ten prominent gynecologists. They all had sections to save life, and all were greatly complicated operations. In regard to the sound, Dr. Ashton has said all that I am capable of saying. I have not used the instrument for many years. It is a common method of determining the existence of pregnancy, particularly among homœopaths, although not confined to them.

In comparison with the former state of the same subject, we must inquire into the causes which must have been at work during the past few years. This private-office work has a great deal to do with it. Many of these men are simply cervix-feelers, and never find anything above it. There may be a mass larger than the uterus to one or both sides, which he fails to find. They are not anxious to find them, and would not be troubled by them. The dysmenorrhœa in infantile uterus has nothing to do with the uterus. Pelvic pain in all infantile conditions of the uterus and pelvic viscera is exceedingly common. In these cases dilatation avails nothing. Dr. Baldy says that he uses the sound once a month. I

presume that he dilates about once a month. I will consider together drainage of the uterus, referred to by Dr. Noble, and the use of the sound and dilator, referred to by Drs. Baldy and Noble. The sound measures about two lines in diameter, but we will say that it measures only one. I am sure that the drainage is quite sufficient through a canal one line or more in diameter. I find that those who have such a love for dilatation always precede it by the use of the sound. If they use it for drainage the indications are not clear.

DR. BALDY: I would ask to what part of my remarks Dr. Price refers. He has entirely misunderstood me. He stated that presumably I dilated for drainage, and that I first pass the sound, which will of itself establish drainage, without the dilator. My remarks were not in regard to dilatation for drainage or anything of the kind. I do not know that I specified what I would dilate for. Time did not admit of my discussing that point. In regard to passing the sound once a month, I do not know that I meant to make that a positive statement. The statement was simply made to illustrate the infrequency with which I use the sound.

DR. PRICE: I thought that I had made that clear. I said that I would call attention to two points—that of drainage, as referred to by Dr. Noble, and the sound and dilator, as referred to by Dr. Baldy. In regard to closure of the cervix, there are a few cases in which the operation is of importance, but the ordinary method of closing the vaginal surface of the cervix only is very imperfect. This forms a large cuspidor-like cavity or retention sac. I have repeatedly split these up, freshened the cervix, and made a perfect cure. I have thrice this summer been called out of the city to open the abdomen in cases in which dilatation had been performed a short time previous.

Disease of the cavity of the uterus and fungous vegetations are far from common. Many healthy uteri are curetted, and it is thought that granulations are found. If the woman had been let alone, she probably would have conceived. The same is illustrated by a class of cases which I have studied among women locked up in a reformatory. Some twenty or thirty women, who had been living lives of chronic inebriety and lust for three or more years, had none of them conceived. After six months' rest, iron, and good diet, the greater number conceived on leaving the institution. In these cases no intra-uterine treatment was employed, and only one examination was made to determine the position of the uterus and its relation to surrounding parts in the pelvis. As a diagnostic instrument, I do not see why any one should want to use the sound. As a student, I never could see what was gained by the use of the sound; in the hands of the trained or experienced it is not needed, and in the hands of the inexperienced it is dangerous.

DOMESTIC CORRESPONDENCE.

LETTER FROM BALTIMORE.

(FROM OUR OWN CORRESPONDENT.)

Prof. Wm. H. Welch on Arterio-Sclerosis—The Attendance at the Medical and Dental Colleges—The opening Lectures—The Johns Hopkins Hospital—The Reconstructed College of Physicians and Surgeons—What the Faculty of the University of Maryland are doing—A new Homoeopathic Medical College—The Baltimore Medical and Surgical Record—Miscellaneous Gleanings.

The colleges and societies have fully resumed work for the season, and with most flattering prospects. Our chief medical society, the "Clinical," elected for its presiding officer for the current year Dr. Hiram Woods, Professor of Diseases of the Eye and Ear at the Woman's Medical College and Assistant Surgeon of the Presbyterian Eye and Ear Hospital, who has been an active worker among the younger set.

The feature of the first business meeting of the same society, held last Friday week, was a paper, or more properly a lecture, by Prof. William H. Welch, of the Johns Hopkins Hospital, on "Arterio-Sclerosis." Prof. Welch devoted his attention chiefly to an exposition of the recent researches of Thoma, which he was able not only to accept but also to confirm by investigations in his own laboratory. The series of pathological changes resulting in the condition known as arterio-sclerosis, originates, according to these authorities, in a weakening and yielding of the middle cord of the arteries. Nature makes an attempt—often abortive though it be—to compensate for this defect by a deposit and consequent thickening of the intima. This view systematizes the subject in its various aspects and shows how under various circumstances as in the fœtus, after labor, in connection with Bright's disease, etc., alterations in the volume of the peripheral circulation are met by a corresponding reduction in the calibre of more central vascular channels. The lecture was illustrated by numerous interesting microscopic and macroscopic specimens.

Among those who took part in the subsequent discussion, more, however, from a clinical than a pathological standpoint, were Drs. Osler, I. Edmondson Atkinson, and Keirle.

The attendance at the Colleges—notwithstanding an anticipated falling off on account of the projected elevation of the standard in 1891 and 1892—is very large. At the University of Maryland there are from 230 to 250 medical students and about 125 in the Dental Department; the College of Physicians and Surgeons has about 304 medical students and the Baltimore Dental College, which is affiliated with it, about 125;

the Baltimore Medical College has about 100, and the Woman's Medical College 18 or 19. The number at the Baltimore University across the Falls is unknown; this institution has organized a Veterinary and a Law Department, Dr. Ward, F.R.C.V.S., having charge of the former.

The opening lectures at the College of Physicians and Surgeons and the Baltimore Medical were delivered by Profs. George J. Preston and Thos. A. Ashby, the former taking for his subject "Higher Medical Education;" at the Woman's Medical College Prof. Jay held forth; the University of Maryland for many years has had no formal opening.

The authorities of the Johns Hopkins Hospital—so far as I have seen—have not repeated their announcement of special courses given last year, although I believe instruction goes on regularly with the internes. The establishment of the medical school in connection with the Hopkins Hospital is delayed, as is well known, on account of lack of funds, the school being a part of the University proper, which has an endowment independent of the Hospital. By a reinvestment of the Baltimore and Ohio stock of the University in good paying securities, that portion of the Hopkins foundation has been relieved of its temporary embarrassment, but it would appear from the appeal which President Gilman made to the wealthy for aid in inaugurating the Medical School, that the funds do not suffice as yet for another large drain upon the University's resources. Judging from the liberality of Baltimoreans to this institution in the last few years, there is every reason to think that the appeal, backed by the President's influence and energetic efforts, will result as successfully in this case as in the former one. The ladies continue their efforts to raise the \$100,000 which they hope and believe will secure admission by women to the privileges of the future medical school. At last accounts some \$60,000 had been raised. From what I have heard there seems to be a strong sentiment in favor of the women among the professors and Trustees of the Hopkins, but whether the latter will decide to make the change when the time comes, especially with so small an inducement as the ladies propose, is quite questionable.

Improvement is the order of the day at our two leading Colleges, especially at the College of Physicians and Surgeons. One could scarcely have realized the possibility, to say nothing of the probability, of the vast changes that have taken place in the condition of this institution within the past two or three years. Their shabby old building, which served the double purpose of a college and hospital, has given place to a grand hospital occupying the entire city spring lot, formerly vacant. In place of the old building itself, a larger and more substantial one is rapidly approaching completion for college purposes exclu-

sively. Whilst a part of the old walls were used in the construction or reconstruction, the arrangement and plan are altogether different, and provision seems to have been made with admirable foresight for the best instruction in medicine attainable under the present methods and with the present resources. Entrance to the ground floor through a wide arched doorway reveals a large reception room, ranged around which are the drug room and nine private apartments for the various clinical departments. The rear of this floor contains apartments for prosecting, vivisection, the manufacture of drugs, and vats for the preservation of forty bodies. A wide stairway leads from the reception room to the floor above. Here are located the reading-room, a spacious and well-lit apartment, the Faculty room, the offices, the chemical apparatus room, a waiting-room, a lecture-room and apartments for the resident physicians and students. An elevator serves for the conveyance of bodies, etc., from the first floor. The rear of the third and fourth floors is occupied by a second lecture-room, which is one of the handsomest I have seen. The lofty ceiling is finished off in wood, the beams and arches which support it producing a fine effect upon the eye. A large chandelier hangs from the centre and a smaller one from the ceiling over the enclosure for the lecturer. Both lecture halls are semi-circular in shape, and contain seats for about 300 pupils; they are provided with strong wooden folding back chairs, the rows of which rise one above the other as in an amphitheatre. The third story front contains the chemical, physiological, histological and pathological laboratories, which are provided—or will be—with necessary apparatus, including a dozen or more microscopes. There are also smaller apartments on this floor for private research. The fourth floor in the lofty mansard roof is appropriated to the purposes of dissection and post-mortem examinations. There are accommodations here for thirty to forty students to dissect at one time. The whole building is heated by steam, and is well lighted; the lecture rooms are to be lighted by electricity. This large outlay by the Faculty, which will cut off their salaries for at least two years, evinces a most commendable determination on their part to be abreast with the better class of medical schools, and they deserve the greatest credit for their really honest efforts and praiseworthy self-sacrifice.

The Faculty of the University of Maryland have recently spent about \$10,000 on their hospital. Besides a general overhauling of the building, a large addition has been erected for the accommodation of the Nurses and the Nurses' Training School, which was instituted under the charge of Miss Parsons, an experienced English nurse. Lectures were delivered during the summer by her and by members of the Faculty to some thirty or more nurses. The change was necessitated by

the departure of the Sisters of Mercy (Catholic) who had been in charge of the building for many years. These Sisters have taken charge of the new City Hospital of the College of Physicians and Surgeons. On their leaving the Faculty decided that the most urgent need of their institution at this time was thorough provision for efficient clinical teaching, of which good nursing is a most essential part. They established their Training School for the purpose of providing a supply of skilled nurses primarily for themselves, and secondarily for the community. The demand for such nurses is greatly on the increase, but what we need are good and competent nurses at moderate prices.

The newspapers announced yesterday the organization of the "Southern Homeopathic Medical College," a new claimant for public patronage in this already overburdened medical centre. Twelve chairs and two lectureships were filled by local practitioners, vacancies remaining in the chairs of surgery and operative surgery. This institution, with its hospital, is the outgrowth of a schism in the homeopathic camp. As they are backed here by a large and wealthy following, the institution will doubtless meet with an early and substantial success.

Simultaneously with the advent of a new college, we are treated to a new medical journal, *The Baltimore Medical and Surgical Record*,—a monthly—T. H. Graham, Editor and Proprietor. The editor, who appears to be a non-medical man, is unknown in medical circles here, at least not to the writer and others. His first number contains forty pages, presenting the usual variety, including a Berlin letter. It is adorned by an engraving and a sketch of Dr. H. P. C. Wilson, of this city. The editor proposes to call to his aid specialists in the various departments, who are expected to contribute original articles, editorials, book reviews and miscellany, for which they are to be duly compensated. The first number presents a very creditable showing, and as the journal is to be only \$1 a year, it will doubtless find a place here and prove a formidable rival to the older *Maryland Medical*.

An important publication has recently emanated from the Johns Hopkins press, being Nos. 3 and 4, of Vol. ii, of the "Johns Hopkins Hospital Reports," octavo, pp. 122. It is devoted to a report of gynecological work done at the Hospital by Dr. Howard A. Kelly and his assistants, Drs. Robb and Williams. It has been looked for in local medical circles with interest for some time, as it was known to be in preparation. As containing the views and ripening experience of one of the most prominent and leading American gynecologists, provided with the amplest means and opportunities for developing his views and carrying out the most elaborate researches.

A brief review of his work may not be without

interest to those interested, many of whom will not have access to the original work. He opens by announcing his working rules to be: 1. Antiseptics up to the moment of beginning the operation; 2. Asepsis through the operation; 3. Preservation of the aseptic state after the operation. Distilled or filtered water alone is used, and instruments are sterilized by steam in a Rohrbeck oven for one-half hour before operation. The patient likewise receives baths for several days, with vaginal douches of the bichloride, 1-1,000, or a 3 per cent. solution of carbolic acid, twice daily. More thorough measures are employed if a hysterectomy be contemplated, as attention to diet, opening the bowels, washing the abdomen with a bichloride solution, 1-1,000, and the administration of $\frac{1}{4}$ gr. of morphia and 30 grs. of bismuth. Minute details are given of the preparation of gauze, towels, sponges and ligatures. The most elaborate toilet of operator and assistants is insisted on—as change of clothes, repeated washing of hands, etc. No antiseptic solutions are used upon the patient during the operation, but distilled water alone, but in dressing the wound the latter is covered thickly with a dry powder of iodoform and boric acid (1 to 7), a thin layer of bichloride cotton is laid over this, then a wide roll of plain absorbent cotton, and the whole held in place by a flannel or muslin bandage. A table is given of fifty cases of abdominal section performed within a period of 139 days. The last case is also numbered 253, implying that the operator has performed that number of sections. There were no exploratory incisions and only two hopeless cases were refused operation. All the cases of ovarian tumor made quick recoveries. He relates a case of pyosalpinx in which the gonococcus Neisseri was found, but only after careful and prolonged search. The patient was a negress, aged 20, and the organism was not found in the other tube, which contained a much larger quantity of pus.

He looks upon the operation for laceration of the cervix uteri, in well-selected cases, as one of the most important of our minor gynecological procedures. A long table is also given of minor gynecological operations. The entire mortality is represented by four cases, viz.:

1. Death five days after vaginal hysterectomy; septicaemia; no satisfactory cause found on post-mortem examination.
2. Death ten days after removal (laparotomy) of diseased tubes and ovaries and a fibromyoma of the uterus; no satisfactory cause for death found at post-mortem.
3. Laparotomy-hystero-myomectomy; peritonitis found at post-mortem.
4. Hystero-myomectomy; a large fibroid tumor filling abdomen; death on fourth day from volvulus; peritonitis found at post-mortem.

Dr. Whitridge Williams contributes a report

of a case of carcinoma of the cervix uteri in a full-blooded negress, a very exceptional occurrence. The work is illustrated by engravings of Dr. Kelly's operating room and by some wood cuts.

ADDRESSES.

THE MEDICAL PROFESSION AS A
PUBLIC TRUST.

*Annual Address before the N. Y. State Medical Association at its
Seventh Session, in the City of New York, Oct. 22, 1890.*

BY JOHN G. ORTON, M.D.,

OF BINGHAMTON, N. Y., PRESIDENT OF THE ASSOCIATION.

The history of medicine through ancient and modern times, reveals the fact that it has always kept pace with the physical and moral sciences, and its origin and growth as an element of civilization, is worthy of consideration and attentive study. It is pleasant, and sometimes profitable to turn on proper occasions from the activities of professional life, to the contemplation of the past, to the sources of our art, to the principles and necessities that called it into existence, to the trials and struggles of our professional ancestry. We shall thereby be the better able to comprehend our own favored position, to understand the extent of our advancement, to what causes we owe our progress, the labors and achievements still before us, and the places of honor to which we ourselves are likely to be assigned when the history of the present shall be written. But I do not intend, certainly not at this time, to call into review the periods which have marked the advent and progress of medicine in the various countries and nationalities of the globe. That has been already done by far abler hands, and is indeed a part of the classical history of our profession.

It is sufficient for my purposes in considering the present position of the medical profession of this country as a "Public Trust," to recognize its status as comprehended under its opportunities for education and instruction, its standard literature and journalism, its social position, its society organizations and ethical spirit, its legal relation, its scientific investigations, and its crowning glory in its opportunities for the prevention of disease and the prolongation of life.

The intelligent people of this country have laid firm hold upon the principle, that knowledge is the universal right, duty, and interest of man, and that the education of the masses is indispensable to the extension and preservation of

free institutions. With the establishment of this fundamental principle, and interwoven into the policy of our State and National Governments, we recognize the reciprocal relations which should subsist between the citizen and the constituted authorities. Our country is our commonwealth. We have all an equal share in her; her laws are alike for the protection of all; her blessings are our common privileges; her glory is our common pride. But common privileges impose a common responsibility, and equal rights can never be disjoined from equal duties. The constitution, which under God, secures our liberties, is in the keeping of us all. It is a sacred trust which no man can delegate; he holds it for himself not only, but for his children, for posterity and for the world. And he who cannot read it, who does not understand its provisions, who could not on a just occasion assert its principles, no more sustains the true character of an American citizen, than the man who would not seal it with his blood.

It is a principle of all good government and older than written constitutions, to provide for the safety of the people, and to secure to them life, liberty, and the pursuit of happiness. Political economy was designed for the improvement of mankind, and that system is a true one which educates and elevates the people; which dispenses equal, exact, and speedy justice; which maintains a high standard of public and private morals; which encourages virtuous industry and seeks to eradicate pauperism and crime.

From the wise system of common schools adopted in this country, and which may be regarded as the true palladium of our freedom, prosperity, and happiness; the door is wide open in the higher schools, in the academies, colleges, and universities for every young man of genius and enterprise. This has been made possible even for the worthy sons of poverty, by private munificence and State patronage; and a liberal education is within the grasp of every deserving student who wills that he will have it. These latter days of the nineteenth century are witnessing the most stupendous strides in every department of science, literature and art; and that man must be indeed a poor observer of the signs of the times, who does not readily associate these

advancements with the modern plans and provisions for education and the diffusion of knowledge.

While every profession and honorable vocation has been stimulated to activity and advanced in power and usefulness, in proportion as it has kept pace with the progress of knowledge; it is with the opportunities afforded the medical profession of this country for education and instruction, that calls for special recognition at our hands. I am not ignorant of the fact that it has been quite the fashion for many years past and even to the present time for essayists, special committees of medical organizations and pessimistic medical writers generally, to deplore the annual exodus of hundreds and thousands of graduates from our colleges. Perhaps the law of supply and demand may not have always operated with precision. Perhaps some or even many of these new disciples of Esculapius, may not have carried with them to their abodes on the distant frontier settlements, all the mature judgment, precision in diagnosis, and skill in treatment, which comes for the most part only by experience and patient, continued study, after college life is ended. But even with the many lamentable exceptions of incompetency and discredit to the profession, I still believe the great majority of the graduates of scientific medicine in this country at the present day are a credit alike to themselves, to the colleges, and to the commonwealth. The time is rapidly approaching, and indeed is even now at hand, when most of the medical institutions organized for instruction, will furnish every facility for a most thorough and efficient education.

The ready acquiescence in the general demand of the profession for an extension of the college term and curriculum, and also a requirement for a proper preliminary educational qualification for entrance upon the study, is evidence of a united desire and effort to elevate the standard of medical education. In part fulfillment of this desire, is the recent enactment in this State of a law creating an independent board of medical examiners; and while with some of its provisions we may well take exceptions, yet as far as the colleges with which we have any affiliation are concerned, and their students, no harm can come to them. While I am a firm believer and advocate of every measure which may tend to maintain and advance the honor and interests of our profession, and recognize the influence of a proper academic training upon the habits, thoughts, and powers of discrimination as well as the advantages and great importance of a well-rounded intellectual culture. I am not yet prepared to say with some, that the doors of our medical colleges should be closed to all persons, except those wearing literary degrees; but I trust the time is near, when their equivalent at least will be the uni-

versal possession of every medical student. With perhaps no exceptions, the announcements of the various colleges of this country for the coming sessions, make it a distinctive feature, that proof of a proper preliminary qualification will be required of students before matriculation or graduation. But while this is encouraging and evidence of some advancement in the right direction, it would be much more satisfactory to the profession if all colleges would state specifically in their announcements the kind of preliminary examinations applicants would be subjected to, or the specific proofs of fitting education required. It is certainly very evident that the trend of the times is in favor of a much higher and more complete preparation for the medical calling; and I trust the day is not distant when not only a minimum qualification will be indicated, but a maximum attainment rightly recognized and honored. Why not have degrees of special significance and distinction in the medical as well as in other professions? The stimulus of emulation is often required to develop the latent talents, and it is but right not only to afford the opportunities, but to recognize and applaud true merit and success. The medical institution that will plant itself upon such a platform, will prove in the end the most popular step ever taken in this country, and around it will cluster an alumni honored at home and abroad. To such an institution endowments are sure to be multiplied until it rests upon an enduring foundation, affording the highest facilities for a thorough and complimentary education, exalting the honor, interests, and usefulness of the profession. But while we are looking forward, working and fondly hoping for the final fulfillment of these perhaps Utopian dreams, still, we may even now ask, are the insinuations true so freely offered from some quarters, that the majority of American medical colleges are far below par, in their opportunities for instruction and their standard of qualifications for graduation? I doubt the justness of this wholesale indictment and slaughter of the innocents without specifications. I am not standing here to shield or excuse any college for dereliction of duty or incompetency, but it seems to me it is high time for the profession to demand a halt in the incessant harangues disparaging to the standing of American medical colleges. Their general abilities for offering abundant opportunities for thorough instruction cannot be truthfully questioned. I believe the great majority of them are more than ready to meet every just requirement of the profession, and that whatever of blame there may be rests at our own doors, in the unqualified and unsuitable material we are permitting or encouraging to engage in the study of medicine. Let every office in the land be permanently closed to students of questionable natural ability and proper preliminary education,

and we shall cease to hear of the incompetency and duplicity of our medical colleges. To those of us who entered upon the study of medicine forty, thirty, twenty, or even ten years ago, it is a surprise and gratification to look over the annual announcements of the colleges for the sessions of 1890 and 1891; or better still to visit those institutions, and be eye witnesses of the many and great opportunities afforded the modern student of medicine, in the extensive curriculum of instruction embraced in the didactic and clinical lectures; the advantages of practical laboratory work in chemistry, physiology, pathology, experimental therapeutics, and other departments of medicine; the admirable arrangements for dissection; the special practical instructions and exercises in the departments of medicine, surgery, gynecology, ophthalmology, and otology designed for graduates and undergraduates; the resources for clinical instruction afforded by the numerous and well equipped hospitals, dispensaries, infirmaries, and asylums; the advantages accruing to the profession from the establishment of post-graduate schools, and polyclinics, and colleges for graduates; and finally the founding of extensive medical libraries and museums, freely accessible to the profession. For all these, and more, we should be profoundly thankful and congratulate ourselves that the closing years of the nineteenth century find the medical profession of this country, with advantages and opportunities for instruction quite equal to those of Great Britain and Continental Europe.

It would consume many years of incessant study and observation to exhaust the resources afforded by such medical centres as Boston, New York, Philadelphia, Baltimore, Chicago, and many cities in the north, south, east, and west. At the risk of criticism, I do not hesitate to affirm, that for the practical every day service of the average American physician, the opportunities afforded in this country for professional instruction, both didactic and clinical, are not only amply sufficient and of the highest excellence, but equally or better adapted to his wants than the renowned institutions of the Old World.

With a general advancement to a higher standard of merit, qualification, and facilities for instruction in our seats of professional learning, the plans adopted for collective investigation of disease, and opportunities afforded for original research; there has arisen for us an elevated, distinctive, and permanent medical literature.

It is impossible to avoid the conviction, that the state of medical literature at any period, is the true and only criterion of the condition of the contemporary science and art; and if the history of medicine sustains this conviction, we may rightfully conclude that it is also true of the present, and that the status of the profession in this country may be inferred from the quality of its literature.

While during the first half of the present century there appeared many standard works of great merit by American physicians, conferring honor upon themselves and upon American medicine and literature; it is during the closing half of the century, that the most marked advances have been witnessed in the rapid issue of volumes of great erudition and acknowledged value; establishing an enviable reputation for American medical scholarship and authority, and the highest appreciation at home and abroad. But the special characteristics of the medical literature of the present day in this country, are largely due to its journals and transactions of its organizations; they comprise indeed the most original matter, and most truly represent the active living thought of the times, and the daily wants of the great mass of the profession. I have no fear of a contradiction in making the assertion, that American medical journalism is not only characteristic of the age and of the country, but has assumed proportions and weight of character unexcelled by any other department of literature, science, or art. The light of medical science emanating from these sources is shedding its powerful rays of quickening influence abroad upon the medical profession of this whole country, molding, guiding, and even controlling their very thoughts and actions in many of the relations of social, ethical, and professional interests.

Honorable and enlightened medical journalism of the present day, is doing, and will do, much more to advance the educational interests and standing of our profession, than all the forces of State and National legislation combined.

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, which from its inception was designed to represent in the broadest sense, the true status and progress of the profession of this country, should be recognized and maintained as the authorized expression of the thought, purposes, and will of American physicians.

A reciprocal relation should exist between THE JOURNAL and the profession, and to this end, it should be on the subscription list of every physician throughout the length and breadth of the land. We are all of us preferred stockholders in that journal, and should see to it that its interests and our own are fully protected. But while acknowledging our loyalty to the Organ of the National Association, we must by no means forget our great indebtedness to those journals issued from the medical press of the larger cities in every section of the country.

They are so replete with the results of laborious research, of large experience, of scientific discovery, and every page filled with the most recent observations and discussions in every department of our science. To rightfully discharge the responsible duties of the trust confided to him, the physician must be informed upon those

methods and advances which increase the usefulness, extent, and exactness of his knowledge; and the greatest and most satisfying aid in all that appertains to progress and improvement, is the reliable medical journal which visits him from month to month, and from week to week. His subscription is an investment compounded many fold.

In the present state of medical science in this country, and the subdivision of its departments for special investigation, we see the activity of united efforts combined in organizations and journals specially devoted to such interests; and hence we find, particularly in the great medical centres, a large increase during the past few years of literature devoted to a definite field of labor. Without calling in question the ultimate utility and effect of this multiplication upon the future of the profession, we may rest assured that the fundamental truths of our science will ever remain, and that we may cheerfully welcome every honest laborer into the fields of our science already "ripe for the harvest."

Our medical journalists have done a great and distinctive service, especially to the younger members of the profession, by inviting and encouraging the frequent expression of original thought for the press.

The systematic and conscientious use of the pen as a means of mental development has long since been fully attested by the recorded experience of the best thinkers and writers of every age. It is the duty then of every physician, not only to select as his daily companions, medical journals devoted to the interests of the profession at large, and work of the general practitioner, and also some publications designed for special fields of labor as his inclination may dictate; but he should also contribute his mite or of his abundance to their columns, recording his observations, his mature thoughts, his conclusions, and sustaining with generous sympathy every effort of real progress in his profession.

Referring to the *social relations* of the medical profession of this country, we are thankful that as yet there are no established ranks, grades, or castes of society, which would assign the members of our profession to a special social standing; but that it is precisely what the education and qualities of the individual make them. The intelligent and gentlemanly physician is not only received as a welcome visitor at the fireside and at the bed of sickness in all shades of society, from the highest in the State to the lowest, the wealthy and the beggar alike; but he is also awarded as honorable a seat in all public assemblies whether social, literary, scientific, or otherwise, as the members of any other class of the community. In part as a compensation for his isolation from the advantages, emoluments, and honors of his highly favored brethren in the

Metropolis; the intelligent, educated rural physician, is not only often a leader in the social affairs of his district, but is usually the central power in every educational, literary, hygienic interest involving the welfare of the community.

The simple title of "doctor," however, does not by any means carry with it a passport into social life, or give him a position above that which his education, habits, and gentlemanly conduct entitles him. It is in the reciprocal relations of the medical profession to the individual that is to be found a field for the highest cultivation of the noblest instincts of our nature. The constant care of the sick, the suffering, and the dying, cannot but imbue the conscientious physician with an appreciation of the greatness of his mission and of the responsibilities he assumes. In the comfort, health, and lives of those committed to his care, he is answerable to the solemn tribunal of his own conscience for carelessness or neglect of duty.

A thorough preliminary preparation and constant efforts for the accumulation of knowledge by research, careful observation, and experience can alone qualify and render his life serene in the consciousness of having faithfully tried to fulfil his professional obligations as a "Public Trust."

The relations between the physician and patient are necessarily and so often of an intimate and confiding character, that the small aggregate of cases of misplaced confidence is a compliment to the integrity of our profession. This relationship involves the strictest rectitude and every moral attribute of the Christian gentleman.

The virtues above all others that a physician must possess, are self-denial and self-devotion, not only to carry him through the slights and crosses in his career, but also to exalt him above all and every sort of temptation, that he may always be the perfectly reliable repository of personal and family honor. This reliability is the most essential quality of the physician's character. No talent, no skill, no genius even, can compensate for its absence. But the multiplied public and private relations of our profession are known to us all, happy indeed are we, if we faithfully strive to guard the trust committed to our care.

Our duties are arduous, peculiar, and responsible, and no illegitimate considerations should divert us from their strict performance. If the physician's best services are not always appreciated and rewarded, if he may never hear the resounding applause of the populace which follows the spasmodic efforts of the orator or statesman, nor his pathway strewn with flowers like the returning conquering hero, yet if he has conscientiously and with fidelity tried to do his whole duty to those committed to his care, when he comes to give up his stewardship he may hear

the welcome plaudit, "Well done thou good and faithful servant."

To the *Society Organizations* of the medical profession of this country, we must look for the effective and permanent influences which have been exerted, giving to it as a body vitality, power, and character. The English of an old Greek proverb, that, "one man is no man," concisely expresses the great truth that man is never independent of his fellow-man. The development of his physical, mental, and moral capabilities cannot be effected alone: nor can the great purposes of life, for which he is intended be accomplished, and the comforts and happiness, which he is constituted to enjoy be realized, without the coöperation and companionship of others. However humiliating this reflection may be to man's feelings of self-sufficiency and self-complacency, he is forced to acknowledge its truth when he observes the progress of individuals and the advancement of civilization. The advantage and even necessity of association for the promotion of useful knowledge has been so generally recognized, that "learned societies," consisting of intellectual men voluntarily united for this purpose have been formed and continued for many generations, especially in the Old World, under names indicative of the particular branch of human learning they have been designed to promote.

The objects of these associations have not been simply the acquiring of knowledge, but the more useful one of communicating it, in announcing discoveries, deducing general laws from numerous facts, correcting false theories, and rendering knowledge more accessible and useful. A society is none the less entitled to the appellation of learned, if it be quite professional, and if its plan be not as comprehensive as that of the Royal Society of England, which is intended for the promotion of general literature, philosophy and natural history.

When we see the most distinguished physicians in Europe and America, those who have done the most to enlarge the boundaries of our knowledge, standing shoulder to shoulder as originators and active supporters of associations, believing them necessary, for mutual improvement and the advancement of medical science; the medical men of this day, young and old, may well distrust their own judgment, if they are inclined to doubt the utility of medical societies. There are abundant reasons why the medical profession should enjoy the full benefit of associated talent, and feel the influence of a liberal, enlightened and earnest consideration of the various topics which must claim the attention of the physician. With the great advantages we possess, we should as associations, and as a profession, strive to develop our science more rapidly and more perfectly in the future than it has been

in the past, and that our progress should be more marked in all that relates to the higher aspirations of our calling. The period in which we now live demands an intelligent and catholic spirit, as a pervading element in the whole body; so that the improvement in the science shall correspond with the progress of our race, in all that is great and worthy of the age. May this Association be the grateful agency in the unification of the members of the medical profession of the State of New York, in all that relates to their honor, to their interests, and to their usefulness.

With the incentives to society organizations, there arose a more formal recognition of the *ethical spirit* or *moral tone* which should pervade and control the profession. It became an important part of a medical education and included, not merely medical etiquette, but rules for the guidance of the physician in all the relations into which he might be called by the practice of his profession. Without arrogating too much and within the bounds of modesty, we may assume it is probable, that not another equally numerous class of men can be found, who more rigidly and tenaciously adhere to rules of an ethical character, than is done by the medical profession of this country. Admitting of exceptions, there is a disposition on the part of the regular profession of medicine, to foster and protect the interests of each other; and with a commanding moral tone to frown upon and discourage every immoral practice and vicious conduct among its members; believing the greater the trust, the greater the betrayal.

Referring to the *legal status* of the medical profession of this country, it may be said with some exceptions, that legislative enactments regulating the practice of medicine have been in the main salutary, and if thoroughly enforced, may be productive of much good to the profession and safety to the people. The highest interests of society require the adoption and enforcement of such legal regulations as will ultimately insure a high standard of education and mental discipline before entering upon the study of medicine, as well as efficient methods of securing the attainment of a fair standard of professional qualification before receiving a license to practice.

The regular medical profession do not ask of the State special privileges and immunities, no, they ask that society should exact greater guarantees from them, and that a still higher standard of qualification be demanded; they ask that the public should take earnestly in hand for self-defense, means for repression against the hordes of impostors, who trade on public credulity; they ask that both the secular and religious press, the clergy and men of position and influence should consider well the moral responsibility they as-

sume in the thoughtless or intentional commendation of the plausible quacks and their worthless nostrums.

It is, however, the *prevailing spirit of scientific investigation* in the medical profession that has marked its career in the past and is leading it on with rapid pace from discovery to discovery, from victory to victory over the forces of nature in the production of disease; alleviating the physical sufferings of humanity, rescuing from preventable disease and from untimely death. There is nothing more satisfactory in the present aspect of medical science or more likely to raise it above the region of empiricism and place it on a higher scientific standard than the efforts now being made to render our knowledge more definite and exact; nor are signs wanting which point to the probability of such a consummation. We see on every side, the more rigid application of the inductive method of investigation brought to bear on the great problems of medicine, and we doubt not that the observations which are being carried on by earnest workers, especially those conducted under the plan of collective investigation, and by original research, will ere long bear still richer fruit leading to generalizations of the most important character, largely increasing our powers of differentiating between the variations which disease presents, diagnosis and prognosis made more easy and exact, and treatment more successful.

The spirit of scientific investigation which is becoming so characteristic of the present period in the history of our profession, must have derived an impetus and beneficial influence, from the more active cultivation of the physical sciences, which has lately assumed an important and proper position in the educational curriculum of the higher schools, academies and colleges of our country.

Resting, as medicine does, on a basis of scientific observation, and depending for its advancement on research and the practical application of discoveries in science, it is intimately associated with the development and progress of other sciences. In fact, there is scarcely nothing in the whole range of nature or of art, which the physician may not make use of for the purposes and accomplishment of his work. There is also another and not unimportant circumstance connected with the more general cultivation of the physical sciences which is destined to exert a beneficial influence upon the status of our profession. I refer to the higher and intelligent estimate in which the scientific physician will be held by the public at large. In proportion to the general diffusion of scientific knowledge in the community will be established for our art a recognition of its just claim on the confidence and gratitude of mankind.

But the crowning glory of the medical profession is its *opportunities for the prevention of dis-*

ease and the prolongation of life. Herein is consummated the responsible trust committed to our profession. In the economy of the State seeking for the preservation of the health and lives of a classes of citizens, it becomes necessary to enact sanitary laws and to enforce obedience to them; but in order that the people may know just what to do and how to protect themselves from the ravages of pestilential disease, State Boards of Health are created for the express purpose of diffusing the needed information. Sanitary laws are simply an application of the science of medicine in the form of remedies or preventives to the people of the State. They teach not only the inestimable blessing, life-giving and life-preserving influences of glowing sunshine, pure air, pure water, and wholesome food; of the importance of ventilation, drainage, disinfection, and vaccination, but also the absolute necessity of a proper use of these great gifts of nature, chemistry and discovery.

It has long been recognized as the peculiar province of the medical profession to aid the authorities and recommendations of the State in all matters connected with public hygiene; and especially is this true, in the efforts to avert an impending scourge or to abate the ravages of those terrible epidemics, which destroy life with the fearful rapidity of a tornado, whose pathway is marked with desolation and while they continue strike a whole community with terror and dismay.

The sacredness of human life and the inestimable value of health are incentives that can be always relied upon to secure the coöperation of all true physicians in every matter relating to the sanitary condition of the State and the lives and health of the people. It is in this relation that our profession can best reciprocate its obligations to the public and honor the trust confided to its keeping. There is indeed a vein of chivalry in the medical profession. It heeds the cry of suffering from the poor and lowly, and no pestilence stricken city has ever made an appeal for aid without meeting with a quick response. It has no secrets, no patents, but always holds its gifts of healing in trust for the public good. But busy as we are with the demands of an exacting profession, it is quite possible that many of us have failed to recognize in its true character, that other and important trust, the service that we could render the community by diffusing among the people by every available method, pertinent, reliable, comprehensive, popular sanitary knowledge.

Medical philanthropy and enlightened statesmanship, have made success possible in a grand sanitary movement throughout this country, by organized effort against preventable disease and unnecessary death, against the ills which torture humanity and enfeeble the State. The individ-

ual physician, each in his own sphere a power, has been foremost among all the agencies to mold public favor for organized hygienic work.

United in their influence, physicians have inspired confidence and a willingness among their patrons and neighbors to cooperate with them in their efforts to discover and remove the preventable causes of disease from their midst. When we cannot legislate, we can still teach; when we cannot command, we can still warn, and neither the existence nor absence of power, neither the expediency nor in expediency of interference by the proper authorities, can exempt us from the duty of knowing what is amiss in the sanitary condition of a community, and diffusing that knowledge far and wide.

Undoubtedly the first and most important step is the education of the masses in the essential facts of sanitary science. There never was so teachable a people as our own. The respect for science is wide-spread among them, and our public education has made a large body in every community sufficiently acquainted with the elements of science to receive with profit its practical application in matters of life and health.

The medical profession can best promote sanitary progress, by aiding in the dissemination of information as to the established facts of the etiology and protection from preventable disease, and the inevitable consequences of their disregard. This can best be attained through sanitary associations and publications, and especially by calling to our aid that important agency and instructor, the secular press, which has indeed become in this country for the citizen what the school is for the child.

Groaning night and day under the weight of its mighty energies to keep pace with the advancement of civilization, commerce, science, art, social, political, and religious activities of the age, the press wields the mightiest power for influence in the land.

It is characteristic of the American mind in its inventive genius and practical application, to utilize every power within its reach, to make subservient every agency to its interests, and there is no nation on the globe where the masses of the people absorb so much reading matter from the infinite variety of publications. The newspaper in this country is not only one of the luxuries, but is almost a necessity in every family; it is true it has its shortcomings and some objectionable features in its tendency to sensationalism, and oft *quasi* advertisement of quackery, in its apparently editorial endorsement of the wonderful cures of some secret or patent medicine; yet it is undoubtedly an institution of the greatest value and power for good, and should be utilized by the medical profession and sanitarians in the diffusion of hygienic knowledge among the people.

In the furtherance of this thought, I offered some suggestions in an address which I had the honor of delivering at the annual session of the Third District Branch of this Association, in June last, on "The Popularization of Sanitary Science," and which, with your indulgence, I desire here to reproduce.

My proposition was this, "That the medical organizations of this State shall be invited to appoint annually a special committee on 'Popular Sanitary Science,' whose duty shall be to prepare or supervise familiar articles for the secular press on subjects involving the care and protection of life and health of the individual and of the community, in accordance with the accepted principles of sanitary science. That State and local boards of health shall also be solicited and urged to publish for free distribution, through the medium of the public schools, tracts on practical sanitation."

From some such plan as I have thus indicated, or the organization of a Central Bureau or Council of Hygiene and Public Health connected with this Association, there would emanate a flood of light and practical knowledge, instructing an intelligent people in the principles, truths, and proper application of sanitary science; making possible a grand sanitary movement against preventable disease, and thus fulfil and magnify the trust committed to our profession. It is fitting that this Association, having a community of sentiment relating to the honor, the interests, and the usefulness of the medical profession; and within and around it the elements of permanency and success, should take the initiative step and afford an example worthy of adoption throughout this whole country.

Whatever of progress there may be in the coming century, in the advancement of our science in all that truly appertains to its highest mission, will emanate from a spirit of honest purpose, of profound study, of patient research, and a full recognition of the obligations resting upon each member of "the medical profession as a public trust."

ANTISEPTIC LIQUID.

The following formula is in use in some of the hospitals and dispensaries as an antiseptic dressing:

Boric acid, 240 grains.
Salicylic acid, 30 grains.
Water, 2 pints. Dissolve.

FOR CARDIAC DROPSY.

R— Digitalis, gr. xij.
Sennæ fol, ʒ ss.
Aquæ bullientis, ʒ vj.
Fiat infusum, et adde:
Sodii iodid, ʒ ij.
Sodii phosphat, ʒ vj.
M.—S. ʒ ss every three to six hours.

—Gerhard.

ORIGINAL ARTICLES.

THE SURGICAL TREATMENT OF NON-PEDUNCULATED ABDOMINAL TUMORS.

Read in the Section of Obstetrics and Diseases of Women at the Forty-first Annual Meeting of the American Medical Association, held in Nashville, Tenn., May, 1899.

BY HENRY O. MARCY, A.M., M.D., LL.D.,
OF BOSTON.

The ovarian cystoma which develop without a pedicle are rare, and yet are met with sufficiently often to make their study of interest and practical importance. They have been called intra-ligamentous, under the belief that they develop within the folds of the broad ligament, but I have never been able to demonstrate such origin. The explanation offered is that, by some error of development, the embryonic ovary becomes displaced. It has also been assumed that adhesions of the ovary to the folds of the broad ligament might cause these to grow with the tumor, and thus form a capsule over it.

The ovary, when not diseased, is often found with some degree of variation of attachment, as well as distribution of vessels. The pedicle may be so short that the deeper portion is almost, or quite within the reflexion of the peritoneal investment of the ligaments. When such a part becomes cystic, it will, of necessity, in its development, carry before it the peritoneum, and with it portions of the broad ligaments. Every operator, of considerable experience, has met with examples of this class of cases, and it has happened to me to find them in considerable variety, both as to the character of the growth and its origin. The variation in point of development will cause a change of relationship of the surrounding organs. The uterus and bladder may be carried quite upwards and to the side opposite the point of origin, when this is nearly central; if it commenced anterior to these organs it will be crowded into the pelvic basin; if posterior to the uterus, the cyst may be deeply planted within the pelvis. I have removed, with great difficulty, such a cyst, multilocular, within a few weeks, where the tumor pressed quite down into Douglas' cul-de-sac, behind the uterus and bladder, completely filling the pelvis.

The attachments also vary greatly in their appearance. They may be thick and vascular, the ligaments so changed as to be recognized with difficulty. In one case, a dermoid cyst, weighing about eight pounds, but the tumor more solid than fluid, the outer fold of the right broad ligament, which was distinctly hypertrophied throughout, was carried over the tumor quite to the base of the liver. In another, a large monocyst, the development appeared to be beneath the peritoneum, posterior to the ligaments, extending

behind the cæcum, quite to the root of the mesentery.

The cysts of the broad ligament are usually single, but they vary considerably in character, two of the most difficult of removal which I have ever met having been proliferous, or papillary growths. It is important for the physician, as well as the surgeon, to be familiar with the varying phases of such development of pelvic tumors, because of diagnosis, as well as treatment. It may and often is impossible to differentiate clearly these growths before section, but the diagnosis must be determined sufficiently to decide upon exploration; as early operations are advised in order to avoid complications which, in their further development, add very greatly to the difficulties and dangers of removal.

The exact knowledge of pelvic tumors must often remain uncertain until after exploratory section, and the most experienced observers are not seldom the least sure of conditions which may exist. Where this is advised, it may seem almost superfluous to add, that the operator should do it with all the care requisite to meet the demands of modern surgery, that he should be prepared for any emergency, and deal with the factors involved therein.

We all remember the intense interest with which, for many years, the disposition of the pedicle of ovarian cysts was held in consideration. It may be assumed that few would now question its treatment by the intra-peritoneal method, with, in all aseptic cases, the closure of the abdominal wound.

The more general method, advised for the treatment of a large class of cystic tumors without pedicle, is a resection of as much of the cyst-wall as possible, and carefully stitching the retained portion to the lips of the abdominal wound, thereby shutting off the general peritoneal cavity, and treating the remaining cyst-pocket as an open wound with drainage. Even this is oftentimes exceedingly difficult, and the resulting mortality rates, in the hands of our most expert operators, are very large.

In the treatment of solid tumors of the pelvis, uterine growths especially, a great majority of operators still follow this method in a modified way, by making, so to speak, a pedicle out of the lower portion of the uterus, and attaching it, after constriction, extra-peritoneally, with the object of making it an external wound. The arguments urged in favor of these methods are similar to those, at an earlier day, advanced for the external treatment of the pedicle of ovarian cysts by the clamp, etc.

In a certain very large measure, the objections to this method of treatment are those which caused the abandonment of the extra-peritoneal treatment of the pedicle, greatly emphasized. Those who attempt the entire removal of the

growth and the closure of its base of attachment, do it by ligation in section, with the parts oftentimes so imperfectly secured, that great danger from hæmorrhage ensues, and frequently loss of life. Most operators who thus treat the basic attachment of the tumors hold subsequent complications in such fear that they do not deem it advisable to close the abdominal wound without drainage which, of itself, is an added danger of serious character.

The latest publication upon the subject by Dr. Meredith, of London,¹ I quote at some length, since it gives the method usually adopted in the Samaritan Hospital, where in all abdominal surgery the drainage tube is in general use.

Complications arising from extension of the growths beneath one, or possibly, both broad ligaments, with accompanying upward displacement and close adherence of the urinary bladder to the anterior surface of the tumor, as a consequence of its original development from the lower segment of the uterine body, often necessitates extensive enucleation in order to form a pedicle for the application of the *serre-nœud* wire. Occasionally, in such instances, the removal of the uterine appendages may be found feasible, and should then be performed in place of the alternative operation of hysterectomy. But, more often than not, in cases of such nature as that above described, the first-named procedure is not available with safety, and the major undertaking has to be faced. The chief dangers entailed thereby are due to hæmorrhage, which must, in the first place, be avoided by securing the ovarian vessels in either side of the uterus. This is to be effected by transfixion and ligature of both broad ligaments below the level of the uterine appendages, and followed by their subsequent division after means have been taken to control the return circulation from the upper portion of the tumor, by the use of compression forceps. The next step required is that of freeing the displaced bladder from its connections with the anterior surface of the tumor. With this object, a horizontal incision through the capsule of the growth, beginning and ending, at the seat of ligature of the broad ligament, is carried across the front of the tumor, passing at a level of half an inch, or rather more, above the upper limit of the adherent bladder, which is then stripped downwards sufficiently to avoid its subsequent inclusion in the *serre-nœud* wire. Should these means not suffice for securing a suitable pedicle, resort must be had to further enucleation, necessitating the constriction of the base of the tumor by the use of an elastic ligature twice looped, and secured by clamping with artery forceps. Care should be taken to include in this ligature both the ovarian pedicles, and also the free border of the previously divided capsule connected with the fundus of the bladder. A horizontal incision through the uterine capsule, connecting at either end with the seat of ligature of the broad ligament, is now carried across the posterior aspect of the tumor, the base of which is then rapidly enucleated sufficiently to admit of the application of the *serre-nœud* wire, below the level of the elastic ligature, which is subsequently removed. The ultimate success of the operation, as before stated, depends in great measure upon the proper adjustment and management of the stump, by the adoption of means for ensuring the early protection of the peritoneal cavity from the dangers entailed upon it by the necrosis of the tissues constricted by the wire. The tumor having been cut away, after transfixion of its pedicle by a stout pin passed immediately above the wire, the distal portion of the remaining stump is to be trimmed down as much as

possible, and its raw surface is then covered in by lacing together the edges of its peritoneal investment with a continuous suture. The margins of the divided parietal peritoneum are now accurately adjusted around the stump in the groove formed by the wire, before being closely united at its upper border by a silk suture, which should also include a fold of the peritoneum covering the posterior aspect of the stump immediately below the wire. The ends of this stitch are then cut short, and the rest of the abdominal incision is closed in the usual manner. Finally, the stump is surrounded and covered in with dry, absorbent dressing, which should be left undisturbed for at least five or six days.

In an interesting paper published by Dr. Skene,² of Brooklyn, after emphasizing the process of enucleation quite as I have practiced it for years, he advises subsequent treatment as follows:

The management of the ligaments after the cystoma is removed, is first directed to the control of hæmorrhage. In some cases a general oozing is all that there is. Occasionally a wounded vessel here and there needs ligating. When the cyst extends deep down into the pelvis there is often very troublesome bleeding from veins. These should be ligated, if possible, but if that cannot be done, pressure with a hot sponge should be tried, and if that fail, styptics may be used. The ligamentous capsule now presents a pouch, the inner surface of which is raw, and from which there will be some bleeding and much serous oozing. This should be treated as follows: The upper portion of the opposing sides should be folded in so as to bring the peritoneal surfaces together, and these should be fixed by a continuous catgut suture. The suturing should begin on both sides, and be from the sides toward the centre, and close the parts, except at a point beneath the abdominal wound, where an open space should be left for the drainage tube. If the ligaments thus brought together by sutures can be brought up to the lower angle of the abdominal wound, they should be fixed to the abdominal wall by silk sutures passed through the ligaments on each side of the opening for the drainage-tube, and then through the wall of the abdomen. When the ligaments cannot be brought up to the wall of the abdomen a drainage-tube without side openings should be carried down to the bottom of the cavity.

While this mode of treatment is perfectly satisfactory in suitable cases, there are difficulties attending the operation in exceptional cases, and hence certain dangers. The cyst-wall may be easily torn, and hence the danger of leaving portions of it. When this happens it is necessary to destroy the secreting surface. This may possibly be done by applying pure carbolic acid. The most difficult part of the operation, in some cases, is to stop the bleeding. This has been referred to; but I may say further, that the oozing at the time of operating, and the liability to suppuration which may occur afterward, render the convalescence rather tedious in many cases.

The late Dr. J. F. Miner,³ of Buffalo, in a paper first published in 1869, in the *Buffalo Medical and Surgical Journal*, upon "Ovariectomy by Enucleation," furnished a contribution to the medical profession of permanent value. He taught the practicability of enucleating the cyst of the ovary from its peritoneal investment, a histological fact long known, but never made available in surgical practice, until brought forward by Dr. Miner. This most distinguished

¹ "Present Position of Abdominal Surgery." *Lancet*, April 19, 1890. Page 836.

³ *Transactions of International Medical Congress* 1876, p. 810.

surgeon sought to make of practical value this fact. He states:

There is no need to point out the advantages of this plan. Those, who have studied the history of ovariectomy, and who are familiar with the difficulties and objections which may fairly be urged against the ordinary methods of procedure, will at once perceive that, if enucleation is successful, there is no pedicle to keep open the lower angle of the wound, or to drag upon the parts. No unfavorable adhesions of the pedicle, no wires to be discharged by suppuration, and no crusts of burned tissue to be provided for. The abdominal cavity has simply been opened, and the diseased part removed, all that is left behind is capable of life.

The stripping of a large portion of the peritoneal investment of the cyst, and returning it within the peritoneum, as advised by Dr. Miner, offers little if any advantage over the use of the ligature in tumors where the pedicle is well-defined. The fear of hæmorrhage, the too general septic conditions, the returning within the peritoneum of a considerable portion of superfluous tissue, caused the method of Dr. Miner to fall into disuse. However, a modification of it, which I have used for a number of years without exception, is of great practical value. It consists in sewing off the pedicle, usually with several double continuous sutures, and then dissecting the peritoneal investment away from the cyst, at its base, to the extent of about an inch upon either side, and then, by a sero-serous continuous tendon suture (stitches taken parallel to the cut tissues), inverting the divided edges. The advantages which this procedure offers are, that the base is constricted sufficiently tightly to control hæmorrhage without producing necrosis or undue nerve tension, while the inversion of the divided edges leaves no freshly cut surfaces for infection.

The cystic tumors of the pelvis which, for any reason, fail to develop a pedicle, almost without exception may be safely treated by a modification of this method. The tumor, if cystic, is emptied of its contents as usual. The peritoneal investment is stripped from the cyst, which is removed by enucleation. Bleeding vessels are temporarily secured by pressure forceps or torsion. The investing tissues are seized by strong clamp forceps and drawn upward by an assistant, so as to define clearly the basic attachment of the growth. Then, with a double continuous tendon suture, they are sewed evenly through, as deeply as convenient beneath the attachment of the cyst, their entire extent, not seldom several inches in length. This completed, the hæmorrhage is securely controlled, and the redundant tissues are trimmed away with scissors, leaving only sufficient material for the inversion of the divided edges by a sero-serous continuous suture. In a very considerable number of cases of this type, I have been enabled to complete safely the operation, and to close the abdominal wound, where, otherwise, it would have been impossible. In two instances the line of the suturing measured about 9 inches. In no

case have I had complication of secondary hæmorrhage, or septic infection.

In illustration I quote from the record of the Boston Gynecological Society the report of a recent specimen, presented October 10, 1889:

Dr. Marcy presented an inflated unilocular cyst of the right broad ligament which he had removed at his hospital the previous week, assisted by Dr. A. P. Clarke, of Cambridge. The case was one of exceptional interest in that it had been allowed to develop until the sac and contents weighed 42 lbs. The girth of the patient below the umbilicus was over 40 inches. The operation was at last necessitated on account of dyspnœa and impeded circulation. The cyst had developed from the right broad ligament, not only without pedicle, but had carried up before it a fold of the peritoneum from its attachment in the median line to a point posterior to and on a line with the head of the cæcum. The question of its removal, therefore, was of difficult solution. A portion of the cyst wall could be brought into the line of the abdominal incision and stitched to the peritoneum, then drained and allowed to close by granulation. This necessitates, at the best, a long and tedious convalescence, rendered doubly objectionable from the weak and exhausted condition of the patient.

The wall of the sac, along the border of its attachment, was covered by extraordinary varicose veins. This seemed to threaten unusual danger from hæmorrhage. The emptied cyst was put on tension and, commencing at a considerable distance from its attachment on either side, the peritoneal investment was divided (as shown upon the inflated specimen), and the cyst was enucleated. The divided edges were caught and held by three or four pairs of Spencer Wells' compression forceps, while Dr. Marcy sewed through its base, with a double tendon suture in an even, continuous seam, measuring about 9 inches in length. Owing to the extraordinary size of the vessels, a second line of sutures was carried parallel to the first through the double fold of the peritoneum, about half an inch nearer to the median line. The superfluous tissues were resected parallel to this, and the peritoneum was intrafolded by a line of continued tendon sutures, sero-serous in character, the needle traversing the tissues parallel to the cut edges. The abdominal wall was closed in Dr. Marcy's usual method by four layers of tendon sutures, and sealed by iodoform collodion.⁴

The advantages of the above method are too obvious to require special mention. The cyst is entirely removed, the basic attachment is closed, constricted, but not devitalized by the even, continuous double suture, applied by means of the long curved needle set in handle with eye near the point, such as is most conveniently used in hernia, and which is familiar to most American surgeons. The tendon suture is preferable to catgut, but either, properly prepared, is trustworthy. Carefully sewed in the above manner, there can be no danger from hæmorrhage. The inverted serous surfaces leave no oozing stump or uncovered wound for absorption. The tissues lie evenly without strain or tension. Lymph in a few hours covers in the suture material and wounds made by the needle. The abdominal cavity, if necessary, is flushed with sterilized water, and the wound closed without drainage. Care must be taken not to include a ureter, not to pierce the bladder, or rectum; but the danger of sewing

⁴The patient was discharged at the end of the third week, union primary.

deeply in this way is really quite less than in the tying off piecemeal by the interrupted suture, as usually done.

There are cysts which, from changes of an inflammatory or other character, cannot be enucleated by the easy process of stripping the investing peritoneum with fingers. The experienced operator, however, will, by a painstaking dissection, usually succeed in saving the surrounding peritoneum. Fallopian tubes which have become pus sacs are often very troublesome in enucleation, but it can generally be effected without rupture and consequent danger from infection. Where the abdominal cavity is septic then drain, but not otherwise. Pelvic abscesses are obviously to be excluded from consideration by methods such as are under discussion.

It is equally important to advocate in this connection, the treatment of the remaining basic tissues in all cases of supra-pubic hysterectomy as well as the semi-solid tumors of the ovary, dermoid cysts, and cysts of the broad ligaments which are often found without a pedicle. Thanks to the labors of Apostoli, of Paris, it is a conceded fact that laparotomy for fibroid tumors of the uterus is considered less necessary than formerly. However, it cannot be doubted that a considerable number of cases are not amenable to treatment by electricity. Where the growth seriously imperils the life of the patient, and the surgical removal of the tumor is wisely taken into consideration, the importance of a pedicle consisting usually of the elongated cervical tissue is a marked factor in the problem, without which most surgeons decline operating. Nevertheless, it is frequently true that the uterine myoma, which fills the pelvic basin, interfering with the functions of its organs, thereby most often demands removal. When thus located, the cervical tissues rarely afford material for furnishing a pedicle, and the external treatment of the stump is impossible.

It is a well known histological fact that the growth of uterine myoma of necessity causes the formation of so-called capsular investment, developed from the surrounding uterine tissue. In rare instances, where the tumor is single, and the uterus has not become too greatly deformed, it may be removed from its capsule, and the uterine wall closed by suturing. The interstitial growths, however, usually develop from different centres and so alter the structure of the organ that the removal of the entire uterus is demanded. Under these conditions, the most available method of procedure consists in the division of the capsules and the enucleation of the growths, controlling hæmorrhage by pressure forceps. After the size of the organ is thus reduced, the remaining portion is put on tension, and the base is sewed evenly through, as near the junction of the peritoneal reflection from the bladder and rectum as

is judged advisable, and the redundant tissue is cut away. These are divided by a V-shaped incision, so as to allow the easy coaptation of the peritoneal investment by a sero-serous continued suture, in the same manner, as advised in the treatment of non-pedunculated cysts. If the condition of the cervical canal seems to demand it, it should be treated by a drop of liquid crystals of carbolic acid, a strong sublimate solution, or the mucous membrane may be cored out by the knife.

When the condition of the growth will allow, it is a great convenience to first push down over the tumor the so-called rubber-dam which is constricted at its base by an elastic ligature. This simple procedure, suggested to me by the common practice of the dentist, encircling the base of the tooth while filling, oftentimes saves the loss of much blood and proves an exceedingly convenient protection to the abdominal organs. When hysterectomy is thus performed, hæmorrhage is under far better control than by the strong ligature which constricts to necrose the tissue. The pressure upon the parts enclosed is even and continuous, the sutures are speedily covered by a fresh deposit of lymph, and open wound surfaces are entirely avoided. Strain and pressure upon the bladder and rectum are minimized and generally entirely wanting. The abdominal wound is completely closed, rendering drainage not alone unnecessary, but superfluous, and when the abdominal wound is properly sealed with iodoform collodion, subsequent infection is impossible.

There can be little doubt that the advantages of this method are many, and yet they are all based upon the fundamental principles of antiseptic surgery. Without a mastery of these principles and a familiarity with their application and religious exactitude in carrying them out, these operations should never be undertaken. The buried animal suture, unless introduced aseptically, thus hidden away in the remote recesses of the body, is sure to be attended with most disastrous results. But when itself, *aseptic* and *aseptically* applied in an *aseptic* wound, it becomes one of the most important factors in modern surgery, the value of which is as yet greatly underestimated and scarcely properly understood.

JACCOUD'S NUTRITIVE ENEMA.

An enema of great nutritive power, and valuable in cases of cancer of the stomach, closure of œsophagus, etc., is produced by M. Jaccoud, as follows :

- R. Beef broth (freshly made) 8 ounces.
Wine, 4 ounces.
Yolks of eggs, 2.
Dry peptone, 1 to 4 drachms.

M. Sig.—Mix and make an enema to be injected in small portions at intervals during the day.

NASAL REFLEXES.

Read before the American Rhinological Association, Louisville, October, 1890.

BY A. B. THRASHER, M.D.,
OF CINCINNATI, O.

There is perhaps no department of modern rhinology more interesting to the specialist or more prolific in material than "nasal reflexes." Indeed, so fertile has been the field that much opprobrium has fallen to our lot by the great diversity of diseases and multiplicity of symptoms which we have attributed to this cause. It does not seem at all strange to the surgeon that *morbus coxarius* should attract our attention by pain in the knee-joint; but he is skeptical when we refer a post-auricular neuralgia to a hypertrophic turbinate. For a thorough understanding of these neuroses we are perhaps more indebted to Hack, of Freiburg, than to any other one man. His monograph¹ on the subject referred to cases of asthma, nightmare, cough, migraine, sneezing, neuralgias, swelling and redness of the skin of the nose, etc., which he had for the most part successfully treated by cauterizing the erectile bodies of the anterior extremities of the lower turbinates.

In 1872 Voltolini² reported a case of reflex asthuma due to the irritation caused by a nasal polyp, and cured by the removal of the growth. Since then numerous cases of asthma have been reported as due to nasal disease, and a large per cent. of asthmatics are now cured by the rhinologist. In 1882 Dr. Carl Seiler,³ of Philadelphia, reports two cases of reflex cough arising from intra-nasal lesions. In the same volume of the "Archives" Dr. Wm. H. Daly, of Pittsburgh, reports cases of hay fever as caused by intra-nasal disease. His observations have been corroborated by Dr. Jno. O. Roe, of Rochester, and since by a host of others both in America and abroad. The same year Hack reports⁴ a number of nasal reflexes. The next year John Noland Mackenzie, of Baltimore,⁵ advances the theory that there are in the nose certain sensitive areas, located more especially over the posterior extremities of the inferior and middle turbinates and the adjacent portion of the septum, which, when subjected to disease or irritation, give rise to the so-called nasal reflexes. Dr. Mackenzie's able paper excited no little attention, and while his conclusions have been somewhat modified, yet they served as an excellent means of directing the rhinologist to a more careful examination into this interesting subject. The same year Dr. Elsberg⁶ mentioned many nasal reflexes, some of which appear to be only remotely connected with the local lesion. Baratoux⁷ says that in a certain number of cases cough and sneezing can be caused by irritating the posterior part of the septum, and he attributes certain reflexes to the pressure on this part of the swollen turbinate or a

polyp. Dr. Cartaz⁸ describes an interesting case of epileptoid convulsions produced by touching an ulcer located on the posterior extremity of a hypertrophied lower turbinate.

Hering, of Warsaw,⁹ describes numerous cases of nasal reflexes. He gives prominence to the pressure of the middle turbinate against the septum, or to the irritation of the middle turbinate by inflammation, by inspissated secretions, or by the pressure of a polyp. Mr. Lennox Browne,¹⁰ under the heading of neuroses of the larynx, mentions a case of epileptiform convulsions which he attributes, and I think quite properly, to intra-nasal irritation. Bosworth¹¹ mentions two cases of salivation as due to intra nasal disease, both in elderly people, and in both cases local treatment was successful.

Gruening,¹² of New York, reports cases of ocular trouble as due to disease of nose, and similar observations have been made by Cheatham, of Louisville,¹³ and by Bettuan, of Chicago.¹⁴ Lennox Browne¹⁵ reports a case of glaucoma cured by the removal of a nasal polyp.

These cases and symptoms might be repeated, almost without limit, but I will conclude with two examples of reflex salivation, which have recently fallen under my observation

Case 1.—Mr. M., æt. 68, musician, nervous temperament, some symptoms of paralysis agitata. Was referred to me July 24, 1890, by Prof. Forcheimer, for obstinate salivation, which had been present since an attack of the "grip" three months before. There was a chronic naso-pharyngitis without marked hypertrophy. The turbinated corpora cavernosa of both nares were engorged and hyperæsthetic, and the pharynx and buccal cavity were filled with an aqueous secretion. The saliva could be seen dripping from Stenson's and Wharton's ducts, and its presence was a serious inconvenience to the patient and of great detriment to his business. The reduction of the local hyperæsthesia was followed by a cessation of the salivary flow.

Case 2.—Mr. N., æt. 51, referred to me by Dr. Ashburn, of Batavia, O., for excessive salivation. He had been subjected to a severe bodily shock five weeks before, since which time his nervous system had been seriously disordered. For four weeks the salivary flow had been so great as to produce marked discomfort. In this case there was present chronic hypertrophy of both lower turbinates, now accompanied by excessive hyperæsthesia. Dr. Ashburn agreed with me in thinking that we had to deal with a reflex salivation from intra-nasal disease, precipitated by the nervous shock lately received. The patient's general condition was so bad that he was unable to undergo any local treatment other than palliative, and I am unable to report the result.

Among the affections which have been attributed to intra-nasal disease or irritation may be

mentioned: asthma; hay fever; cough; spasm of glottis; gastralgia; dyspepsia; tumefaction and redness of nose; œdema of conjunctiva; conjunctivitis; photophobia; epiphora; asthenopia; glaucoma; scotoma; salivation; cardiac palpitation; disorders of smell, taste, hearing and sight; huskiness of voice and aphonia; exophthalmic goitre; rheumatic pains; vertigo; chorea; epilepsy; melancholia; agoraphobia; aprosexia; neurasthenia; migraine; cephalalgia; neuralgias; nocturnal enuresis; many uterine disorders; affections of the genito-urinary mucous membrane, etc. The very number of these reflexes is so great that care must be exercised to prevent mistakes.

Dr. Bosworth has very properly¹⁶ eliminated such of these affections as are probably produced in some other manner than by reflex action. For example, some neuralgias may be caused by pressure on a nerve trunk of engorged tissues and vessels. A conjunctivitis may arise from an extension of inflammation by continuity of tissue through the nasal duct.

As specialists we must carefully examine the nose; but as physicians we must look still further in our search for the often obscure *causus morbi*. We must not let our zeal as specialists overcome our judgment as physicians.

But the reflex being admitted, and the local origin being some intra-nasal lesion, what, let us inquire, produces the reflex?

Hack seems to believe that the vaso-motor paresis of the anterior turbinates, as a rule, causes the irritation which gives rise to the reflex. John N. Mackenzie thinks that the trouble is due to an implication of the nervous ganglia or nerve centres, and that this involvement may be due to frequent irritation of the intra-nasal nerves or to some other impairment of the nervous system, or to a neurotic dyscrasia plus the local intra-nasal irritation.

There must be a nervous temperament, a diseased condition of the nerve centres, and then a local intra-nasal lesion. Dr. Mackenzie's reasoning on this subject is so logical, and his conclusions so just, that I at least endorse his idea of duality in these neuroses, even if I cannot wholly accept the trinity.

That the first irritation of a previously healthy nose in a person whose nervous centres were normal would produce a reflex disturbance I very much doubt. But when this nerve shock has been experienced repeatedly, then it is easy to believe that there might be some impairment of the nervous ganglia because of their over-stimulation. That this abnormal condition of the central nervous ganglia may be more easily produced in a person of nervous temperament, either hereditary or acquired, I can readily believe; and that it may be produced by extra-nasal causes seems to me also possible.

In Case 2, as related above, the patient gave a

history of chronic rhinitis extending over a long period before any reflex symptoms were noticed. Then came the nervous shock, and from extra-nasal causes there was produced the pathological condition of the central nervous system. Then did the intra-nasal irritation call forth a reflex, and then only because of the abnormal excitability of the central ganglia which had been precipitated by other causes.

The engorgement of the erectile bodies from vaso-motor paresis differs essentially from that of true inflammation.

Dr. W. C. Glasgow, of St. Louis,¹⁷ very clearly directs attention to the swelling of the cavernous bodies in some cases without the ordinary symptoms of an inflammatory process. In these cases he has noticed "great swelling of the cavernous bodies, abnormal paleness of the mucous membrane, and profuse discharge of the limpid fluid." There is not increased redness nor an increased supply of normal blood, as would be the case in congestion or inflammation. This condition of vaso-motor paresis is frequently present in the cases of nasal reflexes; but if it is always present it is sometimes masked by active inflammation, so that we see only the ordinary symptoms of congestion and inflammation.

A mechanical, chemical, or thermal irritant may produce this disturbance of the vaso-motors and the engorgement of the erectile bodies. Every local irritation is conveyed by the afferent nerves to the central ganglia and reflected by the efferent to the point of sensation. The repetition of this irritation beyond a certain point, varying in accordance with the condition of the ganglion cells, produces an over-excitability condition of the central ganglia, so that a less and less amount of peripheral irritation is required to produce reflex phenomena. This nervous irritation may become constant and the accompanying reflex be continuous.

One cannot always be positive that a certain symptom is due to a reflex nasal neurosis. Hack has pointed out a test to determine the reflex character of an affection. This is made by applying cocaine to the erectile bodies of the nose, and when fully anæsthetized the reflex phenomena should be abolished. This, however, has not proven a certain test, as many true nasal neuroses are not much affected by the local use of cocaine. Usually the reflex phenomena can be either excited or exaggerated by touching the sensitive area of the nose with a probe, but this is not always true. There will always remain a certain number of cases in which the phenomena are supposed to be produced by intra-nasal irritation, but where it will require the removal of all nasal abnormalities before a positive diagnosis can be made.

There appears to be but little connection between the severity of the reflex symptoms and

the amount of intra-nasal affection. Very little trouble in the nose may give rise to reflex phenomena of great magnitude, and *vice versa*. This fact has many times led to a mistaken diagnosis, as the nares have been pronounced normal when there was present a sufficient amount of inflammation or irritation to give rise to severe reflex trouble. Nor does it by any means follow, when we have to deal with a cough or a supra-orbital neuralgia in a patient presenting marked hyperæsthesia and disease of the nasal mucosa, that the cough or neuralgia is reflex and produced by the evident intra-nasal lesion. The cough may be due to laryngitis and the neuralgia to malaria, and there may be no connection with the nasal disease. Many a nose has been sprayed and burned and cut, and all in vain, for the relief of a symptom which had no connection with the nose. A hypertrophic turbinate does not always give rise to serious trouble, and it is not always necessary to straighten a crooked septum, or cut off a small cartilaginous septal spur.

Since it is probable that the cause of these reflex phenomena may be found in the nose and in a dyscrasia, it is well to direct our efforts at cure in two directions, viz.: to rid our patient of the intra-nasal disease, and at the same time to give attention to the underlying dyscrasia. However skeptical we may be as to the good effects of drugs, we would hardly dare to treat a patient manifestly a subject of lues without mercury and iodide of potash. And if a patient has a periodical supraorbital neuralgia, with an enlarged spleen and a well-marked cachexia, we would not content ourselves with cauterizing the turbinates, however large and inflamed they might be, but would at the same time administer the bark and arsenic and iron to meet the indications for constitutional medication.

The character of the constitutional dyscrasia will determine the constitutional treatment. Just so of the local treatment. Whether a septal spur is removed by a snare, or saw, or drill, or galvanocautery, so that in the end it is well removed, makes but little difference. Treat the local disease so as to remove it as rapidly as possible, with as little resulting damage to the intra-nasal mucosa.

In these reflex disturbances it becomes apparent that the specialist should be broad in his ideas, not viewing the whole world through his nasal speculum, or not expecting to see the cause of all bodily ailments reflected in his rhinoscope.

AN EASY AND SIMPLE METHOD OF PREPARING MACROSCOPICAL SPECIMENS OF THE EYE.

Read in the Section of Ophthalmology at the Forty-First Annual Meeting of the American Medical Association, Nashville, Tenn., May, 1890.

BY J. H. THOMPSON, M.D.,
OF KANSAS CITY, MO.

At many of the large clinics both at home and abroad a quantity of valuable pathological material is wasted because there has been no easy or simple way to preserve it. This is particularly true in ophthalmic institutions, where the attendants are not usually experts in pathological technique or are too busy to attend to the details necessary for a proper mounting of a specimen. If it were not that preparations of the diseased eye are often very valuable the excuse "want of time" would be acceptable, but the result of a little time and work in this line is often so gratifying, that I feel justified in calling your attention to the method I pursued in the preparation of this specimen. Perhaps it is unfortunate that in the hardening process much time is consumed which cannot be avoided, but the technique is easy and can be acquired by following closely the method herein advised. When the eye is removed wash it in cold water, wrap it in a piece of paper and freeze it hard by inserting it in a box of cracked ice and salt. It should remain not less than an half hour in the freezing mixture, remove it, and quickly with a sharp knife or flat razor cut off two sections, one should extend from the cornea to the equator of the eye opening the anterior and vitreous chamber but should avoid injuring the lens if possible. It is only necessary to open the anterior chamber in one place so that the hardening fluids may easily pass in, the other section, much larger than the first, should be cut from opposite surface of the eye and should extend from the edge of the cornea to the posterior pole of the eye on a plane corresponding to the horizontal visual plane and parallel to the optic axis. If the eye is well frozen this can be done without crushing the organ or disturbing the relation of the internal structures, but the lower cut must be so even, that when the eye rests upon a flat surface the scleral edge is in contact all round. The object is that being thus placed upon a piece of glass, when the vitreous fluid melts it will be retained within a scleral cup and hold the internal membranes and structures exactly as they were before the eye was opened. Of course it may be necessary to make the openings at other places to avoid cutting away the bases of tumors or certain diseased parts, but

wherever made they should be as near opposite as possible.

Have ready a glass quart jar half filled with Müller's fluid, and a watch glass, which has glued to it with paraffine four long threads, place the frozen specimen flat on the center of the glass and holding the whole horizontal by suspending it by the threads, lower it into the hardening fluid and fix it an inch or so from the bottom of the jar. I usually use a cork stopper and by passing the threads through a hole in the centre can lower or elevate the specimen without disturbing it. The specimen should remain in Müller's fluid at least six weeks, which should be changed four times. At the end of that time it is ready for alcohol. Remove the eye from the bichromate of potash solution and wash it in a large quantity of water, being careful that during the washing process it is not injured. It is then placed in dilute alcohol twenty-four hours, 90° spirit four hours, and finally absolute alcohol, where it should remain until it is certainly dehydrated: twelve hours is sufficient time. From the alcohol it is transferred to a bottle of turpentine where it should stay until the turpentine has penetrated freely all the tissues, especially the sclerotic coat. It will do so in twenty-four hours, when the specimen has a transparent amber look.

Wherever turpentine will go melted paraffine will follow and inasmuch as we desire to paraffinize the specimen it is only necessary to keep it in melted paraffine long enough. Ordinarily paraffine melts at about 135°, so if the preparation is kept in an oven at that temperature or on a water bath it will suffice, but it is difficult to hold the temperature between 140° and 150° without a thermostat, consequently many men have neither the time nor the patience to carry out that part of the process. In the winter season the steam radiators in our office buildings have a temperature ranging from 130-150 degrees, so if the bottle containing the paraffine is placed on one of these the work can be done without watching and without danger of overheating. Place the bottle holding the eye and an ounce or so of turpentine in a temperature ranging from 130-150°. I usually put the bulb of the thermometer in the fluid and keep it there; from time to time put in pieces of the hardest purest paraffine; by pouring off the fluid, a few drams at the time and adding paraffine to make up the loss, the spirits of turpentine will be finally eliminated when the specimen will be saturated with melted paraffine in which it should remain at least two days. If the temperature should go down and the whole solidify, no harm is done, it can easily be remelted. Some advice to remove the specimen from turpentine directly into melted paraffine. In the eye it will not do, since the heat drives off the spirit from the scleral coat when the paraffine will not thoroughly penetrate, which renders the specimen useless.

The specimen is now ready for the cast. Make a strong paper cylinder one and one-fourth inch in diameter and two inches long, put an ordinary prescription paper on a flat surface, and pour some of the paraffine upon it, enough to cover a space larger than the base of the cylinder; remove the eye from the bottle and quickly place it flat in the centre of the paraffine disc on the paper; it will stick; then cover it with the paper cylinder which should not touch the specimen but should be pressed down into the hardening mass. Fill the mould full with the paraffine from the bottle and let it stand until it is hard. The cast in ordinary weather will not be thoroughly hardened inside of six hours.

If the cast is put in the clamp of a microtome very thin slices can be cut off, but since the best part of the specimen is one-third of an inch or more from the upper surface it is well to carefully pare away the cast either with a very sharp knife or better by working the instrument until the desired part is reached, resharpen the knife and make a section about one five-hundredths of an inch thick. To prevent the section curling some instruments have fixed to the knife a flattener, but an ordinary business card held edgewise on the section as it is cut will keep it flat. If the specimen is properly prepared the cast will be solid and contain no air bubbles, so when a thin slice is cut off of it, it will be without a break and hold a perfect section of the eye.

Procure from a photographer some old negatives, clean them and cut them into slices four inches long by one and one-half inches wide; have on hand some cover glasses one-hundredth inch thick, two by one one-fourth inches square; make a fixer of collodion and camphor chloral two parts to one. With a camel's-hair brush paint the collodion mixture on the slide over a space larger than the section, which should be then carefully laid upon it and covered with a piece of paraffine paper; it may then be pressed flat with the ball of the thumb. I usually flatten with an ordinary knitting needle; remove the paper, place the slide on a heated surface about 140°, until the paraffine begins to melt and the fixer turns opaque. The section is thus glued fast to the glass slide, so when the slide is put in a bottle of turpentine the paraffine is dissolved away nothing remains but the anatomical tissues. The slide may remain in turpentine indefinitely. From turpentine transfer to alcohol in sufficient quantity to dissolve out the turpentine, then to distilled water in which it may be stained by any of the ordinary aqueous stains. I prefer logwood stains for that purpose. When sufficiently colored the specimen is dehydrated in spirits and absolute alcohol, clarified with the oil of clover or spirits of turpentine, and mounted permanently in Canada balsam.

This process, called the paraffine imbedding,

has been extensively used by Dr. Reeves, of Chattanooga, but it has not been recommended in eye work, the celloidion having been considered the best. I have not succeeded with that method so well as I have with the one advised, and I believe that if you will follow the plan suggested in this paper, especially as regards the freezing and hardening process you will succeed by mounting some beautiful and valuable specimens.

CASE OF SARCOMA OF THE CHOROID —OPERATION—NO RECURRENCE IN NEARLY THREE YEARS.

Read in the Section of Ophthalmology at the Forty-first Annual Meeting of the American Medical Association, held at Nashville, Tenn., May, 1890.

BY A. G. SINCLAIR, M.D.,

PROFESSOR OF DISEASES OF THE EYE, EAR, AND THROAT IN THE MEMPHIS HOSPITAL MEDICAL COLLEGE; SURGEON IN CHARGE OF THE EYE AND EAR DEPARTMENT OF ST. JOSEPH'S HOSPITAL, MEMPHIS, TENN.

Malignant intra-ocular growths are of so much importance that every case of the kind should be placed on record, and especially the results of treatment, whether favorable or otherwise, in order that we may learn at what stage of development the disease passes beyond the control of remedial measures. I therefore beg to occupy your time briefly with a report of the following case:

In June, 1887, I was consulted by Mrs. K., 40 years of age, who reported that three years previously she had lost the sight of her right eye while suffering from symptoms which, according to her description, were very like those of acute glaucoma, and that the organ had continued more or less irritable up to the time of presentation. On examination I found vision extinct; conjunctiva moderately injected; pupil somewhat dilated, and motionless; iris discolored; lens cataractous; tension plus 1; pain in the eye, forehead and temple. Although suspecting the presence of an intra-ocular growth, I determined, as my patient was a lady, and cosmetic effects were therefore not to be ignored, before proceeding to enucleation to test the power of iridectomy to overcome the glaucomatous symptoms above enumerated—knowing that if an intra-ocular tumor were indeed present they would soon reappear and render positive the indication for removal of the eyeball.

I performed the operation accordingly, and relief of several weeks' duration followed. The symptoms then recurred in all their former intensity, and on August 14 I enucleated the eye under etherization. Entire relief from all symptoms followed; the patient made a good recovery from the operation, and soon regained her strength and spirits, previously much depressed by her sufferings.

I sent the eye, hardened in alcohol, to the laboratory of the College of Physicians and Sur-

geons, New York, for examination, whence I received in due time the following report:

NEW YORK, November 23, 1887.

Dr. Sinclair, Memphis, Tenn.

Dear Doctor:—The microscopical examination of the eye sent to the laboratory is as follows:

Cornea.—The cuboidal cells of the anterior epithelium are distorted and separated from each other by larger and smaller irregular shaped spaces (probably due to drying in the air). There are also a number of spindle-shaped cells among the cells of the anterior epithelium. At the sclero-corneal junction there are a few scattered pus cells. Lying against the posterior epithelium of the cornea is a layer of spheroidal cells.

Uveal Tract.—Iris is swollen and ciliary bodies flattened on both sides. The choroid just behind one of the ciliary bodies contains a mass of small spindle-shaped cells about 5-7 mm. in diameter.

Retina and Opticus.—Rods and cones absent from retina and there is an increased amount of interstitial tissue. In places the retina is changed to a connective tissue lamina. The optic disc shows a moderate degree of excavation.

Anatomical Diagnosis.—Small spindle-celled sarcoma of the choroid, interstitial retinitis, optic excavation, circumscribed purulent keratitis. Very respectfully yours,

IRA VAN GIESON.

Nearly three years have elapsed since the operation; the patient continues in vigorous health, and there is no sign of a recurrence of the disease.¹

54 Madison street.

A VEST POCKET OPHTHALMOSCOPE CASE.

Read in the Section of Ophthalmology at the Forty-first Annual Meeting of the American Medical Association, held at Nashville, Tenn., May, 1890.

BY FRANK TRESTER SMITH, A.M., M.D.,

OF CHATTANOOGA, TENN.

LATE ASSISTANT SURGEON, NEW YORK OPHTHALMIC AND AURAL INSTITUTE.

I present to the Section an ophthalmoscope case made for me by Meyrowitz Bros. in 1886, and which I have had in constant use ever since. It is made like a spectacle case, the open end being closed with a tightly fitting lid, or like a flattened pencil case such as is used by school-children. It is made of stiff pasteboard, or other light material, covered with morocco.

It presents the following advantages over the form in ordinary use:

1. Size. This is such that it can be carried in the vest pocket. The thickness is about half that of the wooden case.
2. Weight. Being smaller and made of lighter material, it is not as heavy as the ordinary form.
3. Shape. There are no corners and the edges are rounded off.

¹ There is still (Dec., 1890) no sign of a relapse.

4. As a result of the shape we have another advantage: It is dust-proof. The lenses are consequently more easily kept clean.

5. As a further result of the shape we have the advantage of greater durability. The hinges of the ordinary case are soon worn out.

6. It is never necessary to remove the handle from the instrument.

7. The ophthalmoscope can be kept in the case at all times except when in actual use. During office hours it takes too much time to be continually taking the instrument from the case with a lid. By removing the lid the ophthalmoscope can be placed in the case and taken from it more easily than from the vest pocket. The weight of the ophthalmoscope will prevent its falling out of the pocket in stooping.

I use the Knapp ophthalmoscope. The instrument with a tilting mirror would require a thicker case. There is no place in this case for an accessory lens. I find it more convenient to carry this in an eye-glass case in my vest pocket.

THE TORSION OF ARTERIES FOR THE ARREST OF HÆMORRHAGE.

Read at the Sixteenth Annual Meeting of the Mississippi Valley Medical Association, at Louisville, Oct. 9, 1890.

BY J. B. MURDOCH, M.D.,
OF PITTSBURGH, PA.

There is no subject of greater interest to the practical surgeon than the arrest of hæmorrhage. This remark is equally true whether the hæmorrhage comes from a wound accidentally inflicted, or one made intentionally, by the surgeon's knife.

Without the means of stopping the flow of blood from bleeding vessels, the surgeon's art would be greatly crippled, and surgical operations, where blood-vessels must be divided, would be impossible.

There is no sight so appalling as a formidable hæmorrhage. When a large artery is opened, the blood gushes out in an angry stream, the face becomes pale, the color leaves the lips, the respiration becomes sighing, the heart fails to beat, and death closes the scene. Without any knowledge of the circulation or nature of the blood, or of the means by which its flow from a wound could be arrested, what a terrible and mysterious sight it must have been to the early races of men to see one of their number perish from hæmorrhage. What, for instance, must have been the sensation of our first parent Adam, as he looked upon the wounds of his dead son Abel, with the stain of his blood upon the ground. Surgeons from the earliest ages have shared this dread of hæmorrhage, and have ever been striving for the best means of its control.

Upon no subject has our profession been more conservative than upon this one—the arrest of

arterial hæmorrhage. Since the time of Celsus, notwithstanding the numerous methods which have been proposed for this purpose, but two, viz.: the actual cautery and the ligature, have received the endorsement of the profession. But, if the profession has been slow to endorse new methods, its confidence once gained has been most unwillingly surrendered.

From the time of Archigenes, who practiced in Rome shortly after the time of Celsus, up to the time of Richard Wiseman, Sergeant-Surgeon to King Charles II, the red-hot iron was the sole method employed. Thus this method of checking hæmorrhage after amputation not two centuries ago, was the same as that used for fifteen hundred years previous. The pertinacity with which surgeons adhered to the use of the actual cautery after Paré's great discovery of the ligature, well illustrates the fear in which surgeons stood of hæmorrhage. They had used, and had seen their fathers use, the red-hot iron, and, notwithstanding the pain it caused and the interference with primary union, they were unwilling to discard the agent which long usage had taught them was successful.

In 1564, Ambrose Paré published his new discovery, which, to use his own language, "was taught him by the special favor of the sacred Deity." In this publication, as is well known, Paré demonstrated the value of the ligature as a hæmostatic. But, owing to the extreme fear of hæmorrhage, and the criminal neglect of surgeons, it was two hundred years before it was adopted by the profession, and then it came into favor through the influence of Sharpe, one of the surgeons of Guy's Hospital, London, who boldly championed the claims of the ligature to popular confidence.

Since this time nothing has dislodged the position which the ligature has held as a hæmostatic in the opinion of the profession.

The efforts made by Sir James Y. Simpson, of Edinburgh, to substitute acupressure, and the still more recent endeavor of Dr. S. F. Spier, of Brooklyn, to substitute constriction for ligation have most signally failed. The same statement may be made also in regard to torsion as a means of arresting arterial hæmorrhage. It has not received the support of the profession to any great extent, but unlike the other rivals of the ligature, it has had champions for hundreds of years, and still holds a place as a valuable means of arresting hæmorrhage. This subject has received but little attention by modern surgeons. The twisting of an artery to arrest bleeding is of ancient origin. It is spoken of by Celsus. A fact often observed that an arm or leg may be torn from the body with the loss of only a few drops of blood, no doubt suggested the method. It has been advocated by such surgeons as Amussat, Dieffenbach, Schroeder and Syme. But the credit of

bringing it prominently before the profession and establishing its efficiency is due to Mr. Bryant, the present distinguished surgeon of Guy's Hospital, London. At this hospital the ligature is seldom used, torsion being chiefly relied upon. Mr. Bryant tells us in the last edition of his "Surgery," that in two hundred consecutive amputations of the thigh, leg, arm and forearm, all of the arteries were twisted, one hundred and ten of them being the femoral artery, and that in no case was there secondary hæmorrhage.

Mr. Bryant says: "The physiological arguments in favor of torsion are very great, and the practical advantages seem to be no less. After seven years' experience in its practice, applied to vessels of all sizes, the femoral being the largest, I have had no mishap. I have observed that wounds have united more rapidly and kindly, primary union being the rule. There has been less constitutional disturbance after operation, and consequently, less liability to traumatic fever, pyæmia, and other complications such as we are all too familiar with in the practice of surgery. I have had stumps heal in a week, and the patient up in two weeks; without one single drawback, rapid and uninterrupted convalescence following the operation."

Having given this experience of Mr. Bryant, I desire now to give my own as observed at the Western Pennsylvania Hospital of Pittsburgh. At this hospital, torsion is almost exclusively relied upon to check the hæmorrhage from wounded arteries or veins, whether the wound be produced by the surgeon's knife or otherwise. My experience with torsion as a hæmostatic, dates back to the year 1872, when I became a member of the hospital staff. My colleagues had, previous to my connection with the hospital staff, been twisting arteries as large as the radial and ulnar. The facility with which this was done and the fact that the wounds healed kindly and without secondary hæmorrhage, induced me to follow their example, at first timidly, but with success came confidence. Having been successful in the amputation of a forearm with no untoward result, I ventured next to twist the brachial artery after the amputation of an arm; soon after this the axillary, and then the popliteal, and finally the femoral. And now, for the past eighteen years, torsion, for the arrest of hæmorrhage after all surgical operations, has been the recognized, and almost the only method resorted to at this hospital. It is to be regretted that records have not been kept of the number of larger arteries which have been twisted to arrest hæmorrhage.

The following is a table showing the number of arteries divided in cases of amputation where torsion has been resorted to for the arrest of hæmorrhage at the Western Pennsylvania Hospital:

Femoral	116 times.
Popliteal	18 "

Axillary	18 times.
Anterior tibial	317 "
Posterior	317 "
Brachial	81 "
Radial	45 "
Ulnar	45 "

There are two methods by which the torsion may be applied, as is illustrated by the following cuts :

FREE TORSION.

LIMITED TORSION.

- 1st. Limited torsion; and
- 2nd. Free torsion.

In the first method, two pairs of forceps are required. The first pair grasps the vessel at its cut extremity, and pulls it from the sheath. It is then seized by the second pair at a point from one-half an inch to an inch above the cut extremity of the artery; this second pair being held at right angles to the long axis of the vessel. The first pair is then given three or four sharp turns.

By the second method (free torsion), only one pair of forceps is required. It is the one recommended by Mr. Bryant as not being so likely to injure the external coat of the artery. And this is the method which was adopted in the cases which I have given.

A good pair of forceps is required which will hold the end of the artery firmly, and that has no lateral motion, and with serrations blunt enough to obviate any laceration or cutting of the parts seized by the blades. The vessel should then be drawn out as in the application of the ligature, and three or four sharp rotations of the forceps made. In large arteries, such as the femoral, the rotation should be repeated till the sense of resistance has ceased. The ends should not be twisted off. In small arteries the number

of rotations is of no importance, and their ends may be twisted off or not, as may be preferred. In all of the cases mentioned in the above table torsion of the arteries and veins was the method resorted to to control hæmorrhage.

In addition to these cases, of which we have a record, the method of torsion has been the one resorted to in all other surgical operations performed during this period, such as amputations of the female breast, the removal of tumors, the excision of joints, etc. It is within bounds to say that torsion has been resorted to at this hospital in thousands of cases without any mishap. We have had no case of secondary hæmorrhage which could fairly be attributed to the method of controlling the hæmorrhage.

The advantages of torsion as compared with ligation are:

1. The greater facility with which it can be applied.

I am fully aware that this proposition is disputed, but to those who are familiar with both methods, there can be no doubt that torsion is the easier of the two. For the ligation of an artery, an assistant is required to seize the vessel and draw it out while the ligature is applied. For torsion, the surgeon requires no assistant. The vessel must be seized by the forceps in either case. In torsion it only requires three or four turns of the forceps to complete the process, which can be accomplished in as many seconds. When a ligature is applied, let the operator be ever so skilful, the thread may break or slip off the vessel, but if neither of these accidents occur, the process cannot be accomplished in anything like the same time.

2. Torsion is a safer method, being less liable to be followed by secondary hæmorrhage.

This proposition has been absolutely proven by the experience in the use of torsion at Guy's Hospital, London, and I have now given additional proof by the experience given in this paper.

3. Healing is facilitated because the wound is free from any irritating or foreign body.

This proposition is so plain that it should not require an argument. It was true before the antiseptic treatment of wounds had come into such general use, but it is doubly so now. The catgut ligature is no doubt a safer ligature than the silk, for it does not require an ulcerative process for its discharge, and when this ligature has been made thoroughly antiseptic, it is no doubt the best. But a ligature rendered thoroughly antiseptic is not always at hand, and those surgeons who have had most experience with the antiseptic treatment of wounds, will, I think, be the first to admit that, in spite of their most careful attention, septic germs are often introduced into the wounds by means of the ligature. Even after every precaution in preparation and preser-

vation, the handling of a ligature in its application is a frequent source of infection.

But there are other objections to its use. The catgut ligature may dissolve before the artery has become closed by the natural hæmostatic process, or it may unbind. Both of these accidents have been the frequent cause of secondary hæmorrhage.

On a recent visit to some of the principal hospitals in New York City, where the operators and assistants possessed the greatest skill, I was not surprised to see that in many instances a ligature broke, or in other cases slipped off the vessels before they were secured. This was to me exceedingly annoying to witness, when I knew that the vessels could have been so easily twisted while they were in the grasp of the forceps. When the question was asked one of these operators, a distinguished surgeon, "Why don't you resort to torsion?" the reply was, "We are afraid to trust it." This answer might have been given with equal force by Richard Wiseman in the seventeenth century, when asked why he did not resort to the ligature instead of the red-hot iron.

In a matter so important as the arrest of arterial hæmorrhage, it is proper that surgeons should be conservative, but there is such a thing as pushing conservatism too far. In the torsion of arteries, I claim we have an improvement upon ligation; its claims for recognition rest upon physiological arguments, which cannot be shaken, and its reliability as a hæmostatic has been proven by abundant experience.

MEDICAL PROGRESS.

BIOLOGICAL EXAMINATION OF DRINKING-WATER.—MIGULA (*Centralblatt für Bakteriologie und Parasitenkunde*) has come to the conclusion that the number of colonies that are developed in plate cultures, is not an index of the potability of waters examined by this method. He finds, however, that there is a relation in the number of species found in water and its purity. If a large number of varieties are present it speaks generally for the unhealthfulness of the water. We must refer the reader for fuller particulars to the original and the tables which accompany it, representing as they do, over 400 examinations.

He closes with the following conclusions: first, that the number of colonies developed by 1 ccm. furnishes no ground for concluding as to the potability of such waters; second, the bacteria of decomposition are absent from running water; third, the bacteria of decomposition are most numerous in water containing 1,000 to 10,000 germs in each cubic centimeter, though they may be present when the number is as low as fifty, and

they are less frequent when more than 10,000 germs are present; fourth, bacteria of decomposition are only found when several species are present. The relation of number of colonies to number of species is very indefinite.

NEW METHOD OF STAINING RED BLOOD CORPUSCLES.—MIHAJLORITZ (*Centralblatt für Physiologie*) recently called attention to a new method of staining blood corpuscles. He refers to the process of Biondi, in which the blood is mixed with osmic acid and agar-agar and subsequently cut into sections, which may be treated like sections of other tissues. This method is considered by the writer to require too much time, and to be troublesome. He claims to have reached equally good results by staining the blood directly upon a glass slide and subsequently washing in absolute alcohol, clearing with oil of cloves and Canada balsam. The success of the method lies in removing the outer layers so that only a single layer of corpuscles is attached to the glass. This is accomplished by gently passing the finger or a camel's hair pencil over the surface of the clot—the lower layers are left owing to their stronger adhesion to the surface of the glass.

PASSAGE OF TUBERCLE BACILLI THROUGH THE INTESTINAL CANAL.—Some interesting experiments have lately been made by ZAGARI on dogs fed with tubercular food. These are interesting from two points of view. First, that our knowledge of the action of the digestive juices on the tubercle bacillus is small; and secondly, that tubercular processes as affecting the dog have been little studied. Dogs were fed on sputum which had been proved to contain large numbers of tubercle bacilli. After the course of from ten to twenty hours the bacilli were detected by means of the usual color tests in the fæces, and continued to occur for two or three days, occasionally five or six days, after the tuberculous material had been removed from their food. The dogs continued healthy and entirely free from signs of tuberculosis, although the sputum was mixed with their food for some time, and meat known to be tuberculous was also given. Experiments were now made to endeavor to ascertain what substances in the digestive tract prevented the growth of the bacilli. The bacilli found in the fæces were shown by inoculation on other animals to be virulent. It was also demonstrated that washings from the stomach also contained active germs. Although the food was allowed to remain in the stomach for three or four hours before being washed out, yet the organisms were not entirely destroyed. After six hours' stay in the stomach inoculations on guinea-pigs still produced tuberculosis, but their action was delayed. After from seven to nine hours a local infection only was the result, and after from eighteen to

twenty hours no effects at all were noticed. An interesting point in connection with these results is that the gastric juice of a dog contains a higher percentage of acid than in man. As the analysis of the contents of the stomach did not explain why the dogs did not become tubercular, the further course of the bacilli was next investigated. It was shown that the bacilli found their way out of the intestinal canal into the tissues, for the blood of the dogs was proved to be infectious—that is to say, produced tuberculosis when inoculated; the same effect was produced by the lymph from the thoracic duct; also by portions of the liver, when introduced into the peritoneal cavity of a guinea-pig. When portions of the tissues were examined microscopically the result was negative. A few bacilli, however, were found in the spleen. When young dogs were fed with sputum they died, not of tuberculosis, but of a form of "intoxication." Further researches on dogs were then made with pure cultures of tubercle bacilli. When inoculated under the skin a local affection was the result, which usually ran a favorable course. When the injection was made into the pleura a local pleurisy and tubercular disease of the lung were produced which proved fatal. When intravenous injections were tried the results were again negative. The bacilli obtained from the fæces as described above, although virulent, had lost some of their vitality. Pure cultures exposed to a temperature of 55° C. for eight days were not destroyed, whilst the bacilli from the fæces were killed after an exposure of five days. Again, if these bacilli were dried, after from sixty to ninety days they were no longer infectious, whilst Ichill and Fischer have shown that bacilli in pure cultures retain their virulency for a far longer period than this.—*The Lancet*.

A CASE OF TUBERCULAR INOCULATION.—T. DEUKE (*Deut. Med. Wochenschr.*) reports the case of a seven months child of a phthisical mother, that fell and injured its head against a chamber vessel containing some bloody sputum of the mother. The clean cut wound was disinfected and healed rapidly. The cicatrix later began to enlarge, and shortly swelling appeared in the region of the parotid, with suppuration and enlargement of the neighboring glands. This suppuration finally caused the death of the child. In the pus of the part, the tubercle bacillus was found abundantly.

TYPHOID BACILLUS IN DRINKING-WATER.—KARLINSKI (*Archiv. für Hygiene*) has recently made some observations upon the life of the typhoid bacillus, under approximately normal conditions. For the experiments an old cistern with imperfect walls was chosen. The first observations after the addition of 1,000 cubic centimetres of the dejections of a typhoid patient showed an

enormous number of germs containing some twelve different species, including some infusoria. On the third day all of the typhoid bacilli had disappeared. This observation was repeated several times, varying the amount of fæces that were added, but always with a like result. The cistern was then carefully cleaned and filled with pure spring water, in which the writer observed the typhoid bacilli twelve days after they had been added. An explanation for the rapid disappearance of the typhoid bacilli, the writer finds in the speedy development of a large saprophytic germ that destroys them.

THE PHYSIOLOGY AND PATHOLOGY OF SLEEP; WITH OBSERVATIONS ON NONA.—MAUTHNER (*Intern. klin. Rundschau*, 1890, 949), in discussing the various pathological processes whose most prominent symptom is sleep accompanied by extreme muscle-weakness, divides these into those of a more chronic or subacute course, and those of a very stormy acute form. In the first category belong:

1. The "endemic morbid somnolence of the negroes," which is followed by death in the course of two to three months. The symptoms are general apathy and depression, the most extreme muscular weakness without motor paralysis and with intact sensibility, a staggering gait, and constantly increasing somnolence until the power of motion is entirely lost, and the motionless sleep lasts until the fatal end.

2. "Gayet's disease," as illustrated in the case described by Gayet in 1875, the symptoms, course and termination of which possess a close resemblance to the "maladie du sommeil," and which is of especial importance in that an autopsy was obtained.

3. "Gerlier's disease," occurring in the form of small epidemics in Switzerland, and described by Gerlier under the name of "*vertige paralysant*." The symptom of somnolence is less prominent in this affection than are the vertigo and extreme muscular weakness, rendering young, powerful stable-men unfit for any labor.

4. The "*attaque du sommeil*" of hysterical persons, the duration of which may be several months without ending fatally.

All of these more chronic forms—with the exception of the tropical form, of which the author has no certain knowledge in this respect—have a striking focal symptom in common; viz., ptosis with paralysis of the ocular muscles.

The acute forms are represented by the following:

1. "Wernicke's disease," whose symptoms are, from the beginning, a combination of ocular paralysis, staggering gait, and somnolence, or else a final stage of somnolence, after preceding agitation.

2. Unusually long sleep after intoxication, in

which the individual may sleep—as in one case under the author's observation—as long as five days, during which time it is impossible to wake him.

3. "Nona," in case this disease actually exists. The possibility of the existence of this affection cannot be denied, since morbus Wernicke, occurring epidemically or endemically, would end in death the third or fourth week, with somnolence as its most prominent symptom.

The nature of both the chronic and the acute forms of morbid somnolence is undoubtedly that of a *poliencephalitis superior*. The inflammation of the central gray cavities of the third ventricle, the gray matter of the walls of the aqueduct of Sylvius, and that of the floor of the fourth ventricle, give as the most constant general symptoms, general apathy and depression, with excessive muscular weakness, and, in a more advanced stage of the disease, extreme somnolence; while as a result of the extension of the process to the nuclei of the nerves, the focal symptom of ocular paralysis appears.

Basing his opinion on clinical experience and on the pathological appearance in disease of the central gray cavities, the author proposes a theory for the cause of physiological sleep. This theory is, that sleep is to be considered as an evidence of tiring of the central gray cavities. Through the temporary suspension of the function of this portion of the brain, both the centripetal and the centrifugal nervous paths communicating with the cortex are cut off. Consequently sensory impressions are not conducted to consciousness, although the sensory organs on the one hand, and the cells of the cerebral cortex on the other, have not suspended their function. In the same way the motor centres are normally innervated in dreams, but on account of the interruption in the conduction in the central gray cavities, no motion is produced in spite of the normal power of conduction of the peripheral nerves. Finally the focal symptom of ocular paralysis is not absent; for the falling of the eyelids in those becoming sleepy is a true ptosis, while the simultaneous occurrence of double vision indicates the marked disturbance of innervation of the external ocular muscles.—*American Journal Medical Sciences*.

HERPETIC ANGINA.—Under this title BERTILO (*St. Petersburger Med. Wochenschr.*) describes an interesting case of a man who presented himself at the city hospital at Riga. At first he was treated for an ulcer at the base of the tongue, which caused severe pain. As he was markedly emaciated and presented tubercle bacilli in the sputum the ulcer was thought to be tubercular, notwithstanding that the patient had had syphilis some years before. While under treatment a crop of irregularly placed vesicles, with cloudy contents,

presented themselves on the posterior wall of the pharynx. Later these vesicles disappeared leaving an ulcer which was slow to heal. Subsequent crops of vesicles appeared upon the base of the tongue, fauces and walls of the pharynx, these were accompanied by vesicles at the margin of the lips and in one case on the glans penis. The patient finally recovered and was discharged about one month after the beginning of the trouble. The author makes this case a text for a discussion of some of the theories regarding the identity of herpes of the skin and throat.

PERSISTENCE OF THE TYPHOID BACILLUS IN THE BODY.—CHAUTEMESSE (*Semaine Médicale*) reports a case of typhoid fever with so many relapses that the duration may be said to have extended over five months. Orloff has published a case in which a pure culture of the typhoid bacillus was obtained from an osteo-myelitic abscess, nine months after the beginning of the affection. Achalmé has reported a similar case. The writer observes that these cases are rare, but that they teach the possibility of prolonged infection in typhoid. He calls attention to the fact that abscess in this disease is usually caused by the various forms of suppurative bacteria (secondary mixed infection, ref.).

In the discussion Rendu reported a case with three relapses and a duration of three months. Netter, one with a duration of six months and six relapses. In this last case an abscess developed that contained only suppurative bacteria.

AN IMPROVED METHOD OF LAVAGE.—A very simple improvement in the apparatus for washing out the stomach, a procedure often of great value in the treatment of gastric disorders in childhood, has been described by DR. W. BEATTIE NESBITT in the *Archives of Pediatrics*, September, 1890. The fluid is obtained as usual from a siphon bottle placed above the level of the child, but the india-rubber tube from this bottle is connected with the stomach catheter, not by a piece of straight glass tubing, but by a glass tube shaped like a widely open tuning fork; the handle of the tuning fork is connected with the stomach catheter, one limb with the tube from the bottle, and the other with a waste tube conducted into a suitable receptacle. It is convenient to have the tube from the bottle and the catheter of red rubber, and the waste tube of black rubber. The tubes from the two limbs are placed over the forefinger of the right hand, and are held loosely in the palm; either can then be easily compressed by the thumb. When it is desired to fill the stomach, the catheter having been introduced, the waste tube is compressed, and the fluid readily flows into the stomach from the bottle; when the stomach is to be emptied the red or siphon tube is compressed, and the black re-

leased. If the eye of the catheter becomes blocked, as often occurs, the current is easily reversed by compressing the black and releasing the red tube. Dr. Nesbitt recommends the use of a mouth gag, and, after inserting the tube, places the child on its side, with the face slightly downward. Before removing the catheter the stomach is filled quite full. An act of vomiting generally follows the withdrawal of the tube, or if not may be excited by titillating the fauces. "In this way," writes Dr. Nesbitt, "I have often seen removed large pieces of coagulated putrid casein, half an inch to an inch in length, of such a tough leathery consistence that no amount of washing would have broken them up."—*British Medical Journal*.

CASTRATION IN OSTEO MALACIO.—E. TRUZZI reported to the International Congress (*Beilage zum Centralblatt für Gynakologie*) two cases in which the operation was done, followed by recovery. The first case was that of a woman 26 years old who during her first pregnancy, had ostitic pains, but the confinement was spontaneous. The next labor was more difficult and a third was induced before term. After this last both ovaries were removed, which was followed by marked improvement of the osteo-malacio. A second case was that of a woman 34 years of age with osteo-malacio of three years standing, the result in this case was a suspension of the pathological process. From these two cases the author argues that the operation in some way affects the general nutrition favorably, in puerperal as well as non puerperal cases.

Fehling, of Basel (*ibidem*) contributed a paper in which he reported a prompt recovery in eight cases of osteo-malacio in which the uterus and ovaries had been removed after Porro's method. He thought the relation of the operation to the bone disease was shown by the fact that at menstruation the trouble was always worse; the immediate lessening of pain after operation, and the evident marked effect of pregnancy upon the process. Nasse has demonstrated a loss of substance in the bones of the pelvis and it was possible that we might have in these cases, a vaso-motor reflex from the genital organs.

TREATMENT OF IN-GROWING TOE-NAIL.—PURCKHAUER (*Münch Med. Wochenschr.*) recommends the following method which he has tried not only on himself but numerous patients. The offending portion of the nail is painted with 40 per cent. solution of hydrate of potassium, which rapidly softens the outer layers, soon reducing them to the consistence of butter, after which they are scraped away. The proceeding is again repeated until the nail is reduced to the thickness of paper, when it may be removed from its bed and cut away with scissors.

THE MEDICAL STUDY OF CRIMINALS.

The medical reports of physicians connected with jails, prisons, asylums and almshouses, are generally confined to a few statistics and dispensary-like reports, that have little intrinsic value to science. To-day the prison physician finds a new continent suddenly opening before him, of the medical study of crime and the criminal. His services as dispensary physician are insignificant compared with the possible facts and discoveries within his grasp.

The publication of the second volume of LOMBROSO'S great work on criminals, and the papers and discussions of the Second International Congress of Criminal Anthropology at Paris last year, has suddenly given the prison physician prominence. To-day he occupies the most enviable position for original work, in solving some of the great questions of mental science and sociology. Criminality has a distinct symptomology and pathology; crime has a biological factor, and the criminal has an anatomical, physiological, and psychological nature. The legal treatment of this class has failed, and as a consequence, the level of criminality is rising throughout the civilized world. In France, England, Germany, Spain and the United States, the tide of criminality is rising rapidly. In this country the number of criminals in twenty years have increased one-third more than the increase of the population.

It is evident that the treatment of criminals must be from a different standpoint; that crime

must be studied scientifically, and the criminal known physiologically and anthropologically. This Lombroso's works attempts, and a little volume on "The Criminal," published in the *Contemporary Science Series*, gives a very excellent summary.

In this work criminal symptomology is described. In the study of the external physical symptoms distinct cranial and cerebral characteristics are seen. While the average size of the heads differed but little from ordinary people, there was lack of symmetry, and defective development. In the face, a large prominent lower maxillary bone, or a thin retreating jaw was noted in most cases. High cheek bones, large coarse ears, pallid skin, precocious wrinkles that are common to old age; anomalies of the hair; and a physiognomy that is difficult to describe, in which the eye is most prominent, were also noted. In large numbers of criminals there is very striking similarity of appearance. In heredity some remarkable facts appear. In all cases there is an innate predisposition, and an element of contagion from the surroundings. Motor activity in all cases was prominent, and physical insensibility was below the normal in most cases, hence punishment by pain has less influence on the criminal. The eye and its functions were found superior to the average man, while the hearing and sense of smell were below the average. Early use of tobacco, great sensitiveness to climatic changes, vaso-motor insensibility appeared common. Moral insensibility and palsy of all the higher brain forces, suggesting an arrested development, and reversion of type, with moral instability, and want of foresight, seemed present in all cases. This is ascribed to physical insensibility and defects of normal functioning. In intelligence the average criminal is stupid, inexact, lacking in forethought, and strangely imprudent; he is also cunning, hypocritical, loving falsehood and intrigue. Vanity is also very prominent, and emotional instability, and sentiment, and even tenderness and religious emotion are associated with instructive criminality. A literature, language, and philosophy have grown up with this class. The author goes back to the beginning of crime and the conditions which favored its growth, such as environment, nutrition, culture, contagion and other causes. He discovers crime

among children, and women, crime as a profession and its relation to epilepsy, and insanity, and reaches some very suggestive conclusions.

Criminals, like the insane, the idiot, and epileptic, are the results, of natural causes and reversionary types, the roots of which go further back than any acquired disease. Like insanity criminality follows civilization, and cannot evidently be reached by any one plan of treatment. The experiment at Elmira, New York, of the training of youthful criminals, opened up a new vein, and suggests possibilities of medical treatment that is startling. It also suggests that prison physicians and others who come in contact with criminals, may from a scientific study, be able to point out the forces and laws which govern crime and the criminal, and adopt measures of treatment that will neutralize this rising tide of crime which threatens the civilization of to-day. One fact is established beyond question, viz.: our present theories of crime and criminals must be abandoned. The advances of scientific knowledge in the realm of physiology and psychology, sociology, and anthropology, contradict and give no support to the present views.

A few great pioneer students, like Lombroso, and other distinguished physicians of Europe, have gone into this new land of science, and we ask, where are the American physicians with equal facilities and equal enthusiasm? Here is an open field, beyond all rivalry, with the possibility of discoveries that will help on the march of the race, with more certainty than the knowledge of the *poles*.

THE RELATION OF SYPHILIS TO PARETIC DEMENTIA.

This subject was recently discussed in the Congress for Mental Diseases, held in Rouen in August last.¹

DELAPORTE opened the discussion by stating the diverse views held upon this subject, and the necessity of having a special table of causes, for all cases of general paralysis. Also, a second table of the number of syphilitics found among those affected with other forms of insanity.

DUBUISSON, of Quatremare, had noticed a large increase in the number of paralytics, which he

attributed to the increased consumption of alcohol. Out of 1,600 paretics, in only fifty could syphilis be determined. He ranged the causes of paretic dementia, according to their frequency, in the following order: alcoholism, heredity, overwork, syphilis, and traumatism.

REGNIER, of Paris, claimed to have demonstrated that there were two distinct diseases, one known as pseudo-paralysis (FOURNIER) and the other as true dementia, dependent upon causes competent to produce other forms of mental disease. The frequency of syphilis in the antecedents of general paralytics is very variable, according to MENDEL 76 per cent. REGIS, in 318 cases, found a like percentage. On the other hand, CHRISTIAN places the number at only 15 per cent.

RÉGIS, of Bordeaux, said that during the past year he had seen twenty-one paralytics, eighteen of whom were syphilitic, one doubtful, and two non-syphilitic. He especially called attention to the fact that manifestations of syphilis were rare among paralytics, and that many of them might marry and beget healthy children. It was the marks of old disorders that were to be looked for.

CULLERRE, of Roche sur Yon, placed the percentage of syphilitics at 13. He did not think that general paralysis of syphilitic origin had distinct clinical characters, but it was most refractory to specific treatment.

VOISIN, of Paris, said certain restrictions should be placed upon the figures of Régis and Cullerre. They assumed too readily the intervention of syphilis. Out of 560 general paralytics he had found but nine presenting undoubted signs of tertiary syphilis. The symptoms of cerebral tertiary syphilis had distinct characteristics and could be distinguished from the ordinary forms of paralytic dementia.

RIST, of Versailles, said it was impossible to reconcile the statistics of Régis and Voisin. The one had found eighteen syphilitics in twenty-one cases of general paralysis, and the other but nine in 540. This was only to be explained by a very different manner of diagnosing syphilis.

The discussion, with an unimportant addition, was closed at this point, leaving the question of the etiological relation of syphilis in general paralysis, in the position that it has been for many years; and showing the necessity of more accurate clinical study of the subject.

¹ La Semaine Médicale.

SOURCES OF CAFFEINE.

It is said that nearly all the caffeine now made is obtained from tea. For years past it has been asserted, and commonly accepted as the fact, that this alkaloid was identical with that derived from either coffee, cocoa, Paraguay tea, guarana or kola. Latterly, however, this opinion has been unsettled, since the separate study of the alkaloids, derived from these different sources, has shown that a marked difference in the therapeutic effects of some of them can be demonstrated. The production of palpitations of the heart, a peculiarity of theine, may be accounted for in that class of cases that have greatly puzzled some recent observers, when the fact becomes known to them that the tea plant has been substituted for the coffee-berry, as a source of their caffeine. A recent paper by DR. T. CRANSTOWN CHARLES, in the *British Medical Journal*, contains an interesting study of the physiological effects of maté, or Paraguay, tea and its alkaloid, which is also called caffeine, but which seems to be antidotal to the symptoms produced by chronic overdosage with theine. He reports two cases, elderly women, who having been great tea-drinkers, had become troubled with sleeplessness, constipation and headache, and whose condition had been continuously changing for the worse, in recent months; he prescribed the maté tea. After taking it for a week, these patients reported marked improvement; the constipated habit had been broken up, and their bowels had become regular without resort to cathartic drugs, in consequence, as is held by Dr. Charles, of the property possessed by maté, of exciting the peristaltic action of the intestines; and more urine was excreted, while the insomnia and headaches were far less frequent. These good effects still continue, after a nearly continuous exhibition of the maté for more than a year. Dr. Charles adds that seven other persons have found maté serviceable for the relief of headache and constipation, and with whom both tea and coffee had seemed to disagree.

EDITORIAL NOTES.

THE AMERICAN ACADEMY OF MEDICINE will hold its Annual Meeting at Philadelphia, Wednesday and Thursday, December 3 and 4, 1890. Richard J. Duglison, Secretary.

CINCINNATI AUTHORITIES AND CIGARETTE SMOKING.—The chief of police in that city has issued orders to arrest all children found smoking and will hold them in custody until they learn from whom the goods were obtained.

A PHYSICIAN CREMATED.—The body of Dr. A. B. Carpenter, a prominent physician of Cleveland, O., was incinerated at the Buffalo Crematory, October 21.

A NEW MEDICAL JOURNAL.—*The Baltimore Medical and Surgical Record* is the title of a new medical monthly, the first number of which was issued in October. Its purpose is to furnish, at a low price, a monthly review of medical literature, and as the second medical journal in the State of Maryland, will seek especially to serve the profession in that State. The initial number gives promise of a periodical highly creditable to the Editor and valuable to the profession.

KEMMLER'S DEATH INSTANTANEOUS.—Under this heading, the *Chicago Tribune* of October 26 gives a somewhat extended statement from which we quote the following facts: When William Kemmler was executed by electricity in the State's Prison at Auburn, N. Y., last July, Dr. George E. Fell, of Buffalo, one of the attending physicians in charge, took occasion to obtain and preserve some specimens of the executed man's blood for microscopical examination and analysis. The blood, the most important fluid of the body, is, as is well known, affected by any important changes in the system, and the execution afforded an opportunity never before obtainable of ascertaining the effects of a fatal electric shock. These specimens were given to Henry L. Tolman, a well known microscopist of Chicago, to be photographed. The slides thus mounted and photographed are specially interesting—revealing the fact that with blood corpuscles taken from points along the track affected by the electrical current are shrunken to one-third of their normal diameters, have adherent tendencies, and in multitudes of instances are literally shattered. The blood taken after death from the lower extremities was perfectly natural in appearance, indicating that, rapid as is the circulation of the blood, electricity is still more instant in its execution.

THE CONNECTICUT MEDICAL SOCIETY is making preparations to observe its centennial anniversary.

sary in 1892. Dr. Gordon W. Russell, of Hartford, has been invited to prepare a medical history of the Colony and State previous to 1792, and Dr. Francis Bacon, of New Haven, is to write the history subsequent to that date.

THE INSANE HOSPITAL AT BLOCKLY.—The sum of \$150,000 had been appropriated for new buildings in connection with this institution. The Committee on Charities of Philadelphia now recommend an additional appropriation of \$75,000 for their completion.

THE AMERICAN PUBLIC HEALTH ASSOCIATION.—The eighteenth annual meeting of this Association will be held at Charleston, S. C., December 16, 17, 18 and 19, 1890. The President is Dr. Henry B. Baker, of Michigan; Dr. Joseph H. Raymond, of Brooklyn, N. Y., is Secretary; Dr. H. B. Hoelbeck is Chairman of the Committee of Arrangements. The subjects selected for consideration at that meeting will be as follows: "House Architecture;" "Heating, Lighting, Drainage and Ventilation;" "Sewage Disposal;" "Marine Sanitation;" "Control of Tuberculosis;" "Isolation Hospitals;" "Establishments in favorable Climates for persons predisposed to Tuberculosis;" "Schools for Children;" "Sanatoria;" "Permanent Residences," etc.

THE NEW TARIFF AND MEDICAL BOOKS.—Under the new tariff law foreign medical books printed in any other language than English are admitted without the payment of duty.

THE NEW YORK STATE MEDICAL ASSOCIATION held its annual meeting in Mott Memorial Hall, in New York, October 22, 23 and 24, and was in every way a success. The President's Address is presented to our readers in the present number of *THE JOURNAL*, and an outline report of its work will also be found under the head of "Society Proceedings."

SMOOTH SAILING.—The *Medical Record* is led to infer from a hypochondriacal statement made by the *North American Practitioner*, that "the World's Fair matters are not moving altogether smoothly in Chicago." We beg to inform the *Record* and its numerous readers that nothing could be more a matter of fancy and less a matter of fact. It was certainly the dictate of wisdom, on the part of the management, that every precaution should be taken, and that every ques-

tion of sanitation in connection with the Columbian Exposition should be most carefully considered. Good counsellors were selected and their advice accepted. The site is selected, the work is in progress, all matters are moving on smoothly and the management, in the confidence of a grand success, is happy.

TRI-STATE MEDICAL ASSOCIATION.—At the annual meeting of the Tri-State Medical Association the following were elected as officers for 1891: President, Dr. Robert Battey, Rome, Ga.; First Vice-President, Dr. E. T. Camp, Gadsden, Ala.; Second Vice-President, Dr. Richard Douglas, Nashville, Tenn.; Third Vice-President, Dr. D. H. Howell, Atlanta, Ga.; Secretary, Dr. Frank Trester Smith, Chattanooga, Tenn.; Treasurer, Dr. B. S. Wert, Chattanooga, Tenn. On motion the Association adjourned to meet in Chattanooga, Tenn. (date to be decided on), 1891.

PUBLIC MEDICAL LIBRARY IN KALAMAZOO, MICH.—Dr. E. H. Van Deusen, formerly Superintendent of the Michigan Asylum for the Insane at Kalamazoo, but at present retired from active practice, has recently donated to the city of Kalamazoo the sum of \$50,000 for the purpose of the erection of a public library building.

DR. W. S. CHRISTOPHER, of Cincinnati, has been called to fill the Chair of Practice of Medicine, and Clinical Medicine, of the University of Michigan, Ann Arbor.

THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION will hold its next Annual Meeting at Atlanta, Ga., November 11, 12, and 13, 1890. A general invitation has been extended to members of the medical profession to be present at its sessions, and a very general response is anticipated. George J. Engelmann, M.D., of St. Louis, Mo., is President; W. E. B. Davis, M.D., of Birmingham, Ala., is Secretary, and Virgil O. Hardon, M.D., of Atlanta, Ga., is Chairman of the Committee of Arrangements. A full programme has been prepared, and we anticipate a most successful meeting.

COST OF INFLUENZA.—The cost to England of the influenza epidemic is estimated at \$10,000,000; about one-half of this amount having been paid by insurance companies and friendly societies, and the remainder representing loss of wages and disorganization of business.

TOPICS OF THE WEEK.

A SUCCESSFUL EFFORT.

The effort to secure \$100,000 for the purpose of inducing the Trustees of Johns Hopkins University to admit women to their future medical school, which was inaugurated six months ago, has been successful. The fund was formally tendered by Mrs. Henry Winter Davis, representing the subscribers, and accepted by the Trustees October 28. Much interest has been manifested throughout the country in the movement, and committees have been at work in the chief large cities in collecting contributions towards the fund. The matter has been pushed under the impression that if the fund were offered before the opening of the school it would be secured, whereas there might be difficulty later on. In consummating the agreement the Trustees, at the request of the ladies, passed a resolution accepting the fund and the conditions, viz.: that women whose previous training has been equivalent to the preliminary medical course prescribed for men shall be admitted upon the same terms as the latter. The fund is to be invested and known as the Woman's Medical School Fund, and with interest and additions, is to remain invested until, with its aid as a foundation, a general fund has been accumulated of not less than \$500,000, "sufficient for the establishment and maintenance of a medical school worthy of the reputation of this University and fully sufficient as a means of complete medical instruction. Then, and not until then, will a medical school be opened, etc." The Board further declare that they are "satisfied that in hospital practice among women, in penal institutions in which women are prisoners, in charitable institutions in which women are cared for, and in private life when women are to be attended, there is a need and place for learned and capable women physicians, and that it is the business and duty of the Board, when it is supplied with the necessary means, to make provision in its proposed medical school for the training and full qualification of such women for the abundant work which awaits them in these wide fields of usefulness." Judging by the success in raising funds to tide the University over the financial embarrassments of 1888 and 1889, it is quite probable that this bid for general support in favor of one of the most popular movements of the day, by one of the most renowned and progressive of our American Universities, will meet with an early and liberal response.

THE MEDICAL LIFE, ITS OPPORTUNITIES AND DUTIES.

In his Presidential Address delivered before the University of Durham Medical Society, on October 10, and reported in the London *Lancet* of October 18, Prof. Thomas Oliver spoke upon this subject:

In the course of his address he referred to various reasons why the medical life should be devoted to study, and dealt with the aims which should guide the exercise of the study. The aim of each should be how best to discharge the duties of the profession so that life may be spared to others and happiness extended. Such an aim

brings with it a larger heartedness and a truer nobility of character in the end. Speaking of the opportunities afforded to students at the present, he said: "It is our good fortune to enter upon life in the latter part of a century marked by great activity. We are heirs of the knowledge accumulated by our predecessors. The experimental method in medicine has widened our margin of observation. Nearly a century ago, Galvani, the Professor of Anatomy in the University of Bologna, discovered the phenomena of galvanism. His discovery proved eminently suggestive. To his contemporary, Volta, Professor of Physic in the University of Pavia, Galvani's experiments appealed with marvellous power. Volta set himself at once to investigate the sources of the electricity displayed in Galvani's experiments, approaching the subject from the physical rather than the physiological side, and succeeded in giving to science an apparatus by which current electricity is transmitted in a continuous direction, and he has thus supplied us with the means of increasing our knowledge of the nervo-muscular system. Twenty years after this Sir Charles Bell discovered the difference in function between the anterior and posterior roots of the spinal nerves. Magendie, Muller, Claud-Bernard, and Waller contributed their quota to what we know of the functions of the nervous system. It was a beautiful but a bold stroke, too, that of Helmholtz, which led him to determine the rapidity with which nervous action is transmitted through motor nerves. Armed with that increase of knowledge which bids for acts of greater daring, the brain itself has been attacked by physiologists and surgeons, during life, to ascertain the secrets hidden in its convolutions. And, if a larger comprehension of the nervous system has enabled us to solve many problems that had hitherto been regarded as obscure, in other departments the same advance is noteworthy. The discovery of the vaso-motor centres, and the high-class character of the work of Gaskell as regards the anatomy of the sympathetic system, deserve notice ere we pass to another branch in which considerable progress has been made. It would appear that we are on the eve of some great therapeutical discovery: for Koch has announced that he has discovered a cure for tubercle depending upon destruction of the bacillus. I can scarcely leave the subject of micro-organisms without alluding to the brilliant discoveries of Klein within the last few months. Klein, however, has shown that on the udders and teats of the cow were occasionally found sores, the discharge from which, finding its way into the milk, was probably the source of infection. His experiments have brought to light an interesting series of facts. We have seen that in the human subject diphtheria is mostly a local disease, and that in the cat it is also local, but with a special tendency for lung and kidney to become affected. When the same disease is induced in the cow it would seem as if the germs were diffused throughout the body, for they appear in the milk which is secreted, and here is a circumstance which strongly supports that statement. Two of the cats kept by Dr. Klein took diphtheria, the origin of which at first could not be traced; there was no history of any recent epidemic amongst the cats, and their iso-

lation prevented them being infected in the ordinary way. In the same institution were two cows ill with diphtheria, induced by inoculation. Dr. Klein had arranged that their milk was to be thrown away. One of the attendants, disregarding this order, fed the two cats with the affected milk, with the result of causing diphtheria in them; thus was transmitted a truly specific disease from one animal to another, in exactly the same way as it is transmitted from animal to man. Should men despise a position in life, be it what it may, which gives them the opportunities of acting, which obliges them to suffer, and yet gives them the chances of conquering? The child-like spirit of humility is ours that we may at first accept conditions placed upon us over which we have no control; and the spirit of unrest and mental dissatisfaction are ours that, finding ourselves in these circumstances, they become our field of battle, wherein we learn to labor and prevail. To this are your education and manhood tending. Lifted out of circumstances in life as you have been, it is only that you may find that increased knowledge and opportunity have vastly enhanced your responsibility." Dr. Oliver concluded with the following words: "There are two worlds for you to conquer—one, the world of physical suffering, the other of mental sorrow. Patient and resigned in one that you may transcend the mists and clouds oft created by the other, you will, in a calm and clearer atmosphere, not only find answers to some of the great problems of human life, but, with a soul disciplined by experience, aid others to solve the problem for themselves."

THE OLDEST FRENCH BOOK ON SURGERY.

Dr. Pagel of Berlin has found the oldest French work on surgery among the manuscripts of the Royal Library here, and is publishing it in the *Archiv für Klinische Chirurgie*. It was written in the beginning of the fourteenth century, and its author was Henri de Mondeville. He deals in great detail with all the measures necessary for the treatment of surgical cases, and gives exact instructions for the male and female attendants. Many of these instructions afford significant glimpses of domestic life nearly six centuries ago, not only in the palaces of princes, but also in the hovels of the working people and bondsmen. The author frequently intercalates rules for the guidance of the surgeon in his dealings with patients and their relatives. He instructs his professional brethren, for instance, how to wring their fees—"salarium extorquere"—from wealthy but ungrateful patients. Passages of this kind give a vivid idea of the social position of physicians and surgeons in that remote period; they also increase our knowledge of the superstitions of that time. Besides this, the work gives a pretty complete idea of the state of surgery in the fourteenth century. Its author was one of the most eminent surgeons of his time. After studying in Paris and Montpellier, especially under Jean Pitard, he became a professor of medicine and surgery. In 1304 he was appointed physician in ordinary to Philip IV of France, surnamed the Handsome, whom he accompanied to Flanders. He began the book in 1306, but his progress was slow, owing to the multiplicity of his professional engagements. A long de-

lay was caused by the circumstance that he accompanied Philip's brother, Charles de Valois, as army surgeon, to Arras and England. Thus it happened that the book was still unfinished at the time the author died of lung disease, about the year 1318. Besides the Berlin manuscript, Dr. Pagel has used for his edition (the first ever published) three manuscripts belonging to the French National Library, which were lent to the Berlin Library by Leopold Delisle, the head librarian there, for this purpose.—*The Lancet*.

BACILLARY PARTNERSHIPS.

In the course of some experimental investigations on the relationship of microorganisms with diseased conditions, Drs. Cornil and Babés have discovered that a certain affinity exists between particular species. In other words, the development of special varieties may be facilitated, or the reverse, by the presence or preëxistence of certain other varieties. In this way the occasional complication of an existing infectious disease by a second is not the result of mere chance, but is governed by some still undefined conditions of environment. In other instances this association of two or more species of microorganisms is necessary to the evolution of the malady. This association is the rule in the infectious diseases of human beings, and it is often the secondary infection that determines the fatal issue. This partnership arrangement may take place between microbes belonging to more or less nearly related species, as in the case with the organisms of pneumonia and typhoid fever. Or there may be streptococci and bacilli together, as in diphtheria, or several varieties of streptococci, as in the infection of wounds. In fact, there is a large selection of these associations, some invariable, others frequent and a third category, in which the secondary infection is accidental. These facts may possibly throw some light on the rhythm and sequence of the symptoms in the infectious diseases.—*Med. Press.—Times and Register*.

THE INTERNATIONAL MEDICAL CONGRESS AT ROME. IN 1893.

Dr. Guido Baccelli, President of the Accademia Medica of Rome, and Professor of Clinical Medicine at the Sapienza, took the chair at a recent meeting of the Società per il Bene Economico di Roma, to consider the means of ensuring the success of the International Medical Congress to be held three years hence in the Eternal City. Among the adjuncts to that Congress it was decided to form an International Exposition of Hygiene in connection with the Sanitary Department of the programme, and, with that object, to appeal to all the leading industrial and professional centres throughout the peninsula to contribute their best and latest additions to the "Armaementarium Hygienicum," so as to place Italy at as great an advantage as possible in the inevitable contrast between her own sanitary work and that of the other Powers represented on the occasion. Florence, which has hitherto led the van in hygienic progress in Italy, has already promised her energetic cooperation; and other cities, like Turin and Milan, are expected to do likewise. Concurrently with the Medical Congress, an International Exposition of the Industries of All Nations is also being organized, so that Rome will be the busy scene of quite a gathering of the peoples, on a scale she has not yet known since she ceased to be mistress of the world. The early summer months, May or the beginning of June, or the early autumn months, the latter half of September or the beginning of October, are likely to be those selected for the Medical Congress—all risk of malaria at either time being improbable.—*Lancet*.

PRACTICAL NOTES.

THEOBROMINE AND DIURETIN.

It will be remembered that early in the year Dr. Christian Gram, of Copenhagen, published some results of his experience of theobromine as a diuretic, and his conclusions that in diuretin, the sodio-theobromine salicylate, a salt had been obtained which was easily absorbed and strongly diuretic. Under the direction of Dr. Dujardin-Beaumez, further observations have been made by Mme. K. Pomerantz, which, in the main, confirm the statements originally made by Gram. The results she has obtained are briefly as follows: 1. When given in doses of 15 grs. every two or three hours diuretin is a much stronger diuretic than caffeine; 2, when there is considerable cardiac degeneration it should be employed with some caution, especially when there is albuminuria; 3, under the influence of diuretin the force of the cardiac contractions is scarcely affected; 4, diuretin rapidly increases the quantity of urine passed, and the diuretic effect lasts twice or three times as long as that produced by caffeine; 5, the activity does not wear off readily as the patient becomes accustomed to the drug; 6, micturition is not rendered difficult or painful; and 7, diuretin has no action on the central nervous system. Both theobromine and diuretin give good results in cases of dropsy when diuresis is possible; but as the action appears to consist of direct stimulation of the renal epithelium, it is obvious that the activity of the drug is seriously interfered with in cases of advanced kidney disease.—*The Lancet*.

SALICYLIC ACID AND CREASOTE SOAP.

Salicylic acid, 5 parts.
Creasote, 2 parts.
Basic soap, 93 parts.

M. This soap has been found of great service in the treatment of lupus, psoriasis, seborrhœic eczema, parasitic scycosis, favus and tinea tonsurans.

—*Nouveaux Rèmes; Nat. Druggist*.

ALTERATIVE FOR TERTIARY SYPHILIS.

R. Potassii iodid, ʒijss.
Syr. acidi hydriodic, ʒj.
Aquæ destillat, ʒiij.

M. S. ʒij thrice daily, in a wineglassful of rice water (to detect free iodine).

—*Gerhard*.

PHENACETIN IN TYPHOID FEVER.

According to *The Lancet*, "Dr. Sommer has used phenacetin with great success in the treatment of typhoid fever, thus confirming the favorable views of its action which have been expressed by Masius and others. The dose employed for adults was 4 grs., which was repeated from

two to four times during the twenty-four hours. Children were given only half this dose. No less than sixty cases were treated in this way, with but one fatal case, about which it is noted that the patient was not subjected to phenacetin treatment until three weeks from the commencement of the attack. In no case were there any serious complications."

FOR ENLARGED PROSTATE WITH CYSTITIS.

R. Ergotinæ.
Pil. hydrargyri pulv., āā ʒj.
Salolis, ʒiij.

M. et divide in partes æquales No. xx et in capsulas gelatinas dantur.

S. Take one capsule thrice a day.

—*Gerhard*.

FOR UTERINE HÆMORRHAGE.

R. Ext. cannabis Indicæ, gr. viij.
Ext. ergotæ fl., ʒj.
Ext. hamamelis fl., ʒss.
Tinct. cinnamoui, ʒss.

M. S. ʒj every three hours.

—*Montgomery*.

TREATMENT OF SYPHILIS BY RECTAL INJECTIONS OF IODIDES.

According to the *Revue Générale de Clinique et de Thérapeutique*, the following formula may be used by the anus, whenever the stomach is disordered:

R. Iodide of potassium, 15 grs.
Ext. of belladonna, ¼ gr.
Water, 4 ozs. ℥.

The solution must be warm, and is said to be well borne and effective.

TREATMENT OF SMALL-POX.

M. Galewonski, of Paris, reports that in the small-pox hospital at Brunn, in Austria, baths colored red with permanganate of potash are used for the treatment of small-pox. It is stated that after a short stay in the bath the temperature of the patient falls materially, his general health is improved, the pustules are resolved, and recovery sets in.—*Med. Press and Circular*.

CHLOROFORM WATER IN CROUP.

Dr. H. B. Bashere, in the *Medical Record*, states that in the treatment of false croup he has had excellent results from the use of chloroform water, which, in his judgment, is superior to chloral. From 5 to 10 minims of chloroform to an ounce of water and about ½ drachm of glycerine, of which mixture a teaspoonful is given every half hour during the attack and the following day less frequently, say every two hours, but during the evening every hour, according to the difficulty of breathing.

SOCIETY PROCEEDINGS.

Tri-State Medical Association.

Second Annual Meeting, held in Chattanooga, Tennessee, October 14, 15, and 16, 1890.

FIRST DAY—MORNING SESSION.

The Association met in Turner Hall, and was called to order by the President, Dr. J. B. Cowan, of Tullahoma, Tennessee, at 10 A.M. The first session was devoted to introductions, miscellaneous business, etc.

AFTERNOON SESSION.

DR. W. P. McDONALD, of Hill City, Tennessee, contributed a paper entitled

REPORT OF A CASE OF CANCRUM ORIS OR GANGRENOUS STOMATITIS.

The patient, white, was 4 years of age. Dr. McDonald first saw the case on August 5. He found her with some fever, tongue coated brown, with red edges, surface more or less furrowed or full of cracks in the brown coat, her general appearance indicating a very low state of health. Her bowels were inclined to be too loose, and her abdomen seemed to be somewhat distended—tympanitic. With these symptoms he pronounced the case one of typho-malarial fever. He began treatment by giving a mercurial purge, followed by large doses of quinine and bismuth. This treatment was continued for two days, after which he ordered 10 drops of the syrup of iodide of iron after meals, also quinine and bismuth in small doses three or four times a day. This treatment was continued for about ten days, at the end of which time he found the patient had greatly improved.

Fourteen days after seeing the child for the first time, he was called to see the mother, whom he found with nearly the same symptoms as the child first presented. During his absence from the city, another physician had treated an older daughter, whom he supposed had been troubled with the same disease. The child was still improving except complaining of a sore throat. On examination he found several small ulcers on the right side of the mouth, with a general inflammatory appearance of the gums and whole mucous lining of that side of the buccal cavity, with some bleeding from around the teeth. The trouble at first seemed to yield to a wash of chlorate of potassium and creosote, but on the seventeenth day of illness, the inflammation increased rapidly, the whole cheek and side of the face appearing very much swollen, and the inside was fast becoming dark and gangrenous. August 24, a small dark spot about the size of a penny made its appearance externally, just at the right wing of the nose. This rapidly enlarged, in-

volving the wing of the nose and in proportion the tissues on either side of the central spot, and on August 25, it had involved the right side of the nose up to the inner canthus of the eye, also the upper lip to the median line, and had spread rapidly on the cheek, reaching a point where the zygomatic muscles cross the superficial portion of the masseter. The teeth on this side became loose and dropped out, both above and below, indicating deep seated trouble, possibly involving the maxillary bone.

Careful investigation revealed a strumous diathesis existing in the family, but no history of tuberculosis could be ascertained.

According to good authorities cancrum oris more frequently occurs as a sequel of other diseases than *per se*. The statistics of Rilliet and Barthez show that out of 98 cases of this disease, 41 were following measles; 5 scarlet fever; 6 whooping cough; 9 intermittent fever; 9 typhoid fever, and 7 mercurial salivation.

To draw a conclusion in the case by these statistics and by watching the case closely from the start, Dr. McDonald asks, "Did this occur as the sequel of the typho-malarial fever which I diagnosed (remembering the poor state of health the child was in to begin with)? Or was it the result of mercurial salivation produced by the mercury given at the beginning and followed two days after by the syrup of the iodide of iron?"

DR. JAMES E. REEVES, of Chattanooga, said the case was evidently one of gangrene, which is almost necessarily fatal.

PRESIDENT COWAN asked if the character of the disease might not have changed. To which Dr. Reeves replied that there was nothing impossible in medicine, and the disease might have changed.

DR. E. T. CAMP, of Gadsden, Alabama, once saw a case similar to the one reported, which he pronounced gangrene oris, the whole of one cheek being destroyed. There was evidence of mercury having been taken in the early part of the illness of the patient. The case terminated fatally within a few days. The patient was 4 or 5 years old and of the lower class. He thought the gangrene was the result of mercurial poisoning which was administered during the early part of the illness.

DR. JAS. E. REEVES, of Chattanooga, then contributed a paper entitled

ON ALL SIDES A LEARNED DOCTOR.

The author introduced his subject by an earnest plea for higher medical education, stigmatizing cheap medical colleges, with no facilities for imparting instruction, as the greatest stumbling-blocks in the way of true progress. He next paid his attention to the present tendency to make one-sided physicians, and lamented that the department of gynecology was overrun with

cheap performers with the speculum, probe, dull curette, etc., and maintained that the specialist should build on the broad foundation of the general practitioner in order to reach professional eminence.

EVENING SESSION.

DR. ANDREW BOYD, of Scottsboro, Alabama, read a paper on

FRACTURE AT ELBOW JOINT,

and reported cases. He said after reduction there are but two methods of treatment of fracture at the elbow joint, viz., the extended or straight, and the flexed position. The author thinks the flexed position the better of the two, for the reason, 1, that in all cases surgeons fear ankylosis, and it is much better to have a flexed ankylosed arm than a straight one. The comparative use in each is apparent. 2. When splints have remained twenty-five to thirty days, the arm is atrophied and almost helpless; it is therefore easier to overcome the flexor muscles than the extensors, and a patient can extend an arm with more ease than he can flex it.

MR. SIDNEY B. WRIGHT, of Chattanooga, read a paper on

EXPERT TESTIMONY.

He drew the following conclusions: 1. That all the facts proved should be consistent with the hypothesis. 2. That the circumstances should be of a conclusive nature and tendency. 3. That the circumstances should, to a moral certainty, actually exclude every hypothesis but the one propounded to be proved. 4. That mere circumstantial evidence, unless the chain of circumstances is absolutely complete, ought in no case to be relied upon where direct and positive evidence, which might have been given, is withheld by the adverse party.

DR. W. G. BOGART, of Chattanooga, reported a *Case of Neurosis*.

DR. W. S. GAHAGAN, of Chattanooga, read a paper (by title) on *Neuralgia*.

(To be concluded.)

New York State Medical Association.

Seventh Annual Meeting, held at Mott Memorial Hall, New York, Oct. 22, 23 and 24.

DR. JOHN G. ORTON, OF BINGHAMTON, PRESIDENT, IN THE CHAIR.

FIRST DAY.

For President's Address see page 665.

Papers were read as follows: *Prognostics in Medicine*, by Dr. John Cronyn, of Erie County; *The Mimicry of Animal Tuberculosis in Vegetable Forms*, by Dr. E. F. Brush, of Westchester County, and a paper by Dr. A. Palmer Dudley, of New

York, entitled *A New Method of Surgical Treatment in certain forms of Retro-Displacements of the Uterus, with Adhesions*. In the afternoon there was a discussion on *Intra-cranial Lesions*, in which Dr. Jas. J. Putnam, of Massachusetts, Dr. Chas. K. Mills, of Pennsylvania, Dr. Chas. Phelps, of New York, and others, participated.

The questions propounded referred to: What are the present means of localizing intra-cranial lesions? What is the nature of the chief intra-cranial lesions (hæmorrhages, abscesses, tumors), and how can they be discriminated? What are the indications and contra-indications of operative interference in cases of intra-cranial lesions? What are the best modes of operating in cases of intra-cranial lesions? What are the immediate and also the remote results of operative treatment in cases of intra-cranial lesions?

A most interesting feature of the session was a paper on *Hypnotism*, read by Dr. H. Ernest Schmidt. He defended and upheld hypnotism as a remedial agent of the greatest value to the physician, though in a limited sphere. To fortify his position Dr. Schmidt related three cases from his own practice, in which he claimed an absolute cure from hypnotic influences. The first case was that of a sixteen-year-old girl, who suffered with nervous diseases, for which she had been treated by twenty-three physicians without success. Seven applications of hypnotic treatment effected a cure. In a second case neuralgia was cured, and in a third chronic rheumatism yielded to the mysterious influence. Dr. Schmidt attempted no explanation of hypnotic phenomena. His paper excited great interest among the attending physicians.

Dr. John W. S. Gouley, of New York, discoursed upon *Retention of Urine from Prostatic Obstruction; its Nature, Diagnosis and Management*. His treatment of the subject was exhaustive, lucid, and well fortified with numerous cases, and the exhibition of various surgical devices. He was careful to avoid advocating any instrument of universal adaptation, but pointed out the salient features of each.

SECOND DAY.

The morning of the second day, which was very stormy, opened with the Address on Surgery, *The Ligature of Arteries*, by Dr. Stephen Smith, of New York, which was elegantly presented in choice phraseology. The next paper, on *Exophthalmic Goitre*, was read by Dr. E. D. Ferguson, of Troy, N. Y., who confined himself mainly to its therapeutics.

Dr. George E. Fell, of Buffalo, was bulletined to read a paper on *The Death Penalty; Does the Garrote or Hanging ever produce Instantaneous Unconsciousness?* but, much to the disappointment of the audience, was absent.

The discussion on Obstetrics was opened by

Dr. S. B. Wylie Macleod, and involved the following queries: How may the present prophylactic measures in obstetrics be more extended and applied? Is the present technique, in the management of labor and convalescence, in accordance with sound physiology? To what extent have the surgical means of the treatment of labor complications been successful, or should these complications and the process of repair have been more generally left to nature? What influence would a more advanced obstetrical science have on the biological and social condition of the race?

The participants, who appeared in person or sent their papers, were Drs. Ira B. Read, Henry D. Nicoll, Wm. McCollom, Joseph W. Stickler, Geo. T. Harrison, T. J. McGillicuddy, A. Palmer Dudley, Wm. H. Robb, and Alfred L. Carroll.

At the night session Dr. Carlton C. Frederick, of Buffalo, delivered his address on Obstetrics, which touched upon the substantial advances of the year and claimed the attention of the audience until the reading of a paper by Judge Charles H. Truax on *The Medicine of the Classics*, which was replete with wit and humorous allusions.

THIRD DAY.

The morning session of the third day began with a paper by Dr. Martin Cavana, of Oneida, *On Expert Medical Testimony; or the Physician as a Witness*.

Dr. Benjamin M. Ricketts, of Cincinnati, O., an honorary fellow of the Association, read a paper entitled, *Some Observations on Bone and Skin Grafting*. He said: "Grafting, or dermepenthesis in the vegetable kingdom, has been developed to such an extent that there is hardly any limit to what may be done in the way of repair and production, beauty and financial gain being the greatest desiderata. While the results of grafting animal tissue are less gratifying than those of vegetable tissue, much has been done to convince us that the limit is far beyond anything yet attained. The oculists have displayed unbounded energy and exalted skill, as shown by their success in transplanting the cornea of the cat, dog and rabbit to the eyes of human beings, and of mucous membrane to the conjuction, for the correction of deformity as the result of eye troubles in infancy. It is now demonstrated that the nerves of lower animals may be successfully transplanted to the nerve stumps of man. Dr. Redart successfully grafted the skin of a chicken upon a child two years old. Dr. Bartens succeeded in grafting the skin of a dead man seventy years old to that of a boy fourteen years old. Dr. Walfler was equally successful in transplanting the mucous membrane of frogs, rabbits and pigeons to mucous areas in man previously occupied by cicatricial tissue, and was the first to show that mucous membrane remains so if trans-

planted to mucous membrane, and become skin if transplanted to skin.

"I have succeeded in grafting the skin of a frog to that of a tortoise, and the skin of a tortoise to that of a frog; and also in securing the growth of a frog's skin upon the skin of a man fifty-four years old. Bone-grafting is not so far advanced, but has met the same success as skin-grafting. Enough has been accomplished to satisfy me that the day is not far distant when the long bones and ribs of the lower animals will be successfully transplanted to man for the purpose of restoring osseous structures destroyed by any cause whatsoever. I am inclined to believe that the tails of such animals as the cat, dog, opossum, etc., after being divested of the integument and soft tissue, may be transplanted with success. It may be found that the ribs of lower animals can be substituted for the small bones of the hand."

Dr. Thomas H. Manley, of New York, ably discussed the paper, and gave many corroborative instances from his hospital practice. He thought there was a future for the procedure yet undreamed of.

Dr. Joseph C. Greene, of Buffalo, read an interesting paper, detailing in part his personal experience with *Leprosy*, showing its distribution along coast lines, and the localities showing the foci of contagion. He mainly confined himself to the epidemiology and history of the disease. A large map aided in giving force to his remarks.

Dr. Homer O. Jewett, of Cortland, discoursed upon the *Use and Neglect of Blood-Letting*, in which he advocated its therapeutical claims. He gave many instances where relief and perhaps cures in pneumonia, pleurisy and apoplexy were prompt. He thought that delay often deprived the measure of its triumphs.

Dr. John Shrady, of New York, in his paper on *The Psychological Aspects of Insanity*, after touching upon some of the difficulties of diagnosis, referred to the fact that treatment to be successful must consist in antagonizing one emotion with another.

In the afternoon the following papers were read either by the authors themselves or by title: *Tumors of the Orbit and Neighboring Cavities*, by Dr. C. S. Bull, of New York; *Test of Dugas in Dislocation of the Shoulder*, by Dr. F. W. Putnam, of Binghamton; *Early Infant Viability, with Management of Cases*, by Dr. H. C. Hendrick, of McGrawville; *Scarlet Fever in Puerperium, with Cerebral Hemorrhage and Hemiplegia*, by Dr. C. S. Allen, of Greenbush; *Alcoholism as a Vice, and as a Result of Inherited or Acquired Brain Disease*, by Dr. I. de Zouche, of Gloverville.

Dr. Wm. H. Robb, of Amsterdam, exhibited an office battery, simple in construction and easily constructed by a person of ordinary ingenuity. He claimed for it easy portability and as taking up but little space.

Dr. Darwin Colvin, of Clyde, in his contribution with the title *In Abortion, what of the Placenta after the Second Stage*, advocated immediate removal. Drs. A. L. Carroll, S. W. B. M. McLeod, John Parsons and H. O. Jewett coincided with this view. Dr. E. D. Ferguson advised curetting with the finger or wire as the most effectual means of removal.

The other papers, to-wit: *Cysts and Cystic Formations; their Pathology, Diagnosis and Treatment*, by Dr. T. H. Manley, of New York; *Functional Disorders of the Nervous System of Women*, by Dr. T. J. McGillicuddy, of New York; *The Feeding of Infants*, by Dr. J. P. Garrish, of New York; and *A Case of Craniotomy, with Remarks*, by Dr. Jas. W. Guest, of New York, were crowded out by the lateness of the session, but were referred for publication.

Officers were elected as follows: President, Stephen Smith, New York; Vice-Presidents, A. F. Van Vranken, West Troy; J. D. Tripp, Auburn; R. J. Menzie, Caledonia; Members of Council, W. D. Garlock, Little Falls; George Douglas, Oxford; Theodore D. Strong, Westfield. Dr. E. D. Ferguson, of Troy, was re-elected Secretary. The treasurership was left vacant.

At 4 o'clock the retiring President, Dr. John G. Orton, surrendered his seat to his successor, Dr. Stephen Smith. After a brief address by the new President the meeting was adjourned. The new Council was immediately called together, and it was decided to hold the next meeting of the Association in Mott Memorial Hall on the fourth Wednesday of October, 1891.

FOREIGN CORRESPONDENCE.

LETTER FROM LONDON.

(FROM OUR OWN CORRESPONDENT.)

Self-murder on the Continent—Cremation—Opening of Queen Margaret College, Glasgow—Soja Biscuits for Diabetics—Housing of the Working Classes—Miscellaneous Gleanings.

From St. Petersburg comes a thrilling story of a Professor of Medicine who took poison in the very act of lecturing to his class, while in Paris the daily number of cases of self-murder is said to range from twelve to eighteen. Nor is there forthcoming any scientific explanation of the phenomenon of the sort in which the late Mr. Buckle took delight. In the spring people who are tired of life mostly drown themselves in the Seine, in the autumn they prefer to asphyxiate themselves by means of charcoal fumes. That is all the statisticians tell. The question which remains for the present unanswered is, What is the real cause of this alarming predisposition to self-murder?

Miss Graham, M.D., and Miss Baumler, M.D.,

former students of the London School of Medicine for Women, have been appointed lady doctors under the Marchioness of Dufferin's Fund in India. The former will serve at Rangoon and the latter at Lahore.

Cremation appears to be making way in Manchester. The report of the local society states that the limited company formed for the erection of the crematorium has been duly organized and registered, and that about three thousand shares have already been subscribed for. Under these circumstances the question has arisen whether the society may not be considered to have fulfilled its purposes, but on reflection it has been decided that there is room both for the Manchester Cremation Society and the Manchester Crematorium. The report observes, "The crematorium may be erected, but if public attention be not directed to its existence and the benefits arising from its use, the company will fail for want of adequate resort." It is pointed out that in this matter England has been outstripped by other countries. France, Italy, Germany and America all avail themselves to a much larger extent of this method of disposing of the dead. In Paris the Municipal Council has built a crematorium in the cemetery of Pere la Chaise, where in the first eight months 518 bodies were cremated. In Italy, where the first crematory, that at Milan, was built in 1874, there are now forty communes which have built furnaces for themselves. In England, on the other hand, there is but one at the present time, and that is situated at the inconvenient distance of twenty miles from London, and even there the number of cremations has so far reached a comparatively small number.

The present winter has seen the opening of Queen Margaret College, Glasgow. This gives to Scotland the distinction of possessing two schools for the training of lady doctors. It is difficult to believe now, with all the facilities that women enjoy for entering the medical profession, that it is only sixteen years since the London School of Medicine for Women was first opened amidst a storm of derision and contempt. It is history, too, how the University of Edinburgh refused admission to the sex and was backed by a decision of the Scottish Court of Sessions. Yet on the 1st of October, it is found that a fifth school is necessary in addition to those of London, Edinburgh, Dublin and Belfast, to meet the continuous demand from the East for lady doctors. The success which has attended the movement has exceeded the most hopeful claims made for it in years past by its pioneers, while many of its former opponents have frankly confessed that their opinions have been entirely changed on seeing that women doctors neither became unwomanly nor interfered with men in their pursuit of the profession.

It is now more than twenty years since Dr. Forbes Watson drew special attention to the high percentage of nitrogen—over 70 per cent.—contained in the cotyledons of the *Soja hispida* or "Soy" bean of India, but from some cause or other no attempts—or at least no successful attempts, appear to have been made to dietetically utilize the bean. Some new biscuits prepared from the *Soja* have been brought out, and these are stated to be well adapted for use amongst diabetic patients, by reason of the insignificant proportion of starchy and saccharine matters they contain. The biscuits, unlike several "diabetic" productions, are not at all unpalatable, and indeed may be said to be rather nice than otherwise. Consequently they are likely to become popular with patients.

Mr. Ritchie, in his capacity of President of the Local Government Board, has directed the attention of the County Councils in the country, and sanitary authorities, vestries and District Boards of the metropolis, to the provisions of the Act passed last session as to the housing of the working classes. This Act has greatly extended the powers of the local authorities. Heretofore in towns houses could not be condemned unless the medical officer of health alleged that the prevalence of disease in the district might be reasonably attributed to the sanitary defects of the dwellings. Henceforth it will not be necessary to await the outbreak of disease. The stable doors may be locked before the steed is stolen. It will be enough for the medical officer of health to represent that the sanitary defects are dangerous or injurious to the health of the inhabitants or their neighbors. The compensation to be given to the owners of any houses in an unhealthy area acquired for an improvement scheme will not be based on the rental if that rental has been swollen by dangerous overcrowding. If the houses are deemed utterly unfit for habitation, only the value of the land and of the materials of the buildings will be allowed. Apart from improvement schemes, important powers are given to the local authority to deal with unhealthy dwellings. The medical officer of health is expected to keep himself informed about such houses, and where he does not take action of his own accord he is bound to take notice of the complaint of any four neighboring householders. Urban sanitary authorities have also the power, under the new Act, of building and furnishing lodging-houses for the working classes, but this part of the Act cannot come into force in rural districts unless it has been adopted by the sanitary authorities after a local inquiry directed by the County Council.

A rather unusual case occurred at the Dover County Court. A surgeon sued a retired medical practitioner for £21 for professional attendance. Defendant contended that it was the custom in the medical profession not to charge each other

for attendance. Plaintiff and another medical gentleman said that although it was not usual to charge a man in practice, it was usual to charge a retired medical man. With this the judge agreed and gave judgment for the plaintiff.

It appears after all that there is but slender foundation for the alarming report that the influenza epidemic had reappeared in the city of London. One leading practitioner states that he has heard of only four cases, and they were all in one family, while another suggests that the symptoms of other maladies have been mistaken for those of influenza.

The authorities of the Metropolitan Asylum Board have been compelled, in consequence of the rapidity with which fever cases are coming into the London hospitals, to open huts at Gore Farm, Darent, for convalescing patients. For some time past the cases have been coming into the six hospitals at present open at the rate of forty a day, and at the present there are 2,147 cases under treatment.

With the object of continuing the work of popularizing the use of short-hand amongst medical students, an examination in general proficiency in short-hand and the methods of its use will be held at the Examination Hall of the Royal Colleges of Surgeons. G. O. M.

DOMESTIC CORRESPONDENCE.

"Limited Practice" and the Code of Ethics.

To the Editor:—The leading editorial in the *Peoria Medical Monthly* for September, 1890, commences with the following paragraph: "We believe the Code of Ethics of the American Medical Association permits of advertising to the extent of an announcement, 'Practice limited to diseases ———,' following the name of the advertiser." And throughout the article the writer assumes that the Code of Ethics actually gives permission to advertise "practice limited" to this or that specialty, whereas, there is not a word in the Code of Ethics relating to specialties or to "practice limited," as I have had occasion to explain many times. The only clause in the Code referring to advertising is in the following words:

It is derogatory to the dignity of the profession to resort to public advertisements or private cards or handbills, inviting the attention of individuals affected with particular diseases;—publicly offering advice and medicine to the poor gratis, or promising radical cures; or to publish cases and operations in the daily prints, or suffer such publications to be made; to invite laymen to be present at operations, to boast of cures and remedies, to adduce certificates of skill and success, or to perform any other similar acts. These are the ordinary practices of empirics, and are highly reprehensible in a regular physician.

The origin of the phrase, "practice limited," is to be found, not in the Code of Ethics, but in the

report of a committee on a revision of the Code of Ethics made to the Association in 1874, as the following quotation shows:

The Code of Ethics very properly makes no mention of specialties or specialists, but presents plainly the rules necessary for the maintenance of professional character as applicable to all. But we are asked how, then, can those who wish to pursue a special practice make known their position to their brethren and the public? We answer that the title of Doctor of Medicine covers the whole field of practice, and whoever is entitled to that appellation has the right to occupy the whole or any part of the field, as he pleases. The acceptance of this honorable title is presumptive evidence to the community that the man accepting it is ready to attend practically to any and all duties which it implies. As all special practice is simply a self-imposed limitation of duties implied in the general title of Doctor, it should be indicated not by special qualifying titles, such as oculist, gynecologist, etc., nor by any setting forth of special qualifications, but by a simple *honest* notice appended to the ordinary card of the general practitioner, saying, "practice limited to the eye and ear," or to "diseases peculiar to women," or to "midwifery exclusively," as the case may be. Such a simple notice of limitation, if *truthfully* made, would involve no other principle than the notice of the general practitioner that he limits his attention to professional business within certain hours of the day. Neither could it be regarded as a claim to special or superior qualifications. To give the specialist any privileges beyond this, would be to invest him with a special advantage inconsistent with the equality of rights and duties pertaining to the profession.¹

It should be kept in mind that this quotation is simply the reasoning or comment of the committee and not a proposition to be incorporated into the Code. So far from this, the committee, after commenting on several other topics, closed its report with the following declaration: "After carefully reviewing the whole subject your committee do not recommend any alterations in the present Code of Ethics." And on motion of Dr. J. H. Van Deman, of Tennessee, the report was unanimously adopted by the Association.

Whether the suggestion of the committee, that the regular physician who honestly and actually restricts his practice to a fairly defined specialty, may so inform the public by saying on his card "practice limited to ———," is a question about which different opinions have been expressed, and concerning which no judicial action has been taken. But it is certain, as stated by the editor of the *Peoria Medical Monthly*, that the physician who makes such declaration on his professional card, must practice in strict accordance therewith. He cannot declare to the public and his professional brethren that his *practice is limited* to particular diseases or to diseases of particular organs, and continue to take charge of any and all cases that may come in his way, without making himself liable to the charge of deception and unprofessional conduct. And for that reason it is not likely to be generally adopted; simply because only a small percentage of the so-called specialists are willing to actually *limit* their practice to

the legitimate boundaries of their chosen specialty.

Very truly,
Chicago, Ill., Oct. 25, 1890.

N. S. DAVIS.

To the Editor:—Please see page 446, second column, near top of page (for September 20, 1890), where your New York correspondent says: "Consumption being peculiarly a disease of *civilization* (italics mine), is nourished by bad air and overwork amid insalubrious conditions," etc.

Now, just what condition of living constitutes the condition the writer regards "civilization," I am unable to tell; but I do know—from years of personal observation—that our North American Indians, especially those that most nearly approach savagery, not only often die of various forms of phthisis, but are far more subject to tuberculosis (pulmonalis and other forms), than the white people of any city in the United States. And not only so, but the Indians who live and ramble over the Rocky Mountains, from British America to Mexico, are also quite subject to phthisis pulmonalis (and other forms of phthisis), notwithstanding they breathe (when out-doors) the best air on our continent. Your correspondent, and most all our Eastern (American) medical book-makers should, at least, make themselves very familiar with disease in all parts of our own country—to say nothing of foreign parts—before presuming to teach what they do not know.

See in 7th edition of "Da Costa's Diagnosis," page 904, where he says of dengue: "Dengue is generally a harmless disorder, epidemic and contagious."

While the notorious facts, in reference to the effects of dengue here in Texas, as it has prevailed more or less extensively, at times, for many years past, are that it is not a "harmless disorder" in any sense of that term, for it is well known that our puerperal (and pregnant women not advanced to full term) in many (I may say most) cases, lost their lives as a result of dengue, to say nothing of many male (and female) persons who were first made seriously and painfully sick for a week or more, and left invalided for several or many months, and if of consumptive tendency, to die within a year or less, of phthisis. Now is this a "harmless disorder?" Yet Dr. Da Costa is a learned physician, whom we (Americans) are all proud of, and delight to honor, but had he followed the example of the great medical philosopher, Daniel Drake, he would not have fallen into such harmful blunders. Da Costa should have studied dengue "on the ground," in its native domestic habitat, then wrote not as the "scribes" (of Eastern bookdom) but as "one having authority." As the great Trousseau so often urged us, we (as students) as writers, should be always seeing and studying patients, and under

¹ See Transactions, Vol. 25, pp. 30-31, 1874.

all sorts of conditions and environment; then profoundly consider the why and wherefore of all we see and observe. But I hope you will pardon me for "bringing coals to Newcastle"—unbidden at that. Most respectfully yours,

Q. C. SMITH, M.D.

Austin, Texas, Oct. 17, 1890.

BOOK REVIEWS.

THE MEDICAL NEWS VISITING LIST, for 1891.
Philadelphia: Lea Brothers & Co.

Messrs. Lea Brothers & Co. again present their compliments to the medical profession, and place upon the market their Physicians' Visiting List for the ensuing year. In addition to a variety of tables, valuable as a means of ready reference, such as doses, poisons and their antidotes, therapeutic tables, weights and measures, there are others upon artificial respiration, ligation of arteries, signs of dentition, and of pregnancy, urinalysis, and also a table of many of the newer remedies. The present arrangement of the book is the result of years of experience and will be found every way acceptable to the profession.

MISCELLANY.

LETTERS RECEIVED.

Woodhull, Fort Leavenworth, Kansas; Dr. F. S. Dennis, New York City; W. C. Clemison, Warrenton, Mo.; Dr. B. A. Camfield, Chicago; Provident Chemical Works, St. Louis, Mo.; Dr. F. H. Caldwell, Sanford, Fla.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from October 25, 1890, to October 31, 1890.

First Lieutenant J. D. Glennan, Asst. Surgeon, is granted leave of absence for one month, to take effect about the 31st inst. Par. 1, S. O. 146, Dept. Missouri, October 23, 1890.

By direction of the Secretary of War, the following changes in the stations of officers of the Medical Department are ordered:

First Lieut. Chas. E. Woodruff, Asst. Surgeon, is relieved from duty at Ft. Gibson, Cal., and will report in person to the commanding officer, Ft. Missoula, Mont., for duty at that post, relieving Major Calvin DeWitt, Surgeon. Major DeWitt, upon being relieved, will report in person to the commanding officer, Ft. Hancock, Tex., for duty at that post. Par. 6, S. O. 249, A. G. O., Washington, October 24, 1890.

Capt. Charles B. Ewing, Asst. Surgeon, leave of absence granted in S. O. 131, Dept. of the Missouri, September 22, 1890, is extended fourteen days. By direction of the Secretary of War. S. O. 250, A. G. O., October 25, 1890.

Capt. Guy L. Edie, Asst. Surgeon U. S. A. (Ft. Douglas, Utah), is granted leave of absence for one month, on surgeon's certificate of disability. S. O. 80, Hdqrs. Dept. of the Platte, Omaha, Neb., October 27, 1890.

Surgeon Stevens G. Cowdrey, U. S. A., is granted leave of absence for one month, with permission to apply for an extension of fifteen days, to take effect upon the arrival of Acting Asst. Surgeon A. P. Fricke at Ft. Marcy, Par. 2, S. O. 112, Dept. of Ariz., Los Angeles, Cal., October 24, 1890.

Official List of Changes in the Medical Corps of the U. S. Navy for the Week Ending November 1, 1890.

Surgeon F. B. Stephenson, detached from receiving ship "Wabash," and wait orders.

Surgeon H. M. Martin, ordered to the receiving ship "Wabash."

Asst. Surgeon Lewis H. Stone, ordered to the U. S. S. "Pinta."

Asst. Surgeon William F. Arnold, detached from the U. S. S. "Pinta," and granted two months' leave.

Surgeon Thomas Owens, detached from the Coast Survey Str. "Blake," and wait orders.

Asst. Surgeon N. J. Blackwood, ordered to the receiving ship "Vermont."

Asst. Surgeon E. S. Bogert, detached from the U. S. receiving ship "Vermont," and to the Coast Survey Str. "Blake."

Surgeon A. M. Moore, detached from the U. S. S. "Kearsarge," and to the Naval Hospital, Mare Island, Cal.

Official List of Changes of Stations and Duties of Medical Officers of the U. S. Marine-Hospital Service, for the Three Weeks Ending October 25, 1890.

Surgeon W. H. H. Hutton, detail as chairman Board of Examiners revoked; ordered to Washington, D. C., for temporary duty. October 14, 1890.

Surgeon Walter Wyman, to inspect quarantine stations. October 14, 1890.

Surgeon W. H. Long, detailed as chairman, Board of Examiners. October 14, 1890.

Surgeon H. W. Sawtelle, granted leave of absence for five days. October 13, 1890.

Surgeon J. M. Gassaway, granted leave of absence for thirty days. October 11, 1890.

Surgeon Fairfax Irwin, detailed as recorder, Board of Examiners. October 14, 1890.

2. A. Surgeon R. P. M. Ames, granted leave of absence for thirty days. October 14, 1890.

P. A. Surgeon J. H. White, granted leave of absence for thirty days. October 24, 1890.

P. A. Surgeon W. J. Pettus, to proceed to Vineyard Haven, Mass., for temporary duty. October 9, 1890.

Asst. Surgeon T. B. Perry, ordered to examination for promotion. October 9, 1890.

Asst. Surgeon J. J. Kinyoun, ordered to examination for promotion. October 10, 1890.

Asst. Surgeon A. W. Condict, to proceed to Baltimore, Md., for temporary duty. October 18, 1890.

RESIGNATION.

P. A. Surgeon R. P. M. Ames, resignation accepted by the President, to take effect November 15, 1890. October 14, 1890.

THE SURGERY OF THE ABDOMEN, WITH
SOME OF ITS RESPONSIBILITIES.

Read in the Section of Medical Jurisprudence, at the Forty-first Annual Meeting of the American Medical Association, Nashville, Tenn., May, 1890.

BY THOMAS H. MANLEY, A.M., M.D.,

VISITING SURGEON, THE HARLEM HOSPITAL, NEW YORK.

In these days, the closing decade of the nineteenth century; a century which has changed the whole face of civilization, and which has demonstrated by fact, that which it would seem could be but the revelation of a dream, it behooves those of us in life, whose part is confined to the healing art, to not only press forward, with the tide of progress, but we should also look into the retrospective, with a view of reaching a rational estimate of the position which we occupy, to-day.

The application of physics and chemistry, in manufactures, commerce, and the arts has wrought most marvelous changes. Steam and electricity, have annihilated distance; and with the rapid, onward pace of inventive genius, it would seem, that the time is near at hand, when they will wholly supplant manual labor, and entirely supersede animal force as a motor. An intelligent and broad comprehension of Nature's forces, has enabled us, to better understand, vital, physiological, and pathological processes.

While such enormous strides have been made, in the many and varied occupations of man, the healing art has kept well abreast, and in some respects, even ahead, in the race for brilliant achievements.

Experimental chemistry gave to humanity the the greatest boon, ever conferred—anaesthesia. By the aid of chemistry, with the use of the microscope, we need have no more *materies-morbi*. The morbid material is the same, as since the creation of man, but we separate, isolate and distinguish its varied elements, with rapidity and precision.

A better knowledge, and greater familiarity with the agencies of Nature have emboldened us, to explore regions of the body, which heretofore, had been regarded, through tradition, handed down to us, from one generation to another, as

utterly and absolutely beyond the scope of human intervention; and bold indeed were the pioneers, who dared to defy the dogmas, of their age, and and push forward in the face of an unbroken opposition, and break, ground hitherto untrodden.

Among such were Nathan Smith of New Hampshire, and Ephraim McDowell of Kentucky, who about the same time, in widely separated sections of our country, in almost its colonial days, essayed to deal with ovarian tumor by abdominal section. Notwithstanding the rapid and successful progress of the ovarian operation, when all its technique were mastered; yet, surgeons whose pens have illumined the pages of medical literature, and whose names still adorn the profession, hesitated to open the peritoneal cavity for the relief or cure of any sort of neoplasm and condemned especially, every kind of interference, in cases of gunshot or penetrating wounds, of the abdomen. Sad, indeed, was the fate of him, whose bowels became obstructed, from within, or of the soldier on the field of battle whose abdomen, was torn open by shot or shell.

The prejudice of the older surgeons was so unanimous, and emphatic, in condemning interference, in these cases, that it seemed to savor of positive superstition. This appeared all the more so, when they could not well explain the grounds of their objections, and could only say that their experience had led them to this conclusion. In the meantime the microscopists were busy and had discovered a multitude of various pathogenic germs; and Lister had informed the world, how the development of these germs could be prevented, when in the proximity to wounds or traumatism. Now that the patient was spared the torture of the scalpel, by anaesthetics, and the contamination of the peritoneum rendered impossible, it was but natural, that the ambitious and enthusiastic young operator, would split up the mesial plane of the abdomen, with as little hesitation as he would open an abscess.

Indeed so far were distinguished and experienced surgeons carried away with the germ theory of disease, that not long ago they¹ maintained that surgery could scarcely attain further perfection; and a distinguished author says,² that greater

advances have been made in pathology, during the past fifteen years, than during the three, preceding centuries.

When serious, well-informed writers, will allow themselves to make such sweeping unfounded assertions as these, it can hardly be wondered at, that the average practitioner imagines that the millenium has arrived, and he can learn no more.

In no portion of the body, did operators more promptly and boldly put into practical application, those principles enunciated by modern investigators, than in that region in which are lodged the organs of digestion; and reproduction in the female; so frequently, and apparently successfully, that it certainly did seem for a time, that at last, the difficulty of dealing with lesions and growths—traumatic, and pathological—within the peritoneum, was solved. It was said that an exploratory incision, was harmless. An impression prevailed, that one might open and explore the recesses of the complex structure of the peritoneum, with as much impunity as one would raise the lid of a chest, and examine its contents.

As late, as a year ago, our journals, home and foreign, fairly teemed with reports of cases, involving the surgery of the peritoneum; from the learned and conservative professor, down to the humblest members, in the ranks. There were a few, however, who ventured to raise their voices, against what they conscientiously regarded as an abuse; arising from an indiscriminate performance of an operation, which has its limitation. But their warnings were unheard, in the din of the multitude; the new operation gathered fresh strength, and new adherents, until at last, it looked like rank presumption, for any one to question its merits. However, in the progress of time—not a very long time—a halt was called, and within the past year, many of its most ardent advocates, have discovered that very serious consequences may, and do follow abdominal section; and that in the hands of the careless or inexperienced, it may be followed by pathological conditions more serious, than those, for which it was undertaken to cure, or alleviate.

In the present instance I propose to consider briefly, the question of abdominal surgery, from a conservative standpoint.

It is indispensable at the outset, that we strive to master a practically comprehensive knowledge of that structure, designated the peritoneum; summarizing in as few words as possible, its gross anatomy, physiology and pathology. Histologically composed of endothelial cells, with a framework of fibrous tissue; in which are situated the serous follicles, blood-vessels, nerves, and lymphatics. In its entirety it is a gauze-like structure, translucent and elastic. It is composed of various layers, reflexions, and duplications. It contributes partly to the investment of all the abdominal viscera, with few exceptions; and gives

off a coming to those stalk-like structures of connective-tissue, the ligaments, organic, and mesenteric, through which the blood-vessels, nerves, and lymphatics pass, in maintaining the nutrition of the parts, which they support and protect.

It has been described as the visceral and parietal and its cavity, in the male, is a hermetically closed sac. Besides, being supplied by the cerebro-spinal system, the nerves of the peritoneum are in free communication with the solar plexus, whose ganglia are within its folds, and supply all the abdominal viscera.

Physiologically the peritoneal cavity is lymph sac; in the normal state it is destitute of sensation. Its secretion serves the purpose of lubrication, so that the intermittent vesicular movements of the many and varied convolutions may be easily maintained. It will bear without detriment, especially in the female, very considerable distension, provided it is gradually applied. It is of varying dimensions, ever changing with the process of digestion. Its contents are of a solid, liquid, and gaseous nature. It is walled in or enclosed by bony and fleshy structures; the girth, or most dependent portion, consisting almost exclusively of muscular tissues, except, in the mesial plaue, and in the inguinal regions. Many anatomists describe a median-line of fibrous composition, here, but there is none, strictly speaking in the male, or the non-child-bearing woman. Hence, except in the very limited areas stated, it is impossible to divide the abdominal walls without including muscular tissue.

Pathologically the peritoneum like all other serous membranes of its class, is exquisitely sensitive to irritants of every description, and is extremely intolerent to direct manipulation, of any degree whatever; resenting both, invariably, by active inflammatory action of a local or general character. Besides, in inflammations of metastatic type, we often meet with others, occasioned by contact with some of the organs diseased, which it infests.

Peritonitis of every phase or degree, is of very much more frequent occurrence in the female sex; with them it is comparatively seldom mortal, except, that septic variety, associated with the parturient state. Owing to the dangers of infection extending up the genital tract in woman; to lacerations and contusions, inflicted by the indiscreet or unskilled accoucheur in instrumental delivery, and lastly to the singular development of tumors, and degenerative processes, seen seldom except in woman, we may easily account for the greater frequency of inflammation, in this membrane, with them.

To account for the difference in mortality, in the sexes; we may explain it, in part at least, by the fact, that physical suffering, is much better borne, with woman. They survive a hæmorrhage, which in the male, must be inevitably

mortal, in connection with operations involving the peritoneum.

There is another factor which tells against the male sex, in this situation; which strange to say I have never seen mentioned by authors; I refer to the respiratory act, which in the male, is nearly, wholly abdominal, while in the female it is thoracic. The lower trunk of the latter, may be tightly and motionlessly braced, by a corset or binder, with comfort; which if applied to the male, would promptly induce asphyxia.

We all know, how quickly, and frequently fatal peritonitis is, with the sterner sex, when tympanitis is well developed, while a woman tolerates it, without very serious inconvenience.

Taking the abdominal contents as a whole, we find nothing anatomically, physiologically or pathologically, which indicates, that they are not, subject to the same mutations and influences, as other regions of the body.

THE TRAUMATIC SURGERY OF THE ABDOMEN.

It has usually been understood in our profession that the duties of the surgeon commence, where those of the physician end; and that while it is impossible for the surgeon to ever attain eminence in his art, who is not thoroughly conversant with the properties, qualities, and actions of medicines, yet his aid is seldom invoked except when these have failed, or are inadmissible. Exclusively of traumatism I question the propriety of the surgeon ever undertaking an operation of serious gravity, without, first consulting with the physician, for it is my conviction, that it is with the latter to decide, when to do an operation, and with the former, to perform it.

My experience latterly, has been, that this prudential course, is at present, being generally disregarded, very much it is feared, to the disadvantage of the patient. And in no class of cases in my judgment is this coöperation more essential and imperative, than in the lesions involving the peritoneum.

A man or woman is shot or stabbed in the abdomen; perhaps he is violently crushed; fallen from a great height, or has been run over by a vehicle; he has sustained a traumatism in the ventral region. The medical attendant is called. He finds his patient in more or less shock, and somewhat dazed. His pulse is quick, and thready, and he is alarmingly prostrate.

Now perhaps by a careful examination, one may be able to decide with some accuracy, the extent of injury. If a serious injury whether for instance, a solid viscus has been penetrated or lacerated, etc. The state of the abdomen may indicate, where no well marked constitutional symptoms prevail, whether there be extensive hæmorrhage.

Little more than this can be gleaned on an immediate examination. The physical diagnosis

of abdominal lesions is an art, unlearned. All is yet, uncertainty, doubt, and conjecture; and no living man can predicate what an abdominal incision will reveal, in a very large number of lesions. This state of affairs must remain, until the physics of acoustics is brought to the perfection of optics. The medical attendant will direct his attention towards giving his patient relief from pain, and tiding him over immediate shock. Now when distress has been appeased, and provided that death is not impending the physician is allowed a breathing spell. Perhaps for the first time in his life, he actually realizes what a severe abdominal injury is. The time for theorizing is past, the time to act, has come. Is his patient's vital current slowly draining away, into the peritoneal cavity? Has the bowel ruptured, or has the urinary bladder burst?

If it appears to him that some one of these accidents have occurred, what will be done?

Will the surgeon wait on nature and treat the case on general principles or will he take time by the forelock and anticipate her?

If he is an orthodox antiseptist, and believes that septic contamination is the only danger, attendant on laparotomy, if he imagines that the deductions drawn from experiments on the lower animals are applicable to man; if he is ignorant of the serious consequences which may follow the mere handling of the intestine; then indeed he is guilty of positive, criminal neglect if he fail to make the exploratory incision.

Here and now, we come to the knotty part, of our subject, we have arrived at that point where it becomes imperative, to decide which road to take; which line that will lead to the safest terminus; whether or not, it may not, be as well to rely on nature's unaided powers, or whether having in mind the obscure character of all abdominal lesions, one is not justified in making an exploratory incision.

Until a very recent period the consensus of opinion was that if a laparotomy was done at all, in abdominal traumatism it should be performed promptly; some even maintaining that it added nothing to shock. As a consequence, in the city of New York alone, within the past six years—from October, 1883, till October, 1889—thirty abdominal sections were made for penetrating gunshot and stab wounds of the belly.

The mortality attending those operations was something appalling, as we will later see; though with few exceptions they were done under every possible precaution, which all our well equipped hospitals provide, under the hands of skilled and veteran operators, with an ample corps of trained assistants, and nurses. Very few survived the ordeal. No doubt, but with many of the cases the wounds were mortal; but there are not a few, in which the intra-peritoneal injury was not extensive; and one of those reported, was a case in

which no lesions of any kind were discovered among the viscera; yet the patient succumbed, immediately on closing the main incision. Hence while none can doubt but the exploratory incision, saved a few lives, there can be no question, on the other hand while admitting this, that more than one life was cut short by efforts adopted to save it.

That this is not a statement of speculative conjecture, with a prejudicial bias, has been definitely settled by Dr. Lewis A. Stimpson's statistical and analytical monograph of last autumn, on "Penetrating Gunshot Wounds of the Abdomen." According to the figures there presented the mortality was, when the peritoneum was opened, much greater than when the cases were treated by the expectant plan. This may be partly explained, on the hypothesis that none were submitted to operation; but the worst cases. Against this, however, we have the evidence in many of the cases spared the scalpel, of grave lesions. In many of those cases it is more than probable that the patients or their friends' emphatic objection against any sort of evisceration stayed the operator's hand.

So much being conceded, with reference to operations involving the peritoneum, we should strive to seek out the causes which lead to disaster, and try to obviate or eliminate them, but before we leave this part of the subject, it may be well to investigate the processes by which the full functional activity of the parts may be restored by the *vis medicatrix nature*.

Shock follows all serious disturbances of the abdominal cavity. The vital powers, for a time are at a low ebb, and preclude every sort of violent interference, until reaction is well established. Next to bleeding in this situation, after an injury comes inflammation. This is always a serious sequel when extensive. Always perforation of the bowel is a serious matter, when it occurs below the ileo-cæcal valve, for here the final act of digestion ends and, only below here, do we find real fæces.

The intestinal contents during healthy digestion, above the cæcum, while capable of exciting acute inflammatory action, cannot, and do not, possess, the toxic, putrid properties of the lower gut, and in the dog at least, small quantities do no harm whatever, except to excite adhesive inflammation. As a rule, however, unless the intestine is extensively wounded, very little of its contents can escape. In gunshot wounds, the well-known valvular puncture made by the missile is immediately and permanently filled, by the contraction and eversion of the mucous coat, completely obliterating the rent. Simultaneously, with this salutary provision of nature, peristalsis ceases, while the work of repair is going on. If the patient survives, inflammation promptly ensues, and if of a limited and moderate degree its

presence is indispensable as a factor of repair. The peritoneum possesses a most singular propensity when inflamed to take on adhesions with everything in which it comes in contact. It will wall off the sound from the diseased, in a most marvelous manner, in this way preserve the general cavity from contamination or invasion. If the inflammation take on a septic course, the patient is surely doomed; but much will depend on surroundings, the nursing, and medical attendance, for its development.

(To be concluded.)

THE SCIENTIFIC ASPECTS OF MEDICAL HYPNOTISM, OR TREATMENT BY SUGGESTION.

Read before the Chicago Medico-Legal Society, October 4, 1890.

BY M. H. LACKERSTEEN, M.D., M.R.C.P., ETC.,
PROFESSOR OF MEDICAL PHYSICS AND ELECTRO-THERAPEUTICS;
CHICAGO POST-GRADUATE SCHOOL OF MEDICINE.

Mr. President and Gentlemen:—

Of all the extensive additions made to modern therapeutics nothing seems to have attracted so much general attention as hypnotism.

Of all modern remedial measures hypnotism has secured perhaps the most numerous, zealous, and competent investigators: and yet it is without doubt the least popular with the profession. Since the time when chloroform was first employed as a means of reducing the pain of childbirth, nothing has occurred in the history of medicine of so revolutionary a character as the use of hypnotism. Nothing has excited at once so much expectation, apprehension, horror, hope, credulity and skepticism as the voluminous writings of the savants who have pursued hypnotic researches during the last eight or ten years; and yet it is by no means a new invention or discovery.

We are told that the practice of hypnotism dates far back into almost prehistoric times; and under various names and institutions it is supposed to have influenced generations of mankind. In ancient India, Egypt, and Greece it was practiced by the religious teachers who held it to be supernatural, and such teaching no doubt gave considerable power to the priesthood, and invested it with much authority in the estimation of the people. It is also supposed to have been the source of many of the tales of magic and miracle during the middle ages in the cure of disease and the relief of human suffering. However this may be, hypnotism, as it is known today, originated with James Braid, of Manchester. He demonstrated the fact that by fixing the attention or the gaze on any object, a person could

¹ This paper was prepared in compliance with the request of the President of the Chicago Medico-Legal Society, made to the writer in February, 1890.

be hypnotized, thus controverting the theory of Mesmer of the existence of a magnetic fluid which was supposed to pass from the operator to the subject in producing the condition known as the Mesmeric trance.

Thirty years ago Liebault, of Nancy, in France, was able to dispense with even the necessity of gazing at an object in order to obtain hypnosis. He found that the mere suggestion of sleep, made to a willing and susceptible patient, was sufficient to induce it. Prof. Bernheim who had studied the question with Liebault, and had accepted the latter's views, published a book on suggestions in 1884. He reported several examples of the curative effects of hypnosis, the phenomena of which he declared to be entirely of a psychical nature.

In 1878 Charcot began his public classes in which he drew attention to the physical states of hystero-epileptics during hypnosis. Among his pupils and followers, as we all know, are a great many distinguished French and German savants; but Charcot's researches had little effect upon the further pursuit of the inquiry. Not until the successful methods of the Nancy school had become known through Bernheim did the question become an active one throughout the civilized world. Hypnotism has now found an entrance into Switzerland, Belgium, Holland, Denmark, Sweden and Norway, into Russia, Greece, Italy, Spain, England, America and Germany. A really stirring activity has, however, only lately set in, and it began about two years ago when the publication of Forel's writings demonstrated the great importance of hypnotism for therapeutics. Since then upwards of 1,000 books and pamphlets have appeared, and the subject has claimed attention in almost every local medical society, and every National and International Medical Congress.

The hypnotic condition so nearly resembles ordinary sleep that Braid has designated it by its Greek synonym, and Liebault considers the two states as identical. Bernheim frequently mentions this fact: "There is nothing," he says, "by which to differentiate this induced sleep from natural sleep." Moll, however, does not so easily agree to an identification of the states. "I do not think," he says, "that we can make a close comparison between sleep and hypnosis. I think it a misuse of words (to say that hypnotized persons are asleep), since there are a whole series of hypnotic states in which not one symptom of sleep appears, and mistaken conclusions are often drawn from the mistaken terminology, with resulting confusion." That the sleeping is different from the waking state is evident, but as to how different careful study alone can determine. Dreams are due chiefly to nerve stimulation during sleep, that is, they are due to external suggestion. The character of the stimulation

forms some part of the dream plot. Any description of sense-stimulation will result in dreams in which all the senses seem to take part; but as these impressions which contribute to the dream have not been balanced by the faculties, because of the dissociation of the receiving mind from the external world (intimate correspondence between which alone produces the consciousness of reality), there is no coherence, order, and substantiality in our dreams to resemble experience. It is rather of the character of a mirage than of a landscape perspective.

It is said that when the dream is light, the nerve stimulation producing the dream is remembered by the sleeper when he wakes, but that dreams in heavy sleep are not remembered.

These facts, I think, are also present and recognized in hypnosis, with this difference, that, whereas there is a great decrease of self-consciousness in sleep, this self-consciousness is just what remains intact in light hypnosis. In deep hypnosis the case is essentially different. It is characterized by sense delusions which are just the same thing as our ordinary dreams. The opinion that by far the greater number of dreams are induced by sense stimuli gains more and more adherence. This receptivity to stimuli which reach the brain unregulated by the consciousness and mistakenly interpreted, is a phenomenon of both sleep and hypnosis. The method employed to make external suggestion in hypnosis often suffices to induce dreams in sleep. At the most there is only a quantitative difference since most sense delusions are directly suggested in hypnosis, while in sleep dreams are caused as we have seen by some peripheral stimulus which undergoes special elaboration in the brain of the sleeper. As we find that the origin and purport of dreams are the same in sleep and hypnosis, it follows that in all probability the dreams of hypnosis are no more injurious to health than the dreams of sleep. But Rieger and Konrad say that hypnosis is nothing but an artificial madness. Meynert maintains that it is an experimentally produced imbecility. Luys compares it to general paralysis of the insane and others to "melancholia attonita." "These different comparisons," says Moll, "show the want of unanimity among authors, for the forms of mental disorder we call imbecility and mania are as unlike as a pea and a rose, which are both plants, but of utterly different kinds; and no two states of mental disorder could be more unlike than imbecility and mania." Moll in advocating his cause against the charges of these objectors argues as follows: "When hypnosis is thus compared to mental disorder it is generally forgotten that susceptibility to suggestion is the chief phenomenon of hypnosis. But it is a mistake to think that susceptibility to suggestion is an essential phenomenon of mental disorder; if

it were, mental disorders could be cured by suggestion, which is hardly ever possible. By means of suggestion in hypnosis forms of hypnosis may be induced which resemble mental derangement, *i.e.*, spontaneous mania or "melancholia attonita" beside forms of imbecility, etc. But we can also induce paralysis and stammering by suggestion, and yet hypnosis is not a state of paralysis or stammering. We can suggest pain in hypnosis, and yet hypnosis is not a state of pain. And how the light stages of hypnosis in which only certain motor effects are caused by suggestion can be called states of mental disorder is not clear to me, unless a person is to be called mentally unsound simply because he cannot open his eyes. But even the susceptibility to suggestion which exists in such mental disorders as delirium tremens or the kalaniotic of Kahlbaum must not be without further ceremony identified with the susceptibility we find in hypnosis. I need only say "wake" to the hypnotized subject and the state ends; but there is no disease which can be guided and ended at a moment's notice like hypnosis."

A great many objections have been raised against hypnotism as a therapeutic agent. As I have already given Moll's answers to a few of these, I shall let him answer some of the other objections in his own words. He earnestly warns people not to consider hypnosis absolutely safe; others have said the same thing but have somewhat exaggerated the danger. This point he says must be seriously weighed. But it is never asked whether a remedy ought not to be dangerous; we only ask if we cannot avoid the danger by careful and scientific use of it. "What can never do positive harm can never do positive good," is an assertion made by Rust. This is to a great degree justifiable, though perhaps exaggerated. For I think I may say that there are few remedies in medicine which would not injure if carelessly and ignorantly used. There are even medicines which may injure however carefully used, because we do not know exactly under what conditions they become hurtful. I need not speak of morphia, strychnine and belladonna which have sometimes done injury even when the maximum dose was not surpassed. Neither will I speak of the dangers of surgical operations. I need only point out that an apparently harmless medicine may have very likely already done more mischief than hypnotism. Many deaths have resulted from the use of potassium chloride, and unfortunately this drug can still be bought and retailed without a medical prescription. Severe collapse has been observed after the use of antipyrin, antifebrine and exalgine. I will add to these one of the most recent medicines, sulphonal, which is supposed to be a perfectly harmless hypnotic drug. A death from it has recently been published. And

Billroth has lately pointed out great dangers from carbolic acid, which is constantly used. If we gave up the use of these medicines we might give up medicine altogether, as everything employed might do harm. Whether there are dangers in the use of drugs or not is not the question. Rather we must ask, 1. Do we know under what conditions the danger appears? 2. Can we remove these conditions and the consequent danger? 3. If we cannot, does the advantage to be gained by the patient outweigh the danger he runs? The answer to these questions is in favor of hypnotism; we know perfectly under what conditions it is dangerous, which we do not know about some drugs; we are able in certain cases to exclude these conditions by using the proper and harmless methods and thereby preventing danger. But it may be objected that though a short use of hypnotism may not be hurtful, a long one involving a repeated induction of the state might be so. The objection is justifiable. But it might also be made against the use of various drugs, since we do not yet know whether a long use of them might not cause chronic poisoning. Experience is the only way to decide such a question, and Liebault, who has used hypnotism therapeutically for thirty years, has watched cases for a long time without finding any bad consequences.

Among the remaining objections to suggestive therapeutics the assertion that they do not produce any lasting impression or cure may be mentioned. This may be answered as follows: The results are by no means transitory; on the contrary a large number of lasting cures have been observed and published; the author himself having seen many cases where there was no relapse for years. One cannot ask for more. The objection that the improvement may be only temporary is thus not justified. But even were this so we must still rejoice to have found a way of procuring even temporary relief. In any case therapeutics are not yet so far advanced as to give us the right to reject a remedy merely because it only affects symptoms, or has often merely a temporary value. If we were to reject remedies which suppress the phenomena of disease for a time only, we might abandon a large part of therapeutics, perhaps the whole. Besides, from some methods of treatment nothing but a temporary improvement is expected, and yet this temporary improvement is considered to prove the value of the method. Remedies should not be weighed and measured by different standards.

A further objection to treatment by hypnotic suggestion is that there may be suggestions without hypnosis. This is exactly the standpoint which the school of Nancy have always taken up, although it is often difficult to distinguish between hypnosis and suggestion. This is the

heart of the present movement which shows us how extensive is the empirical use of suggestion in therapeutics. It is also the real reason of the strong opposition to hypnotism. We hereby see how often suggestion occurs spontaneously in ordinary life and medical practice. Hypnotism, by means of which we can make suggestions artificially, shows us what a great mistake has been made in estimating previous therapeutics, since we have neglected to consider the mental element in the action of the various drugs. The physiological effect only was regarded; it was quite forgotten that many remedies have only a suggestive value.

Ewald will not concede the same rank to suggestive treatment as to other methods, *e. g.*, electro-therapeutics, treatment by drugs, etc. Forel's reply to him refutes his objections. "Ewald," he says, "protested against the expression *medical treatment by hypnotism*. He said that medical treatment meant the medical art, and medical knowledge, and that every shepherd boy, tailor, and cobbler could hypnotize; only self-confidence would be necessary. I, for my part, think it right to protest against this way of treating a scientific question. Has not medicine drawn a countless number of its remedies from the crudest empiricism, from the traditions of the 'shepherd boys?' Cannot every cobbler inject morphia, apply blisters, and give aperients if he has the material? Yet we do not despise these remedies, nor baths, nor massage, etc. But Prof. Ewald deceives himself greatly if he believes that a delicate agent like hypnosis, which affects and modifies the highest and most refined activities of our minds, could be manipulated by a shepherd, or ought to be handed over to him. Medical science and psychological knowledge, the ability to diagnose and practice, are all necessary to its use. It is true that laymen have succeeded with it, just as charlatans have succeeded, and continue to succeed, in all provinces of medicine. Should we on that account leave the practice of medicine to them? Long enough, much too long, science has left the important phenomena of hypnosis to shepherd boys and their like; it is high time to make up for the delay, and to devote ourselves to a thorough examination of the series of phenomena which can complete our views of psychology and of the physiology of the brain. Medical therapeutics must not remain behind, when great results are to be obtained. But these results can only be obtained by a thorough study of the proper hypnotic methods."

The enthusiasm of the more ardent advocates of hypnotism on the one hand, and the skepticism of its opponents on the other, have left the matter in an uncertain state in the minds of many physicians. The clairvoyance of the mesmerizing mountebanks, the animal magnetism and electrobiology of a host of ignorant quacks, and the

authority of Charcot concerning the transference of thought, the actions of magnets, and of drugs at a distance, have tended to throw discredit on the whole subject. False theories have been elaborated, and the most absurd explanations offered to account for some of the hypnotic phenomena; so that conservative physicians and physiological students who pride themselves on being orthodox scientists, turn away from this new fad and condemn what they cannot understand. Facts, however, are not to be rejected merely because the explanation offered of them proves to be unsatisfactory or even erroneous. But when the actions of the hypnotized patients may be readily explained without appeal to the marvellous, and without doubting the good faith of those who practice hypnotism, it is reasonable to inquire and examine, test and try, in order to ascertain if there is any likelihood of good to result from its use, and if so, to rescue it from incompetent hands, and put it in its proper place in therapeutics.

The word hypnotism seems to me to be incapable of exact definition. It designates all those conditions resembling natural sleep, but artificially produced without the aid of drugs. The methods of hypnotizing are either by uniform sensory stimulation or by suggestion. The easiest way is for the subject to fix his eyes upon some object which is kept near to and a little above him, so that he must converge and turn up his eyes to see it. This means will operate rapidly if the subject is expecting to be sent to sleep. But the hypnotic state may be induced without any sensory stimulation by simply suggesting to the subject that he is about to sleep, and if he is particularly susceptible, it is only necessary to stand in front of him, to look at him fixedly and to say "Sleep."

Many are hypnotized instantly, but some require half an hour or more. The more insusceptible cases need two, three, or even four sittings before they are hypnotized. Some people may be made to pass into the hypnotic state at a specified time after the suggestion. The successful instances reported by Beaunis are where the operator says, "I am going to count ten, when I get to six you will sleep;" or "Count to ten, when you get to eight you will sleep;" or "Go to that door, open it, when you have done so you shall sleep." Bernheim states that those who are easily affected may be hypnotized by writing to them, or by telephone. Those who are very susceptible need only think that they are about to undergo hypnotization, and they will become hypnotized; thus one may say to them, "You will be hypnotized in five hours," and when the time comes, they will pass into the hypnotic state.

There are different degrees of the hypnotic condition, and the school of Charcot and the Nancy school differ radically in their subdivi-

sions. It is difficult, however, to recognize any sharp distinctions, seeing that the degrees of hypnotism are merely according to the depth of the hypnotic sleep. The more simple and common-sense division would be into somnolence or light sleep, hypotaxia, or medium sleep, and somnambulism, or profound sleep. As a general thing, the sleep produced by suggestion, remains the chief measure for bringing the suggestion into complete action. Suggestion produces sleep or slumber; hardly is this present when the suggestibility increases as the result of the sleep, and usually so much the more, the deeper the sleep becomes.

In somnolence or light sleep, the individual is so slightly influenced that by employing all his energy he can resist the suggestion and open his eyes. In hypotaxia he can no longer open his eyes, but is quite conscious of his surroundings, yet he must submit to a part of the suggestions, or to all, with the exception of amnesia. Somnambulism, or deep sleep, is characterized by amnesia after waking, and by post-hypnotic phenomena.

Hypnotic phenomena are of a physical and psychical nature. The light hypnotic influence under suggestion will manifest effects on motility—inability to move, with contraction and automatic movements. It is more decided when it affects the will and causes automatic obedience. In a more intense degree, suggestion produces sleep or an illusion of sleep; and the yet more advanced degrees of suggestion affect the sensorial and sensory spheres, memory and imagination. On waking, the subject may remember nothing that has happened; or he may, if a hint is given to him; or he may easily recollect it all. He usually reacts to impressions that he receives through the senses, which are often very acute, but this reaction is entirely that of an automaton.

Suggestions can be made which shall take effect after waking. These are included in the term post-hypnotic suggestion. One may suggest that the subject on waking shall not see a certain person or thing, or that he shall be able to see the person but not hear him. These instances are examples of what is called a negative hallucination. Post-hypnotic suggestion is chiefly used in the cure of diseases, especially if they are functional, it being suggested to the patient that when he awakes from the hypnotic state he will suffer from none of his previous symptoms. It may be suggested that at some particular time the subject shall do this or that act. This is the suggestion *à échéance*. Beaunis gives an instance of a woman who acted upon a suggestion *à échéance* as long as 172 days after it was made.

Hypnotism produces no effect on the vasomotor system, but by suggestion in hypnotic sleep the strangest phenomena have been reported. Hypnotism increases the rapidity of the respira-

tions, which, however can be diminished by suggestion. Increased susceptibility to suggestion, which hypnotism produces in the patient, gives it its chief claim to recognition as a therapeutic measure.

In short, the patient is an automaton in the hands of his physician. He feels what he is told to feel, his temperature is raised or lowered from one to three degrees F., and his pulse is rendered normal by suggestion. He forgets his troubles by suggestion, and by suggestion he experiences an agreeableness and comfort for which there is no actual physical warranty. Now in the name of all that is good, what else can a physician desire?

I have not said a word about the physiological explanation of hypnotic phenomena, or of the mechanism of suggestion. I leave this to the physiologists, and psychologists, who grace this assembly with their presence, and who are ready to take part in the discussion of hypnotism after I have done with my paper. All that I have briefly put forth here I have gathered from the writings and reports of others. It is a very imperfect presentation of the subject, as might be known by the perusal of anyone of some fifty works on hypnotism, and most of you are acquainted with them all.

(To be concluded.)

CASES OF PENETRATING STAB WOUNDS OF THE ABDOMEN; LAPAROTOMY; RESULTS.

Read at the Meeting of the Mississippi Valley Medical Association, at Louisville, Ky., October 9, 1890.

BY H. C. DALTON, M.D.,

SUPERINTENDENT CITY HOSPITAL, ST. LOUIS.

I report to-day six cases of laparotomy for penetrating stab wounds of the abdomen in which the viscera were injured, one death and five recoveries.

Case 1. Wound of Descending Colon and Ileum; Laparotomy; Recovery.—Edward T., colored, æt. 16, was admitted to the City Hospital July 23, 1890. Two hours previous he was stabbed with a long, narrow-bladed "chicken knife."

The wound of entrance was quite small and situated in the left iliac region, near the free extremity of the twelfth rib. Two inches of omentum protruded. The patient's general condition was excellent; there was but little pain; pulse 62, respiration 23, rectal temperature 100° F. Percussion gave dullness in the left lumbar and iliac regions. The liver dullness was greatly diminished.

After thorough antiseptic precautions, an incision 4 inches long was made in the left linea semilunaris. Considerable blood and fecal matter were found in the cavity. There were two holes in the descending colon and one in the ileum.

The holes were closed by continuous iron-dyed silk sutures, the blood and fæces washed out, and the abdomen closed. A rubber drain was left in the wound. Recovery was uneventful. Patient was discharged well eleven days after admission.

Case 2. Wound of Mesentery; excessive Hæmorrhage; Laparotomy; Recovery.—Nathan B., æt. 29, admitted October 1, 1889, was stabbed an hour before admission, intestines protruding immediately upon receipt of the injury. In this condition he ran four blocks up a high hill with his assailant close upon his heels.

When admitted he was in profound shock, pulse 120 and quite weak, extremities cold; cold perspiration on forehead, temperature subnormal. Examination showed a mass of intestines (ascending colon and small intestine) protruding from a wound in the right hypochondriac region in the axillary line, 3 inches from the costal border. The mass was blue, almost black, and covered with dirt.

After thoroughly washing the intestines the wound was enlarged to the extent of 4 inches. A gash 2 inches long was found in the mesentery. One of the large vessels of the same was cut and bleeding profusely. This was tied, the wound in the mesentery closed with a continuous catgut suture, a large amount of blood washed from the peritoneal cavity, and the wound closed. A glass drainage tube was left in the wound. The temperature rose to 104° F. on the next afternoon, after which his recovery was uninterrupted.

Case 3. Wound of Cæcum; Fæcal Entravasion; Laparotomy; Recovery.—William W., colored, æt. 15, bootblack, admitted October 7, 1889. He was stabbed two hours before admission. His pulse was 80, small and soft; temperature 99.8° F., respiration 24; general condition excellent.

The knife penetrated an inch internal to, and a little above, the right anterior superior spine of ilium. An incision 2 inches in length was made at the site of the wound in the right linea semilunaris. A large ragged hole was found in the cæcum, as well as a considerable amount of blood and fæcal matter in the iliac and pelvic regions. The hole in the gut was closed by interrupted silk sutures, the blood and fæces washed out, and a glass drainage tube, reaching to the bottom of the pelvis, was left in the lower angle of the wound. The patient made a rapid recovery, temperature never going higher than 101° F.

Case 4. Wound of Descending Colon; Laparotomy; Septic Peritonitis; Death.—John W., æt. 27, admitted November 18, 1889. An hour before admission he was stabbed in the left lumbar region. Three inches of omentum protruded. The wound was enlarged sufficiently to allow of the return of the omentum, and an examination with the finger. No visceral wound could be detected by the touch. Patient's general condition was so good (pulse 80, temperature normal, respiration

20), that I was led to believe the intestines were uninjured, hence did not perform laparotomy.

The next morning, fifteen hours after the receipt of the injury, I was mortified to find my patient's abdomen distended, pulse and respiration fast, temperature elevated, and pain great. In fact, septic peritonitis was in full blast. I now did what I should have done at first, *i. e.*, made a free opening in the left linea semilunaris. The intestines were quite inflamed and adherent, blood and fæces surrounded the colon, and a large irregular hole was found in the posterior portion of the latter. This was closed and the abdomen washed out. But it was too late, for my patient never rallied, and died in a few hours from shock and peritonitis—the result of my timid, vacillating, unsurgical policy. Had I boldly opened the abdomen and made an *ocular* inspection, as I have since done in *every* case of penetrating stab wound, I believe a life would have been saved, and your reporter saved from making this humiliating confession.

I have condemned, and still condemn, Senn's hydrogen gas test in gunshot wounds of the abdomen, but in this case I am persuaded it would have been wise to resort to its use, as I believe it would have given affirmative results.

Case 5. Wound of Liver and Stomach; Laparotomy; Recovery.—Dred M., colored, æt. 18, admitted September 1, 1890. Two hours before admission he was stabbed in the abdomen. His condition was good, rectal temperature 100° F., pulse 72, respiration 32. He complained but little of pain.

The wound (a small one) was situated 3 inches above, and 2 inches to the right of, the umbilicus. An incision was made from the ensiform cartilage to the umbilicus. A wound $\frac{3}{4}$ of an inch in length was found on the upper surface of the liver, 2 inches from its lower border. Another wound of similar size was found on the under surface of the liver, separating the organ from a portion of the neck of the gall bladder. A third hole was found in the anterior portion of the stomach, near its pyloric end.

The wound on the upper surface of the liver was closed by a single heavy catgut suture. The suture was introduced $\frac{3}{4}$ of an inch from the wound, passed deeply into the liver substance, and out again $\frac{3}{4}$ of an inch on the opposite side. To close the lower wound a suture had to be passed into the peritoneal coat of the gall-bladder and deep into the liver substance. The hole in the stomach was closed by three interrupted silk sutures. A considerable amount of fluid and dark clotted blood was washed from the belly cavity. In spite of the fact that the apposition was good between the gall-bladder and liver, there was considerable oozing of blood from this point. To control this about 30 inches of gauze, 2 inches wide, was packed around it, the ends of

the strips were left protruding from the upper angle of the median incision. The surgical wound was closed by interrupted silk sutures.

The operation lasted three-quarters of an hour. Two hours after the operation the pulse was 84, rectal temperature 100° F., respiration 26. Little if any shock followed the operation. The gauze was removed on the second day and the drainage hole closed. He was not allowed to swallow water till the fourth day, except occasionally to wet his lips. Water and food were given per rectum. He was given fluid food per orum on the seventh day.

The patient recovered rapidly. His temperature never exceeded 101.4° F.; his pulse-rate was never over 100.

Case 6. Stab Wound of Liver and Intestine; Laparotomy; Recovery.—August F., æt. 21, bartender, was admitted August 21, 1890. He received three penetrating stab wounds an hour and a half before admission to the hospital. One wound was an inch below the costal border, and 4 inches to the left of the median line. Three inches of omentum protruded from this wound. The second was an inch above and 2 inches to the right of the umbilicus. The third was situated in the seventh interspace in the right axillary line. The patient was suffering greatly from shock; temperature subnormal; pulse 100 and weak; respiration 30.

The wound on the left side was enlarged to 3 inches, the omentum returned, and the intestine in the locality examined and found uninjured. The wound to the right of the median line was enlarged and a ragged hole of good size was found in the jejunum. This was closed by four interrupted silk sutures. As there seemed to be no fæcal extravasation, and but little blood, I did not wash out the peritoneal cavity, but contented myself with sponging the intestines in the neighborhood of the wound.

By slightly enlarging the thoracic wound I was enabled to determine that the liver was cut. A considerable quantity of dark blood followed the withdrawal of the finger. In order to reach the wound in the liver I resected 4 inches of the seventh rib, and split up the diaphragm 3 inches. This gave me a good view of the hepatic wound. There was considerable hæmorrhage from this point. By introducing a sponge on a long holder I managed to remove a good deal of clotted blood from this locality. The liver wound was an inch in length and about 2 inches deep. This was closed by one deep, heavy catgut suture, care being taken to introduce and withdraw the needle at least $\frac{3}{4}$ of an inch from the margins of the wound. Unless a good portion of the liver is thus involved in the suture, the latter will cut its way through when tied. For this reason, also, care was taken not to continue the tightening of the suture after the margins of the wound were

approximated. The diaphragmatic and cutaneous wounds were closed by continuous catgut sutures. The closure of the wound of the diaphragm was rendered quite difficult in consequence of its movements during respiration. Drainage was not used. The operation lasted an hour and a half.

For three days the patient's pulse-rate remained at about 120, his temperature 102° F., and respiration 30. From this time on his recovery was uninterrupted. There was no peritonitis nor pleurisy. He was discharged well September 20, 1890.

I believe I made a mistake in this case in not making a median incision. I could then have closed the parietal peritoneum on each side, and could have accomplished all I did by the two incisions. By making the latter I doubled his chances for a ventral hernia. I fancy, however, there are few of us who cannot look back after an operation and see where we could have done better.

One point I desire to lay particular stress upon, *i. e.*, that in all penetrating stab wounds it is our bounden duty to go to the *bottom* of such wounds and *see* what damage has been done. It will not do to do as I did in the above fatal case, trust to the introduction of the finger and the *tactus eruditus*. Nor will it do to trust to the patient's general condition, for we have many times seen cases of gunshot and stab wounds with seemingly no perturbation, when in fact the patients were fatally injured.

Should a stab wound penetrate the thorax inferiorly, and in a downward direction, it behooves us to enlarge the wound sufficiently, even if we have to resect a rib, to enable us to determine whether or not the diaphragm has been penetrated. Should such be the case we should open the abdomen as near the site of penetration as possible. In other words, act as we should do when the peritoneum is penetrated through the abdominal wall. With perfect asepsis we can risk a great deal in abdominal operations. I believe it adds but little risk to a case of penetrating stab wound to enlarge it sufficiently to give us an *ocular* inspection of the parts beneath. It will not do to *guess* in such cases.

Since reporting my last cases of stab wounds I have operated eight times in cases in which there were no visceral injuries, all the patients recovering without an untoward symptom.

I would not be willing to place implicit confidence in the Senn gas test in such cases. Having been once deceived by it, I naturally doubt its infallibility.

Up to date I have done twenty-three laparotomies for penetrating stab wounds of the abdomen, with three deaths and twenty recoveries.

STATE PRELIMINARY EXAMINATIONS FOR MEDICAL STUDENTS.—Nearly three hundred persons attended the first State preliminary examinations in New York and Brooklyn this fall.

THE TREATMENT OF ALL FRACTURES
OF THE FOREARM, EXCEPT OF THE
OLECRANON PROCESS, BY EX-
TENSION, COUNTER-EXTEN-
SION AND FORCED
SUPINATION.

Read at the Annual Meeting of the Mississippi Valley Medical Association, at Louisville, Ky., October, 1890.

BY X. C. SCOTT, M.D.,
OF CLEVELAND, O.

In calling your attention to this mode of treatment I hope to convince you that it is superior to any other method, that you will not condemn it untried as an old doctor friend of mine did, and who said to me, "Doctor, it may be all right, but I do not think it will do because I have not tried it myself." Give it a fair trial and you will be convinced that it can be carried out in a simple manner and that it is better and far superior to any other method, by being adapted to every form of fracture of the forearm, except that of the olecranon process of the ulna.

2. Two strips of adhesive plaster are applied in the same manner to the palmar surface of the hand and tied together.

3. The splint being well padded is applied to the dorsal surface of the arm and forearm. A broad piece of adhesive plaster is applied to the radial side of the forearm above the point of fracture and carried around behind the elbow and splint to the same point on the ulnar side, that it started from on the radial, and fastened. Crossed strips of plaster are also applied to keep the ends of the broad piece in place.

4. Another broad band of adhesive plaster fastens the arm to the upper part of the splint, and in addition I have been accustomed to throw a bandage around this part of arm and splint.

5. After the plaster is well set, the end of a piece of elastic rubber webbing, on the other end of which a buckle is fastened, is passed from the under surface through the opening in the end of the splint through the loops formed by the two strips of adhesive plaster on the dorsal surface of the hand, thence back through the opening in

The splint is made of two pieces of board fastened together securely at right angles. The shorter piece extending up the back of the arm about two-thirds the distance from the elbow to the shoulder, and the longer piece extends along the back of the forearm to four inches beyond the tips of the fingers. These pieces should be one inch wider than the arm and forearm and also well padded. The dressing of the limb is carried out in the following manner:

1. Two strips of strong adhesive plaster are applied longitudinally to the dorsal surface of the hand, commencing at the wrist or higher up, if the fracture is located higher, and extending beyond the tips of the fingers, are tied together at their free ends, forming a loop.

splint and carried forward over the end of splint, and back through the loops formed by the strips of plaster on the palmar surface of the hand, forward towards end of splint; and fastened by the buckle attached to the other end of this elastic band or strap.

The advantage of this procedure is, that should either the dorsal or palmar strips of adhesive plaster become relaxed or loosened, one or the other can be tightened without disturbing or affecting the other.

6. Thus having made extension and counter-extension, supination is easily accomplished by means of a strap of adhesive plaster one and a half inches wide applied to the carpal or bulbar portion of the hand, passing from the radial side

backwards around the splint to the ulnar side and thence to the front of the hand overlapping the place of starting. No other dressing is necessary except in cold weather; it is well to throw a bandage around the limb to protect it from the cold.

In all cases of fracture of the forearm there should be a careful reduction of the broken fragments before the splint is applied. This is especially true in regard to cases of fracture of the lower end of the radius and, in addition, when the fracture occurs at this region of the radius there should be a careful examination in regard to whether the ulna is dislocated or not, and if found dislocated it should be reduced before any dressing is applied to the limb.

In every case of fracture of the radial shaft or of both bones that I have seen and examined, when they have been treated by either the anterior, or posterior, or both anterior and posterior combined, or pistol-shaped splint in the semi-pronated position, have shown more or less loss of supination, while pronation has not been affected unless there has been an ankylosis between the radius and ulna. The only way that this serious impairment to the rotation of the arm can be prevented is by forced supination of the lower fragment so that its plane may correspond with the supine position of the upper fragment.

Should the fracture occur at any point between the places of insertion of the tensor and quadratus muscles, and when the lower fragment is brought into a supine position, there should not be perfect supination of the upper fragment, it can be remedied by applying a band of adhesive plaster just above the point of fracture in the same manner as before directed to apply it to the hand to bring about supination. Yet in the cases which I have treated this extra piece of plaster has not been necessary.

This question of supination is not new, for it was recognized by Hippocrates and his contemporaries, and by many surgeons since then. Probably Mr. Lonesdale, among modern surgeons, deserves more credit than any other for his researches and calling the attention of the profession to the importance of the supine position in treating fractures of the forearm. It is surprising that modern authors, while recognizing the importance of this position, have not had the courage to come out firmly, condemning any other mode of treatment. Is it because that there are so many imperfect results from the methods of treatment that have been in vogue that they are afraid that they may be in danger of encouraging suits for malpractice? There seems no good reason why any one should cling to any form or method of treatment, which is acknowledged to give, in a majority of cases, impaired motion.

Every surgeon and anatomist recognizes the fact that the radius and ulna are as widely separated in

the supine as in any other position of the two bones, and therefore in as little danger of an ankylosis taking place as if they were dressed or placed in a semi-pronated position.

Some who have not tried this mode of treatment may think that an arm dressed in a supinated position is less comfortable than in semi-pronation. This is a false conclusion—as the writer can testify from a personal experience; nor has he ever heard a patient complain on account of the arm being dressed supine but, on the contrary, in each and every case, the patients have expressed themselves gratified with the ease and comfort experienced from this mode of dressing.

For my own part I have never been able to comprehend why the pistol splint should have been invented or used in cases of fracture of the lower end of the radius, as it forces the hand into a constrained, painful and unnatural position. The surgeons who employ the pistol-shaped splint have deluded themselves into the belief that by forcing the hand into this constrained position, that they are enabled to elevate the upper end of the fragment. They appear to forget the important fact that in fractures of the lower end of the radius, that there is always more or less dislocation of the ulna and laceration of the radio-ulnar and other ligaments at the wrist-joint, so that there is no means or fulcrum by which the necessary force can be applied to accomplish their object. The man who first used the pistol-shaped splint must have been studying the times of the Inquisition to have found such a relic of barbarity. The sooner it is abandoned in practice the better it would be for humanity. It is a false assumption that by means of the anterior-posterior splints, the radius and ulna can be forced apart, unless so much pressure is made that it will impair the circulation and jeopardize the vitality of the parts; moreover, only the slightest pressure on the wrist can be tolerated for any length of time.

Another serious objection to both the anterior-posterior and pistol splints, is that the forearm is completely enveloped with bandages, and the condition of the fracture and limb cannot be examined, at any time, without removing all dressings and splints. Neither of these two kinds of splints are applicable to cases of fracture of both bones nor to cases of compound fractures where drainage is necessary. I question whether there ever has been a case of fracture of the shafts of both radius and ulna, treated by the anterior-posterior splints, that has recovered without more or less deformity and loss of motility, especially supination.

The broad angular splint and mode of dressing to which attention is called, allows an inspection of the broken limb at all times without removing the dressings or splint, and by making the neces-

sary opening in the splint affords the means for perfect drainage in cases of compound fractures. Dressed in this manner the fragments, in cases where both bones are broken, would be supinated and extended by the extension and counter-extension so that there would be no shortening caused by the overlapping of the broken ends, nor loss of supination from the upper fragments being supinated while the lower fragments are semi-pronated. If this angular splint is used, it will be impossible for any deviation of the fragments from any improper pressure of the sling in which the limb is carried, for the splint being made longer and wider than the arm and hand, the extension and counter-extension keeps the broken bone or bones fixed fast between two fixed splints, so that they cannot sag either towards the radial or the ulnar side of the splint, and thus receive any pressure from the sling on the hand or the shaft of the bone which will be detrimental.

It is easily understood, that when one or both bones are broken, and there is a tendency for the broken ends to crowd together, there is no means so efficacious for their separation as extension and counter-extension acting through the stretched muscles and connecting tissue by which the muscles attached to the bones, will draw the fractured ends apart, better than can be obtained from pressure by compresses, even when carried to such a degree that it is dangerous to the vitality of the limb. This is equally true in those cases of fracture of the lower end of the radius when it has been supposed that the upper end of the lower fragment will be drawn towards the ulna by the quadratus muscle. Whether this deviation can take place I question, for there is no interosseous space between the two bones at this place, so that such a deviation seems impossible, but granting that it does take place is there any means which will so well and effectually overcome it as extension and counter-extension and forced supination acting through and assisted by the stretched muscles, tendons and connective areola tissues surrounding the parts involved.

It is a well known fact, that with the ordinary way of treating Colles' and other fractures and injuries of the wrist-joint, there often remains in many cases, for a long time, if not permanent, more or less swelling, commencing at the upper margin of the annular ligament and extending upwards, caused by an effusion of lymph into the sheaths of the tendons and the areolar tissue around them. The ankylosis and permanent impairment of the wrist-joint, and in the use of the fingers, which frequently follows, can be prevented if treated as I have suggested in this paper; for passive motion can be made of the fingers and tendons from the time of the accident and the condition of the injured parts can be inspected daily, so that if the effusion of lymph and

swelling becomes too great, application of remedies, which favor absorption, can be made without disturbing the dressings or splint.

Finally, what are the advantages claimed for this mode of treatment?

1. It is suitable to every form of fracture of the forearm, whether of one or both bones, either simple or compound, except that of the olecranon process of the ulna.
2. The apparatus is simple in construction and easy to apply.
3. It is more rational and meets all indications better than any other splint or form of dressing.
4. It meets and overcomes that impairment of motion, so frequently met with by surgeons, in fractures of the radius or radius and ulna, *i. e.*, loss of supination while pronation remains intact.
5. Because with its employment, passive motion can be commenced from the time of the accident and thus afford the best means of preventing ankylosis and stiffening caused by effusion into the sheaths of the tendons, impairing the usefulness of the wrist, hand and fingers.
6. The condition of the injured limb or fracture can be examined at all times, and, if desirable, local applications can be made of remedies which combat inflammation and favor the absorption of any exudation that may have taken place, without disturbing the dressing or apparatus.
7. The same splint and dressing can be used with equal benefit in all cases of dislocations or injuries at or of the wrist-joint.

I believe that I was the first, in my inaugural thesis (College Physicians and Surgeons, Medical Department of Columbia College, New York) in March, 1869, to call attention to the importance of treating fractures of the forearm by extension, counter-extension and forced supination. In the same year Mr. Frank Hamilton's attention was called to the use of this splint and mode of treatment. Since 1870, in all editions of his great work on "Fractures and Dislocations," a woodcut is displayed of the apparatus as applied to the forearm, and most honorable mention is made of it, both in the chapters on fractures of the radius and of both radius and ulna.

In Stimson's work on "Fractures," page 442, the same woodcut is displayed, evidently copied from Hamilton's work, and it is the only splint shown for the treatment of fractures of the shafts of both bones; yet, in reading his reference to it, although commendatory, I am compelled to say that this excellent author does not seem to comprehend the great and important principles in its use or application.

127 Euclid avenue.

A FRESH outbreak of influenza is reported from Copenhagen. Between Oct. 5 and 11 the number of cases known to have occurred was 34.

THE CLINIC.

REMOVAL OF A DERMOID CYST.

A Clinical Lecture, delivered at the Hospital of the University of Pennsylvania, October 8, 1890.

BY WILLIAM GOODELL, M.D.,

PROFESSOR OF GYNECOLOGY.

[Reported by LEWIS H. ADLER, JR., M.D., Resident Physician of the Episcopal Hospital; Late Resident Physician of the University Hospital.]

This woman is 22 years old; she appears to be quite strong and healthy-looking, but such is not the case. Her menstrual periods, for over four years, have been accompanied with a considerable amount of pain, and for the last eight months she has been practically a cripple. I have ascertained her trouble to be a tumor, about the size of an orange, situated in the ovarian region of the right side of her abdomen. This tumor seems to be adherent from every direction. She has been already under the care of many physicians, and has taken medicine of various kinds, but without any permanent improvement or alleviation of her severe suffering.

There has been some suspicion of venereal trouble; but in spite of our treatment, based upon this hypothesis, her symptoms have been growing worse and worse, and her pain more and more severe. The apparently large number of adhesions already noted as existing in this case would lead me to suspect a previous history of peritonitis, but I have been unable to elicit such an account.

Some years ago I would have hesitated to operate, in the manner proposed in this case, before such a large number of students, for fear of poisonous germs in the atmosphere, that might set up an inflammation and be deleterious to the patient. In addition to this fact, a few years ago I would have been afraid to operate upon a patient who was menstruating, lest there might be some germs present to induce sepsis. But now the dangers in both of these instances have been greatly lessened by the introduction of antiseptics, so that modern surgeons are highly gratified at the success that they have obtained with the proper observance of antiseptic precautions, even in the most crowded lecture-rooms.

In reference to an operation of election, I should always prefer to select a time when the patient is between her periods of menstruation; mainly on account of æsthetic reasons; for the danger formerly involved in operation performed during, or about, the menstrual period, is now considerably lessened under the new *régime* of treatment. Some surgeons go so far as to say that the danger is entirely annulled, and that you can operate as well at one time as another; but, in my opinion, this is carrying the matter a little too far, when hysterectomy is concerned.

The two great secrets of success in abdominal

surgery are excessive cleanliness and deliberate care in the breaking up of adhesions. Sometimes, out of respect for public opinion, I use carbolic acid as a disinfectant (1 to 40 solution), but hot air and boiling water are the best germicides.

The patient before us has been carefully prepared for operation—the abdomen scrubbed and a vaginal douche of bichloride of mercury, 1 to 2,000, used; the bladder emptied and the pubic region shaved. It was formerly my custom to shave this region on the day preceding the operation; but as this needlessly alarmed the patient, I now defer it, as in this instance, until after the anæsthetic has been administered.

Everything being in readiness, the instruments immersed in boiling water, in which is a solution of carbolic acid; my hands and the hands of my assistants being chemically clean; I rewash the abdomen with a 1 to 1,000 solution of corrosive sublimate and, standing upon the right side of the patient, begin the operation by an incision in the median line of the abdomen. First, however, I estimate the thickness of the skin, so that I shall know exactly how deep down to cut, lest I should enter the peritoneal cavity. In making my incision, I am careful to direct it along the track of the conjoined tendon of the belly of the internal oblique and transversalis muscles, so that they will reunite without difficulty.

Having now cut through the skin, muscles and fasciæ, I come to the peritoneum, which latter lies behind the recti muscles, separated by a celluloadipose tissue. Before opening the peritoneum, the hæmorrhage incurred thus far is checked with catch forceps. While I am tying the vessels, I also have time for the woman to get over her present attack of vomiting; judging from the persistence of this symptom, I fear she has had something to eat since this morning. The danger of any food being taken shortly before an operation is that there may be large masses of food in the stomach, which, during the etherization, may be vomited up and drawn into the larynx, producing suffocation; or, if the incision in the abdominal wall be a large one, there is a possibility of some of the intestines being forced through the opening.

All possible antiseptic precautions having been taken thus far, and all the bleeding vessels secured, I now divide the præperitoneal fat—which is here thicker than usual—and then seize hold of the peritoneum with two forceps, raise it up nick it. The tumor is to the left side of the abdomen and behind the uterus. For this reason I am obliged to make the incision longer than is ordinary. Accordingly, I push the omentum aside and then proceed to empty the cyst, first taking the precaution to immerse the end of the aspirator in a 1 to 2,000 solution of the bichloride of mercury.

I now examine all of my instruments, in order to be certain as to their number and condition. As a general rule, little tumors are rather harder to operate upon than larger ones, for the reason that the working room is less.

The present tumor looks like a rare form of growth, called a dermoid cyst. Its contents are curious, and are very irritating to the lining membrane of the abdominal cavity; for this latter reason the greatest care has to be exercised in order to prevent infection of the abdominal cavity, and a consequent septic peritonitis. I shall keep the contents of this cyst for a further examination, as it is a very pretty example of this kind of a growth. It contains a small plate of calcareous matter, some light hairs, a nipple like that of the mammary gland, and some white cheesy-like substance, the exact nature of which I shall not be able to declare until it is examined microscopically.

This tumor is rather more difficult to remove than is the case in the ordinary run of similar operations, for the reason that it has a short and broad pedicle. Before cutting away the tumor I shall tie the pedicle with a provisional slip-knot.

We now ask ourselves: What are dermoid cysts? This is a question in regard to which pathologists have not yet become satisfied. We generally find in them hairs—most commonly of a light color, and teeth. We sometimes find in them bone fragments; but the most common constituents are hairs, teeth, and cheesy material such as comes from sebaceous glands, viz.: skin products, and it is for this reason that these curious growths are called *dermoid* cysts—in other words, skin-like tumors.

For a long time they were explained by what I call the "blasted theory"—partly because I cannot understand it, and partly because it contends that the epiblastic portions of an ovum, which form the skin, hair and teeth, become misplaced by dipping down into the hypoblast and becoming mixed up with other embryonic cells. Dermoid cysts are sometimes found in the testicles, but more commonly in the ovary, so that the theory is now gaining ground that they are, as a rule, developed from some addled human eggs; and it is no longer considered necessary, as it once was, that an ovum should have been fructified by the spermatozoa, in order for it to become the basis of a dermoid cyst.

Another theory once in vogue, was that of parthenogenesis, or virgin birth; that is to say, imperfect effort at transmitted fertility—a property peculiar to many insects—the aphidæ, for instance—one copulation being sufficient to keep up fructification for several generations of descendants. Let me here take the opportunity, while I am on this subject, to correct the statement I made in the beginning of my lecture, that this trouble in the case before us, was probably

of specific origin, as this tumor abundantly explains all the symptoms, without an appeal to syphilis.

Let me also repeat what I said in the beginning of my lecture in regard to these cysts containing irritating substances and, therefore, more or less poisonous to the peritoneal cavity, the practical lesson from this being that when you are removing a tumor, and have even a suspicion that it is a dermoid cyst, you should take the greatest precautions, by the introduction of antiseptic sponges beneath and around it, to prevent the possibility of any of its contents escaping into the peritoneal cavity, wherein they will certainly induce a dangerous, not to say disastrous inflammation.

Having now counted the instruments and the sponges and removed the cyst, the pedicle of which I have tied with a carbolated silk ligature, passed through the centre of the stalk and tied upon either side, I am ready to close the abdominal walls. First, however, the abdominal cavity must be thoroughly cleansed, particularly in Douglas' pouch and in the peritoneal fold between the bladder and the womb, as otherwise peritonitis or septicæmia may follow. After this is done a large flat sponge is placed over the intestines, under the wound, in order to catch the blood that issues from the suture tracks. Each suture is double-threaded—that is to say, has a needle upon each end, which allows its being passed from within outward. Each needle is inserted about $\frac{1}{4}$ of an inch away from the edge of the wound, and I am careful to include in the sutures all the layers of the parietes, in order to avoid ventral hernia.

In this instance, I shall not use a drainage tube; these instruments are indicated in cases where cysts break during removal, in cases of serious adhesions, of old women with lowered vitality, or in septicæmia, and are always to be removed generally in from twenty-four to forty-eight hours, when the serum discharged is no longer bloody, but pink or straw-colored.

All the sutures having been inserted, the flat sponge previously mentioned is removed, and the abdomen reexamined to see if any oozing has occurred; all being found dry, I now count the sponges and instruments again, in order to make sure that none are left behind within the cavity of the abdomen—finding the count correct, I catch in the hand all the sutures on my side, and my assistant does the same upon the opposite side. The edges of the wound are brought firmly together, and, at the same time, all the air is expelled from the abdominal cavity. Each suture is now tied by means of the surgeon's knot. As the abdominal walls are fat and thick, there is some eversion of the outside edges of the wound, so that I shall be obliged to insert a few additional superficial stitches, in order to hold the upper parts of the wound together; for, if we are

careful to get like parts in apposition—the skin connected with the skin, and the fasciæ with the fasciæ—we shall get union by the first intention; otherwise, if this precaution be not taken, the union will be by granulation.

The entire wound being closed, the ends of the sutures are gathered together in one hand and cut off several inches from the knots. I now proceed to dress the case with my favorite dressing, which consists of:

1. Powdered iodoform sprinkled over the surface of the abdomen, particularly into the umbilicus.
2. Sublimated cotton.
3. Broad adhesive strips of rubber plaster to hold the previous dressing in place.
4. A wide flannel binder, smoothly pinned with safety pins.

To-morrow at 1 o'clock, or within twenty-four hours, the patient is to have a cup of tea, and she will consider this the best cup of tea that she has ever tasted in her whole life. If she suffers in the meantime from collapse, she is to have sips of whisky. If she has excessive thirst, she will have enemata of beef-tea.

I trust that she will be able to get along without any opiate, because opium has the effect of stopping the bowels and the other emunctories; but, if she suffers very much, she is to have a hypodermatic injection of morphine.

After getting the tea to-morrow, she is to receive for the first few hours a dessertspoonful of milk, which is to be administered every hour; and, if it be well received, she will by nightfall be able to take one tablespoonful every hour for several hours, and then two tablespoonfuls every two hours. This quantity is to be gradually increased, so that by the end of the third day she will be getting during the twenty-four hours as much milk as she can retain and readily digest.

As I mentioned previously, she is to receive no opium, unless it is absolutely necessary to relieve pain, because it has the tendency to stop the bowels; moreover, though it was once considered necessary after these abdominal operations to keep the bowels closed for a week or more, such an opinion is no longer in vogue among medical men.

The bowels are to be moved on the second or third day, and the greatest precautions are to be taken in order to prevent any constipation in this case. She is to be urged not to hesitate to pass her wind, no matter who may be present at the time, lest the distended bowels exert a pressure upon the region of the wound and set up a peritonitis. If she does fill with wind, let the bowels be moved on the second day. For this purpose, I generally order a Seidlitz powder, adding to the contents of the blue paper a dessertspoonful of Rochelle salt. If she vomits, she is to receive large doses of calomel, for the reason that this medicine is heavy and not liable to be vomited. I give as much as 10 or 20 grs. at once and repeat it until bowels

are moved, having given as much as 75 grs. during the twenty-four hours, feeling sure that, at least, a part of this heavy substance must have been kept down, however violent the vomiting may have been.

If the flatus be low down in the intestines and reachable, it is sometimes removed by the introduction into the rectum, or even higher when necessary—into the sigmoid flexure of the colon—of a flexible catheter. In any case, should tympanites or septicæmia become evident, let the bowels be moved. This latter condition is shown by peritonitis, by the pulse rising above 120, and the temperature going above 102° F., when ice is to be applied to the head.

Should obstinate vomiting occur, ice will be given or sinapisms applied to the epigastrium.

As a rule, it is necessary to catheterize for a day or so after these operations, but it is to be avoided as much as possible, as the too frequent use of that instrument is likely to cause an irritable bladder that is not easily amenable to treatment.

From a week to eight or nine days, the primary dressing will be ready to be removed and the stitches taken out.

MEDICAL PROGRESS.

STRYCHNINE IN THE TREATMENT OF WEAK HEART.—I have derived very great benefit in the treatment of weak heart from the administration of strychnine in gradually-increasing doses. I usually begin with a prescription consisting of 1 grain of the sulphate of strychnine to 1 ounce of dilute phosphoric acid, and of this I give the first day 10 drops three times, the next day 11 drops three times, and so on, increasing the doses a drop each day until some indication of the physiological action of the drug is obtained. This usually consists of a slight rigidity of the muscles of the neck or calves of the legs. The administration is then stopped for a day or two, and then resumed as before. This process may be continued as long as appears necessary. I am quite sure that I have frequently succeeded in giving tone to weak hearts when even digitalis has failed to produce permanently beneficial results.

Within the last few years I have made great use of cocaine as a heart tonic. So far as I know the first published account of its efficacy in this direction was made by Dr. Beverley Robinson, of New York, but I had employed it, for the purpose of giving tone to the heart, several years before his observations were made known. Its action in this respect is readily perceived by the stethoscope, the sphygmograph, and by feeling the

pulse. Moreover, its influence is markedly shown in the ability which it gives the patient to take increased exercise without suffering from dyspnoea or inordinate cardiac action. I usually begin its administration with a dose of $\frac{1}{6}$ of a grain three times a day, and gradually increase this in the course of a month up to 1 grain. It is well, I think, to give it in combination with wine, although this is by no means necessary. I employ for this purpose the so-called restorative wine of coca, which consists of 2 grains of the hydrochlorate of cocaine to the pint of Malaga wine. A wineglassful contains $\frac{1}{6}$ of a grain of cocaine. After this quantity is taken for two or three days, I have the patient add a powder of $\frac{1}{6}$ of a grain to each dose, and so on until the total quantity amounts to a grain. In some cases it is not advisable to increase the dose. Cocaine, more than any other medicine with which I am acquainted, appears to possess the property of exhibiting its effects without any augmentation of the dose, and in such instances the original quantity may be continued indefinitely without deleterious effects. On the contrary, usually with marked beneficial results.—W. A. Hammond, *Therapeutical Gazette*.

THE ETIOLOGY AND TREATMENT OF TETANUS.

—At a recent meeting of the Academy of Medicine M. NOCARD read a paper by M. PEYRAUD on this subject. M. Peyraud, having inoculated a number of rabbits with an infusion which he made from hay, says he was able by this means to bring on an attack of tetanus in 50 per cent. of the animals inoculated. The animals thus inoculated succumbed in the proportion of five out of every six. M. Peyraud has a theory that a chemical substance capable of exciting symptoms analogous to those caused by the invasion of the system by a given microorganism will prove by inoculation to be a vaccine against the ravages of the microbe. He has applied this theory to strychnine, considered as the vaccine against tetanus. His method of proceeding was as follows: He injected hypodermically for a period of five or six days a dose of strychnine, varying the dose according to the size of the animal and the appearance of the convulsions. The animals being thus prepared, he inoculated them with pus obtained from an animal previously dead of tetanus. Ten of such rabbits were inoculated; but, in addition to these ten already prepared, he inoculated, as a controlling experiment, four others not previously protected by strychnine vaccination. The whole four non-vaccinated ones died and three of the ten vaccinated. The death of three of the prepared animals was attributed to a supplementary injection of strychnine which proved too strong. M. Nocard repeated these experiments by following a somewhat different method. He prepared a pure culture of

tetanic bacilli from a lamb. Then he took ten rabbits and injected under the skin of each, for five days in succession, ten drops of a solution of sulphate of strychnine of the strength of 1 in 1000. He next inoculated the ten with his bacillary culture, controlling the experiment by at the same time inoculating ten untouched rabbits with the same culture. The result, however, was that they all died in from three to five days. He repeated the experiment with slight modifications, but the result was not less disastrous. The conclusion, therefore, was obvious.—Paris Correspondence, *The Lancet*.

BLOODLESS TONSILLOTOMY.—PROFESSOR J. TOISON, of Lille (*Rev. de Thér. Méd. Chir.*, October 1), discusses the various methods of reducing or removing enlarged tonsils. He begins by saying that excision of the tonsils with the bistoury or the guillotine is gradually losing favor among surgeons on account of the risk of hæmorrhage. Ignipuncture with the thermo-cautery or the galvano-cautery is often useful, but should be reserved for cases in which the tonsils are only moderately enlarged and can be sufficiently reduced in one or two sittings, and for cases in which some anomaly of shape in the hypertrophied glands makes it difficult to remove them with a cutting instrument. For ordinary cases, Professor Toison uses a new snare of his own invention, which, according to him, effectually obviates all danger of bleeding. The apparatus consists of a *serre-nœud*, the metallic loop of which, instead of being free, is fixed by three silk threads to a blunt ring fixed to the distal end of the instrument. The ring is passed over the tonsil, which is then seized with forceps; the wire loop is next pulled home in the usual way, the traction being sufficient to snap the silk threads which fix it temporarily to the ring. The tonsil is thus cut through without bleeding. Professor Toison has performed this operation several times since last April; in no case has there been any hæmorrhage.—*Brit. Med. Jour.*

MERCURY DURING ALBUMINURIA.—The question as to whether mercury is likely to be injurious in cases in which albumen is present in the urine, is one of much importance to the surgeon as well as the physician. Many surgical complications occur to patients who are the subjects of chronic renal disease, and conditions are often presented in which, were there not a prejudice against it, mercury would seem to be desirable. I have myself chiefly been concerned with this dilemma in cases of syphilis, and have long been in the habit of prescribing mercury without much regard to the state of urine. Nor have I ever seen reason to regret doing so. The following quotation from a Report on Medicine by the late Dr. Prichard, of Bristol (1835), is not without its

interest in reference to this question. Dr. Prichard refers to cases in which dropsy was the condition requiring treatment.

"It seems to have been the opinion of Dr. Bright, and the observation was strenuously enforced by Dr. Blackall, that mercury is injurious in all cases of this description. I shall take the liberty to state that this question has been brought to the test of experiment, during several years, at the Bristol Infirmary. In numerous cases of dropsy, with albuminous urine, the treatment advised by Dr. Blackall has been fully tried, and it has failed to produce a cure; but the same cases terminated in recovery under a moderate use of mercurial remedies."—Mr. Jonathan Hutchinson in *Archives of Surgery*.

VAGINAL HYSTERECTOMY FOR CANCER.—FLAISCHLER (*Deutsche med. Wochenschrift*, No. 29, 1890) reports twenty cases of total extirpation operated upon in the past five years, with three deaths from sepsis. Seven patients had since died from the disease, and eleven had no recurrence, of whom six had been operated upon at least three years before. He insists upon greater care in the selection of cases, not so much because of the immediate as of the remote results of the operation. Only those are suitable for the radical operation in which there is strong probability that the cure will be permanent. It is not justifiable to remove every uterus which can be easily drawn downward when there is suspicious induration in the broad ligaments. Sometimes it is impossible to determine positively, even under ether, whether the perimetrial tissues are involved or not, or to decide between malignant and simple inflammatory indurations in the broad ligaments. Under these circumstances it is better to give the patient the benefit of the doubt.

According to Volkmann, a patient can only be regarded as cured when three years have elapsed after the operation without recurrence, while Fritsch places the limit at six years. Tanner believes that while a patient may be said to be cured, it is only a question of a few or many years before the disease returns. Fleischler regards the latter view as too pessimistic, although sufficient evidence has not yet been accumulated to decide positively against it. He thinks that the total extirpation is no more dangerous than high amputation (!); the latter operation should be regarded as a transitional step in the development of the former, and is not to be compared with it.—*Am. Jour. Med. Sciences*.

EFFECT OF CERTAIN SUBSTANCES ON THE RED CORPUSCLES.—M. MAVET, of Lyons, read an interesting paper at the recent meeting of the French Association for the Advancement of Science, in which he gave an account of the effects of various neutral salts and of chloral on

the red corpuscles of the blood. Solutions of the strength of 1 or 2 per cent. of chloride of sodium, chloride of potassium, sulphate of soda, phosphate of soda, bicarbonate of soda, and sulphate of magnesia all at first temporarily destroy the elasticity of the corpuscles and then dissolve or disintegrate the stroma. Solutions of the strength of 5 per cent. or more diminish the size of the corpuscles and harden them. The chloride of sodium has the most preservative primary action, but is most destructive on prolonged contact. As is well known, it has been recommended for washing the blood (in a 0.6 per cent. solution) in certain cases of poisoning. Sulphate of soda has a great tendency to preserve the chemical properties of the corpuscles, but makes them much more rigid than does chloride of sodium. It is not suited for intravenous injections, but is very useful in the laboratory for washing the corpuscles before preparing hæmoglobin from them. For this purpose it is better than the 3 per cent. solution of chloride of sodium, which is commonly employed, but which has a considerable tendency to dissolve the corpuscles. Chloride of potassium has a great preservative action, but cannot be used for intravenous injections owing to its toxicity. Carbonate of soda in weak solutions is very preservative. Phosphate of soda in weak solutions renders the corpuscles rigid for a long time; it preserves their form well, and so is useful in diluting the blood for the purpose of counting the corpuscles. Sulphate of magnesia does not dissolve them, but changes their shape more than any of the other salts. Hydrate of chloral is very destructive to the corpuscles when it is in a concentrated solution, but not when it is of less strength than 5 per cent. Intravenous injections of the latter, which may be repeated several times daily, are very valuable in tetanus, in uræmic convulsions, to calm the violent spasmodic attacks in rabies, and in some painful diseases where hypodermic injections of morphia are inefficacious or badly borne. Of course the effects on the heart, respiration, and urine must be carefully watched.—*The Lancet*.

ANTISEPSIS IN GYNECOLOGY AND MIDWIFERY.—DR. AUVARD (*Arch. de Tocologie*, August, 1890) describes his method of insuring clean instruments and preventing them from fouling when packed in their cases and boxes. The handles of the knives are of the same metal as the knives themselves; glass is avoided as much as possible, since it is less easy to disinfect than metal. Friction of instruments, after use, with emery powder is purely æsthetic. Soaping and brushing is necessary to wash off visible impurities, but the process does not destroy germs. Immersion in antiseptic fluids not strong enough to damage the metal is good, but not absolutely efficacious. Catheters and forceps may be thoroughly disin-

fectured by fire, the instrument, well cleaned, being passed through the flame of a spirit lamp, or else a few drops of spirit may be poured into the metal box in which the instruments are packed. The flame must be applied for about a minute to the instrument. Boiling water is easily procured, and is good for knives, etc., which it does not spoil, but it tarnishes steel and nickel. The most perfect method, however, of rendering these delicate instruments aseptic, is the stove. The *autoclave*, or compressed vapor stove, is not so good as a dry-heat stove like Poupinel's. The instruments, laid out in a metal box, should be left for half an hour in the stove at a temperature of 150° C., being 50° C. above boiling point. Dr. Auvard finds that a high temperature blunts the knives. Strong antiseptic solutions alone avail for India-rubber and glass tubes. Obstetric and gynecological cases made of leather should not be constructed so that the instruments are fixed in straps against the leather. The instruments should be rolled up in a calico or longcloth sheet, which must be washed at least once a fortnight.—*Brit. Med. Journal*.

IDENTITY OF HUMAN AND ANIMAL DIPHTHERIA.—In support of this proposition, M. DELTHIL points out that diphtheria may be met with in many different animals with symptoms almost identical. The bacillus of the disease in man, when inoculated on animals, multiplies with rapidity; and the disease itself may be retransmitted to man with its original characters. From these facts, and from the history of the disease, M. Delthil concludes it is identical in man and animals. He records thirteen personal observations, and cites in addition several facts noted by different observers, all of which go to show that the transmission of diphtheria from animals, and especially from birds, to man has taken place under circumstances often diverse and little thought of. In conclusion, he urges that if the identity and transmissibility of human and animal diphtheria are admitted, it follows that stables, poultry-yards, dovecots, etc., are very likely to contain the germs of the disease, and to favor in consequence its spread. He therefore urges the necessity for a thorough and constant inspection of all markets, poultry-yards, and dwellings where domestic animals and fowls may be kept, and he points out that the initiative in this respect has already been taken in Germany, Italy and Switzerland.—*The Lancet*.

THE USE OF BROMOFORM.—In the *Medical Record* for September 6, 1890, DR. LOUIS FISCHER reports sixteen cases of children treated in the German Polyclinic of New York, the majority of whom were, as a rule, poorly nourished subjects, living in tenements in badly ventilated rooms, and in all respects under the least favorable con-

ditions of hygiene. In all of these cases, nevertheless, the most marked improvement and rapid cure is said to have followed the use of bromoform. The doses which he administered were the following:

For children under and up to 1 year of age, 2 to 3 drops three times a day. Children from 2 to 4 years of age, 3 to 4 drops three or four times a day, depending upon the severity of the case. Children up to 8 years of age, 4 to 6 drops three or four times a day. The doses were usually increased on the third day, and in very severe cases on the second, by adding 1 drop to a single dose. The time required for a cure was variable, in some cases ten days being enough to effect a cure, while others required almost four weeks.

This remedy may be given in a small teaspoonful of water; but as, from its weight, it sinks to the bottom of the spoon, care must be taken to see that the child swallows the bromoform and that it does not remain in the spoon. As a rule, no difficulty will be experienced in giving it to children, as bromoform has a pleasant taste and is readily taken. If the bromoform turns brown, it contains free bromine, and should then not be administered.—*Therapeutic Gazette*.

STRYCHNINE AS AN ANTITETANIC VACCINE.—DR. PEYRAUD (*Bull. de l'Acad. de Médecine*, No. 40, Oct. 7, 1890) gives an account of some experiments carried out with soil taken from a covered in enclosure in which wine was stored, and in which no horses had entered within the memory of the inhabitants, and which had not in any way been cultivated since the store was erected. Dust from forage when inoculated induces tetanus in 50 per cent. of the animals experimented on, but soil taken from this wine store induced tetanus in 100 per cent., five out of every six of the animals inoculated dying. Having obtained this virulent material, Dr. Peyraud carried out a series of experiments to test his theory that strychnine, which produces many of the symptoms of tetanus, would probably act as a vaccine; he, therefore, injected 0.5 milligram of strychnine in solution every day for five days. Ten rabbits so vaccinated and four test rabbits were inoculated with a small portion of tissue from near the wound in an animal in which tetanus had been produced experimentally, and the wounds were carefully closed. Of the fourteen animals the four test rabbits, and three of those vaccinated, died. In a second series of experiments, seven prepared rabbits and fourteen test rabbits were inoculated with tetanic virus six days after the strychnine inoculation had been stopped; thirteen of the test animals and four of the prepared animals died.

MM. Verneuil, Trasbot and Nocard were appointed as a committee to test the accuracy of such an important statement, but unfortunately, they were unable to obtain as good results as Dr.

Peyraud had recorded. They found that the soil was undoubtedly capable of producing tetanus in a certain proportion of rabbits, but in their hands this proportion was only 11 per cent., whilst as regards preventive inoculation, 0.6 of a milligram of sulphate of strychnine injected daily for five days did not protect a single one of eight rabbits against the action of a pure cultivation of the bacillus of tetanus. They were killed as rapidly and with the same symptoms as eight test rabbits. All died in from three to five days. Thinking that the dose of strychnine might be too small, they gave to ten rabbits 1 milligram of sulphate of strychnine; one of the animals died. The next day they injected 0.9 of a milligram, and another of the animals died; the third day, 0.8 of a milligram, and only two or three of the animals showed symptoms of strychnine poisoning. On the fourth and fifth days the same dose was administered to the remaining eight rabbits. On the sixth day, the eight prepared rabbits and four test rabbits received 10 drops of a pure culture of the bacillus of tetanus, with the result that the whole twelve were dead at the end of five days, and the reporters conclude that, although an important fact has been demonstrated by M. Peyraud as regards the presence of the tetanus bacillus in non-cultivated and undisturbed soil, his experiments on preventive inoculation with strychnine against tetanus are vitiated by some important fallacy, as the committee were unable to obtain the same results.—*Brit. Med. Journal*.

RECENT HYPNOTICS.—DR. H. DEHIO (*Petersburg med. Wochenschr.*, No. 33, 1890), gives the result of trials of various hypnotics in the Dorpat Clinic for Nervous and Mental Diseases. Hypnone in doses of 10 to 15 drops was useless, and methylal and chloralamide were found of little use in the few cases in which they were tried. Paraldehyde was and remains the most reliable hypnotic used in the clinic. In severe cases a dose of 5 to 6 grams was followed by another of 3 to 4 grams; this was found sufficient to give a night's rest. As a rule the drug acted well, but sometimes only slight sleep followed, and in other cases tolerance was soon established. But these occasional disadvantages are counterbalanced by the fact that the drug, even in large doses, does not influence the heart or respiration. Paraldehyde may upset the digestion, causing diarrhœa. The medicine must be pure, it must not redden litmus paper. If kept exposed to daylight or in badly-stoppered bottles it soon becomes acid. After the prolonged use of paraldehyde the following symptoms may appear: loss of appetite, gray coloration of the face, dryness of the skin, and loss of body weight; at the same time the drug does not produce somnolence. These symptoms disappear on discontinuance of

the drug. Paraldehyde, however, is the sheet anchor in the Dorpat Nerve Clinic. Amylene hydrate was also found of use, and has the advantage of not affecting the digestive tract, although it may produce headache and depression. Urethan is of service in doses of 45 to 90 grains in mild cases of insomnia. Sulphonal was given in doses of 15 to 60 grains. It was not found so useful as paraldehyde and amylene hydrate. Drowsiness, weakness, and incoördination of gait were noticed after its administration. In mania it acts only slightly, also in progressive paralysis. In many cases of excessive motor disturbance, such as occurs in mania and delirium tremens, all these hypnotics are practically useless. Hydrochlorate of hyosine ($\frac{1}{10}$ of a grain) is the best remedy in these conditions.—*British Medical Journal*.

INTRA-UTERINE TYPHOID INFECTION.—P. ERNST (*Ziegler's Beiträge*) describes an interesting case of intra-uterine infection. The child, a premature birth from a mother infected with typhoid fever, died on the fourth day after birth, death being preceded by a fine reddish irruption, on the lower extremities and abdomen. The post-mortem examination showed injection of the stomach, enlarged spleen and icterus. Cultures were made from the blood and spleen that developed colonies of typhoid bacilli. Microscopic examination of the spleen showed masses of bacteria plugging the small capillaries in the Malpighian bodies. The peculiar situation of these bacilli showed that a large number of germs had passed into the circulation of the child at one time. This, the author thought, was explained by a trauma sustained by the mother a few days before the birth, in which a considerably quantity of blood had been discharged by the vagina. This injury to the placenta furnished the opportunity for foetal infection. Unfortunately, a satisfactory examination of the placenta and liver of the child could not be made.

A NEW METHOD OF EXAMINING THE LIVER.—A new method of examining the liver, more especially its lower border, is proposed by GLENARD (*Weekly Medical Review*, August 2, 1890). The patient lies on his back, while the physician, sitting to his right, on the edge of the bed, passes the four fingers of his left hand under the right hypochondrium of the patient, so as to press out the lumbar region, while the thumb, applied more anteriorly, makes gliding motions from below upward. If the patient now makes deep inspirations, the thumb will distinctly feel the lower margin of the liver.

SATURDAY, NOVEMBER 15, 1890.

ONE ASPECT OF THE RELATION WHICH
PATHOLOGY BEARS TO THERAPEUTICS.

The best part of modern medicine is undoubtedly founded upon a pathological basis, *i. e.*, on the changes in tissues which we can discover by an examination of their gross or minute structures, such changes for the most part being either quantitative or qualitative, physical or chemical. Unfortunately for the human organism, the power of regenerating damaged or changed structures is not inherent in it to any considerable degree.

Certain of the lower animals are capable of reproducing limbs or even organs which have been experimentally or accidentally removed. The lobster can reconstruct a complete and perfect claw, or the tadpole a new tail, and further illustrations of this reconstructive capacity are perfectly familiar to the biologist. In man, however, regeneration is usually limited, with few exceptions, to that important though less highly organized group known as the connective tissues. That a liver cell, for instance, or any other parenchymatous or functional cell, was ever reproduced to effect repair in human tissues, is a controverted point, but the weight of evidence seems to be that such regeneration does not take place. This is in accord with a supposed law that the more highly organized or specialized a tissue becomes, the further is it removed from that reproductive function which it primitively possessed, and hence the less is it capable of cell generation or regeneration.

Most of us, if allowed a moment's reflection,

will accord the bulk of our success in treatment of disease to that oft cited something, the *vis medicatrix nature*, which, if we are reasonable, we have endeavored to aid by the intelligent use of dietetic, hygienic and therapeutic measures. But what is to be done when the *vis* is wanting? Now, since it has been seen that Nature is incapable of reproducing any of that class of highly organized cells to fill the place of those irreparably damaged by disease, then certainly our whole field of successful therapeutics lies anterior to much that is called pathological. Pathology, in other words, too often dealing with tissues that have advanced beyond the hope of repair. And the task here imposed would be too great for therapeutics in its present state of advancement. But pathology has created a high ideal for it to struggle toward.

Disturbance in function is usually our first guide, and furnishes those indications which we treat; fortunately, also, this first evidence of disease precedes structural change, then by following the clue Nature, or Nature and art, succeed in bringing the process that has gone astray back to the performance of its duties physiologically. We shall suffer much disappointment if we think to restore that which we call pathological, for tissues and their cells, when in this state, have often lost their function. We must then encounter a most difficult problem, *i. e.*, that of establishing a lost function. Art is better able to augment where there is a deficiency or reduce where there is an excess, and even bring back to a physiological standard where there is perversion, than to restore what is lost; Nature, too, even failing here at times.

Pathology makes no compromises with therapeutics. As a fundamental branch of the medical sciences, pathology has been conscious of its own importance from the beginning, and has not been backward in laying down laws or imposing new tasks upon its more ancient though less stable colleague. In this nineteenth century, therapeutics has a leader which it must struggle to obey, but no matter if it does fall short, it need be held in no contempt; a feeling too often engendered at the present day in the mind of the student who has thoroughly imbibed the pathological spirit of the age, especially if he has come under the influence of the German school.

When the medical world gets a great truth, it

often loses much of value when it drops the old in its efforts to seize the new. But in time there is a reappraisal, and the old and new are placed relatively where they belong. Let not, therefore, modern pathology give rise to therapeutic skepticism, but rather render more effective our efforts to deal with disease.

ETHER INTOXICATION.

MR. ERNEST HART, the distinguished editor of the *British Medical Journal*, recently gave an address before the Society for the Study and Cure of Inebriety on this topic.

It has been known for several years, that ether was used for purposes of intoxication in some of the northern counties of Ireland. DR. RICHARDSON, of London, and others called attention to this fact and showed that it was increasing. This address of Mr. Hart groups many of the facts, and presents a most startling picture of this new intoxicant. It appears that somewhere about 1842, ether was sold freely, and used as a beverage in County Derry, Ireland. In 1860 and 1870 it had spread to many of the adjacent towns and counties, and became notorious. It was sold openly by the glass and in larger quantities, and seems to have been used by the poor people, because it was a cheap form of intoxicant.

The Catholic clergy were the first to denounce the practice, but the fear of eternal damnation was not strong enough to suppress it. The demand continued as before, only the use was more secret and less open. Both Protestant and Catholic clergy petitioned parliament to regulate this ether traffic, and also the magistrates called attention to the evils following its use; but practically nothing has been done. Cookstown, Draperstown, and Maghira seem to be great centers in which ether is sold for a beverage. At Cookstown over two tons of methylated ether were sold last year. From Belfast and Londonderry, equally large quantities were shipped to various towns and villages in these northern counties. Each year the traffic is becoming more and more concealed. Several large London ether manufacturers, and also Edinburgh firms, have been making increasing quantities of methylated ether for this demand. This is obtained by removing nearly all the methyl pro-

ducts from methylated spirits, leaving a cheaper ether; this is one of the ethers prepared from rectified spirits, and is sold at wholesale at one-seventh the cost of medicinal ether on the market. It is believed that the breaking up of illicit stills in these counties gave a great impetus to ether drinking, which was cheaper than any other intoxicant that could be obtained.

The peculiar fascination which follows the use of this drug, is the rapid pleasing exhilaration and excitement which comes on a few moments after it is used. This is followed by mental confusion and stupor which wears off as quickly as it came on. At first no particular depressing after effects follow, and the man can become intoxicated and sober half a dozen times a day, at a cost of not more than one or two cents for each two or three drachms. Most of the habitués take two or three drachms three or four times daily, followed by water to cool the mouth and throat. Formerly it was only the poor people of the villages and country who used it, now it has extended to all classes, and is used entirely for its effects. After a time the stomach and brain become affected, and complex forms of gastritis and dyspepsia appear. The brain suffers very profoundly, mania and melancholy are very common. Organic heart disease is also prevalent. Several cases of death have been noted of persons who, while exhaling large quantities of spirits, lit a match and accidentally set fire to the vapors of the breath causing instant death. Generally the effects are much the same as that which follows from alcohol, only more rapid in its interference with the nutrition, and damage to the nerve structure and glandular system.

Its use can not be concealed, as so much of it is exhaled, and a person who has used it is quickly detected by the odor of his breath. Dr. Hart thinks that the use of ether as a beverage is growing in other sections of the country. In Lincolnshire and in London there is clear evidence that ether inebriety has become established. But for some unknown reason it is concealed, both the seller and user are very secretive and do not make any publicity of their infatuation. Mr. Hart suggests that the sale of ether should be regulated the same as any poisons, and that legislatures should take action at once before the evil has reached such proportions as to make it almost impossible to reach it. DR. KERR, Presi-

dent of the Society for the Cure of Inebriety, in an interview on this subject remarked:

People of England have no conception of the terrible hold which this passion for ether-drinking has taken upon men and women in the North of Ireland. A person walking through the crowded and narrow streets of some of the villages there notices the fumes of this drug, with which houses and population seem to be saturated. The market places, the railway carriages, even the churches, reek with its penetrating odor, and one goes away with the sad but true impression that many of the people have become victims to a habit as deadly in its effects as it is new in the history of human weaknesses.

. . . . How many tons of the drug are swallowed by the population of the counties Derry, Tyrone, and Armagh, where the habit is spreading with alarming rapidity, it is impossible to say, for want of accurate information. The amount, however, must be enormous.

Why these people use ether is for the same reason the world over:

Because they are suffering from a disease just as real as consumption or cancer, although not so recognized. I mean, the disease of inebriety, of which the craving for ether in the North of Ireland is one form, just like the craving for alcohol, or morphine, or chloroform, or opium, or cocaine, which, by the way, is the latest thing in the way of hypodermic injections among the fashionable people of London.

Speaking of this form of inebriety he says:

An ounce of ether is enough for a single drink, and costs, after allowing a retailer 100 per cent. profit, only a penny. So you see, for a sixpence a man and his wife can pay all the expenses of a very comfortable spree. Yes, the stuff is sold openly in all the dramshops and groceries, and, to my mind, the only wonder is, given the superior cheapness of ether over alcohol and its thoroughly satisfactory qualities as a drink-producing agent, that the habit of ether drinking has not spread over the whole of Ireland, and, indeed, invaded England and the rest of the world.

It has been claimed that Father Mathew was the cause of the present state of things, inasmuch as he, by his preaching, persuaded the people in Draperstown, in the South of Derry, to renounce all forms of alcoholic drink. This they did, but, having discovered accidentally that ether would answer their purpose quite as well as alcohol, they substituted the former for the latter, and, in spite of Father Mathew's eloquence and well-meaning efforts, Draperstown has continued in a chronic state of drunkenness, although of another kind. Although the people in these districts are consuming enormous quantities of ether every year, the amount of alcoholic drinks sold there has not decreased.

The English papers have taken up this subject, and the government will undoubtedly order an inquiry into the extent and nature of this evil.

In this country a number of isolated cases have been observed, and some writers on inebriety

have warned physicians against presenting forms of ether as narcotics, especially in alcoholic or opium cases. There is evidently danger in this direction in certain cases, and the outcome of this new form of intoxicant and the efforts to suppress it will be watched with increasing interest in this country.

EDITORIAL NOTES.

ACCIDENTAL DEATH OF A PHYSICIAN FROM CHLOROFORM.—Dr. Justus E. Gregory, a well-known physician of Brooklyn, was killed on October 25, by an overdose of chloroform. He had been accustomed to inhale this anæsthetic for the relief of facial neuralgia. On the evening of his death he inhaled a dose of twenty drops on a handkerchief, he felt some relief but called for another dose, and five minutes later was found dead. Dr. Gregory was 49 years of age. He had been a surgeon in the army during the war of the rebellion.

A CRISIS IN BACTERIOLOGY.—Prof. Koch has not abandoned his "momentous investigation," as *The Lancet* calls it, at the Charity Hospital at Berlin; eight patients in Prof. Senator's wards of that hospital being stated to be the number of consumptives that are now under the mysterious Koch treatment. The intimation has been published that in at least two of these patients there have been manifest signs of improvement. The eminent Prof. Leyden, supposed to be the only one of Koch's colleagues who is entirely conversant with the new treatment, has expressed himself most hopefully of the ultimate success of the discovery. It is further intimated that no further disclosure of the treatment will be made until about the middle of December, at which time Koch will have proceeded far enough with his experiments to cast aside the veil of secrecy which is imposed on all, both patients and their attendants, who have participated in them. The letters and telegrams that have been sent to Koch since the adjournment of the Congress are several hundreds in number, and they all remain unanswered pending this investigation upon the patients at La Charité. It can readily be inferred that the continued reticence of Koch has been the wise and proper course, in view of the damage that might have resulted from an immature disclosure, more especially if he has been him-

self misled. Where so much is at stake the cautious and truly scientific attitude of the great bacteriologist commends itself to all men of science. "We may be," says *The Lancet*, "on the verge of a revolution in therapeutics, and bacteriology itself is on its trial in this momentous investigation." The subjugation of the rebellious bacillus of tubercle almost of necessity carries with it the downfall of other disease germs having a less vitality or resisting power.

JEFFERSON MEDICAL COLLEGE.—A serious episode in the history of this college has arisen in the middle of its busiest season. On October 27, if we are correctly advised, the Trustees voted to vacate the chair held by Prof. Bartholow, that of Therapeutics and Materia Medica, basing their action on the ground that the veteran professor is no longer mentally capable of holding the position. Dr. Bartholow proposes to oppose this action, saying that he is as competent, both physically and mentally, to perform the duties of his chair as ever he was, and that the students attending his lectures this year have expressed no dissatisfaction with his instructions. In fact, if the press despatches are correct, his class of students appears to have taken sides with him, and many of them have declared that they will withdraw from the college if a substitute lecturer shall be appointed by the Trustees. Already have numerous possible candidates for the professorship been named, inclusive of Drs. H. Morris, S. Solis-Cohen, T. J. Mays and J. C. Wilson, all of Philadelphia, and S. O. L. Potter, of San Francisco.

JOHNS HOPKINS HOSPITAL COURSE OF POST-GRADUATE INSTRUCTION.—During the coming year, a course of practical instruction to medical graduates will be arranged by the faculty of the Johns Hopkins Hospital, taking up especially the subjects of medicine, surgery, gynecology and obstetrics.

CAN INEBRIATES BE CURED?—The *British Medical Journal* says: We have been accustomed to hear from the Committee on Legislation for Inebriates, the Society for the Study and Cure of Inebriety, and other disinterested associations, that inebriety is curable to a considerable extent. According to certain Austrian wiseacres, we have been the victims of a vain if pleasing delusion, and our encouraging reports have been but brilliant romances. The Permanent Committee of

the Lower Austrian Diet have had under consideration a proposition to establish curative retreats for inebriates. Upon this project the Austrian Sanitary Board has opened a furious bombardment. In a recent report they declare that they cannot recommend the establishment of asylums for drunkards, and the enactment of a law authorizing enforced detention in such institutions. The reason they allege for this remarkable opposition to a highly laudable piece of legislation, is that "it is very questionable whether alcoholism can be cured at all." It is puzzling to conjecture on what authority or experience such a statement could have been made. The records of such homes, where the patients are treated as persons laboring under a disease, both in America and England, show that at least one-third of all the cases, whose after-history has been ascertained, have done well. This is a substantial measure of success, especially when the period of addiction prior to reception into a home is taken into account. That average period preceding treatment has been in the Dalrymple Home eight and one-half years. The Austrian Sanitary Board, apparently as an after-thought, add that in any case the probability of cure is too small to warrant special legislation or heavy expenditure. We have little doubt that this extraordinary attack upon so useful a proposal will stimulate independent inquiry into the results of such special treatment and legislation. The encouraging success thus far obtained elsewhere cannot fail when made known effectually to triumph over the present temporary, if powerful, opposition.

A MOHAMMEDAN FEMALE PHYSICIAN.—Dr. Razie Koutlairoft-Hanum, a young Mohammedan woman, who was born in the Crimea, recently passed a creditable examination as physician and surgeon at Odessa, and now enjoys the distinction of being the first woman of her creed to engage in the practice of medicine as understood by western nations.

THE DIDACTIC LECTURE MUST GO.—The medical college course has been lengthened to three years in almost every reputable college, and now, says the *Indiana Medical Journal*, it is time to take the next step in progress and abolish the didactic lecture. This is the view which the *Record* has advocated, and it is one which must in time be adopted.—*Medical Record*.

TOPICS OF THE WEEK.

MEDICINE AMONG THE MONGOLS.

In Mongolia, the practice of medicine rests chiefly with the priests or Buddhist lamas, whose system is quite elaborate, but based for the most part on superstition. Instead of paying occasional visits to a patient, their method is to reside in his house until recovery or death takes place, or the case is decided to be incurable. The people have great confidence in drugs and medical regimens, including the water-cure, the latter object causing them to resort to springs, both hot and cold, that are somewhat abundant in Mongolia and Northern China. They place implicit confidence in the medical knowledge of the foreign missionaries who visit their inhospitable country, but express wonder and astonishment when their proffered recompense is refused by the latter. A very frequent affection among the Mongols is the itch, due in large degree to their repugnance to the washing of either their persons or garments. In their tents they live so closely together that if one of them gets the itch all soon have it. Various other skin diseases are prevalent among them. Rheumatism is of frequent occurrence, and the remedy largely used for that trouble consists of kneading or a kind of massage; they make use of a "rheumatism stick," a piece of wood so bent that any part of the body can be reached by the patients in their self-application of the kneading process. A peculiar disease, called Narry, due to their indulgence in their native spirituous liquor, is frequent; the stomach becoming intolerant of food so that the patient ultimately dies of starvation. For the bite of a dog they apply to the wound a portion of the fur of the animal; literally "the hair of the dog" is their remedy. They use the loadstone in powdered form as a cure for ulcers, deafness, etc. They attribute many diseases to the influence of the planets and constellations, to offenses committed, and to fate. Hygiene or preventive measures do not enter much into their scheme of treatment.—*Press and Circular*, October 15.

DRAM DRINKING DOCTORS.

The last number of the *Journal of Inebriety* has the following:

"From a long letter written by an eminent medical man, we condense the following: I was greatly shocked at the number of persons intoxicated at the banquet given to the International Medical Congress at Berlin. My surprise was increased to note that many of them were eminent German and French teachers of medicine. I had supposed medical men, accustomed to use wine and beer daily, were less likely to be intoxicated than the partial abstinent American or Englishman, who naturally are more easily affected by large quantities of wine. At the banquet given to the congress at London, a small number of medical men were stupidly intoxicated, and at Washington the number was still less. As far as could be observed those cases were mostly persons not well known. At Berlin it was the opposite; many very prominent men and leaders were offensively hilari-

ous or stupid. The drinking seemed to be of a reckless, impulsive character, which is only seen in low life in this country. At London and Washington, men who were notably excessive users of spirits drank with reserve and caution, and gave no evidence of intoxication, but at Berlin it was the contrary. The doctor concludes, that the moderate beer and wine drinker has far less power of control, and is far more likely to be delirious or stupid from excess of spirits, than the self-reliant occasional drinker in America or England. He believes that the American physicians are the most temperate in the world, and exhibit more pride of character and personal respect at banquets where there is a general unbending of social restraints.

"To this we would add, that in our opinion it is always a sad reflection on the manhood of the medical man, who after a protracted study abroad, brings home with him foreign customs of moderate use of wine and spirits. It implies a degree of ignorance and parrot-like imitation that becomes more and more apparent every year. The physician, of all others, should be the last one to use spirits in moderation or excess. The use of alcohol as a beverage is direct evidence of ignorance of the teachings of modern science and failure to keep up with the growth of medical advance. We believe no facts are sustained by stronger evidence than these."

STAGNATION OF POPULATION IN FRANCE.

The so-called depopulation of France, which really only signifies the fact that the French population has in nine years increased so slowly as to have become almost stationary, is a subject of much interest from a statistical as well as a political point of view. An official notice has, within the last few days, been issued in Paris giving a summary of the vital statistics of France for 1889. The actual number of births registered in France, without regard to population, have steadily declined from 937,944 in 1883, to 880,000 in 1889; the birth-rate per 1,000 having declined in the same period from 24.8 to 23.0. Compared with the other European birth-rates, this low birth-rate in France stands out in striking contrast; the rate is 37.0 in the German Empire, 38 in the Austrian Empire, 37 in Italy, and 44 in Hungary. The excess of births over deaths in France last year was but 86,000; indeed, if the deaths had not shown a remarkable decline, the excess of births over deaths would have been very much smaller. The deaths recorded in France last year were 794,000, and were considerably fewer than in any year since 1874; the death-rate, which had averaged 22.1 in the preceding five years, declined last year to 20.7, but exceeded the death-rate in England and Wales by no less than 2.8 per 1,000. The marriage-rate in France, that is the proportion of persons married, was 14.2 per 1,000 last year, a lower rate than in any year since 1870, when the recorded rate was distinctly abnormal, owing to the German invasion and occupation. It is a noticeable fact that the recorded marriage-rate in France is now scarcely lower than the rate in England and Wales, although the birth-rate in the two countries is so widely divergent. Indeed, so different is the age constitution of the French population to that of the

English population, that the French marriage-rate, calculated upon persons of marriageable ages, actually exceeds the English marriage-rate calculated in the same manner. The low birth-rate in France, compared with that in England, is therefore entirely due to the smaller proportion of births to each marriage, although it is also a fact that the marriage-rate in France has steadily declined in recent years, as has been the case in most other European countries, including England and Wales.—*British Medical Journal*.

ALCOHOLIC CIRRHOSIS IN A CHILD.

Dr. H. M. Biggs has recently presented before the New York Pathological Society a specimen of advanced cirrhosis of the liver, obtained by him at the autopsy of a boy aged only 13 years, whose body also presented all the other usual lesions of chronic alcoholism. It was reported to Dr. Biggs that when the deceased was a baby of 2 years old, he had a bronchitis for which whisky was prescribed. As the child seemed to take a liking to the latter, his parents permitted him to gratify his taste for it, without let or hindrance, and during recent years they had given him money to spend for alcoholic drink. His capacity for disposing of alcohol became so increased that he would take from six to eight drinks of whisky each day, of about 1½ oz. to each beverage. On the day of his death he bought a larger quantity than usual and took it all at one drink. He was found semi-comatose, some hours later, and never rallied. At the post-mortem examination the liver and other organs presented nearly the same pathological appearances that mark alcoholic saturation in the adult.

REMOVAL OF MICRO-ORGANISMS FROM WATER.

Dr. Kruger, considering the fact that more bacteria are usually present in rivers than in lakes, notwithstanding that lakes themselves in many cases are more or less polluted by rivers passing through populous towns, believes that this rapid decrease in the number of organisms may very possibly be due in part to the action of direct sunlight, but in the main to the tendency of water in a comparatively undisturbed state to deposit and precipitate. He therefore carried out a number of experiments with a view to determine how far the removal of organisms was brought about by the mere mechanical deposition of inert matter and also by precipitation as a result of chemical action. The mechanical precipitants employed, all in a state of fine powder and sterilized, were alumina, brick dust, clay, chalk, sand, coke, and charcoal. Water obtained from an ordinary service-pipe was impregnated with a liquid containing a bacillus growth of a species incident to tap-water. This was divided into two portions—one for precipitation with the inert substance, and the other was untreated for the sake of comparison. Experiments were similarly carried out in which precipitation was obtained as a result of chemical action such as is brought about by the addition to the water, containing naturally lime, magnesia, etc., substances like wood ash, sulphate of alumina, and slaked lime. The general conclusion come to by the au-

thor from the results obtained is that undoubtedly large numbers of bacteria are carried down by inert substances merely sinking in the water, but that the action is very considerably increased when, in addition to mechanical deposition, a chemical precipitation also takes place. The corollary is evident—inert substances do mechanically assist in the precipitation of microorganisms, but preference should be given to chemical treatment.—*Druggists' Circular*.

STERILIZED MILK.

So-called "sterilized milk" by no means always deserves its name, in some cases being much fuller of germs than ordinary unboiled milk fresh from the cow. Herr Kohlmann, of Leipsic, on subjecting two specimens of milk sold as sterilized to examination, found that one of them really was so, no germs being discoverable; while the other specimen contained 350,000 germs per cubic centimetre. For the purpose of comparison other examinations were made, and it was found that a sample of fresh milk bought in the street contained about 160,000 germs per cubic centimetre—that is to say, less than half the number in the second sample of so-called sterilized milk. Milk boiled in the kitchen contained 158 germs per cubic centimetre; distilled water kept in an open vessel, 430; waterworks water, 1,064; and water from the Hofbrunnen, 12,000. Herr Kohlmann suggests that the failure of whatever process was used to sterilize the milk may have been due either to water having been mixed with the milk before the process was commenced, or perhaps to too long a time having been allowed to elapse between milking and sterilizing. This last point exercises a very great effect, as is shown by Freudenreich's observations. He found that milk which when received contained only 9,300 germs to the cubic centimetre, after being kept for three hours at 60° F. contained 10,000; after six hours, 250,000; and after twenty-four hours, no less than 5,700,000. It would therefore appear that our knowledge of the conditions under which milk may be readily sterilized is at present somewhat insufficient, and that reports of the results of the feeding of infants with milk which is reputed to be sterilized must always be received with a good deal of skepticism unless specimens of the milk have been frequently examined by a competent person.—*The Lancet*.

DISINFECTION AFTER DIPHTHERIA.

The Conseil d'Hygiène Publique et de Salubrité for the Seine Department passed the following resolution on a report presented by Dr. Dujardin-Beaumetz on September 19: In cases of diphtheria the patient's dwelling should be disinfected free of cost by men belonging to the "disinfecting brigade;" their services can be obtained on application to the Prefect of Police. All things which have been in contact with the patient must be baked in the steam ovens provided by the municipal authorities. For the disinfection of rooms, sulphur (60 grams for each cubic metre of space) should be used, and the floors and every part of the room which can be washed should be cleansed with 1 in 1,000 sublimate solution. The room should be occupied only after it has been carefully dried and thoroughly ventilated.

PRACTICAL NOTES.

CAFFEINE IN PNEUMONIA.

Te Gempt claims that the use of caffeine is indicated in the course of acute fibrinous pneumonia when the heart begins to be enfeebled, the blood pressure of the aortic system lowered, or when the pulse becomes unusually frequent or irregular. The use of the drug should be begun before symptoms of collapse appear. It should be used at the beginning of the disease in debilitated persons, drinkers, old people, and in subjects of cardiac disease. When used at the proper time and in sufficient doses it diminishes the frequency of the pulse and of the respiration, and increases arterial pressure, lowers temperature, and produces a sensation of well-being. After the period of apyrexia it is unnecessary to continue its administration.—*Revue des Sci. Méd.*, January, 1889; *Western Med. Reporter*.

CHRYSOPHANIC ACID IN ACNE.

Dr. Metcalf highly recommends this agent in acne. He says he has not failed to cure perfectly any case in which the treatment has been adopted. The face is to be washed with soap and well dried, at night. Before retiring, the parts in which the acne is, are to be well rubbed with an ointment of 3 grains of the acid to the ounce of vaseline, and this is repeated nightly until a sharp inflammation of the skin ensues. The inunction is then omitted till the dermatitis is gone, when it is repeated. In most cases a 3-grain ointment is of sufficient strength, but occasionally the strength is to be increased up to 5 grains to the ounce, or even more. The patients are to be cautioned about the staining of their fingers and clothes and to guard their eyes.—*Can. Lancet*.

ADMINISTRATION OF CHLORALAMID.

Much depends upon the proper administration of the new hypnotic, chloralamid, to obtain the full effect and satisfactory and beneficial results. The dose is from 15 to 60 grains, with an average dose of 30 grains. Chloralamid is soluble in about 20 parts of cold water, and in 1½ parts of alcohol.

An additional caution is necessary: Never dissolve or dispense chloralamid in hot water or warm solutions, as the heated preparation decomposes.

The best modes of administration are:

1. In a teaspoonful of whiskey or brandy.
2. In properly proportioned solutions with wine, spirits, or spirituous compounds.
3. In a small cup of cold water or cold tea.
4. In powder form, in wafers or cachets washed down with cold water.

The following formulas have come well recommended and bear the stamp of general approval and adoption:

Dr. W. Hale White (*British Medical Journal*) says: "I always prescribe it with spirit; 20 grains will dissolve in 1 drachm of rectified spirit in fifteen minutes, and water may be added to this solution without reprecipitating the drug. A good way of giving it is to tell the patient to dissolve it in a little brandy, add water to his liking, and drink it shortly before going to bed."

From an editorial in the *Medical Summary*, Philadelphia, we quote:

R. Chloralamid, 4 drachms.
Spts. vini gallici, 4 ounces.
Curaçao, 4 ounces.

℞. A teaspoonful (15 grains chloralamid) in water and repeated in four hours if necessary.

Dr. John Aulde suggests:

R. Chloralamid, 4 drachms.
Spts. frumenti, 3 ounces.
Elix. aurantii, sufficient to make 4 ounces.

℞. Take one tablespoonful (30 grains chloralamid) in water.

Another popular prescription, extensively used in New York is this:

R. Chloralamid, 4 drachms. '
Tinct. cardamom. comp., 2 ounces.
Elixir simplex 2 ounces.

℞. Take a teaspoonful as a dose.

This further suggestion is taken from the *Medical News*: Schmidt employs chloralamid hypodermically, the solution used being 13 grains of chloralamid dissolved in 5 drams of distilled water. Sixteen minims of this subcutaneously is usually a sufficient dose, and acts more rapidly than larger doses given by the mouth.—*Notes on New Remedies*.

INFANTILE CONVULSIONS.

Dr. Jacobi first orders a purgative dose of calomel and then follows in a few hours by:

R. Chloral hydrat., gr. iv.
Potas. bromid., gr. viij.
Aqua, } āā f ʒ j.
Syrupi, } .

Sig. One dose for a child 2 years old.

VOMITING OF PREGNANCY.

R. Cerii oxalat., gr. j.
Ipecacuanhæ, gr. j.
Creasoti, gtt. ij. ℞.

Sig. This is to be taken every hour until nausea is controlled.

—Prof. Goodell, Philadelphia.

AN OINTMENT FOR CHAPPED HANDS

is recommended in the *Provincial Med. Journal*, consisting of menthol, 15 gr.; salol, 30 gr.; olive oil, ½ drachm; and lanolin, 1½ oz. It is said to alleviate the pain on the first application.

SOCIETY PROCEEDINGS.

Tri-State Medical Association.

Second Annual Meeting, held in Chattanooga, Tennessee, October 14, 15, and 16, 1890.

(Concluded from page 695.)

SECOND DAY—MORNING SESSION.

The Association was called to order by the President at 9 A.M.

The first paper read was by DR. J. C. SHEPARD, of Winchester, Tennessee, entitled

A FEW REMARKS ON THE FEVERS OF MIDDLE TENNESSEE AND THEIR TREATMENT.

He said the great malarial period extended from the settlement of the country up to about 1840, during which all the fevers of the country were malarial and periodical. Commencing about 1840, the great typhoid period extended until near 1860. During this period malarial fevers were almost, if not entirely, unknown, and typhoid was dominant everywhere and every case was typical. About 1860, or a little sooner, there was a return of malarial fever, but in connection with typhoid fever. This was the typho-malarial period, which continued for fifteen or twenty years.

About 1880, or somewhat earlier, the characteristic symptoms of both typhoid and malarial fever commenced to disappear and have continued until now. This is the period of fusion. We now have only one fever, which is a continued fever, not typically typhoid, nor malarial, nor even typically typho-malarial. There is not now, nor never was, a continued malarial fever, *per se*, in Middle Tennessee, said the speaker.

Of treatment but little is to be said. Cold water baths Dr. Shepard considers impracticable. New antipyretics should be given with caution. He believed that there was entirely too much quinine used in the continued fevers of Middle Tennessee. Physicians could not afford to dispense with alcoholics yet.

DR. L. P. BARBER, of Tracy City, Tennessee, followed with a paper entitled

A CONTRIBUTION TO THE STUDY OF THE CONTINUED FEVERS OF THE SOUTH,

in which he said the continued fevers of the South, their nosology and etiology, form a subject now justly attracting much attention, a subject upon which much is yet to be learned, and over which the medical world is considerably at variance. Only a close and accurate study of the disease by competent observers, in many and different localities, and a thoughtful comparison of these observations with free discussion will advance our knowledge of their nature, and shed light on the vexed question of its cause.

From the first days of his practice, this disease,

so common to all parts of Tennessee and its adjoining States, had proved of great interest to him. Encouraged by the recent vigorous inquiry and research in this direction, he began some fifteen months since to keep a record of all fevers that occurred in his private practice, and the comparison of the cases, irrespective of their different designations, had helped him toward a decision as to the nosology of continued fever.

Dr. Barber then reported a large number of interesting cases, after which the two papers were discussed conjointly.

DR. G. W. DRAKE, of Chattanooga, in opening the discussion, said that the human body is an aggregation of tissue cells, and that there are found among these cells, in various localities or tissues, certain loose cells, migratory, amoeboid, which he would call the police force intended to protect the tissues against the invasion of foreigners. When the foreigner which produces typhoid fever attacks Peyer's patches and the solitary glands, the migratory cells from all adjacent parts, and possibly distant, rush to the conflict. The result is great destruction of life of both microbes and phagocytes, and their putrefying remains produced typhotoxin and probably other alkaloids. He believed typhoid fever to be produced by a germ once external to the body, but said a "judicious skepticism" was allowable as to whether Eberth's bacillus was the sole cause and absolutely necessary to be present in all cases.

DR. JAMES E. REEVES said it was undoubtedly a fact that the malarial influence was slowly but surely traveling northward.

DR. J. A. LONG, of Long's Mills, Tennessee, related his experience in McMinn County, Tenn. The fevers there had all the symptoms of typhoid fever. There were many non-typical cases. Some were cases of typhoid in a malarial diathesis. He believed that some cases of malarial fever continued because quinine was given in too small doses.

DR. H. BERLIN, of Chattanooga, presented some micro-photographs as an evidence of the existence of microbes in these fevers.

DR. GEO. A. BAXTER, of Chattanooga, suggested the use of salol and naphthol in their treatment.

DR. J. B. MURFREE, of Murfreesboro, Tenn., thought it was impossible to have two fevers at once. He said there was no typho-malarial fever. We have mild cases of typhoid as well as of other fevers. The use of antiseptics is the proper method of treating typhoid, together with proper nutrition and stimulation.

DR. REEVES asked Dr. Murfree if he thought typhoid was contagious. DR. MURFREE said it was to a certain extent.

DR. P. D. SIMS, of Chattanooga: Our fevers are not all either malarial or typhoid. We have another fever dependent upon filth. It may be

called *sewage* or *drainage* fever. It is adynamic in type and is liable to take on most of the symptoms of specific typhoid fever. This is the fever now upon us, arising from the continued and increasing pollution of our water supply from sewage sources.

DR. T. Y. PARK, of Peavine, Ga., suggested that as these fevers presented the symptoms of both fevers, it was practical to use the term typhomalarial, as we cannot make the public understand the technical points of difference and we cannot examine our cases for the microorganisms.

DR. GEO. A. BAXTER, of Chattanooga, presented a paper on

SILICATE OF SODA, SOME NEW METHODS OF USE IN SURGERY.

The paper chiefly had reference to a silicate jacket made by a new process of hardening the silicate, which it is claimed is an improvement on all other jackets inclusive of the plaster-of-Paris, woven wire, or watch spring now in use for the treatment of spinal injuries or disease. It is lighter, equally durable, equally immobile when on, and capable of removal at any time, and of adjustment to any lateral pressure desired.

AFTERNOON SESSION.

The Association was called to order at 2 P. M., by the President.

DR. RICHARD DOUGLAS, of Nashville, Tenn., contributed a paper on

ABSCESS OF THE LIVER.

He said that abscess of this organ is the result of absorption of some morbid product from the intestine, or from some ulcerated surface. The bacteria enter the circulation and are deposited in the liver where abscess is formed. This may be with a normal temperature.

Case—Four months after an attack of typhoid the patient had a chill, slight pyrexia, a trace of jaundice, this lasting only a few days. There was a globular swelling in the right hypochondriac region. The only symptoms were a dull heavy pain and tenderness. No general local disturbance. Diagnosis confirmed by aspiration. A free incision let out eight ounces of inodorous pus. Recovery in four weeks. In these cases the adhesions are diagnosed by palpation. When pus is detected it should be evacuated at once. Bleeding per aspiration needle or leeches applied to the abdomen he considers useful, although there is some risk attending aspiration.

DR. G. W. DRAKE said that phagocytosis may furnish an explanation of the occurrence of abscesses in the various tissues and organs of the body, including the liver. The abscess may be a circumscribed locality in which was waged the hardest fought battles between the phagocytes and microbes, containing the disorganized remains of the slain, together with the products of decom-

posing tissue cells and microbes, under the dominion of chemical force, the flow of nerve-force into the contents of the pus cavity being interrupted, or the nerve force transmuted into chemical force, if the doctrine of correlation of physical may be extended to include nerve force.

DR. E. E. KERR, of Chattanooga, reported a *Case of Gall Stones*.

DR. J. B. MURFREE, of Murfreesboro, read a paper on

UTERINE FIBROMA.

He said a uterine fibroma is a morbid growth developed within the walls of the uterus, and is composed of muscular fibro-cells, fibro-plastic material and cellular tissue, and is due to a perversion of nutrition. It is non-malignant and homologous in its structure. Pain, hæmorrhage, rectal and cystic irritations, indigestion, dropsy and exhaustion are some of its results. They threaten life by hæmorrhage, inflammation, septicæmia and pressure.

The treatment is divided into four methods: 1. Symptomatic; 2. General (by medicine); 3. Electrolysis; 4. Surgical.

By the first method we simply treat the symptoms as they arise and ward off threatened dangers. Hæmorrhage is the most troublesome symptom and is best treated by quietude, opiates, etc. The hot douche and the tampon are useful.

The general treatment is by the administration of medicines to cause the absorption of destruction of the tumors. Medicines are powerless to cause the absorption of a fibrous tumor and do no good, except to build up the general system. Ergot is given to cause the death and expulsion of the tumor. Dr. Murfree has no confidence in ergot for this purpose.

The treatment by electrolysis has met with some success and is worthy of trial. It is especially adapted to the interstitial variety.

Surgical treatment is most usually resorted to for the permanent relief of uterine fibroma. It consists in the removal of the tumor by traction, torsion, excision, enucleation, ecrasement and hysterectomy. When the tumor projects into the uterine cavity it is best removed by excision. When it is interstitial it should be treated by electricity. When subperitoneal it had better be let alone unless the woman's life is a burden and death is threatening when it should be removed through a laparotomy or by hysterectomy. Hysterectomy should never be resorted to as an ideal operation, but only as a forlorn hope. But conditions do arise when it is eminently proper and should unhesitatingly be performed.

DR. WM. H. WATHEN, of Louisville, Kentucky, said the more frequently he goes into the pelvis the more often does he find that his diagnosis is not the same as it was before he had operated. Apostoli's method he considered dan-

gerous in private practice. To be successful one must be one of the most exclusive specialists. The tumor may be lessened in size, but there were, as far as he knew, no cures. A fibroma should not be interfered with unless it gives trouble.

DR. RICHARD DOUGLAS wished to emphasize what Dr. Wathen had said regarding Apostoli's treatment. From observation at his clinics and enquiries in the hospitals in Paris, he had not found any cases that were cured, but he had heard of two cases that died as the result of the treatment, one of them being in the practice of Dr. Keith, of London.

DR. L. P. BARBER, of Tracy City, Tenn., said that Apostoli's method was certainly of great promise, notwithstanding the remarks of Drs. Douglas and Wathen. He saw something of the results of the treatment during the past summer, and he had the following results from his friend, Dr. Franklin H. Martin, of Chicago. Of 200 cases, three only received no benefit. About 14 per cent. received some benefit for a time, but this finally ceased. 84 per cent. were symptomatically cured, with a number of cases of actual cures. Dr. Martin has had no deaths in all his experience with electricity as compared with the results of hysterectomy and the use of the knife generally. The result, to the unprejudiced, Dr. Barber thinks, is certainly in favor of the use of electricity in the right hands.

DR. MURFREE, in closing, said he felt that much could be accomplished by Apostoli's method.

DR. WM. H. WATHEN followed with a paper entitled

LAPAROTOMY *versus* ELECTRICITY IN ECTOPIC PREGNANCY.

He said that electricity, the only foeticidal means now recognized as orthodox by physicians who practice destroying the life of the foetus in ectopic pregnancy without laparotomy, is no longer used for this purpose where the pregnancy has continued beyond three and a half or four months, and it is seldom used after the third month. At this time the foetus cannot be killed except by electro-puncture, and the complications and the deaths consequent upon this practice have been so numerous that the most radical advocates of electricity are afraid to introduce the electrodes into the gestation sac. The use of electricity in extra-uterine pregnancy is practically confined to the United States, and while it is advocated by men of recognized ability and learning in obstetrics and gynecology, he was constrained to believe that very soon it will have no support.

Dr. Wathen here entered into an argument in favor of laparotomy, for the difficulty and sometimes the impossibility of diagnosing extra-

uterine pregnancy in the early months is so manifest to experienced physicians, that it would be ridiculous to claim that in all these cases pregnancy existed; while in the cases where laparotomy is done a diagnosis may positively be made by seeing the embryo or the chorionic or placental villi. If the embryo or foetus in an extra-uterine pregnancy is killed by electricity, a more or less diseased condition of the pelvic structures is left that endangers the health or life of the woman; the dangers usually being increased as pregnancy advances. But if a laparotomy is done there is no obstructed tube, or other pathological condition left, and if the woman recovers from the immediate effects of the operation she is entirely cured. Her life is no longer in jeopardy because of the danger of pelvic abscess, sepsis, or exhaustion following an effort to discharge the suppurating contents of the gestation sac through fistulous tracts in the rectum, vagina, bladder or through the abdominal walls. If we could eliminate the cases where there was an error in diagnosis we would find that the mortality from the use of electricity and the bad after results are far in excess of what follows laparotomy in the practice of experienced operators.

EVENING SESSION.

The Association met in Stone Church, and was called to order at 7:30 P.M.

An Address of Welcome was delivered by Dr. G. W. Drake, which was responded to by Dr. G. C. Savage, of Nashville.

Then followed the *President's Address*, entitled

THE DOCTOR.

He said that the man that starts out to be a doctor must understand that it is a life of toil. There is no flowery way to the royal degree of excellence. The laggard, the indolent, the careless never enter the temple of fame. The slug-gard never tastes of the royal feast spread for the earnest, industrious worker. He knows nothing of the grandeur of mental comprehension of the real medical scholar. The doctor must be educated, not as that term seems to be understood in these days. Modern education, Dr. Cowan feared, was too much a process of stuffing and cramming. The word education meant more than this. To educate was to draw out, to enlarge, to expand, to develop, and to strengthen.

THIRD DAY—MORNING SESSION.

DR. T. HILLIARD WOOD, of Nashville, Tenn., contributed a paper on

HYPERTROPHY OF THE TONSILS,

in which he said the treatment adopted for relief of hypertrophy of the tonsils had been subject to many variations. The treatment for the reduction of enlarged tonsils was divided into local, constitutional and operative. If the enlargement be due to swelling of the mucous membrane or to

engorgement and congestion of the tonsil, the application of astringents may be of service. The most useful local remedies in the hands of the author are the sub-sulphate and the perchloride of iron, about one to six or eight in water or glycerine, and alum or tannin in powder. But where there is real overgrowth, the remedy, as Mackenzie well observes, must be of a destructive character, and escharotics, not astringents, must be used. Among escharotics, London paste is useful and should be applied once or twice a week. This will produce a slough, and repeated applications will reduce the gland to a normal size.

Constitutional measures to effect reduction of the tonsils includes remedies to combat the diathesis upon which the enlargement often depends, such as iodide of potassium, cod liver oil and the general tonics, as the preparation of iron, and the bitter tonics.

With reference to operative treatment, excision by the tonsillotome is most popular, although the writer prefers the bistoury and vulsellum forceps. The operation is rendered painless by applying to the tonsil a solution of cocaine, and by injecting, with a hypodermic syringe, a few drops of the same solution into the substance of the gland. As a rule, general anæsthetics should not be used. To reduce to a minimum the danger from hæmorrhage, we have comparatively bloodless operations by the cold snare, igni-puncture, and the galvano-cautery amydatome. Of these the galvano-cautery amydatome seems preferable, and is highly recommended by Wright, of Brooklyn. Igni-puncture is tedious, requiring repeated applications, and attended by considerable pain. Moreover, it cannot be employed in the cases of refractory children.

DR. N. C. STEELE, of Chattanooga, said the amount of hæmorrhage depended upon the condition of the tonsil. He would use the bistoury in adults and the tonsillotome in children.

DR. E. T. CAMP has been able to reduce hypertrophied tonsils without operation, by using iodized phenol locally and general remedies.

DR. GEO. A. BAXTER suggested painting the tonsil with flexible collodion.

DR. SAVAGE said there were two indications for operating upon the tonsils, viz.: repeated attacks of tonsillitis, and where breathing was interfered with. He uses only Mathews' tonsillotome. Never uses cocaine. From personal experience and observation he knew the operation was not very painful.

DR. GAHAGAN suggested cold food in cases of incipient tonsillitis and plenty of cold liquids.

DR. REEVES thinks in removing the tonsils we leave cicatricial tissue and so alters the voice. He uses tincture of iodine. He thinks cocaine will not control the hæmorrhage.

DR. WILLIS F. WESTMORELAND, of Atlanta, Georgia, said the frequency of enlarged tonsils

was due to exposure, hence the greater number of cases observed in males. He would operate as soon as they gave trouble. He prefers the bistoury. Cocaine he has abandoned on account of increased bleeding. Igni-puncture was too painful.

DR. FRANK TRESTER SMITH, of Chattanooga, resorts to igni-puncture where he cannot get consent to excision. Bleeding after the use of cocaine may continue for a long time. He said the indications for operating with him were interference with breathing, impairment of the voice, and recurrent tonsillitis. The voice after operation improved as a rule.

AFTERNOON SESSION.

DR. E. A. COBLEIGH, of Chattanooga, read a paper entitled

A CASE OF REMARKABLE INJURY WITH RECOVERY,

and exhibited the patient.

The following history was obtained while Dr. Cobleigh was making a physical examination: "An old well used for supplying boilers with water had been inadequate for the purposes of a rapidly enlarging factory in Chattanooga, and for a considerable period of time work had been going on in the way of deepening said well till it had reached sixty feet below the surface. During the day a heavy steel drill had become so dull that another and smaller one had been substituted for it while the larger one went above for grinding on the power grindstone near the mouth of the shaft. This had been sufficiently sharpened, a loop of rope fastened around it, and a fellow workman was lowering it to the men below when the noose loosened at a depth of about ten feet from the surface, slipped off, and let the implement go dashing down on the men at the bottom with no warning worth mentioning, and it had struck the patient, after falling about forty-five or fifty feet.

At the bottom of the well some of the men were holding the drill (then in use), while the wounded fellow was standing upright on a rough little platform about eighteen inches high, which had been built to afford the striker an elevation from which to wield his sledge to the best advantage.

The implement went down sharp and nearly or quite perpendicular. It struck the man on the back of the neck and ploughed through the tissues to emerge from the right side of the chest, there protruding about eight inches, absolutely impaling him. He stepped down from the platform, supporting himself against the side of the well, and called on a fellow workman to pull out the drill. A stalwart negro with both hands tried to pull out the drill, but failed. He mounted the platform and tried again by a steady pull, which did not budge the impaling instrument; and in

his excitement to get the thing out, he gave it that to and fro motion, with the powerful leverage of the long handle, which one sees resorted to in pulling posts out of the ground. At this procedure the drill loosened and he extracted it from above, just the reverse to its direction of entry.

The patient was now placed in a bucket, very imperfectly fastened to the well rope with a noose passed around him, and holding himself mostly by his own efforts was drawn to the surface, placed in a chair and conveyed to the work-room adjoining the office. The patient is 28 years of age, stands five feet and eleven inches high, weighs 185 pounds, and has a magnificent physique.

Examination developed the fact that the wound of entrance was situated one and one-half inches to the right of the spinous process of the fifth cervical vertebra, just at the point where his neck began to broaden toward the shoulders, and the drill had only missed the spinal column by a hair's breadth. Passing downward and very slightly forward and to the right, leaving rather a smooth opening oval in form from above (perpendicularly), with somewhat inverted edges, it resembled the old-fashioned wounds of entrance of round shot, not very large—not so immense as one would expect from the size of the wounding instrument, yet sufficiently so for the cervical muscles and fascia to show plainly in the wound, especially if forcibly opened. The shape of the wound made it close like a valve, yet air was entering and being expelled with a pink froth at nearly every respiratory effort, though there was no considerable hæmorrhage.

From here the drill passed into the chest cavity between the scapula and the clavicle, at its very apex, without damage to either of these bones, impinging on the third and fourth ribs, which were both fractured from behind right in the line of the wound—evidently the fragments being parted as by a wedge while the drill was *in situ*—then passing down on the anterior and outer surface of the fifth and sixth ribs without injury to either, and emerging by a great gaping and ragged wound, with much eversion of its edges, just at the inferior border of the latter rib and over the interspace below, its centre being at the time of the examination two inches below and one and a half inches to the right of the nipple. There was only moderate bleeding from the wound, into the opening of which Dr. Cobleigh readily introduced the tips of three fingers, and no air was escaping here. The skin and subcutaneous tissues seemed to be so absolutely deadened by the magnitude of the injury sustained as to have absolutely lost all their normal elasticity. He passed two fingers up the tract of the wound their full length, entering the pleural cavity with their tips under the broken ends of the lower fractured rib, which could be distinctly felt. Every-

thing felt torn and indefinite, the ends of the broken bone easily removable, but he was not able by touch to satisfy himself with any degree of reasonable force whether the subjacent lung surface was injured or not, though he thought it was. From top to bottom of the wound in its entire length it measured in a direct line at that time fourteen and a half inches, and the patient must have had buried in his anatomy fourteen and a half inches of steel, an inch in diameter.

On withdrawal of the fingers the wound closed by collapse of its sides, and prevented any profuse degree of hæmorrhage externally. There was intense pain and a marked degree of shock, as shown mainly by the pulse, the mind remaining clear throughout. The integument, however, was quite clammy, and the patient complained of a great deal of chilliness, without any pronounced rigor. There was extreme rapidity and difficulty of respiration, some gasping, and Dr. Cobleigh was strongly of the opinion that the patient would die in a short time, especially as he found the signs of depression increasing rapidly, the pulse losing all tone, flickering, irregular, intermittent, and the mucous surfaces blanching.

DR. WILLIS F. WESTMORELAND, of Atlanta, Ga., read a paper on *Morbid Reflex Neuroses Amenable to Surgical Treatment*.

DR. H. CRUMLEY, of Chattanooga, presented a case resembling epilepsy, which was examined by members of the Association.

DR. J. R. RATHMELL, of Chattanooga, reported a *Case of Abscess of the Liver*.

Dr. Rathmell also reported a *Case of Typhoid Fever*, and Dr. W. C. Townes, of Chattanooga, presented specimens of the intestines, spleen and mesentery of the case.

DR. TOWNES then followed with a paper on *Dilated Cardiac Hypertrophy, with Nephritic Complications*, illustrating his paper by specimens of the condition and others for comparison.

EVENING SESSION.

DR. R. J. TRIPPE, of Chattanooga, reported a *Case of Peritonitis*, which occurred in a strong, muscular, heavy-set negro, who had been struck with a crowbar across the abdomen. Patient died.

DR. C. H. HOLLAND, of Chattanooga, reported a *Case of Phlegmonous Abscess*, occurring in an unusually large man, 25 years old, 6 feet high, and weight 349 lbs.

DR. J. H. ATLEE, of Chattanooga, followed with the report of a *Case of Ovariectomy*.

DR. FRANK TRESTER Smith read a paper on *Flourescein in the Diagnosis of Diseases of the Eye*.

DR. J. E. PURDON, of Cullman, Ala., contributed a very elaborate paper on the *Dynamics of Mediumism*, and, after a long and careful study of the subject, drew fifteen conclusions.

DR. W. C. MAPLES, of Bellefonte, Ala., read a paper on

SOME IRREGULAR FORMS OF EPILEPSY, WITH REPORT OF A CASE.

He thinks his case was either one of epilepsy or hystero-epilepsy. In some respects it closely resembled hystero-epilepsy. His reasons for thinking it a case of epilepsy were:

1. The amount of fever. In hystero-epilepsy there is generally but little or no fever. Some authors hold that we may have a true hysterical fever, but the weight of authority is against that opinion.
2. The complete unconsciousness.
3. The biting of the tongue. Hystero-epileptics seldom or never injure themselves.
4. The facial expression and pupillary phenomena. The facial expression is generally calm and serene throughout a hystero-epileptic attack.
5. The absence of hysterical phenomena in the intervals between the attacks.
6. The sex. While hystero-epilepsy does occur in males, all authors are agreed that it does so quite seldom.

The treatment was by large doses of bromide of potassium by the mouth, and morphine hypodermically. There were no sequelæ.

DR. J. D. GIBSON, of Birmingham, Ala., presented a paper on

URETHRAL STRICTURE AND ITS COMPLICATIONS.

In the use of sounds, he considers the spherical, or the acorn-pointed sound, the most convenient and practical instrument for the detection of stricture; while Otis and Weir and many others had their special instruments. Dr. Gibson said that if he were compelled to use only one instrument in the cure of all strictures, he would use the sound. He believed that when it was properly used, that there were very few strictures that could not be relieved, and better so by it than any other means; and that the only stricture necessary to invoke the aid of the urethrotome was the old, tight and unyielding stricture in the pendant urethra and meatus. Young and inexperienced men were apt to be disappointed in the use of the sound, simply because they tried to go too fast; the idea should be to dilate the stricture and produce absorption, and not rupture. Internal urethrotomy, while often abused, was a most potent means of treating urethral stricture, it being especially applicable for old and firm strictures in the pendant urethra and meatus.

DR. P. S. HAYES, of Chicago, followed with a paper entitled

NOTES ON APOSTOLI'S METHOD OF THE TREATMENT OF UTERINE FIBROIDS.

He said that one of the best demonstrated facts in the Apostoli operation was the arrest of all uterine hæmorrhages, excepting those cases that are due to puerperal condition. All observers unite in recognizing that the positive pole is the one to be connected with the intra-uterine electrode. To the thinking physician the query is,

why the positive? And the answer comes that in electrolysis, especially when the electrolyte—the fluid undergoing electrolysis—is blood, the clot formed around the positive pole is small and dense, while that around the negative pole is large and flabby. Knowing as we do that oxygen, chlorine and the acids are liberated at the positive pole when electrolysis is performed on the tissues of the body, and also knowing that hydrogen and alkalis are liberated around the negative pole, we have only to apply our knowledge of the action of the acids and alkalis respectively on the blood to explain the observed phenomena.

The occurrence of uterine hæmorrhage does not contra-indicate the use of the method. One of his patient's suffering from menorrhagia came to his office stating that she was drenched with the discharge and came for relief, as it was much easier to come to his office than to go home. The excessive flow did not occur until after she had come down town. Dr. Hayes used the intra-uterine electrode connected with the positive pole, and allowed a current of from 60 to 80 milliamperes to pass for eight minutes. The patient then went home, a distance of three miles, and was in bed the remainder of the day. The next day she was about the house and the flow had nearly ceased. This period was by far the least severe she had had in several months, and the amount of time spent in bed was three-fourths less. The flow was diminished in like amount. Should opportunity again offer itself to use Apostoli's method during a non-puerperal hæmorrhage, Dr. Hayes said he would not hesitate to use it as the best means of securing its arrest.

NECROLOGY.

ARTHUR B. CARPENTER, M.D., of Cleveland, O., died suddenly at his residence October 15, at the age of 37, of fatty degeneration of the heart. Up to within three hours of his death he appeared in robust health. Dr. Carpenter was eminently a self-made man, of commanding presence and genial address; he had obtained a large practice in the domain of gynecology, to which subject he had contributed many valuable articles. He was an active worker and took a prominent position in the local and national medical societies. In his untimely death the medical profession of Ohio has lost a most valuable member. According to an expressed wish his remains were cremated at Buffalo.

HENRY JACOB BIGELOW, M.D., L.L.D., died at his summer home in Newton, Mass., October 30, aged seventy-two. He was educated in the

Boston Latin School and the Harvard Medical College (Class of 1841), besides seeking further instruction in foreign cities. Later, he was for a long time surgeon to the Massachusetts General Hospital; and for twenty years he filled the chairs of surgery and chemical surgery at Harvard without an assistant. He was active in the earlier experiments with anæsthetics, and in November, 1846, made the original announcement in this country of their discovery. He has been an extensive writer and lecturer on surgical topics. One of his works on the mechanism of dislocation by the flexion method (1869) is still an authority. He contributed many valuable papers to the American Medical Association, such as the "Action of Water on Lead Pipes;" articles on Anæsthesia, embracing its statistics, "Cinchona Cultivation," "Gutta Serena in Urethral Strictures," "Operation for Hernia," and a very suggestive treatise on "Nature and Disease." The above, however, lays no claim to being a complete list. Dr. Bigelow's labors and attainments secured for him membership in many American and European societies, among them the American Academy of Arts and Sciences, the Société Anatomique, the Société de Biologie and the Société de Chirurgie of France. A sister and a son, Dr. Wm. S., of Boston, survive him.

DR. MONTROSE A. PALLAN died in New York, on October 1. He was born January 2, 1836, in Vicksburg, Miss. His father, a Virginian, was professor of obstetrics in the St. Louis Medical College for twenty-seven years. Dr. Pallan received his medical education at the St. Louis University, from which he graduated in 1856. He spent two years in the medical schools and hospitals of London, Paris and Berlin, and then settled in St. Louis, where he remained till 1884, when he was called to the chair of gynecology in the medical department of the University of the City of New York. During the war Dr. Pallan was medical director of Gen. Henry A. Wise's Legion in 1861, of Gen. William J. Hardee's army corps in 1862, and later of the Department of Mississippi until February, 1863. Subsequently he was sent to Canada by the confederate government to report on the condition of the confederate prisoners on Johnson's Island. He returned to Richmond in 1864, went to Paris, and obtained surgical and medical supplies for the confederate armies. He was sent to Montreal again, but was captured on his way back to the South, and held on parole in New York until the end of the war. He was professor of gynecology in the Humbolt Medical College in 1866-67, adjunct professor of obstetrics in the St. Louis Medical College 1867-68, professor of gynecology in the St. Louis College of Physicians and Surgeons 1869-70, professor of anatomy in the

Missouri Medical College 1871-72, and professor in the medical department of the University of the City of New York 1874-82. In 1883 he assisted in forming the Post-Graduate Medical College. He also served as surgeon to the Charity Hospital.

BOOK REVIEWS.

TRANSACTIONS OF THE MICHIGAN STATE MEDICAL SOCIETY. Twenty-fifth Annual Meeting, held at Grand Rapids, June 19 and 20, 1890.

The volume opens with a fine steel engraving of its President, Dr. George E. Frothingham, of Detroit, and the annual address delivered by him had reference to "The Desirability of Extensive Organization, and Pursuit of a Fixed Policy, as a Means of promoting our Professional Interests." The necessity of organization as a means to success is fully discussed. The creation of the State Board of Health was the result of organized effort, and special reasons for the enlightenment of the people exist in that State by reason of the relations of medicine to the State University. He deals ably, severely and justly with sectarian medicine, and emphasizes the necessity for a higher estimate of scientific studies in the attainment of a liberal education.

The annual address on Surgery was delivered by Dr. J. F. Groner, of Big Rapids, upon "The Causes of Suits for Malpractice and their Remedies." The measure of the surgeon's responsibility is clearly set forth, and citations of judicial decisions are made, and as an important means for the prevention of malpractice suits he advises the enacting of "a law compelling the plaintiff to give bonds to remunerate the defendant a certain percentage of amount for which the suit was brought, providing he fails to sustain his case."

Dr. W. F. Breakey, of Ann Arbor, delivered the annual address on practice of medicine, his subject being "The Mutual Obligations and Responsibilities of the Physician and the People in promoting Medical Science." He discusses the means of promoting such advancement and fully considers the subject of legitimate and illegitimate advertising, as related to medicine and surgery. The relations of legislation are well considered, and the Code of Ethics has an endorsement that should require nothing further in its vindication. He says: "In the majority of cases it is the violator of the Code who violates the code of gentlemanly and honorable conduct."

The subject of the annual address on obstetrics and gynecology, presented by Dr. J. N. Martin, of Ann Arbor, was that of "The Relations of Constitutional Conditions to Diseases of the Female Genital Organs." Mental conditions and influences are ably considered in connection with

the varying conditions of these organs, as well as the more prominent sympathetic relations with other organs and the reciprocal influence upon the general health.

The proceedings and the papers presented in the Sections during the two days form a volume of nearly five hundred pages. The high order of merit obtains both in the papers presented and in the discussions which follow. The arrangement and the publication reflect credit upon the Editor, Dr. Charles W. Hitchcock, of Detroit, and the publishers. The Michigan State Medical Society has a fine record in the past and the promise of a splendid future.

ANNUAL OF THE UNIVERSAL MEDICAL SCIENCES: A YEARLY REPORT OF THE PROGRESS OF THE GENERAL SANITARY SCIENCES THROUGHOUT THE WORLD. Edited by CHARLES E. SAJOUS, M.D., and seventy associate editors; assisted by over two hundred Corresponding Editors, Collaborators, and Correspondents. Illustrated with Chromo-Lithographs, Engravings and Maps. In 5 Volumes. Philadelphia, New York, Chicago, Atlanta, and London: F. A. Davis. 1890.

We doubt whether the medical profession at large appreciates at what an immense expense of time, talent and labor this valuable annual has been brought out. The publisher, F. A. Davis, has shown a most commendable enterprise both in the venture he has made and in the admirable manner in which he presents these five volumes to the profession. The preparation of such an annual review of the entire domain of medical science has only been possible by reason of the rare ability of the editor-in-chief, with the assistance of an immense staff of sub-editors, embracing a large number of the ablest medical writers in America, the enumeration of whose names would stand for the best possible commendation of the entire work.

In these five volumes we have the cream of medical literature, and the very latest of investigations for the current year. Over eight hundred journals in all the civilized languages are made to contribute to this enterprise. Rare discrimination is manifested by the sub-editors in the selection and presentation of their individual work, and under each general head all that is essential, fresh and valuable comes to the reader in a most available form.

It is impossible to particularize, but after an extended and careful examination of the several volumes, we have only words of commendation for the entire work.

The methods of reference are simply perfect. With such a library, for instance, as that of the "Newberry" at command, by the aid of these volumes, ready reference can be made to all the important papers written in any modern language

on any special subject during the last current year—the essential points being here reproduced.

No public library should be without the series, and no man in our profession who desires to keep himself fully abreast of the times can afford to dispense with this representative of all the leading journals in the world.

The American profession is indebted to the editor, and to his corps of sub-editors, and to the enterprise of the publisher, for the presentation of an Annual for 1890, such as is nowhere else to be found either at home or in Europe.

We earnestly hope that this work will be so fully appreciated, and the encouragement be such, that the enterprise will be carried forward year by year for the benefit of the profession and for the credit of American medical literature.

PRACTICAL ELECTRICITY IN MEDICINE AND SURGERY. By S. A. LIEBIG, JR., Ph.D., Assistant in Electricity, Johns Hopkins University; Lecturer on Medical Electricity, College of Physicians and Surgeons, Baltimore; Member of the American Institute of Electrical Engineers, etc., and GEORGE H. ROHÉ, M.D., Professor of Obstetrics and Hygiene, College of Physicians and Surgeons, Baltimore; Visiting Physician to Bay View and City Hospital; Director of the Maryland Maternité; Associate Editor *Annual of the Universal Medical Sciences*, etc.

In part one of this new book is considered, 1, Electricity; 2, Magnetism; 3, Batteries; 4, Storage Electricity, etc. In Part I the authors say "are discussed the various forms of electrical and magnetic apparatus likely to be of use to the physician in his daily experience with electricity, as well as the most suitable arrangement of cells for any given work, the construction and use of galvanometers, the theory of the chemical actions taking place in the storage-cell or accumulator, and the best methods of caring for the batteries."

Part II discusses: 1. Electro-Physiology; 2. Electro-Diagnosis; 3. Electro-Medical Apparatus. This section "takes up first the effect of electric currents upon the various tissues and organs of the body in health, then shows how these effects are modified by disease, and indicates the methods by which these modifications are utilized for purposes of diagnosis." A chapter follows descriptive of the various appliances most useful in electro-therapeutic work, which may be considered as immediately introductory to the section on electro-therapeutics.

Part III contains chapters on, 1. General Therapeutic Effects of Electricity and Methods of Application; 2. Special Electro-Therapeutics; Appendix and Index. Part III, then, discusses the application of electricity in the treatment of disease. The methods by which electricity is made available for therapeutic purposes are described, and in subsequent chapters the modes of applica-

tion of this agent in the treatment of the diseases of the various organs are indicated. Particular attention has been given to the applications of electricity in gynecology, diseases of the male genito-urinary organs, and in diseases of the skin.

UEBER FEUERBESTATTUNG. — Vortrag gehalten am abende des 13 Februars, 1890, im Naturwissenschaftlichen Vereine zu Mülhausen im Elsass. By PROF. DR. FRIEDRICH GOPPELS-ROEDER. With 5 wood cuts and an appendix. Pp. 108. Mülhausen: Wenz & Peters.

In this small monograph we have a critical review of the subject of cremation from a hygienic as well as historical standpoint. The author first considers the various methods of disposing of the dead: mummification, embalming, and various other methods of preserving bodies, as well as earth burial, and their rapid destruction by chemical means. Then follows a lengthy review of cremation in ancient times, as well as its progress of late years in different parts of the world. The volume closes with an excellent chronological list of the publications relating to cremation.

It has been said that "comparisons are odious," and it would be invidious to say aught against this work, especially as it has been written with a charitable object; as we are informed on the title page the net receipts of the sale of the work are to be devoted to maintaining the vacation colony for poor and sick children located in Mülhausen. The author has, however, chosen a subject already worn threadbare, and although we have earnestly sought for the *raison d'être* within the covers, we can but think that the work is justified by the noble object for which it was undertaken, and which we trust that it will in a great measure fulfil.

STORIES OF A COUNTRY DOCTOR. BY WILLIS P. KING, M.D.

None but the doctor who had been there could have written this book, and hardly one of a thousand at that. Frontier life here has many a graphic description. The real is often more tragic than the unreal, and the sublime, the ridiculous, the humorous and the pathetic are oftentimes artfully and strangely commingled. While neither the writer, who sees so much of the humorous side of men and things, nor his patients, will be apt to die of dyspepsia yet the undertow of influence is always in the right direction, and many a rattling sermon is found in an unsuspected place. His chapter on consultations is drawn to the life, and as to the Code of Ethics—bearing in all relations of society and among men of every vocation—he rates it as the highest law in the universe outside the Bible, and if the authority of the Bible be not recognized, then surely as the highest law imaginable. Ethics, as related to medicine, holds doctors not only to a strict ac-

countability for their conduct one with another, but holds them just as firmly to a strict accountability for their conduct towards their patients and the public generally. He says "if the people generally understood the Code as every good physician ought to understand it, they would all be strong advocates of it." Upon this subject Dr. King is eminently sound. In his closing chapter he pays his respects to quacks and quackery in a way true to life and highly amusing. The book is published by the Hudson-Kimberly Publishing Co., Kansas City, Mo., contains 400 pages, and is well illustrated.

MISCELLANY.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from November 1, 1890, to November 7, 1890.

- First Lieut. Nathan S. Jarvis, Asst. Surgeon, so much of Par. 2, S. O. 208, A. G. O., September 5, 1890, as directs him to temporary duty at San Carlos, Ariz. Ter., is revoked. On the expiration of his present sick leave of absence, Lieut. Jarvis will report in person to the commanding officer, Ft. Bayard, N. M., for duty at that station. Par. 13, S. O. 254, A. G. O., October 30, 1890.
- First Lieut. Philip G. Wales, Asst. Surgeon, is relieved from station and further duty at Ft. Huachuca, Ariz. Ter., and assigned to duty at San Carlos, Ariz. Ter., where he is now temporarily serving. Par. 13, S. O. 254, A. G. O., October 30, 1890.
- Capt. William J. Wakeman, Asst. Surgeon, is relieved from duty at Ft. Bidwell, Cal., to take effect on the final discontinuance of that post, and will then report in person to the commanding officer, Ft. Huachuca, Ariz. Ter., for duty at that station. Par. 12, S. O. 254, A. G. O., October 30, 1890.
- Capt. William H. Arthur, Asst. Surgeon, is relieved from duty at Ft. Bayard, N. M., and will report in person to the commanding officer, Ft. Grant, Ariz. Ter., for duty at that post, relieving First Lieut. William B. Banister, Asst. Surgeon. Lieut. Banister, on being relieved by Capt. Arthur, will repair to this city, and report for duty to the commanding officer, Washington Bks., D. C. Par. 12, S. O. 254, A. G. O., Washington, October 30, 1890.
- Lieut. Col. Dallas Bache, Surgeon U. S. A., Medical Director, Dept. of the Platte, is granted leave of absence for one month. Par. 6, S. O. 82, Dept. Platte, Omaha, Neb., November 1, 1890.
- Official List of Changes in the Medical Corps of the U. S. Navy for the Week Ending November 8, 1890.*
- P. A. Surgeon J. M. Edgar, ordered to the U. S. S. "San Francisco." November 10, 1890.
- Asst. Surgeon L. W. Spratling, ordered to the U. S. S. "San Francisco." November 10, 1890.
- Medical Inspector Chas. H. White, ordered to the U. S. S. "San Francisco." November 10, 1890.
- P. A. Surgeon Horace B. Scott, placed on the Retired List October 31, 1890.
- P. A. Surgeon Richard Ashbridge, surveyed and sent to Hospital, Philadelphia, Pa.
- Asst. Surgeon R. M. Kennedy, detached from Navy Yard, League Island, and ordered to U. S. training ship "Richmond."
- Asst. Surgeon L. W. Atlee, ordered to the Navy Yard, League Island, Pa.

THE SURGERY OF THE ABDOMEN, WITH SOME OF ITS RESPONSIBILITIES.

*Read in the Section of Medical Jurisprudence, at the Forty-first
Annual Meeting of the American Medical Association,
Nashville, Tenn., May, 1890.*

BY THOMAS H. MANLEY, A.M., M.D.,
VISITING SURGEON, THE HARLEM HOSPITAL, NEW YORK.

(Concluded from page 625.)

THE SURGICAL MANAGEMENT OF TRAUMATIC PERITONITIS.

Acting on the good old maxim that "an ounce of prevention is worth a pound of cure" we have endeavored to dispense with therapeutic measures formerly in vogue, in the treatment of peritonitis, by resorting to operative interference in wounds within the abdomen, and have generally succeeded, but unfortunately, lost most of our patients. Septic infection can be absolutely prevented by flushing with antiseptic fluids, and by drainage. But reliable antiseptics are all irritants, unhappily, and leave everything they come in contact with, more prone to adhesive inflammation than ever. Further, antiseptic flushing has been so often followed by mortal collapse, that now, many distinguished operators, have discarded it altogether. The means taken to save, then, will often destroy the patient's slender chance of recovery. Hence we must regard laparotomy under those circumstances, like a hip-joint amputation, always as a capital operation, of the first magnitude.

We still read of the many and varied methods devised by ingenious and enthusiastic surgeons, for the purpose of simplifying the technique of intestinal operations. I shall not readily forget the impression Prof. Senn made on myself, when I listened to his original and famous monograph on intestinal surgery. The vivid and seductive manner in which he portrayed the great number of experimental operations within the peritoneum, from a mere puncture, to the excision of many yards of intestine, completely amazed and confounded his audience, as it has since, a large part of the medical world.

From thence what could the surgeon do, when

perforations are suspected, but cut down; and if he found a considerable segment destroyed, cut it out, and oppose the divided ends, throwing a fold of mental graft over the annular seam; or if necessary go above or below as the case might be, lay open the intestinal walls, *tête-a-tête*, restoring the bowel's continuity by making an opening in each, and adjusting these margins with some kind of absorbable collar. But I have found from personal experimentation on the intestine of the dog, that no reliable clinical inferences, could be drawn from such operations. The canine suffers but little shock, when the abdomen is opened, and owing to the great thickness, and remarkable tensile strength of the gut, it can be readily manipulated without laceration or injury. With them we have total want of mental association, with their physical condition. The element of psychological influence, as a factor, in the way of fear, suspense and apprehension is absent.

Further, extensive, prolonged and most searching observations on experimental intestinal surgery were made in the early part of the present century; in England, by Calison, Bell, Travers, and Hennan, and in France particularly, by Joubert, Gelly, and Lembert; the latter who first used the suture associated with his name; on animals, but never on living man; but these investigations were not largely extended to the human family and were condemned, with general accord. Wounds of the peritoneum have from time immemorial been regarded with most serious apprehension; for lesions in this situation of a traumatic character, always have been attended with a great mortality. With the aid of ether it was hoped that the shock might be diminished, and with antiseptics infection prevented. It was soon found, however, that anæsthetics and antiseptics have their dangers. The pump-like action of the diaphragm in men seriously interferes with primary union.

Again, the very large incision in the median line necessary for purposes of inspection, leaves a tendency to hernia, for it must be remembered that a very large opening must be made for the extrusion of the intestines, and especially if any of the fixed viscera are wounded. The bowel after repair must enter its abode, through the same aperture by which it came.

Very much has been said about the short time occupied necessarily, when advantage is taken of modern methods, so-called, in doing an intestinal resection. This is perhaps, most loudly proclaimed by those who have never done an enterectomy on a human being. They allege that fifteen or twenty minutes are ample. These statements are most delusive and dangerous. I believe I am within the limit, and close to fact, when I say that the surgeon doesn't live who can do full justice to his patient, and perform an operation involving the resection of a wounded intestine, in less than *two full hours*; timing the operation, from when the original incision is made to the completion of the dressings. This isn't any haphazard assertion, for I have timed myself, and some of our best known surgeons; with perfect light, every possible facility, and a corps of trained assistants.

There are many almost insurmountable obstacles in the way of surgical treatment of those cases under consideration, by laparotomy.

The profound constitutional disturbance, collapse, and prostration, make immediate interference, extremely hazardous; whereas if we wait for full reaction and hold off many hours, active inflammation with all its embarrassing complications will menace us.

Along with this, now the patient has marked bodily weakness; low in spirits, and has a most pronounced aversion to every sort of surgical aid which contemplates the least mutilation. Added to this, the subcutaneous tissues have become congested and œdematous, and the inflamed bowel enormously distended. Adhesions will be found, in every direction.

Now it may be urged on theoretical grounds that many of those penetrating wounds are inevitably fatal if we treat them on conservative lines, and decline to actively interfere. How extensive an injury the abdominal viscera may sustain, and recover from, can only be determined by practical observation, and the accumulated experience of many investigators. We have had too many well authenticated instances of intestinal penetration, by missiles, to have any doubt about the wonderful, recuperative, power of the alimentary tube.

The stomach after a full meal has been torn through by a projectile, as in Hinton's case, wherein a young man was assaulted with murderous intent, by his mistress, immediately after breakfast, the grumous mass flowing copiously through the aperture of entrance. With rest, moderate doses of opium and topical treatment he made a good and rapid recovery, and with no fistulous opening remaining.

It is said that an injury causing a laceration of the gall-bladder, or its ducts, with bile extravasation was always fatal. But Paroisse has reported a case in which a man was stabbed in the region

of the liver, wherein after the wound closed painful abdominal distensions followed. Paroisse tapped him three times removing, more than four gallons, of pure bile. The patient recovered perfectly.

Having detailed some of the serious dangers which menace the patient, when he sustains a penetrating wound of the intestine, and a few of the difficulties which lie in the way of treatment by recent methods; let us see how cases do in which the innovations of modern surgery are largely dispensed with, and the warnings of a past generation of renowned military surgeons is not entirely unheeded; when more is left to nature. At first sight this seems not only perplexing, but incomprehensible; though on second thought, when the processes of repairs are carefully studied; when the structural elements, the physiological peculiarities are carefully borne in mind the problem is capable of a simple solution, which I will endeavor to explain, as I regard it.

A man being shot, the ball penetrating the peritoneum, divides a blood-vessel or intestine, in transit. For the instant, it would seem as though, simultaneously with the flash of the explosive, life was annihilated. The victim staggers, reels, and falls. For a few seconds he seems actually dead. The cerebro-spinal centres are palsied, and there are no manifestations of life, except now and then a feeble gasp, and a flickering, intermittent pulse. The features are sunken and he is deathly pale. The skin is covered with a cold clammy perspiration; the body is limp and motionless.

An intestine is perforated. If this is the case, then we must have a free communication from the bowel into the peritoneal cavity.

Not necessarily, by any means. In the first place, because the gap in the gut is at once filled in, more or less completely, around the circumference of the wound, and secondly, because, there is, physically, no such thing as a cavity within the abdomen. All its contents lie in close contact, the parietal muscles, maintaining a constant, uniform, unremitting pressure, on all the viscera.

Bearing in mind a well known law in natural philosophy, with respect to liquids always flowing in the direction of least resistance, we can understand, why there is not in every case of intestinal puncture a free escape into the adjacent parts. We do not have it, because the pressure is as great, without as within the lumen, of the intestine. But little air can enter through the bullet-track, as its walls fall in, and collapse. It would be fair to assume, however, in spite of this salutary provision, that when peristaltic action would commence, it would seriously disturb the quiescent state, so essential to recovery. It is interesting to note just what does take place. When a limb or organ is maimed, it at once

assumes a passive state; tolerating no disturbance or motion without enduring the most torturing pain. We witness the intestine respond to the same identical law; as when wounded, active vermicular motion instantly ceases. It is the same in all acute congestions or inflammation of it. As a consequence we find our patient persistently constipated, often for many days or even weeks, in peritonitis, with perfect impunity. Not a few laparotomies have been done in such cases, under the supposition that there is some mechanical impediment obstructing the bowel; but failure to find a constriction and verify it, promptly, post-mortem, demonstrated this peculiarity of the intestinal tube when inflamed, with its serous-coat.

Hæmorrhage within the peritoneal cavity in moderate quantities, is promptly absorbed.

Constitutionally the patient should be kept on low diet free from pain; and at ample rest, under all circumstances. Before closing this part of our subject, it is necessary, to give by figures, the actual mortality attending those cases which we have considered. I quote from one of the most reliable contributions lately published, by one of our most enthusiastic and able advocates of surgical interference, and a man of rare and commanding attainments.

Dr. Stimpson gives the results of treatment by interference and non-interference in cases which occurred in New York City prior to October, 1890. He says of laparotomy for gunshot wounds of the abdomen, that it was performed on thirty patients with a mortality of 83.66 per cent., or one recovery out of six. There were treated in different hospitals of the city in the preceding ten years 37 cases of the same class of wounded, by non-operative interference with 17 recoveries and 20 deaths, or 45.94 per cent. cures. He quotes the French surgeon Minier's reports of the late campaign in Tonquin, of gunshot wounds of the peritoneum in 63 cases treated by expectant plan; 53 deaths or mortality 78 per cent. Such then is the actual status of the operation for penetrating gunshot wounds of the peritoneum.
